FOREWORD

IJCNLP2011, where Anna(s) meet the king(s) for sharing knowledge in natural language

IJCNLP2011 is held in Chiang Mai. It is a historic city situated in the northern part of Thailand. Organizing the conference in this part of Asia made us think of the classic movie "The King and I" (1956), where King Mongkut of Siam invited Anna Leonowens an Anglo-Indian school teacher to Siam to teach his family English. Similar to the movie, IJCNLP2011 brings together scientists and practitioners from the East and West in pursuit of the knowledge of natural language processing (NLP).

Virach, Hitoshi and I compiled this passage collaboratively online using our own iPads. Despite us being physically apart, in Thailand, Japan and Hong Kong respectively, our collaborative editorial work went smoothly with virtually no distance. The increasing popularity of smart handheld devices, such as iPhones and iPads has practically made the world flat. The hurdles and boundaries between people have effectively been lifted enabling friends and relatives over the globe to keep in close contact with each other. We use email, blog, facebook and twitter regularly and ubiquitously for communications. Non-traditional they may be, the languages for communication over these channels are natural as they are used by the netizens (human) for information exchange. Processing of these natural languages is inevitably unconventional and the task is challenging, which requires much innovation. For this reason, NLP is a key research area both in the industry and in universities worldwide. Therefore, it is not surprising that we have received over 500 submissions from different countries around the world in this year's IJCNLP. This number is in fact the largest in the history of the conference series.

Organizing a conference of the scale of IJCNLP2011 (with over 300 participants) is never easy. We worked closely as a team in the past ten months. It is really not easy for us to express our gratitude to any one individual. The names of the hard working conference officers, the track chairs, the workshop chairs, the tutors as well as the reviewers are enlisted in the proceedings. We owe everyone a billion. Without their hard work IJCNLP2011 would never have reached this stage. So please help me praise and thank them when you meet them in the conference.

Chiang Mai is a cultural city full of history and traditions, with many famous attractions such as its melodious colloquial language, Lanna style of clothing, mellow taste of food, etc. During the conference period, we will experience the "Loi Krathong Festival" where people float krathong (floating basket) on a river to pay respect to the spirit of the waters. IJCNLP2011 in November Chiang Mai is unique. It coincides with the unforgettable Lanna Festival. Locally known as "Yi Peng", the festival will bring to you a memorable cultural experience. You will witness a multitude of Lanna-style sky lanterns (khom loi, literally "floating lanterns") gently rising in the air. These lanterns resemble large flocks of giant fluorescent jellyfish gracefully floating by through the sky. Honestly, these attractions are just too good to be missed.

Dear friends and colleagues of the world NLP communities, honorable guests of Chiang Mai, we are glad to see you in IJCNLP2011. We hope you find the technical program useful to your research and can discover something insightful at the end. And before closing, as one often said "seeing is believing", we urge you to spare some time after the conference to explore and to enjoy the city.

Ka Poon Kap (thank you)

Kam-Fai Wong, General Chair, The Chinese University of Hong Kong (CUHK), China

Virach Sornlertlamvanich, Organization Co-Chair, National Electronics and Computer Technology Center (NECTEC), Thailand

Hitoshi Isahara, Organization Co-Chair, Toyohashi University of Technology, Japan

November 7, 2011

PREFACE

As the flagship conference of the Asian Federation of Natural Language Processing (AFNLP), IJCNLP has now rapidly grown into a renowned international event. IJCNLP 2011 covers a broad spectrum of technical areas related to natural language processing. The conference includes full papers, short papers, demonstrations, a student research workshop, as well as pre- and post-conference tutorials and workshops.

This year, we received a record 478 valid paper submissions, which is well beyond our initial expectations. This represents an increasing interest of research on NLP and the growing reputation of IJCNLP as an international event. The 478 submissions include 385 full-paper submissions and 93 short-paper submissions from more than 40 countries. Specifically, approximately 61% of the papers are from 16 countries and areas in Asia Pacific, 22% from 16 countries in Europe, 14% from the United States and Canada; we also have 2% of the papers from the Middle East and Africa, and 1% from South America.

We would like to thank all the authors for submitting papers to IJCNLP 2011. The significant increase in the number of submissions and the wide range of demographic areas represent a rapid growth of our field. We would also like to thank the 22 area chairs and 474 program committee members for writing over 1400 reviews and meta-reviews and for paving the way for the final paper selection. Of all 478 submissions, a total of 176 papers were accepted, representing a healthy 36% acceptance rate. The accepted papers are comprised of 149 full papers (8+ pages), of which 107 are presented orally and 42 as posters, and 27 short papers (4+ pages) where 25 are presented orally and 2 as posters. We are extremely grateful to the area chairs and program committee members for all their hard work, without which the preparation of this program would not be possible.

We are delighted to have invited three strategic keynote speakers addressing different application aspects of NLP for the Web in IJCNLP2011. Mathew Lease will talk about "crowdsourcing", which is a trendy and effective means to perform a task that requires hundreds/thousands of people, such as corpus tagging. Wai Lam will present the latest techniques for information extraction, which is essential for today's Internet business. And last but not the least, Mengqiu Wang, Vice President of Baidu, the largest Internet search company in China, will share with us the recent trends in search and social network technologies and how NLP techniques can be applied to improve performance in the real world. These speeches will surely be informative and enlightening to the audience leading to many innovative research ideas. We are excited about it and are looking forward to them. Best paper awards will be announced in the last session of the conference as well.

We thank General Chair Kam-Fai Wong, the Local Arrangements Committee headed by Virach Sornlertlamvanich and Hitoshi Isahara, and the AFNLP Conference Coordination Committee chaired by Yuji Matsumoto, for their help and advice. Thanks to Min Zhang and Sudeshria Sarkar, the Publication Co-Chairs for putting the proceedings together, and all the other committee chairs for their work.

We hope that you enjoy the conference!

Haifeng Wang, Baidu

David Yarowsky, Johns Hopkins University

November 7, 2011

Honorary Conference Chair

Chaiyong Eurviriyanukul, Rajamangala University of Technology Lanna, Thailand
Chongrak Polprasert, Sirindhorn International Institute of Technology, Thailand
Thaweesak Koanantakool, NSTDA, Thailand

General Chair

Kam-Fai Wong, The Chinese University of Hong Kong, China

Program Co-Chairs:

Haifeng Wang, Baidu, China
David Yarowsky, John Hopkins University, USA

Organisation Co-Chairs:

Virach Sornlertlamvanich, NECTEC, Thailand
Hitoshi Isahara, Toyohashi University of Technology, Japan

Workshop Co-Chairs:

Sivaji Bandyopadhyay, Jadavpur University, India
Jong Park, KAIST, Korea
Noriko Kando, NII, Japan

Tutorial Co-Chairs:

Kentaro Inui, Tohoku University, Japan
Wei Gao, The Chinese University of Hong Kong, China
Dawei Song, Robert Gordon University, UK

Demonstration Co-Chairs:

Ken Church, Johns Hopkins University, USA
Yunqing Xia, Tsinghua University, China

Publication Co-Chairs:

Min Zhang, I2R, Singapore
Sudeshna Sarkar, IIT Kharagpur, India

Finance Co-Chairs:

Vilas Wuwongse, AIT, Thailand
Gary Lee, POSTECH, Korea

Sponsorship Co-Chairs:

Asanee Kawtrakul, Kasetsart University, Thailand
Methinee Sirikrai, NECTEC, Thailand
Hiromi Nakaiwa, NTT, Japan

Publicity Committee:

Steven Bird, University of Melbourne, Australia
Le Sun, CIPS, China
Kevin Knight, USC, USA
Nicoletta Calzolari, Istituto di Linguistica Computazionale del CNR, Italy
Thanaruk Theeramunkong, SIIT, Thailand

Webmasters:

Swit Phuvipadawat, Tokyo Institute of Technology, Japan
Wirat Chinnan, SIIT, Thailand

Area Chairs:

Discourse, Dialogue and Pragmatics
David Schlangen, The University of Potsdam, Germany

Generation /Summarization
Xiaojun Wan, Peking University, China

Information Extraction
Wenjie Li, The Hong Kong Polytechnic University, Hong Kong

Information Retrieval
Gareth Jones, Dublin City University, Ireland

Language Resource
Eneko Agirre, University of the Basque Country, Spain

Machine Translation
David Chiang, USC-ISI, USA
Min Zhang, Institute for Infocomm Research, Singapore
Hua Wu, Baidu, China

Phonology/morphology, POS tagging and chunking, Word Segmentation
Richard Sproat, Oregon Health & Science University, USA
Gary Lee, Pohang University of Science and Technology, Korea

Question Answering
Jun Zhao, Institute of Automation, Chinese Academy of Sciences, China

Semantics
Pushpak Bhattacharyya, Indian Institute of Technology, India
Hinrich Schuetze, University of Stuttgart, Germany

Sentiment Analysis, Opinion Mining and Text Classification
Rafael Banchs, Institute for Infocomm Research, Singapore
Theresa Wilson, Johns Hopkins University, USA

Spoken Language Processing
Chung-Hsien Wu, National Cheng Kung University, Taiwan

Statistical and ML Methods
Miles Osborne, The University of Edinburgh, UK
David Smith, University of Massachusetts Amherst, USA

Syntax and Parsing
Stephen Clark, University of Cambridge, UK
Yusuke Miyao, National Institute of Informatics, Japan

Text Mining and NLP Applications
Juanzi Li, Tsinghua University, China
Patrick Pantel, Microsoft Research, USA

Table of Contents

Part A: Full Papers

Part B: Short Papers

Conference Program

November 9

(9:00-9:20) Welcome

(9:20-10:20) Keynote – Mengqiu Wang (Baidu)

(10:20 - 10:50) Coffee Break

(10:50-12:05) Text Mining I

Analyzing the Dynamics of Research by Extracting Key Aspects of Scientific Papers
Sonal Gupta and Christopher Manning

Dependency-directed Tree Kernel-based Protein-Protein Interaction Extraction from Biomedical Literature
Longhua Qian and Guodong Zhou

Learning Logical Structures of Paragraphs in Legal Articles
Ngo Xuan Bach, Nguyen Le Minh, Tran Thi Oanh and Akira Shimazu

(10:50-12:05) Machine Translation I

Extracting Pre-ordering Rules from Predicate-Argument Structures
Xianchao Wu, Katsuhito Sudoh, Kevin Duh, Hajime Tsukada and Masaaki Nagata

Context-Sensitive Syntactic Source-Reordering by Statistical Transduction
Maxim Khalilov and Khalil Sima'an

Discriminative Phrase-based Lexicalized Reordering Models using Weighted Reordering Graphs
Wang Ling, João Graça, David Martins de Matos, Isabel Trancoso and Alan W Black

November 9 (continued)

(10:50-12:05) Machine Learning I

Active Learning Strategies for Support Vector Machines, Application to Temporal Relation Classification
Seyed Abolghasem Mirroshandel, Gholamreza Ghassem-Sani and Alexis Nasr

A Fast Accurate Two-stage Training Algorithm for L1-regularized CRFs with Heuristic Line Search Strategy
Jinlong Zhou, Xipeng Qiu and Xuanjing Huang

Automatic Topic Model Adaptation for Sentiment Analysis in Structured Domains
Geoffrey Levine and Gerald DeJong

(10:50-12:05) Discourse / Dialog I

Multi-modal Reference Resolution in Situated Dialogue by Integrating Linguistic and Extra-Linguistic Clues
Ryu Iida, Masaaki Yasuhara and Takenobu Tokunaga

Single and multi-objective optimization for feature selection in anaphora resolution
Sriparna Saha, Asif Ekbal, Olga Uryupina and Massimo Poesio

A Unified Event Coreference Resolution by Integrating Multiple Resolvers
Bin Chen, Jian Su, Sinno Jialin Pan and Chew Lim Tan

(12:05-13:30) Lunch

(13:30-15:10) Machine Translation II

Handling verb phrase morphology in highly inflected Indian languages for Machine Translation
Ankur Gandhe, Rashmi Gangadharaiah, Karthik Visweswariah and Ananthakrishnan Ramanathan

Japanese Pronunciation Prediction as Phrasal Statistical Machine Translation
Jun Hatori and Hisami Suzuki

Comparing Two Techniques for Learning Transliteration Models Using a Parallel Corpus
Hassan Sajjad, Nadir Durrani, Helmut Schmid and Alexander Fraser

A Semantic-Specific Model for Chinese Named Entity Translation
Yufeng Chen and Chengqing Zong

November 9 (continued)

(13:30-15:10) Text Mining II

Mining Revision Log of Language Learning SNS for Automated Japanese Error Correction of Second Language Learners
Tomoya Mizumoto, Mamoru Komachi, Masaaki Nagata and Yuji Matsumoto

Modality Specific Meta Features for Authorship Attribution in Web Forum Posts
Thamar Solorio, Sangita Pillay, Sindhu Raghavan and Manuel Montes-Gomez

Keyphrase Extraction from Online News Using Binary Integer Programming
Zhuoye Ding, Qi Zhang and Xuanjing Huang

Improving Related Entity Finding via Incorporating Homepages and Recognizing Fine-grained Entities
Youzheng Wu, Chiori Hori, Hisashi Kawai and Hideki Kashioka

(13:30-15:10) Semantics I

Enhancing Active Learning for Semantic Role Labeling via Compressed Dependency Trees
Chenhua Chen, Alexis Palmer and Caroline Sporleder

Semantic Role Labeling Without Treebanks?
Stephen Boxwell, Chris Brew, Jason Baldridge, Dennis Mehay and Sujith Ravi

Japanese Predicate Argument Structure Analysis Exploiting Argument Position and Type
Yuta Hayashibe, Mamoru Komachi and Yuji Matsumoto

An Empirical Study on Compositionality in Compound Nouns
Siva Reddy, Diana McCarthy and Suresh Manandhar

November 9 (continued)

(13:30-15:10) Syntax I

Feature-Rich Log-Linear Lexical Model for Latent Variable PCFG Grammars
Zhongqiang Huang and Mary Harper

Improving Dependency Parsing with Fined-Grained Features
Guangyou Zhou, Li Cai, Kang Liu and Jun Zhao

Natural Language Programming Using Class Sequential Rules
Cohan Sujay Carlos

Treeblazing: Using External Treebanks to Filter Parse Forests for Parse Selection and Treebanking
Andrew MacKinlay, Rebecca Dridan, Dan Flickinger, Stephan Oepen and Timothy Baldwin

(15:10-15:30) Coffee Break

(15:30-17:10) Text Mining / Information Extraction

Cross-Language Entity Linking
Paul McNamee, James Mayfield, Dawn Lawrie, Douglas Oard and David Doermann

Generating Chinese Named Entity Data from a Parallel Corpus
Ruiji Fu, Bing Qin and Ting Liu

Learning the Latent Topics for Question Retrieval in Community QA
Li Cai, Guangyou Zhou, Kang Liu and Jun Zhao

Identifying Event Descriptions using Co-training with Online News Summaries
William Yang Wang, Kapil Thadani and Kathleen McKeown

November 9 (continued)

(15:30-17:10) Phonology / Morphology I

Automatic Labeling of Voiced Consonants for Morphological Analysis of Modern Japanese Literature
Teruaki Oka, Mamoru Komachi, Toshinobu Ogiso and Yuji Matsumoto

S^3 - Statistical Sandhi Splitting
Abhiram Natarajan and Eugene Charniak

Improving Chinese Word Segmentation and POS Tagging with Semi-supervised Methods Using Large Auto-Analyzed Data
Yiou Wang, Jun'ichi Kazama, Yoshimasa Tsuruoka, Wenliang Chen, Yujie Zhang and Kentaro Torisawa

CODACT: Towards Identifying Orthographic Variants in Dialectal Arabic
Pradeep Dasigi and Mona Diab

(15:30-17:10) Sentiment I

Enhancing the HL-SOT Approach to Sentiment Analysis via a Localized Feature Selection Framework
Wei and Jon Atle Gulla

Fine-Grained Sentiment Analysis with Structural Features
Cäcilia Zirn, Mathias Niepert, Heiner Stuckenschmidt and Michael Strube

Predicting Opinion Dependency Relations for Opinion Analysis
Lun-Wei Ku, Ting-Hao Huang and Hsin-Hsi Chen

Detecting and Blocking False Sentiment Propagation
Hye-Jin Min and Jong C. Park

November 9 (continued)

(15:30-17:10) Machine Learning II

Efficient induction of probabilistic word classes with LDA
Grzegorz Chrupala

Quality-biased Ranking of Short Texts in Microblogging Services
Minlie Huang, Yi Yang and Xiaoyan Zhu

Labeling Unlabeled Data using Cross-Language Guided Clustering
Sachindra Joshi, Danish Contractor and Sumit Negi

Extracting Relation Descriptors with Conditional Random Fields
Yaliang Li, Jing Jiang, Hai Leong Chieu and Kian Ming A. Chai

(18:00-21:00) Poster/Demo (Pre Function Level 1) + Reception

November 10

(9:00-10:00) Keynote – Matt Lease (University of Texas)

(10:00 - 10:30) Coffee Break

(10:30 - 12:10) Information Retrieval I

Attribute Extraction from Synthetic Web Search Queries
Marius Pasca

Japanese Abbreviation Expansion with Query and Clickthrough Logs
Kei Uchiumi, Mamoru Komachi, Keigo Machinaga, Toshiyuki Maezawa, Toshinori Satou and Yoshinori Kobayashi

Mining Parallel Documents Using Low Bandwidth and High Precision CLIR from the Heterogeneous Web
Simon Shi, Pascale Fung, Emmanuel Prochasson, Chi-kiu Lo and Dekai Wu

Crawling Back and Forth: Using Back and Out Links to Locate Bilingual Sites
Luciano Barbosa, Srinivas Bangalore and Vivek Kumar Rangarajan Sridhar

November 10 (continued)

(10:30 - 12:10) Syntax II

Grammar Induction from Text Using Small Syntactic Prototypes
Prachya Boonkwan and Mark Steedman

Transferring Syntactic Relations from English to Hindi Using Alignments on Local Word Groups
Aswarth Dara, Prashanth Mannem, Hemanth Sagar Bayyarapu and Avinesh PVS

Generative Modeling of Coordination by Factoring Parallelism and Selectional Preferences
Daisuke Kawahara and Sadao Kurohashi

Syntactic Parsing for Ranking-Based Coreference Resolution
Altaf Rahman and Vincent Ng

(10:30 - 12:10) Generation / Summarization

TriS: A Statistical Sentence Simplifier with Log-linear Models and Margin-based Discriminative Training
Nguyen Bach, Qin Gao, Stephan Vogel and Alex Waibel

Social Summarization via Automatically Discovered Social Context
Po Hu, Cheng Sun, Longfei Wu, Donghong Ji and Chong Teng

Simultaneous Clustering and Noise Detection for Theme-based Summarization
Xiaoyan Cai, Renxian Zhang, Dehong Gao and Wenjie Li

Extractive Summarization Method for Contact Center Dialogues based on Call Logs
Akihiro Tamura, Kai Ishikawa, Masahiro Saikou and Masaaki Tsuchida

November 10 (continued)

(10:30 - 12;10) Spoken Language Processing

Indexing Spoken Documents with Hierarchical Semantic Structures: Semantic Tree-to-string Alignment Models
Xiaodan Zhu, Colin Cherry and Gerald Penn

Structured and Extended Named Entity Evaluation in Automatic Speech Transcriptions
Olivier Galibert, Sophie Rosset, Cyril Grouin, Pierre Zweigenbaum and Ludovic Quintard

Normalising Audio Transcriptions for Unwritten Languages
Adel Foda and Steven Bird

Similarity Based Language Model Construction for Voice Activated Open-Domain Question Answering
Istvan Varga, Kiyonori Ohtake, Kentaro Torisawa, Stijn De Saeger, Teruhisa Misu, Shigeki Matsuda and Jun'ichi Kazama

(12:10-13:55) Lunch

(13:55-15:10) Machine Learning III

The application of chordal graphs to inferring phylogenetic trees of languages
Jessica Enright and Grzegorz Kondrak

Cross-domain Feature Selection for Language Identification
Marco Lui and Timothy Baldwin

A Wikipedia-LDA Model for Entity Linking with Batch Size Changing Instance Selection
Wei Zhang, Jian Su and Chew-Lim Tan

November 10 (continued)

(13:55-15:10) Information Retrieval II

Discovering Latent Concepts and Exploiting Ontological Features for Semantic Text Search
Vuong M. Ngo and Tru H. Cao

CLGVSM: Adapting Generalized Vector Space Model to Cross-lingual Document Clustering
Guoyu Tang, Yunqing Xia, Min Zhang, Haizhou Li and Fang Zheng

Thread Cleaning and Merging for Microblog Topic Detection
Jianfeng Zhang, Yunqing Xia, Bin Ma, Jianmin Yao and Yu Hong

(13:55-15:10) Dialog/Discourse II

Training a BN-based user model for dialogue simulation with missing data
Stéphane Rossignol, Olivier Pietquin and Michel Ianotto

Automatic identification of general and specific sentences by leveraging discourse annotations
Annie Louis and Ani Nenkova

An Evaluation of Alternative Strategies for Implementing Dialogue Policies Using Statistical Classification and Hand-Authored Rules
David DeVault, Anton Leuski and Kenji Sagae

(13:55-15:10) Sentiment II

A POS-based Ensemble Model for Cross-domain Sentiment Classification
Rui Xia and Chengqing Zong

Ensemble-style Self-training on Citation Classification
Cailing Dong and Ulrich Schäfer

Back to the Roots of Genres: Text Classification by Language Function
Henning Wachsmuth and Kathrin Bujna

November 10 (continued)

(15:10-15:30) Coffee Break

(15:30-17:10) Machine Translation III

Transductive Minimum Error Rate Training for Statistical Machine Translation
Yinggong Zhao, Shujie Liu, Yangsheng Ji, Jiajun Chen and Guodong Zhou

Distributed Minimum Error Rate Training of SMT using Particle Swarm Optimization
Jun Suzuki, Kevin Duh and Masaaki Nagata

Going Beyond Word Cooccurrences in Global Lexical Selection for Statistical Machine Translation using a Multilayer Perceptron
Alexandre Patry and Philippe Langlais

System Combination Using Discriminative Cross-Adaptation
Jacob Devlin, Antti-Veikko Rosti, Sankaranarayanan Ananthakrishnan and Spyros Matsoukas

(15:30-17:10) Semantics II

Word Sense Disambiguation by Combining Labeled Data Expansion and Semi-Supervised Learning Method
Sanae Fujita and Akinori Fujino

Combining ConceptNet and WordNet for Word Sense Disambiguation
Junpeng Chen and Juan Liu

It Takes Two to Tango: A Bilingual Unsupervised Approach for Estimating Sense Distributions using Expectation Maximization
Mitesh M Khapra, Salil Joshi and Pushpak Bhattacharyya

Dynamic and Static Prototype Vectors for Semantic Composition
Siva Reddy, Ioannis Klapaftis, Diana McCarthy and Suresh Manandhar

November 10 (continued)

(15:30-17:10) Information Extraction

Using Prediction from Sentential Scope to Build a Pseudo Co-Testing Learner for Event Extraction
Shasha Liao and Ralph Grishman

Text Segmentation and Graph-based Method for Template Filling in Information Extraction
Ludovic Jean-Louis, Romaric Besançon and Olivier Ferret

Joint Distant and Direct Supervision for Relation Extraction
Truc-Vien T. Nguyen and Alessandro Moschitti

A Cross-lingual Annotation Projection-based Self-supervision Approach for Open Information Extraction
Seokhwan Kim, Minwoo Jeong, Jonghoon Lee and Gary Geunbae Lee

(15:30-17:10) Syntax III

Exploring Difficulties in Parsing Imperatives and Questions
Tadayoshi Hara, Takuya Matsuzaki, Yusuke Miyao and Jun'ichi Tsujii

A Discriminative Approach to Japanese Zero Anaphora Resolution with Large-scale Lexicalized Case Frames
Ryohei Sasano and Sadao Kurohashi

An Empirical Comparison of Unknown Word Prediction Methods

Abstract

We present a method for characterizing a research work in terms of its focus, domain of application, and techniques used. We show how tracing these aspects over time provides a novel measure of the influence of research communities on each other. We extract these characteristics by matching semantic extraction patterns, learned using bootstrapping, to the dependency trees of sentences in an article's abstract. We combine this information with pre-calculated article-to-community assignments to study the influence of a community on others in terms of techniques borrowed and the 'maturing' of some communities to solve other problems. As a case study, we show how the computational linguistics community and its sub-fields have changed over the years with respect to their foci, methods used, and domain problems. For instance, we show that part-of-speech tagging and parsing have increasingly been adopted as tools for solving problems in other domains. We also observe that speech recognition and probability theory have had the most seminal influence.

1 Introduction

The evolution of ideas and the dynamics of a research community can be studied using the scientific articles published by the community. For instance, we may be interested in how methods spread from one community to another, or the evolution of a topic from a focus of research to a problem-solving tool. We might want to find the balance between technique-driven and domain-driven research within a field. Establishing such a rich insight of the development and progress of scientific research requires an understanding of more than just the "topics" of discussion or citation links between articles, which have been used in the previous work to study trend and impact of articles. As an example, to determine whether technique-driven researchers have greater or lesser impact, we need to be able to identify styles of work. To achieve this level of detail and to be able to connect together how methods and ideas are being pursued, it is essential to move beyond bag-of-words topical models. This requires an understanding of sentence and argument structure, and is therefore a form of information extraction.

To study the application *domains*, the *techniques* used to approach the domain problems, and the *focus* of scientific articles in a community, we propose to extract the following concepts from the articles

> **FOCUS**: an article's main contribution
> **TECHNIQUE**: a method or a tool used in an article, for example, expectation maximization and conditional random fields
> **DOMAIN**: an article's application domain, such as speech recognition and classification of documents.

For example, if an article concentrates on regularization in support vector machines and shows improvement in parsing accuracy, then its FOCUS and TECHNIQUE are regularization and support vector machines, and its DOMAIN is parsing. In contrast, an article that focuses on lexical features to improve parsing accuracy and uses support vector machines to train the model has FOCUS as lexical features and parsing, the TECHNIQUE being lexical features and support vector machines, and its DOMAIN still is parsing.[1] In this case, even though TECHNIQUEs and DOMAIN of both papers

[1] A community vs. a DOMAIN: a community can be as broad as computer science or statistics, whereas a DOMAIN is a specific application such as Chinese word segmentation.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1–9,
Chiang Mai, Thailand, November 8 – 13, 2011.

are very similar, the FOCUS phrases distinguish them from each other. Note that a DOMAIN of one article can be a TECHNIQUE of another, and vice-versa. For example, an article that shows improvements in named entity recognition (NER) has DOMAIN as NER, however, an article that uses named entities as an intermediary tool to extract relations has NER as one of its TECHNIQUEs.

Our work uses information extraction patterns to extract the above three category phrases from articles. The phrases are extracted by matching semantic patterns in dependency trees of sentences. The input to the extraction system are some seed patterns (see Table 1 for examples) and it learns more patterns using a bootstrapping approach. Using a bag-of-words based approach, such as topic models, for this problem is not straightforward; true to their name, topic models generally only identify the topic or area of a paper (such as 'parsing' or 'speech recognition'), and neither provide nor label different cross-cutting aspects like techniques used or the application domain of the paper.

As a case study, we examine the articles published in the computational linguistics community. We study the influence of the community's sub-fields, such as parsing and machine translation, using the FOCUS, TECHNIQUE, and DOMAIN phrases extracted from the articles. We use the document collection from the ACL Anthology dataset[2] (Bird et al., 2008; Radev et al., 2009), since it has full text of papers available. To get the the sub-fields of the community, we use latent Dirichlet allocation (Blei et al., 2003) to find topics and label them by hand.[3] However, our general approach can be used to study any case of the influence of academic communities, including looking more broadly at the influence of statistics or economics across the social sciences.

We study how communities influence each other in terms of techniques that are reused, and show how some communities 'mature' so that the results they produce get adopted as tools for solving other problems. For example, the products of the part-of-speech tagging (POS) community have been adopted by many other communities that use POS tagging as an intermediary step, which is also confirmed in our results.

We also show the timeline of influence of communities. For example, our results show that formal computational semantics and unification-based grammars had a lot of influence in the late 1980s. The speech recognition and probability theory fields showed an upward trend of influence in the mid-1990s, and even though it has decreased in recent years, they still have a lot of influence on recent papers mainly due to techniques like expectation maximization and hidden Markov models. Therefore, our results show that overall they have been the most influential fields in the last two decades. Probability theory, unlike speech recognition, is traditionally not a separate sub-field of computational linguistics, but it is an important topic since many papers use and work on probabilistic approaches. We also show that the study of influence is different from studying popularity or hotness of communities, such as in (Griffiths and Steyvers, 2004; Hall et al., 2008), which is based on the expected number of papers published in the community in a given year.

Contributions We introduce a new categorization of key aspects of scientific articles, which is (1) FOCUS: main contribution, (2) TECHNIQUE: method or tool used, and (3) DOMAIN: application domain. We extract the aspects by matching semantic patterns to dependency trees and learn the patterns using bootstrapping. We propose a new definition of influence of a research community in terms of its key aspects adopted as techniques by the other communities. We present a case study on the computational linguistics community using the the three aspects extracted from its articles, both for verifying the results of our system, and for showing novel results for the dynamics and the overall influence of computational linguistics sub-fields. We introduce a dataset of abstracts labeled with the three categories.[4]

2 Related Work

While there is some connection to keyphrase selection in text summarization (Radev et al., 2002), extracting FOCUS, TECHNIQUE and DOMAIN phrases is fundamentally a form of information extraction, and there has been a wide variety of prior work in this area. Some work, including the seminal (Hearst, 1992), identified patterns (ISA relations) using hand-written rules, while other work has learned patterns over dependency graphs (Bunescu and Mooney, 2005). This work builds

[2] http://www.aclweb.org/anthology

[3] In this paper, we use the terms communities, sub-communities and sub-fields interchangeably.

[4] The dataset is available at http://cs.stanford.edu/people/sonal/fta for the research community.

on previous successful use of bootstrapping learning techniques in NLP (Yarowsky, 1995; Collins and Singer, 1999; Riloff and Jones, 1999); in its use of dependency patterns it is perhaps especially close to (Yangarber et al., 2000).

Topic models have been used to study popularity of communities (Griffiths and Steyvers, 2004), the history of ideas (Hall et al., 2008), and scholarly impact of papers (Gerrish and Blei, 2010). However, topic models do not extract detailed information from text as we do. Still, we use topic-to-word distributions from topic models as a way of describing sub-fields.

Demner-Fushman and Lin (2007) used hand written knowledge extractors to extract information, such as population and intervention, in their clinical question-answering system to improve ranking of relevant abstracts. Our categorization of key aspects is applicable for broader range of communities, and we learn the patterns by bootstrapping. Li et al. (2010) used semantic metadata to create a semantic digital library for chemistry and identified experimental paragraphs using keywords features. Xu et al. (2006) and Ruch et al. (2007) proposed systems, in clinical-trials and biomedical domain, respectively, to classify *sentences* of abstracts corresponding to categories such as introduction, purpose, method, results and conclusion to improve article retrieval by using either structured abstracts,[5] or hand-labeled sentences. Some summarization systems also use machine learning approaches to find 'key sentences'. The systems built in these papers are complimentary to ours since one can find relevant paragraphs or sentences and then extract the key aspects from them. Note that a sentence can have multiple phrases corresponding to our three categories, and thus classification of sentences will not be enough.

3 Approach

In this section, we explain how to extract phrases for each of the three categories (FOCUS, TECHNIQUE and DOMAIN) and how to compute the influence of communities.

3.1 Pattern Matching and Learning

From an article's abstract and title, we use the dependency trees of sentences and a set of semantic extraction patterns to extract phrases in each of

[5]Structure abstracts, which are used by some journals, have multiple sections such as PURPOSE and METHOD.

FOCUS	present → (direct object) work → (preposition_on) propose → (direct object)
TECHNIQUE	using → (direct object) apply → (direct object) extend → (direct object)
DOMAIN	system → (preposition_for) task → (preposition_of) framework → (preposition_for)

Table 1: Some examples of semantic extraction patterns that extract information from dependency trees of sentences. A pattern is of the form $T \rightarrow (d)$, where T is the trigger word and d is the dependency that the trigger word's node has with its successor.

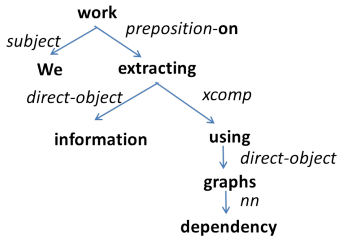

Figure 1: The dependency graph for '*We work on extracting information using dependency graphs*'. Our semantic patterns (shown in Table 1) will extract '*extracting information using dependency graphs*' as FOCUS, and '*dependency graphs*' as TECHNIQUE.

FOCUS, TECHNIQUE and DOMAIN categories. A dependency tree of a sentence is a parse tree that gives dependencies (such as direct-object, subject) between words in the sentence. Figure 1 shows the dependency graph for the sentence 'We work on extracting information using dependency graphs.' Each semantic pattern is of the form $T \rightarrow d$, where T is a trigger word (such as 'use', 'present') and d is a dependency (such as 'direct-object'). We start with a few handwritten patterns (some shown in Table 1) and learn more patterns automatically using a bootstrapping approach. We run an iterative algorithm that extracts phrases using semantic patterns and then learns new patterns from the extracted phrases. The details of each step are described below.

Extracting Phrases from Patterns A dependency tree matches a pattern $T \rightarrow (d)$, if (1) it contains T, and (2) the trigger word's node has a successor (dependent or granddependent upto 4 levels) whose dependency with its parent is d. In the rest of the paper, we call the subtree headed by the successor as the matched phrase-tree. We extract the phrase corresponding to the matched phrase-tree and label it with the pattern's category. For example, the dependency tree in Figure 1 matches the FOCUS pattern [*work → (preposition_on)*] and the TECHNIQUE pattern [*using → (direct-object)*]. Thus, the system labels the phrase corresponding to the phrase-tree headed

by 'extracting', which is 'extracting information using dependency graphs', with the category FOCUS, and similarly labels the phrase 'dependency graphs' as TECHNIQUE.

We have special rules for paper titles since authors usually include the main contribution of the paper in the title. We label the whole title as FOCUS if we are not able to extract a FOCUS phrase using the patterns. For titles from which we can extract a TECHNIQUE phrase, we label rest of the words (except for the trigger words) with DOMAIN. For example, for title 'Studying the history of ideas using topic models', our system extracts 'topic models' as TECHNIQUE using the pattern [*using* $\rightarrow$ *(direct-object)*], and then labels 'Studying the history of ideas' as DOMAIN.

Learning Patterns from Phrases After extracting phrases with patterns, we want to be able to construct and learn new patterns. For each sentence whose dependency tree has a subtree corresponding to one of the extracted phrases, we construct a pattern $T \rightarrow (d)$ by considering the ancestor (parent or grandparent) of the subtree as the trigger word T, and the dependency between the head of the subtree and its parent as the dependency d. The weighting of newly constructed patterns is done as follows. For a set of phrases (P) that extract a pattern (q), the weight of the pattern q for the category FOCUS is $\sum_{p \in P} \frac{1}{z_p} count(p \in \text{FOCUS})$, where z_p is the total frequency of the phrase p. Similarly, we get weights of the pattern for the other two categories. Note that we do not need smoothing since the phrase-category ratios are aggregated over all the phrases from which the pattern is constructed. After weighting all the patterns that have not been selected in the previous iterations, we select the top k patterns in each category (k=2 in our experiments). Table 3 shows some patterns learned through the iterative method.

3.2 Communities and their Influence

We define communities as fields or sub-fields that one wishes to study. To study communities using the articles published, we need to know which communities each article belongs to. The article-to-community assignment can be computed in several ways, such as by manual assignment, using metadata, or by text categorization of papers. In our case study, we use the topics formed by applying latent Dirichlet allocation (Blei et al., 2003) to the text of the papers by considering each topic as one community. In recent years, topic modeling has been widely used to get 'concepts' from text; it has the advantage of producing soft, probabilistic article-to-community assignment scores in an unsupervised manner. We combine these soft assignment scores with the phrases extracted in the previous section to score a phrase for each community and each category as follows. The score of a phrase p, which is extracted from an article a, for a community c and the category TECHNIQUE is calculated as

$$tScore(c, p, a) = \frac{1}{z_p} count(p \in \text{TECHNIQUE} \mid a) P(c \mid a, \theta) \quad (1)$$

where the function $P(c \mid a, \theta)$ gives the probability of a community (i.e., a topic) for the article a given the topic modeling parameters θ. The normalization constant for the phrase, z_p, is the frequency of the phrase in all the abstracts.

We define influence such that communities receive higher scores if they use techniques earlier than other communities do or produce tools that are used to solve other problems. For example, since *hidden Markov model* introduced by the speech recognition community and *part-of-speech tagging* tools built by the part-of-speech community have been widely used as techniques in other communities, these communities should receive higher scores than the nascent or not-so-widely-used ones. Thus, we define influence of a community based on the number of times its FOCUS, TECHNIQUE or DOMAIN phrases have been used as a TECHNIQUE in other communities. To calculate the overall influence of one community on another, we first need to calculate influence because of individual articles in the community, which is calculated as follows. The influence of community c_1 on another community c_2 because of a phrase p extracted from an article a_1 is

$$tInfl(c_1, c_2, p, a_1) = allScore(c_1, p, a_1) \sum_{\substack{a_2 \in D \\ y_{a_2} > y_{a_1}}} tScore(c_2, p, a_2) C(a_2, a_1) \quad (2)$$

where the function $allScore(c, p, a)$ is computed the same way as in Eq. 1, but by using $count(p \in \text{ALL} \mid a)$, where ALL means the union of phrases extracted in all three categories. The variable D is the set of all articles, and y_{a_2} means year of publication of the article a_2. The summation term computes the influence of the phrase p extracted

from the article a_1 on all the articles from the community c_2 published at a later date. The function $C(a_2, a_1)$ is a weighting function based on citations, whose value is 1 if a_2 cites a_1, and λ otherwise. If λ is 0, the system calculates influence based on just citations, which can be noisy and incomplete. In our experiments, we used λ as 0.5 since we want to study the influence even when an article does not explicitly cite another article. The technique-influence score of community c_1 on community c_2 in year y is computed by summing up the previous equation for all phrases (P) and for all articles in D. It is computed as

$$tInfl(c_1, c_2, y) = \sum_{p \in P} \sum_{\substack{a \in D \\ y_{a_1} = y}} tInfl(c_1, c_2, p, a) \quad (3)$$

Straightforwardly, the overall influence of community c_1 on the community c_2 and on all other communities is calculated as

$$tInfl(c_1, c_2) = \sum_y tInfl(c_1, c_2, y) \quad (4)$$

$$tInfl(c_1) = \sum_{c_2 \neq c_1} tInfl(c_1, c_2) \quad (5)$$

Next, we present a case study over the sub-fields of computational linguistics using the influence scores described above.

4 Experimental Setup

Dataset We studied the computational linguistics community from 1965 to 2009 using titles and abstracts of 15,016 articles from the ACL Anthology Network and the ACL Anthology Reference corpus (Bird et al., 2008; Radev et al., 2009). We found 52 pairs of abstracts that had more than 80% of words in common with each other, and thus while calculating the influence scores, we ignored the influence of earlier-published paper on the later-published paper in the pairs. We used the Stanford Parser (Marneffe et al., 2006) to generate dependency trees of sentences. For testing, we hand labeled 474 abstracts with the three categories to measure the precision and recall scores. For each abstract and each category, we compared the unique non-stop-words extracted from our algorithm to the hand labeled dataset. We calculated precision, recall measures for each abstract and averaged them to get the results for the dataset.

When extracting phrases from the matched phrase trees, we ignored tokens with part-of-speech tags as pronoun, number, determiner, punctuation or symbol, and removed all subtrees in the matched phrase trees that had either relative-clause-modifier or clausal-complement dependency with their parents since, even though we want full phrases, including these sub-trees introduced extraneous phrases and clauses. We also added phrases from the subtrees of the matched phrase trees to the set of extracted phrases.

We used 13 seed patterns for FOCUS, 7 for TECHNIQUE and 15 for DOMAIN. When constructing a new pattern, we ignored the ancestors that were not a noun or a verb since most trigger words are a noun or a verb (such as *use*, *constraints*). We also ignored conjunction, relative-clause-modifier, dependent (most generic dependency), quantifier-modifier, and abbreviation dependencies[6] since they either are too generic or introduced extraneous phrases and clauses.

Learning new patterns did not help in improving the FOCUS category phrases when tested over a hand labeled test set. It got relatively high scores when using just the seed patterns and the titles, and hence learning new patterns reduced the precision without any significant improvement in recall. Thus, we learned new patterns only for the TECHNIQUE and DOMAIN categories. We ran 50 iterations for both categories, which was chosen as a reasonable trade-off between pattern precision and recall based on some earlier pilot experiments. After extracting all the phrases, we removed common phrases that are frequently used in scientific articles, such as 'this technique' and 'the presence of', using a stop words list of 3,000 phrases. The list was created by taking the top most occurring 1 to 3 grams from 100,000 random articles with an abstract in the ISI web of knowledge database[7]. We ignored phrases that were either one character or more than 15 words long. In a step towards finding canonical names, we automatically detected abbreviations and their expanded forms from the full text of papers by searching for text between two parentheses, and considered the phrase before the parentheses as the expanded form (similar to (Schwartz and Hearst, 2003)). We got a high precision list by picking the top most occurring pairs of abbreviations and their expanded forms and created groups of phrases by merging all the phrases that use same abbreviation. We then changed all the phrases in the extracted phrases dataset to their canonical names.

Table 2: Extracted phrases for some papers. The word 'model' is missing from the end of some phrases as it was removed during post-processing.

We also removed 'model', 'approach', 'method', 'algorithm', 'based', 'style' words and their variants when they occurred at the end of a phrase.

Baseline To compare against a non-information-extraction based baseline, we extracted all noun phrases, along with phrases from the sub-trees of the noun phrase trees, from the abstracts and labeled them with all the three categories. In addition, we labeled the titles (and their sub-trees) with the category FOCUS. We then scored the phrases with a tf-idf inspired measure, which was the ratio of the frequency of the phrase in the abstract and the sum of the total frequency of the individual words, and removed phrases that had the tf-idf measure less than 0.001 (best out of many experiments). We call this approach as 'Baseline tf-idf NPs'.[8]

To get communities in the computational linguistics literature, we considered the topics generated using the same ACL Anthology dataset by Bethard and Jurafsky (2010) as communities. They ran latent Dirichlet allocation on the full text of the papers to get 100 topics. We hand labeled the topics and used 72 of them in our study; the rest of them were about common words. When calculating the scores in Eq. 1, we considered the value of $P(c \mid a, \theta)$ to be 0 if it was less than 0.1.

5 Results and Discussion

Extraction

The total numbers of phrases extracted were 25,525 for FOCUS, 24,430 for TECHNIQUE, and 33,203 for DOMAIN. The total numbers of phrases after including the phrases extracted from subtrees of the matched phrase trees were 64,041, 38,220 and 46,771, respectively. Examples of phrases extracted from some papers are shown in Table 2.

[8]As discussed in Section 1, using an unsupervised or weakly-supervised bag-of-words based approach is not straightforward for identifying FOCUS, TECHNIQUE and DOMAIN of an article, and hence we do not compare against one.

TECHNIQUE	DOMAIN
model → (nn)	improve → (direct-object)
rules → (nn)	used → (preposition_for)
extracting → (direct-object)	evaluation → (nn)
identify → (direct-object)	parsing → (nn)
constraints → (amod)	domain → (nn)
based → (preposition_on)	applied → (preposition_to)

Table 3: Examples of patterns learned using the iterative extraction algorithm. The dependency 'nn' is the noun compound modifier dependency.

Approach	F_1	Precision	Recall
FOCUS			
Baseline tf-idf NPs	35.60	24.36	66.07
Seed Patterns	**55.29**	**44.67**	**72.54**
Inter-Annotator Agreement	53.33	50.80	56.14
TECHNIQUE			
Baseline tf-idf NPs	26.65	17.87	**52.41**
Seed Patterns	20.09	23.46	21.72
Iteration 50	**36.86**	**30.46**	46.68
Inter-Annotator Agreement	72.02	66.81	78.11
DOMAIN			
Baseline tf-idf NPs	30.13	19.90	**62.03**
Seed Patterns	25.27	**30.55**	26.29
Iteration 50	**37.29**	27.60	57.50
Inter-Annotator Agreement	72.31	75.58	69.32

Table 4: The precision, recall, and F_1 scores of each category for the different approaches. Note that the inter-annotator agreement is calculated on a smaller set.

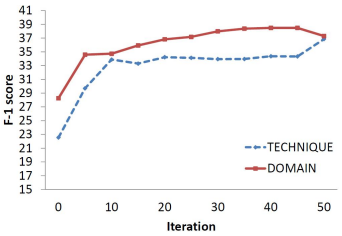

Figure 2: The F_1 scores for TECHNIQUE and DOMAIN categories after every five iterations. For reasons explained in the text, we do not learn new patterns for FOCUS.

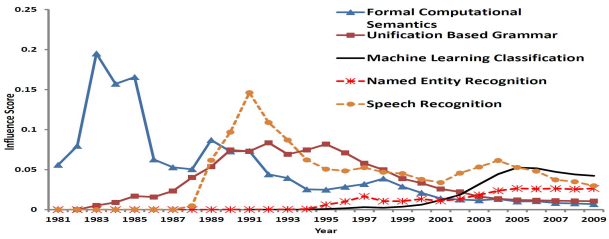
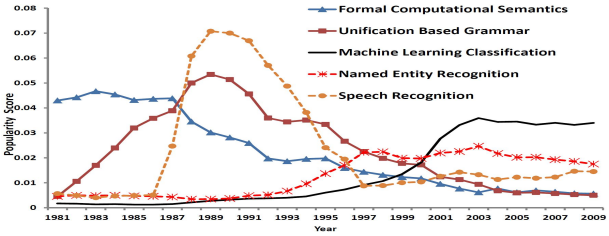
Table 4 compares precision, recall, and micro-averaged F_1 scores for the three categories when we use: (1) only the seed patterns, (2) the combined set of learned and seed patterns, (3) the baseline, and (4) the inter-annotator agreement. We calculated inter-annotator agreement for 30 abstracts, where each abstract was labeled by 2 annotators,[9] and the precision-recall scores were calculated by randomly choosing one annotation as gold and another as predicted for each article. We

[9]The first author annotated 30 abstracts and two doctoral candidates in computational linguistics annotated 15 each.



(a) The influence of communities in each year.



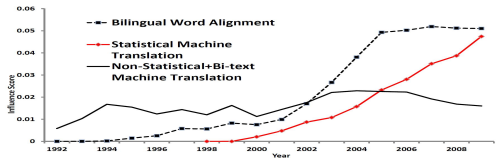
(b) Popularity of communities in each year.

Figure 3: The first figure shows influence scores of communities in each year. The second figure shows the popularity of each community in each year (see (Hall et al., 2008)), which is measured by summing up the article-to-topic scores for the articles published in that year. The scores are smoothed with weighted scores of 2 previous and 2 next years, and L1-normalized for each year. The scores are lower for all communities in late 2000s since the probability mass is more evenly distributed among many communities.

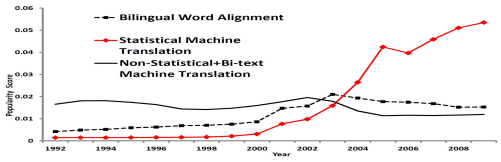
can see in the table that both precision and recall scores increase for TECHNIQUE because of the learned patterns, though for DOMAIN, precision decreases but recall increases. The recall scores for the baseline are higher as expected but the precision is very low. Three possible reasons explain the mistakes made by our system: (1) authors sometimes use generic phrases to describe their system, which were not annotated with any of the three categories in the test set but were extracted by the system (such as 'simple method', 'faster model', 'new approach'); (2) the dependency trees of some sentences were wrong; and (3) some of the patterns learned for TECHNIQUE and DOMAIN were low-precision but high-recall. Figure 2 shows the F_1 scores for TECHNIQUE and DOMAIN after every 5 iterations.

Influence

Table 5 shows the most influential communities overall (computed using Eq. 5) and their respective influential phrases that have been widely adopted as techniques by other communities. We can see that speech recognition is the most influential community because of the techniques like hidden Markov models and other stochastic methods it introduced in the computational linguistics literature, which shows that its long-term seeding influence is still present despite the limited recent



(a) The influence of communities in each year.



(b) Popularity of communities in a each year.

Figure 4: Comparing machine translation related communities in the same way as in Figure 3. The statistical machine translation community, which is a topic from the topic model, is more phrase-based.

popularity. Probability theory also gets a high score since many papers in the last decade have used stochastic methods. The communities part-of-speech tagging and parsing get high scores because they adopted some techniques that are used in other communities, and because other communities use part-of-speech tagging and parsing in the intermediary steps for solving other problems.

Figure 3(a) shows the change in a community's influence over time, and Figure 3(b) shows the change in its popularity. The popularity of a community is the sum of article-to-topic scores for the community topic and for all articles published in a given year.[10] The scores in both figures are normalized such that the total score for all communities in a year sum to one. Compare the relative scores of communities in Figure 3(a) with the relative scores in Figure 3(b). We can see influence of a community is different from the popularity of a community in a given year. As mentioned before, we observe that although influence score for speech recognition has declined in recent years, it still has a lot of influence, though the popularity of the community in recent years is very low. Machine learning classification has been both popular and influential in recent years. Named entity recognition's popularity has decreased since 2003, though its influence has either increased or remained same. Figure 4 compares the machine translation communities in the same way as we compare other communities in Figure 3. We can see that statistical machine translation (more phrase-based) community's popularity has steeply increased in the last 5 years, however, its influ-

Table 5: The top most influential communities, along with the top most words that describe the communities obtained by the topic model, and the corresponding most influential phrases that have been widely used as techniques. The third column is the score of the community computed by Eq. 5.

Community	Communities that have influenced most (descending order)
Named Entity Recognition	Chunking/Memory Based Models; Discriminative Sequence Models; POS Tagging; Machine Learning Classification; Coherence Relations; Biomedical NER; Bilingual Word Alignment
Statistical Parsing	Probability Theory; POS Tagging; Discriminative Sequence Models; Speech Recognition; Parsing; Syntactic Theory; Clustering+DistributionalSimilarity; Chunking/Memory Based Models
Word Sense Disambiguation	Clustering + DistributionalSimilarity; Machine Learning Classification; Dictionary Lexicons; Collocations/Compounds; Syntax; Speech Recognition; Probability Theory

Table 6: The community in the first column has been influenced the most by the communities in the second column. The scores are calculated using Eq. 4

ence has increased at a slower rate. On the other hand, the influence of bilingual word alignment (the most influential community in 2009) has increased during the same period, mainly because of its influence on statistical machine translation. The influence of non-statistical machine translation has been decreasing recently, though slower than its popularity. Table 6 shows the communities that have the most influence on a given community (the list is in descending order of scores by Eq. 4).

6 Future Directions

We are working towards incorporating the date of publication of the articles to learn better patterns to increase precision and recall of the system. We are also exploring ways to use our system for studying citation and co-authorship networks. We plan to study the dynamics and impact of broader communities like biology, statistics and the social sciences. The approach can also be used to study innovation in interdisciplinary research, since we can track if interdisciplinary research results in applying old techniques from one community to solve problems in other community, or if it results in the evolution of better suited techniques.

7 Conclusions

This paper presents a framework for extracting detailed information from scientific articles, such as main contributions, tools and techniques used, and domain problems addressed, by matching semantic extraction patterns in dependency trees. We start with a few hand written seed patterns and learn new patterns using a bootstrapping approach. We use this rich information extracted from articles to study the dynamics of research communities and to define a new way of measuring influence of one research community on another. We present a case study on the computational linguistics community, where we find the *influence* of its sub-fields and observed that speech recognition and probability theory have had the most seminal influence.

Abstract

Structured information plays a critical role in many NLP tasks, such as semantic relation extraction between named entities and semantic role labeling. This paper proposes a principled way to automatically generate constituent structure representation for tree kernel-based protein-protein interaction (PPI) extraction. The main idea behind our approach is that the critical portion in a constituent parse tree for PPI extraction can be automatically determined by the shortest dependency path between the two involved proteins, while other portion can be regarded as noise and ignored safely. Evaluation on multiple PPI corpora shows that our dependency-directed tree kernel-based method achieves promising results. This justifies the effectiveness of tree kernel-based methods for PPI extraction, in particular the advantage of dependency-directed constituent structure representation.

1 Introduction

Since determining protein interaction partners is crucial to understand both the functional role of individual proteins and the organization of the entire biological process, there is a significant interest in protein-protein interaction (PPI) extraction. However, manual collection of relevant PPI information from thousands of biomedical research papers published every day (e.g. MEDLINE) is so time-consuming and labor-demanding that automatic extraction approaches with the help of NLP techniques become necessary.

In principle, PPI extraction is much like the semantic relation extraction subtask (so called Relation Detection and Classification, RDC) defined by the ACE project (ACE, 2002-2007) in the newswire domain. Therefore, various kinds of machine learning methods have been borrowed from the newswire domain to the biomedical domain: feature-based methods (Mitsumori et al., 2006; Giuliano et al., 2006; Sætre et al., 2007; Liu et al., 2010) and kernel-based methods (Bunescu et al., 2005a; Erkan et al., 2007; Airola et al., 2008; Kim et al., 2010).

Early studies on PPI extraction employ feature-based methods. However, the feature-based methods often fail to effectively capture the structured information, which is essential to identify the relationship between two proteins in a constituent or dependency-based syntactic representation.

With the wide adoption of kernel-based methods to many NLP tasks, particularly for semantic relation extraction and semantic role labeling, various kernels such as subsequence kernels (Bunescu et al., 2005a) and tree kernels (Li et al., 2008) have been applied to PPI extraction. On one hand, dependency-based kernels, such as edit distance kernels (Erkan et al. 2007), graph kernels (Airola et al., 2008) and subsequence kernels (Kim et al., 2010), show some promising results for PPI extraction. This suggests that dependency information plays a critical role in PPI extraction, much like semantic relation extraction in the newswire narratives (Culotta and Sorensen, 2004; Bunescu et al., 2005b). On the other hand, while tree kernels based on constituent parse trees achieve great success in semantic relation extraction (Zhang et al., 2006; Zhou et al., 2007a; Qian et al., 2008) and semantic role labeling (Moschitti, 2004; Zhang et al., 2008) from the newswire narratives, they haven't been fully explored for PPI extraction in the biomedical domain. Considering the similarity between the task of PPI extraction from the biomedical domain and that of relation extraction from the newswire domain, one question naturally arises: "How can kernel-based

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 10–19,
Chiang Mai, Thailand, November 8 – 13, 2011.

PPI extraction benefit from the constituent parse tree structure?"

To address this question, this paper presents a principled way to automatically generate a precise and concise constituent parse tree representation for kernel-based methods, motivated by the success of employing dependency information in PPI extraction. This is done by taking advantage of the shortest dependency path between two involved proteins in the dependency parse tree structure of a sentence. Specifically, only the words appearing on the shortest dependency path and their associated constituents in the constituent parse tree are considered as necessary and thus kept as the essential part of the constituent parse tree. In this paper, we refer to it as SDP-CPT (Shortest Dependency Path-directed Constituent Parse Tree). Experimental results on several major PPI corpora show the effectiveness of dependency-directed constituent structure representation and its preference over other state-of-the-art structure representations.

The rest of this paper is organized as follows. First, related work in PPI extraction is overviewed in Section 2. Then, Section 3 elaborates our shortest dependency path-directed constituent parse tree structure. Section 4 reports the experimental results on major PPI corpora. Finally we conclude our work in Section 5.

2 Related Work

Due to space limitation, this section only gives an overview on kernel-based methods on PPI extraction in the biomedical domain as well as semantic relation extraction in the newswire domain. For details about feature-based methods, please refer to related studies in the biomedical domain (Mitsumori et al., 2006; Giuliano et al., 2006; Liu et al., 2010) and those in the newswire domain (Zhao et al., 2005; Zhou et al. 2005, 2007b), respectively.

PPI extraction in biomedical domain

Representative kernel-based methods on PPI extraction take advantage of lexical or dependency information.

Bunescu et al. (2005a) adopt a generalized substring kernel over a mixture of words and word classes to extract protein interactions from biomedical corpora and semantic relations from newswire corpora. Particularly, they achieve the F1-score of 54.2 in extracting protein interactions from the AIMed corpus. Erkan et al. (2007) first define two similarity functions based on cosine similarity and edit distance among dependency paths between two entities, and then incorporate them in semi-supervised learning for PPI extraction using SVM and KNN classifiers. Sætre et al. (2007) use a tree kernel over dependency structures from two parsers and achieve the F1-score of 52.0 for PPI extraction from the AIMed corpus. Airola et al. (2008) introduce an all-dependency-paths graph kernel to capture complex dependency relationships between words and attain a significant performance boost at the expense of computational complexity. They achieve the F1-score of 56.4 in PPI extraction from the AIMed corpus. Kim et al. (2010) adopt a walk-weighted subsequence kernel based on shortest dependency paths to explore various substructures such as e-walks, partial match, and non-contiguous paths. They achieve the F1-score of 56.7 on the AIMed corpus.

Semantic relation extraction in newswire domain

In the literature, various kernels-based methods (Zelenko et al., 2003; Culotta and Sorensen, 2004; Bunescu et al., 2005b; Zhang et al., 2006; Zhou et al., 2007a; Qian et al., 2008) have been widely used in semantic relation extraction in the newswire domain. In particular, Zhang et al. (2006), Zhou et al. (2007a) and Qian et al. (2008) adopt convolution tree kernels (Collins and Duffy, 2001) over constituent parse trees and show great success with comparable or even better performance than feature-based ones, motivated by the pioneer work of Moschitti et al. (2004; 2008) on semantic role labeling.

While convolution kernels (Haussler et al., 1999) can effectively capture structured information in discrete objects, the key problem for tree kernel-based methods lies largely in how to appropriately represent structured syntactic information inherent in relation instances. Zhang et al. (2006) discover that the Shortest Path-enclosed Tree (SPT) achieves the best performance among five tree setups. Zhou et al. (2007a) further extend it to Context-Sensitive Shortest Path-enclosed Tree (CS-SPT), which includes necessary predicate-linked path information. Qian et al. (2008) propose to automatically determine the appropriate part of a constituent parse tree by considering constituent dependencies on each node along the shortest path between two entity mentions and discarding irrelevant nodes. However, their adopted constituent dependency rules are manually constructed and thus difficult to adapt to other domains and languages.

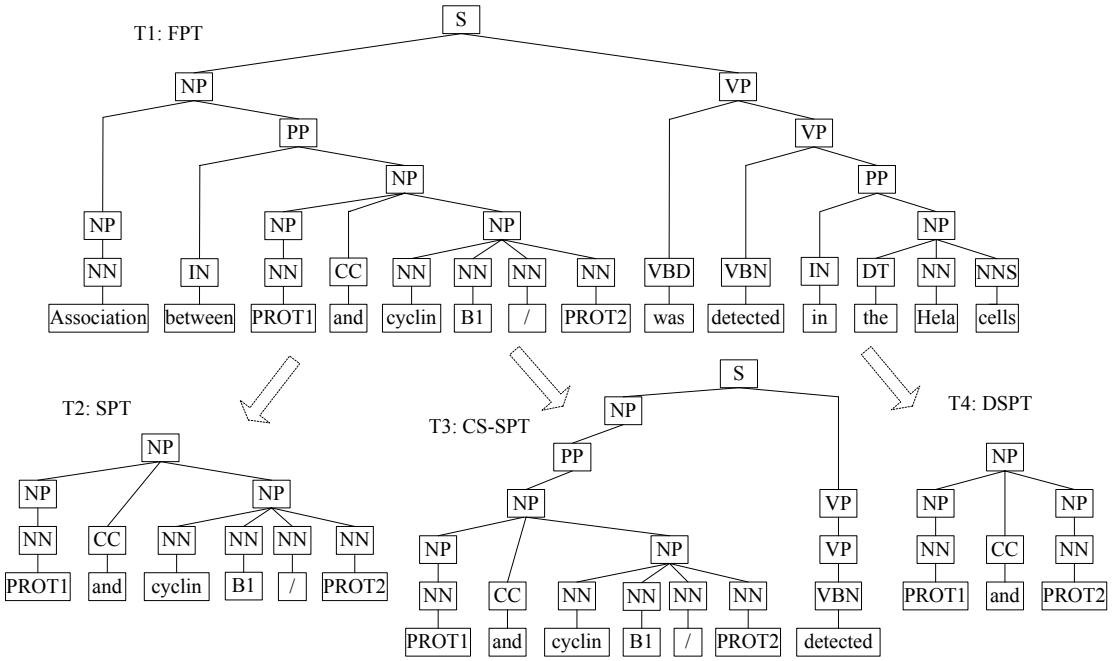

Figure 1. Different tree setups for a PPI instance between PROT1 and PROT2 from sentence "Association between PROT1 and cyclin B1 / PROT2 was detected in the HeLa cells." in the AIMed corpus

In this paper, we make use of the shortest dependency path in the dependency tree to refine the constituent parse tree. Specifically, all the words which appear on the shortest dependency path, together with their associated constituents, are kept in the constituent parse tree, while other constituents are removed, forming a Shortest Dependency Path-directed Constituent Parse Tree (SDP-CPT).

3 Constituent Structure Representation

This section first illustrates the limitations of commonly-used constituent parse tree setups, then emphasizes the importance of shortest dependency path in representing the constituent parse tree, and finally presents the shortest dependency path-directed constituent parse tree (SDP-CPT).

3.1 Limitations of Current Tree Setups

It is widely acknowledged that the key problem for the success of tree kernel-based semantic relation extraction is how to represent the constituent parse tree in a precise and concise manner. Zhang et al. (2006) explore five kinds of tree setups and find that the Shortest Path-enclosed Tree (SPT) achieves the best performance. However, unlike the locality of semantic relations in the newswire domain (Zhou et al., 2005), most of PPI instances in the biomedical domain spans a relatively long distance, leading to more complexity and diversity (Bunescu et al., 2005c; Airola et al., 2008). Therefore, it is not surprising that previous tree kernels over constituent parse trees have not yet achieved promising results for PPI extraction just as they do in the news domain. Miyao et al. (2008) conduct a comprehensive comparison of different syntactic representations for PPI extraction and find that the phrase structure tree in the form of the constituent parse tree (called PTB in their paper) performs significantly worse than the other representations. Tikk et al. (2010) extensively compares different kernel-based methods on PPI extraction and show that the tree kernel over the constituent parse tree only achieves the F1-score of 34.6 on the AIMed corpus. Actually, our preliminary experiment on PPI extraction via the convolution tree kernel over SPT only achieves the F1-score of about 47 on the AIMed corpus. Such poor performance can be justified to a certain extent via a typical instance as illustrated in Figure 1, where the interaction between PROT1 and PROT2 (their actual names have been replaced) can be only determined by the overall constituent structure of the sentence. Obviously, SPT will fail to identify this interaction instance since SPT ignores the constituents outside the shortest path (Figure 1: T_2: SPT).

For the Context-Sensitive SPT (CS-SPT), as proposed in Zhou et al. (2007a), which extends necessary predicate-linked path information outside SPT, some critical information is still missing while there exists some noisy information. For the instance as shown in Figure 1 (T_3: CS-SPT), although the word "detected" and its asso-

ciated constituents are added, the more important portion of "association between" and their associated constituents are still missing while the noisy words "cyclin B1 / " still remaining.

In order to overcome the shortcomings in SPT and CS-SPT, Qian et al. (2008) propose a dynamic syntactic parse tree (DSPT) by exploiting constituent dependencies to refine the constituent parse tree. Specifically, they manually devise five categories of constituent dependencies, motivated by various kinds of lexical dependencies. When refining each node along the shortest path in the constituent parse tree, these constituent dependencies are used to determine how to remove or reduce futile constituents, eventually leading to a more precise and concise parse tree structure. However, this tree structure still suffers from the following three shortcomings:

1) It disregards the constituents beyond the lowest common ancestor to the tree root, similar to CS-SPT as proposed in Zhou et al. (2007a). This may be largely due to the locality of semantic relations as defined in the ACE RDC corpus, which Zhou et al (2007a) and Qian et al. (2008) tackle.
2) The rules adopted to tackle constituent dependencies are manually constructed and thus may not be easily adapted to other domains and languages. For example, while the constituent dependencies related to noun phrases are effective in the newswire domain (e.g. the ACE RDC corpus), this may not be true for PPI extraction in the biomedical literature.
3) The constituent dependencies have been divided into only five categories. Such division may be too coarse to reflect the substantial difference between various kinds of dependencies (considering there are 55 kinds of minor-typed dependencies for the Stanford Dependency representation).

In this paper, we attempt to address these problems by considering the shortest dependency path in the dependency parse tree for reshaping the constituent parse tree in a principled way in the context of PPI extraction from the biomedical literature.

3.2 Shortest Dependency Path

Lexical dependencies can indicate both local and long-range relationships among words occurring in the same sentence. Such dependency relationships offer a condensed representation of the information necessary to assess the relationship between two proteins or entities. In order to capture the necessary information inherent in the depedency parse tree for extracting PPI instances, various kernels based on dependency paths, such as edit distance kernel (Erkan et al., 2007), all-dependency-path graph kernel (Airola et al., 2008), and walk-weighted subsequence kernels (Kim et al., 2010) have been proposed. Likewise for semantic relation extraction in the newswire domain, the kernels on dependency trees (Culotta and Sorensen, 2004) and the shortest dependency path (Bunescu et al., 2005b) have been proposed. One common characteristic to these kernels is that they all contain the shortest dependency path and usually assign more weights to them than to other ones, similar to the graph kernel proposed by Airola et al. (2008). This indicates the importance of the shortest dependency path over other paths in the dependency path tree or the dependency graph.

Currently, there are two established dependency representations available, viz. CoNLL scheme (adopted by CoNLL'2007 and CoNLL'2008 Shared tasks) (Nivre et al., 2007; Surdeanu et al., 2008) and Standford scheme (adopted by Stanford parser) (de Marneffe et al., 2006). These two schemes differ significantly in the representation of passive construction, position of auxiliary and modal verb, or coordination. It is generally acknowledged that the Stanford scheme is closer to the targeted semantic representation from the perspective of relation extraction (Buyko and Hahn, 2010). Particularly, among the four styles of Stanford representations, "collapsed dependency" can much simplify patterns in relation extraction since dependencies involving preposition, conjunct as well as referent of relative clause are effectively collapsed to reflect direct dependencies between content words. Therefore, the collapsed variant of Stanford scheme is adopted in this paper to refine the constituent parse tree as described in the next subsection.

3.3 SDP-CPT: Shortest Dependency Path-directed Constituent Parse Tree

Considering the importance of dependency path in PPI extraction and the effectiveness of employing dependency information to refine the constituent parse tree for tree kernel-based semantic relation extraction in the newswire domain, it is a natural idea to automatically generate the proper constituent parse tree with the help of the shortest dependency path. Specifically, we can reshape the constituent parse tree by making use of the shortest dependency path between two proteins. Figure 2 describes the procedure to

generate the Shortest Dependency Path-directed Constituent Parse Tree (SDP-CPT).

Note that Step 3(a) in Figure 2 is necessary since a dependency tuple of the type "prep_*xx*(*governor*, *dependent*)" implies a relationship between the preposition *xx* and the *dependent*, which is important to PPI. For Step 3(b), when a word on which the two proteins are directly or indirectly dependent is discovered, it is natural to add this path for maintaining the integrality of SDP-CPT.

Input: a sentence and two proteins in it
Output: an SDP-CPT
Steps:

1) Given the input sentence, generate the constituent parse tree using a constituent parser, and various dependency tuples using a dependency parser.
2) Given the two proteins, extract the shortest constituent path (SCP, i.e. the shortest path-enclosed tree) from the constituent parse tree and construct the shortest dependency path (SDP) from the dependency tuples.
3) For each word along the SDP, add the corresponding leaf word node and its upper constituents to the SCP. Particularly,
   a) when the dependency type is "prep_*xx*", such as "prep_of", the preposition *xx* and its associated constituent are also added;
   b) when the word to be added is outside the SCP, a new path from the current lowest common ancestor to one of the added words' ancestors is also added.
4) Merge any two consecutive NP/VP nodes along the paths into a single one.

Figure 2. Procedure for generating SDP-CPT

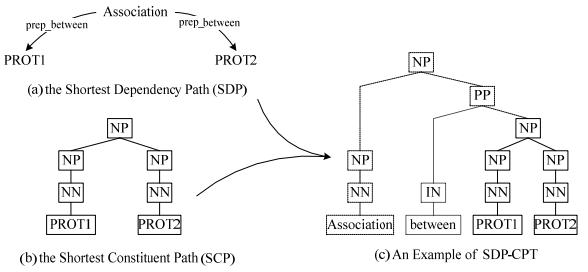

Figure 3. Generation of an example of SDP-CPT

In order to demonstrate the process of generating a SDP-CPT, we take the sentence and the two proteins shown in Figure 1 as an example. Figure 3 illustrates the detailed generation process. First, the shortest dependency path (SDP) and the shortest constituent path (SCP) are generated as depicted in Figure 3(a) and 3(b) respectively. Then, every word in the SDP is added into the SCP together with its associated constituents. In this case, since the two protein names in the SDP share a common ancestor "Association", the word "Association" together with its constituent ancestors are added into the SCP and a new path "NP→PP→NP" is created as rendered by the dashed lines. Finally, since the dependency type between "PROT1" and "Association" is *prep_between*, the preposition word "between" and its constituent ancestors are added into the SCP as rendered by the dotted lines. Since no further post-processing is necessary in this example, SDP-CPT is eventually formed. Compared to other tree setups in Figure 1, namely SPT, CS-SPT and DSPT, obviously SDP-CPT is much more concise and precise for this PPI instance.

4 Experimentation

This section systematically evaluates the performance of our shortest dependency path-directed constituent parse tree (SDP-SPT) on PPI extraction across several major PPI corpora.

4.1 Data Sets and Preprocessing

In order to fairly compare our work with other PPI extraction systems, we use five PPI corpora, i.e., AIMed (Bunescu et al., 2005a), BioInfer (Pyysalo et al., 2007), HPRD50 (Fundel et al., 2007), IEPA (Ding et al., 2002) and LLL (Nédellec, 2005). Particularly, most of the evaluation is done on the widely-used AIMed corpus, which contains 177 Medline abstracts with PPI instances, and 48 abstracts without any PPI instances. Totally, there are 4,084 protein references and around 1,000 annotated protein-protein interactions in this data set.

In this paper, a potential PPI instance is generated for any pair of two proteins in a sentence That is, if a sentence contains *n* proteins, $\binom{n}{2}$ protein pairs are generated. In particular, all the self-interactions (59 instances) are removed and all the PPI instances with nested protein names are retained (154 instances), as adopted in most literature. Eventually, 1000 positive instances and 4834 negative instances are generated. Besides, for a potential PPI instance, the two involved proteins are replaced by PROT1 and PROT2 respectively in order to blind the learner for fair comparison with other work. Finally, all the sentences in these corpora are parsed using the Stanford Parser[1] to generate both the con-

[1] http://nlp.stanford.edu/software/lex-parser.shtml

stituent parse trees and their corresponding dependency tuples.

4.2 Classifier and Evaluation Metrics

In our experimentation, we select Support Vector Machines (SVM) as the classifier since SVM represents the state-of-the-art in the machine learning research community. In particular, we use the SVM^{light} (Joachims, 1998) with the convolution tree kernel function SVM^{light}–TK (Moschitti, 2004)[2] to compute the similarity between two constituent parse trees.

Evaluation is done using 10-fold document-level cross-validation, each of which contains 90% of documents as the training data and 10% as the test data. Particularly, for the AIMed corpus we apply the exactly same 10-fold split as widely used in a series of relevant studies (e.g., Bunescu et al., 2005a; Giuliano et al., 2006). Following conventions, the parameters C for SVM is set to the ratio of negative instances to positive ones in respective corpora, and λ for the convolution tree kernel is set to default 0.4. Furthermore, the OAOD (One Answer per Occurrence in the Document) strategy is adopted, which means that the correct interaction must be extracted for each occurrence. This guarantees the maximal use of the available data, and more importantly, allows fair comparison with relevant work. All the experiments are evaluated using commonly-used Precision (P), Recall (R) and harmonic F1-score (F1). As an alternative to F1-score, the AUC (*area under the receiver operating characteristics curve*) score is proved to be invariant to the class distribution of the test dataset. Therefore, we also provide the AUC score of our system for referrence as by Airola et al. (2008).

4.3 Experimental Results

Comparison of different lengths of dependency paths on the AIMed corpus

Table 1 reports the performance of PPI extraction on the AIMed corpus corresponding to different lengths of the dependency paths using all kinds of dependency types. Here, two partial dependency paths on SDP, starting from each of the two proteins respectively, are utilized to generate the tree representation. The length of these two paths is shown in the 1st column. The words corresponding to the nodes on these two paths together with these words' associated constituents in the parse tree are added to SCP. For example, the length of 0 (L0) means that not a single word or constituent will be added to SCP, while the length of 1 (L1) means that the words corresponding to the parents of two proteins on SDP and these words' associated constituents in the parse tree are added to SCP. Meanwhile, the performance of the SPT setup is also listed as the baseline for comparison.

Length	P (%)	R (%)	F1	AUC
SPT	57.0	40.7	47.1	79.9
SCP+L0 (SCP)	45.0	19.5	26.5	67.9
SCP+L1	59.7	45.8	51.4	80.2
SCP+L2	59.2	51.7	55.0	82.3
SCP+L3	58.0	51.9	54.6	82.2
SCP+L4	59.3	54.0	56.2	82.6
SDP-CPT	59.6	54.3	56.7	82.7

Table 1. Performance comparison of PPI extraction on the AIMed corpus with different lengths of dependency paths using all kinds of dependency types

This table shows that the constituent parse tree directed by the shortest dependency path (SDP-CPT) achieves the best performance of 59.6/54.3/56.7/82.7 in P/R/F1/AUC, significantly outperforming SPT by 9.6 units in F1 and 2.8 units in AUC largely due to the substantial increase in recall. This indicates that SDP-CPT can remove much noise in SPT while adding some useful information. It also shows

- The performance of the SCP corresponding to the length of 0 is lowest, since they contain no information derived from the shortest dependency path.
- With the increase of the length of dependency paths, more and more useful information derived from SDP is included in the constituent parse tree and the performance reaches the highest for SDP-CPT (all the words corresponding to all the nodes on the SDP and their associated constituents are added).

In summary, the above results suggest that SDP-CPT can achieve the best performance. Therefore, all the subsequent experiments adopt the SDP-CPT setup unless specified.

Contribution of different kinds of dependencies on the AIMed corpus

Table 2 compares the contribution of various kinds of dependencies in SDP-CPT on the AIMed corpus. All the typed dependency relations are grouped into 4 major classes, namely *Modifier*, *Argument*, *Conjunction* and *Others*. For every major type, minor dependency types, if

[2] http://ai-nlp.info.uniroma2.it/moschitti/

any exists, are further ordered by their potential importance. The percentage of occurring frequency with which each minor type is employed when generating the SDP-CPT with respect to the total number of dependency tuples is listed in Column 2. Particularly, the tree setup without using any dependency type, which corresponds to that with the length of 0 (SCP) in Table 1, is displayed at the top row. Furthermore, the dependency types are added in two different ways:

- Individual: the dependency types are added individually with their performance scores shown inside the parentheses;
- Accumulative: the dependency types are incrementally added one by one with their performance scores shown outside the parentheses. The "+" sign before the type means that its addition can boost the performance in F1-score or AUC score and thus will be passed down to the next iteration.

Typed Dependency	%	P(%)	R(%)	F1	AUC
SCP+L0	-	45.0	19.5	26.5	67.9
Argument					
+subj	10	52.5 (52.6)	33.2 (33.2)	40.4 (40.4)	72.7 (72.7)
+obj	31	56.2 (53.8)	46.2 (42.4)	50.4 (47.0)	76.6 (76.6)
+arg-others	2	56.1 (48.8)	47.0 (14.6)	50.9 (21.3)	76.5 (68.6)
Modifier					
+nn	10	58.1 (54.9)	53.4 (38.5)	55.1 (44.6)	81.4 (77.5)
+prep	20	58.2 (53.4)	55.2 (39.2)	56.6 (44.8)	83.1 (76.2)
+mod-others	5	**59.1** (46.8)	**57.6** (15.7)	**58.1** (22.3)	**83.3** (67.3)
Conjunction	12	58.9 (48.9)	55.0 (23.5)	56.7 (30.5)	82.8 (69.8)
Others	10	58.4 (47.5)	53.8 (14.8)	55.8 (20.4)	83.0 (69.5)

Table 2. Contribution of different typed dependencies on the AIMed corpus with the SDP-CPT setup in the accumulative mode (outside parentheses) and in the individual mode (inside parentheses)

Table 2 shows that with the addition of all *Argument* types and all *Modifier* types, the SDP-CPT attains the best performance of 59.1/57.6/58.1/83.3 in P/R/F1/AUC as shown in bold fonts, outperforming the SDP-CPT with all dependency types added (59.6/54.3/56.7/82.7 in P/R/F1/AUC). Particularly, it shows

- The dependency types of *subj*, *obj, prep* and *nn* yield substantial performance improvement both in the accumulative mode and in the individual mode;
- The dependency types of *Conjunction* and *Others* harm the performance in the accumulative mode, though *Conjunction* improves the performance in the individual mode;
- It is interesting to note that while the dependency types of *arg-others* and *mod-others* harm the performance in the individual mode, they slightly improve the performance in the accumulative mode.

Since the governors of *subj* and *obj* types are verbs, those of the *prep* type are nouns and prepositions, and those of the *nn* type are nouns, the above results are consistent with our observation that some verbs like "bind" or "interact", some prepositions like "with" or "of", and some nouns like "interaction" or "expression", on which two proteins are directly or indirectly dependent, are particularly important for PPI extraction. Henceforth, in the following experiments all the *Argument* and *Modifier* types are included while the *Conjunction* and *Others* types are excluded.

Tree setups	AIMed	BioInfer	HPRD 50	IEPA	LLL
Ratio of POS/NEG	1000/ 4834	2534/ 7119	163/ 270	335/ 482	164/ 166
MCT	31.8 (78.0)	53.8 (76.7)	48.0 (73.4)	62.3 (78.6)	77.1 (73.4)
SPT (baseline)	47.1 (79.9)	54.2 (73.7)	61.3 (81.6)	66.6 (82.2)	79.4 (86.1)
CS-SPT	46.5 (80.2)	54.5 (74.5)	63.6 (79.9)	66.8 (81.0)	80.1 (86.0)
DSPT	50.0 (77.8)	58.3 (78.5)	66.0 (80.3)	68.6 (80.9)	77.3 (79.3)
SDP-CPT	**58.1** (83.3)	**62.4** (83.6)	**68.8** (83.4)	**69.8** (82.0)	**84.6** (89.2)

Table 3. Comparison of F1-score(outside parentheses) and AUC(inside parentheses) between SDP-CPT and different tree setups across major PPI corpora

Comparison of different constituent parse tree structures across major PPI corpora

Table 3 compares the performance of F1-score (outside parenthesis) and AUC (inside parentheses) between SDP-CPT and the previously-used tree setups across major PPI corpora. Particularly, SPT is used as a baseline and for comparison we re-implement two other effective tree setups for semantic relation extraction in the newswire domain, i.e. CS-SPT (Zhou et al., 2007a) and DSPT (Qian et al., 2008). Significance tests are conducted between each of them and the baseline.

Additionally, the numbers of positive and negative instances in each corpus are reported in the 1st row and the performance scores of MCT (Minimum Complete Tree, the complete sub-tree rooted by the lowest common ancestor of the two proteins under consideration) are also listed in the 2nd row for reference. The table shows

- Among all tree setups SDP-CPT performs best and significantly outperforms SPT consistently on most PPI corpora.
- CS-SPT slightly outperforms SPT on most corpora while DSPT performs divergently on different corpora. The reason that DSPT performs excellently in the newswire domain (Qian et al., 2008) but not so much for PPI extraction may be that the heuristic rules they use to prune the constituent trees are more suitable for the newswire domain, thus limiting their capability of domain adaptation.

In summary, the above results suggest the superiority and generality of our SDP-CPT on various kinds of PPI corpora from the biomedical literature.

PPI extraction systems	P(%)	R(%)	F1
Our SDP-CPT kernel	59.1	57.6	**58.1**
Dependency path: Kim et al. (2010)	61.4	53.3	56.7
Dependency graph: Airola et al. (2008)	52.9	**61.8**	56.4
Word subsequence: Bunescu et al. (2005a)	**65.0**	46.4	54.2
Constituent parse tree: Tikk et al. (2010)	39.2	31.9	34.6
BOW+Dependency path: Sætre et al. (2007)	**64.3**	44.1	52.0
BOW+Constituent parse tree: Miyao et al. (2008)	50.9	56.1	53.0
Global+Local context: Giuliano et al. (2006)	60.9	57.2	59.0
Dependency+Predicate Argument Structure: Miyao et al. (2008)	54.9	**65.5**	59.5
BOW+Shortest Path+Depencency graph: Miwa et al. (2009)	-	-	**64.2**

Table 4. Performance comparison of kernel-based PPI extraction systems on the AIMed corpus

Comparison of kernel-based PPI extraction systems on the AIMed corpus

Table 4 compares our kernel-based system with other state-of-the-art kernel-based ones on the AIMed corpus using the exactly same 10-fold data splitting. It shows that our individual kernel-based system performs better than all the other individual kernel-based systems on the AIMed corpus. Particularly, our SDP-CPT kernel significantly outperforms the Partial Tree kernel over constituent parse trees (Tikk et al., 2010). It even significantly outperforms the composite kernel combining BOW and constituent parse trees (Miyao et al., 2008). Although our individual kernel performs worse than the composite kernels as adopted by Miyao et al. (2008) and Miwa et al. (2009), the strength of our kernel-based system lies in the simplicity of our shortest dependency path-directed constituent parse tree.

5 Conclusion and Future Work

This paper presents a principled way to automatically generate the constituent parse tree for PPI extraction by making use of the shortest dependency path between two proteins. Although previous research indicates the difficulty of employing constituent parse tree information for PPI extraction due to the relatively long distance between two proteins, our detailed analysis and evaluation indicate that the constituent parse tree can achieve promising results for PPI extraction. Moreover, our dependency-directed constituent parse tree structure provides a general way to automatically determine the constituent parse tree for a wide class of related learning tasks, such as semantic relation extraction, semantic role labeling and even coreference resolution.

For future work, we would like to apply our approach to other NLP tasks. Meanwhile, we will investigate the effect of constituent parse information on dependency-based relational learning in better exploring the synergy between dependency and constituent-based syntactic information.

Abstract

This paper presents a new task, learning logical structures of paragraphs in legal articles, which is studied in research on Legal Engineering (Katayama, 2007). The goals of this task are recognizing logical parts of law sentences in a paragraph, and then grouping related logical parts into some logical structures of formulas, which describe logical relations between logical parts. We present a two-phase framework to learn logical structures of paragraphs in legal articles. In the first phase, we model the problem of recognizing logical parts in law sentences as a multi-layer sequence learning problem, and present a CRF-based model to recognize them. In the second phase, we propose a graph-based method to group logical parts into logical structures. We consider the problem of finding a subset of complete sub-graphs in a weighted-edge complete graph, where each node corresponds to a logical part, and a complete sub-graph corresponds to a logical structure. We also present an integer linear programming formulation for this optimization problem. Our models achieve 74.37% in recognizing logical parts, 79.59% in recognizing logical structures, and 55.73% in the whole task on the Japanese National Pension Law corpus.

1 Introduction

Legal Engineering (Katayama, 2007) is a new research field which aims to achieve a trustworthy electronic society. Legal Engineering regards that laws are a kind of software for our society. Specifically, laws such as pension law are specifications for information systems such as pension systems. To achieve a trustworthy society, laws need to be verified about their consistency and contradiction.

Legal texts have some specific characteristics that make them different from other kinds of documents. One of the most important characteristics is that legal texts usually have some specific structures at both sentence and paragraph levels. At the sentence level, a law sentence can roughly be divided into two logical parts: *requisite part* and *effectuation part* (Bach, 2011a; Bach et al., 2011b; Tanaka eta al., 1993). At the paragraph level, a paragraph usually contains a main sentence[1] and one or more subordinate sentences (Takano et al., 2010).

Analyzing logical structures of legal texts is an important task in Legal Engineering. The outputs of this task will be beneficial to people in understanding legal texts. They can easily understand 1) what does a law sentence say? 2) what cases in which the law sentence can be applied? and 3) what subjects are related to the provision described in the law sentence? This task is the preliminary step, which supports other tasks in legal text processing (translating legal articles into logical and formal representations, legal text summarization, legal text translation, question answering in legal domains, etc) and serves legal text verification, an important goal of Legal Engineering.

There have been some studies analyzing logical structures of legal texts. (Bach et al., 2011b) presents the RRE task[2], which recognizes the logical structure of law sentences. (Bach et al., 2010) describes an investigation on contributions of words to the RRE task. (Kimura et al., 2009) focuses on dealing with legal sentences including itemized and referential expressions. These works, however, only analyze logical structures of legal texts at the sentence level. At the paragraph

[1] Usually, the first sentence is the main sentence.

[2] The task of Recognition of Requisite part and Effectuation part in law sentences.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 20–28,
Chiang Mai, Thailand, November 8 – 13, 2011.

level, (Takano et al., 2010) classifies a legal paragraph into one of six predefined categories: A, B, C, D, E, and F. Among six types, Type A, B, and C correspond to cases in which the main sentence is the first sentence, and subordinate sentences are other sentences. In paragraphs of Type D, E, and F, the main sentence is the first or the second sentence, and a subordinate sentence is an embedded sentence in parentheses within the main sentence.

In this paper, we present a task of learning logical structures of legal articles at the paragraph level. We propose a two-phase framework to complete the task. We also describe experimental results on real legal data.

Our main contributions can be summarized in the following points:

- Introducing a new task to legal text processing, *learning logical structures of paragraphs in legal articles*.
- Presenting an annotated corpus for the task, the *Japanese National Pension Law corpus*.
- Proposing a two-phase framework and providing solutions to solve the task.
- Evaluating our framework on the real annotated corpus.

The rest of this paper is organized as follows. Section 2 describes our task and its two sub-tasks: *recognition of logical parts* and *recognition of logical structures*. In Section 3, we present our framework and proposed solutions. Experimental results on real legal articles are described in Section 4. Finally, Section 5 gives some conclusions.

2 Formulation

Learning logical structures of paragraphs in legal articles is the task of recognition of *logical structures* between *logical parts* in law sentences. A logical structure is usually formed from a pair of a *requisite part* and an *effectuation part*. These two parts are built from other kinds of logical parts such as *topic parts*, *antecedent parts*, *consequent parts*, and so on (Bach, 2011a; Bach et al., 2011b)[3]. Usually, consequent parts describes a law provision, antecedent parts describes cases in which the law provision can be applied, and topic parts describe subjects which are related to the law provision. In this paper, a logical structure can be defined as a set of some related logical parts.

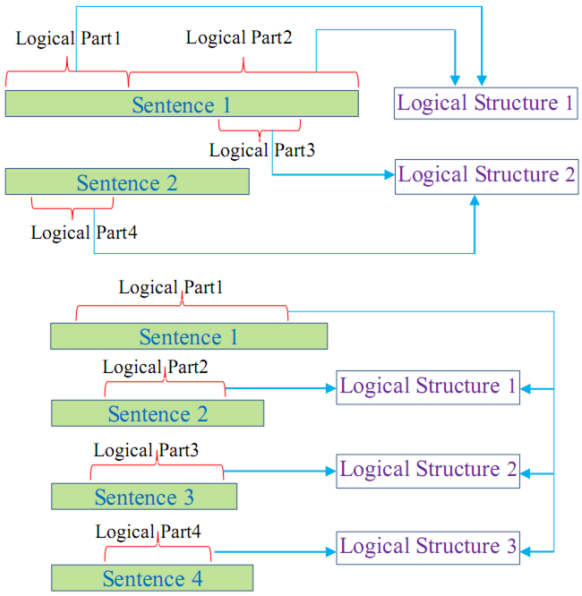

Figure 1: Two cases of inputs and outputs of the task.

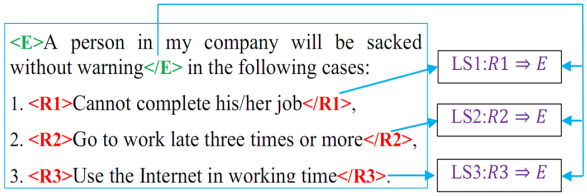

Figure 2: An example in natural language (E means *Effectuation part*, R means *Requisite part*, and LS means *Logical Structure*).

Figure 1 shows two cases of the inputs and outputs of the task. In the first case, the input is a paragraph of two sentences, and the outputs are four logical parts, which are grouped into two logical structures. In the second case, the input is a paragraph consisting of four sentences, and the outputs are four logical parts, which are grouped into three logical structures. An example in natural language[4] is presented in Figure 2.

2.1 Sub-Task 1: Recognition of Logical Parts

Let s be a law sentence in the law sentence space S, then s can be represented by a sequence of words $s = [w_1 w_2 \dots w_n]$. A legal paragraph x in the legal paragraph space X is a sequence of law sentences $x = [s_1 s_2 \dots s_l]$, where $s_i \in S, \forall i = 1, 2, \dots, l$. For each paragraph x, we denote a log-

[3] We only recognize logical structures (a set of related logical parts). The task of translating legal articles into logical and formal representations is not covered in this paper.

[4] Because law sentences are very long and complicated, we use toy sentences to illustrate the task.

ical part p by a quad-tuple $p = (b, e, k, c)$ where b, e, and k are three integers which indicate *position of the beginning word*, *position of the end word*, and *sentence position* of p, and c is a logical part category in the set of predefined categories C. Formally, the set P of all possible logical parts defined in a paragraph x can be described as follows:

$P = \{(b, e, k, c) | 1 \leq k \leq l, 1 \leq b \leq e \leq len(k), c \in C\}$.

In the above definition, l is the number of sentences in the paragraph x, and $len(k)$ is the length of the k^{th} sentence.

In this sub-task, we want to recognize some *non-overlapping* (but possibly *embedded*) logical parts in an input paragraph. A solution for this task is a subset $y \subseteq P$ which does not violate the *overlapping* relationship. We say that two logical parts p_1 and p_2 are *overlapping* if and only if they are in the same sentence ($k_1 = k_2$) and $b_1 < b_2 \leq e_1 < e_2$ or $b_2 < b_1 \leq e_2 < e_1$. We denote the *overlapping* relationship by $\sim$. We also say that p_1 is *embedded* in p_2 if and only if they are in the same sentence ($k_1 = k_2$) and $b_2 \leq b_1 \leq e_1 \leq e_2$, and denote the *embedded* relationship by $\prec$. Formally, the solution space can be described as follows: $Y = \{y \subseteq P | \forall u, v \in y, u \not\sim v\}$. The learning problem in this sub-task is to learn a function $R : X \rightarrow Y$ from a set of m training samples $\{(x^i, y^i) | x^i \in X, y^i \in Y, \forall i = 1, 2, \ldots, m\}$.

In our task, we consider the following types of logical parts:

1. An antecedent part is denoted by A
2. A consequent part is denoted by C
3. A topic part which depends on the antecedent part is denoted by T_1
4. A topic part which depends on the consequent part is denoted by T_2
5. A topic part which depends on both the antecedent part and the consequent part is denoted by T_3
6. The left part of an equivalent statement is denoted by EL
7. The right part of an equivalent statement is denoted by ER
8. An object part, whose meaning is defined differently in different cases, is denoted by Ob
9. An original replacement part, which will be replaced by other replacement parts (denoted by $RepR$) in specific cases, is denoted by $RepO$.

Compared with previous works (Bach et al., 2011b), we introduce three new kinds of logical parts: Ob, $RepO$, and $RepR$.

2.2 Sub-Task 2: Recognition of Logical Structures

In the second sub-task, the goal is to recognize a set of logical structures given a set of logical parts.

Let $G =< V, E >$ be a complete undirected graph with the vertex set V and the edge set E. A real value function f is defined on E as follows:

$f : E \rightarrow R, e \in E \mapsto f(e) \in R$.

In this sub-task, each vertex of the graph corresponds to a logical part, and a complete sub-graph corresponds to a logical structure. The value on an edge connecting two vertices expresses the degree that the two vertices belong to one logical structure. The positive (negative) value means that two vertices are likely (not likely) to belong to one logical structure.

Let G_s be a complete sub-graph of G, then $v(G_s)$ and $e(G_s)$ are the set of vertices and the set of edges of G_s, respectively. We define the total value of a sub-graph as follows:

$f(G_s) = f(e(G_s)) = \sum_{e \in e(G_s)} f(e)$.

Let Ω be the set of all complete sub-graphs of G. The problem becomes determining a subset $\Psi \subseteq \Omega$ that satisfies the following constraints:

1. $\forall g \in \Psi, |v(g)| \geq 2$,
2. $\cup_{g \in \Psi} v(g) = V$,
3. $\forall g_1, g_2 \in \Psi | v(g_1) \subseteq v(g_2) \Rightarrow v(g_1) = v(g_2)$,
4. $\forall g \in \Psi, \cup_{h \in \Psi, h \neq g} v(h) \neq V$, and
5. $\sum_{g \in \Psi} f(g) \rightarrow$ maximize.

Constraint 1), *minimal constraint*, says that each logical structure must contain at least two logical parts. There is the case that a logical structure contains only a consequent part. Due to the characteristics of Japanese law sentences, however, our corpus does not contain such cases. A logical structure which contains a consequent part will also contain a topic part or an antecedent part or both of them. So a logical structure contains at least two logical parts. Constraint 2), *complete constraint*, says that each logical part must belong to at least one logical structure. Constraint 3), *maximal constraint*, says that we cannot have two different logical structures such that the set of logical parts in one logical structure contains the set

of logical parts in the other logical structure. Constraint 4), *significant constraint*, says that if we remove any logical structure from the solution, Constraint 2) will be violated. Although Constraint 3) is guaranteed by Constraint 4), we introduce it because of its importance.

3 Proposed Solutions

3.1 Multi-layer Sequence Learning for Logical Part Recognition

This sub-section presents our model for recognizing logical parts. We consider the recognition problem as a multi-layer sequence learning problem. First, we give some related notions.

Let s be a law sentence, and P be the set of logical parts of s, $P = \{p_1, p_2, \ldots, p_m\}$. $Layer^1(s)$ (outer most layer) is defined as a set of logical parts in P, which are not embedded in any other part. $Layer^i(s)$ is defined as a set of logical parts in $P \setminus \cup_{k=1}^{i-1} Layer^k(s)$, which are not embedded in any other part in $P \setminus \cup_{k=1}^{i-1} Layer^k(s)$. Formally, we have:

$Layer^1(s) = \{p | p \in P, p \not\prec q, \forall q \in P, q \neq p\}$.

$Layer^i(s) = \{p | p \in Q^i, p \not\prec q, \forall q \in Q^i, q \neq p\}$, where

$Q^i = P \setminus \cup_{k=1}^{i-1} Layer^k(s)$

Figure 3 illustrates a law sentence with four logical parts in three layers: Part 1 and Part 2 in $Layer^1$, Part 3 in $Layer^2$, and Part 4 in $Layer^3$.

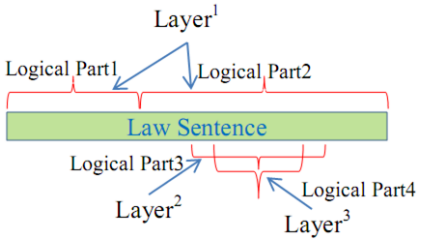

Figure 3: A law sentence with logical parts in three layers.

Input Sentence	w_1	w_2	...	w_{k-1}	w_k	w_{k+1}	w_{k+2}	...	w_{n-1}	w_n
Layer1	Topic Part 2 (T_2)					Consequence Part (C)				
Layer2						Left Side Part (EL)				
Labels in Layer1	I-T_2	I-T_2	...	I-T_2	E-T_2	I-C	I-C	...	I-C	E-C
Labels in Layer2						O	I-EL	...	E-EL	O

Figure 4: An example of labeling in the multi-layer model.

Let K be the number of layers in a law sentence s, our model will recognize logical parts in K steps. In the k^{th} step we recognize logical parts in $Layer^k$. In each layer, we model the recognition problem as a sequence labeling task in which each word is an element. Logical parts in $Layer^{i-1}$ will be used as input sequence in the i^{th} step (in the first step, we use original sentence as input).

Figure 4 gives an example of labeling for an input sentence. The sentence consists of three logical parts in two layers. In our model, we use IOE tag setting: the last element of a part is tagged with E, the other elements of a part are tagged with I, and an element not included in any part is tagged with O.

Let K^* be the maximum number of layers in all law sentences in training data. We learn K^* models, in which the k^{th} model is learned from logical parts in the $Layer^k$ of training data, using Conditional random fields (Lafferty et al., 2001; Kudo, CRF toolkit). In the testing phase, we first apply the first model to the input law sentence, and then apply the i^{th} model to the predicted logical parts in $Layer^{i-1}$.

3.2 ILP for Recognizing Logical Structures

Suppose that G' is a sub-graph of G such that G' contains all the vertices of G and the degree of each vertex in G' is greater than zero, then the set of all the maximal complete sub-graphs (or cliques) of G' will satisfy all the *minimal*, *complete*, *maximal*, and *significant* constraints. We also note that, a set of cliques that satisfies all these four constraints will form a sub-graph that has two properties like properties of G'.

Let Λ be the set of all such sub-graphs G' of G, the sub-task now consists of two steps:

1. Finding $G' = argmax_{G' \in \Lambda} f(G')$, and
2. Finding all cliques of G'.

Each clique found in the second step will correspond to a logical structure.

Recently, some researches have shown that integer linear programming (ILP) formulations is an effective way to solve many NLP problems such as semantic role labeling (Punyakanok, 2004), coreference resolution (Denis and Baldridge, 2007), summarization (Clarke and Lapata, 2008), dependency parsing (Martins et al., 2009), and so on. The advantage of ILP formulations is that we can incorporate non-local features or global constraints easily, which are difficult in traditional algorithms. Although solving an ILP is NP-hard in general, some fast algorithms and available tools[5]

[5]We used *lp-solve* from http://lpsolve.sourceforge.net/

make it a practical solution for many NLP problems (Martins et al., 2009).

In this work, we exploit ILP to solve the first step. Let N be the number of vertices of G, we introduce a set of integer variables $\{x_{ij}\}_{1 \leq i < j \leq N}$. The values of $\{x_{ij}\}$ are set as follows. If $(i, j) \in e(G')$ then $x_{ij} = 1$, otherwise $x_{ij} = 0$. ILP formulations for the first step can be described as follows:

//- - - - - - - - Objective function - - - - - - - -//

$$Maximize : \sum_{1 \leq i < j \leq N} f(i, j) * x_{ij} \quad (1)$$

//- - - - - - - - - - Constraints - - - - - - - - - -//

$$Integer : \{x_{ij}\}_{1 \leq i < j \leq N}. \quad (2)$$

$$0 \leq x_{ij} \leq 1, (1 \leq i < j \leq N). \quad (3)$$

$$\sum_{i=1}^{j-1} x_{ij} + \sum_{k=j+1}^{N} x_{jk} \geq 1, (1 \leq j \leq N). \quad (4)$$

The last constraint guarantees that there is at least one edge connecting to each vertex in G'.

The second step, finding all cliques of an undirected graph, is a famous problem in graph theory. Many algorithms have been proposed to solve this problem efficiently. In this work, we exploit the Bron-Kerbosch algorithm, a backtracking algorithm. The main idea of the Bron-Kerbosch algorithm is using a branch-and-bound technique to stop searching on branches that cannot lead to a clique (Bron and Kerbosch, 1973).

The remaining problem is how to define the value function f. Our solution is that, first we learn a binary classifier C using maximum entropy model. This classifier takes a pair of logical parts as the input, and outputs $+1$ if two logical parts belong to one logical structure, otherwise it will output -1. Then, we define the value function f for two logical parts as follows:

$f(p_1, p_2) = Prob(C(p_1, p_2) = +1) - 0.5$.

Function f will receive a value from -0.5 to $+0.5$, and it equals to zero in the case that the classifier assigns the same probability to $+1$ and -1.

4 Experiments

4.1 Corpus

We have built a corpus, Japanese National Pension Law (JNPL) corpus, which consists of 83 legal articles[6] of Japanese national pension law. The architecture of JNPL is shown in Figure 5. The law consists of articles, articles consist of paragraphs, and paragraphs contain sentences. A sentence may belong to items, sub-items, or sub-sub-items of a paragraph.

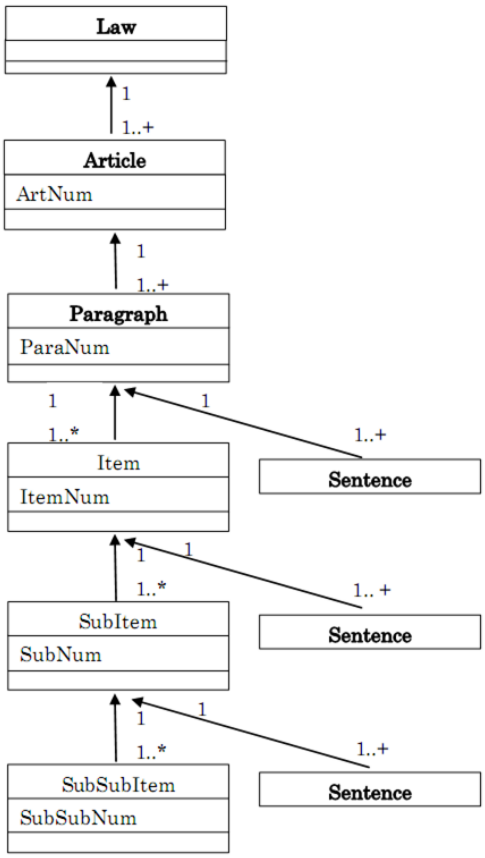

Figure 5: The architecture of JNPL.

Figure 6 illustrates the relationship between a law sentence and logical parts. A law sentence may contain some logical parts, and a logical part may be embedded in another one.

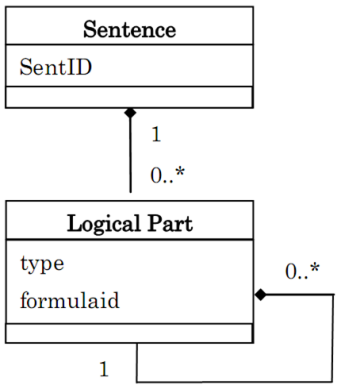

Figure 6: Relationship between a sentence and logical parts.

In our corpus, a logical part is annotated with information about its *type* (kind of part) and *formula-id* (logical parts with the same id will be-

[6]Because building corpus is an expensive and time-consuming task, we only annotate a part of JNPL.

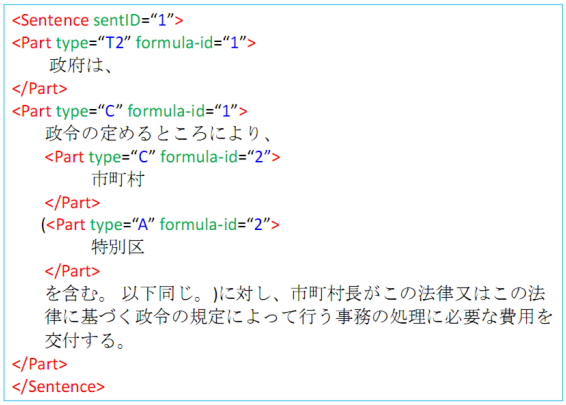

Figure 7: An annotated sentence in the JNPL corpus. The sentence contains two logical structures with four logical parts.

long to one logical structure). An example of annotated sentence in the JNPL corpus is shown in Figure 7.

We employed two people in a data-making company, who analyzed and annotated our corpus. The corpus consists of 83 legal articles, which contain 119 paragraphs with 426 sentences. On average, each paragraph consists of 3.6 sentences. The total number of logical parts is 807, and the number of logical structures is 351. On average, each paragraph consists of 6.8 logical parts and 3 logical structures.

Table 1 shows some statistics on the number of logical parts of each type. Main types of parts are A(35.4%), C(30.7%), T_2(14.1%), ER(7.1%), and EL(6.8%). Five main types of parts make up more than 94% of all types.

4.2 Evaluation Methods

We divided the JNLP corpus into 10 sets, and conducted 10-fold cross-validation tests. For the first sub-task, we evaluated the performance of our system by precision, recall, and F_1 scores as follows:

$$precision = \frac{|correct\ parts|}{|predicted\ parts|}, recall = \frac{|correct\ parts|}{|actual\ parts|},$$
$$F_1 = \frac{2*precision*recall}{precision+recall}.$$

For the second sub-task, we used MUC precision, recall, and F_1 scores as described in (Vilain et al., 1995). We summarize them here for clarity.

Let $P_1, P_2, \ldots, P_n$ be n predicted logical structures, and $G_1, G_2, \ldots, G_m$ be the correct answers or gold logical structures. To calculate recall, for each gold logical structure $G_i (i = 1, 2, \ldots, m)$, let $k(G_i)$ be the smallest number such that there exist $k(G_i)$ predicted structures $P^i_1, P^i_2, \ldots, P^i_{k(G_i)}$ which satisfy $G_i \subseteq \cup_{j=1}^{k(G_i)} P^i_j$:

$$recall = \frac{\sum_{i=1}^{m}(|G_i| - k(G_i))}{\sum_{i=1}^{m}(|G_i| - 1)}.$$

To calculate precision, we switch the roles of predicted structures and gold structures. Finally, F_1 score is computed in a similar manner as in the first sub-task.

4.3 Experiments on Sub-Task 1

4.3.1 Baseline: Filter-Ranking Perceptron Algorithm

We chose the Filter-Ranking (FR) Perceptron algorithm proposed by (Carreras and Marquez, 2005; Carreras et al., 2002) as our baseline model because of its effectiveness on phrase recognition problems, especially on problems that accept the *embedded* relationship[7]. We use FR-perceptron algorithm to recognize logical parts in law sentences one by one in an input paragraph.

For *beginning/end* predictors, we got features of words, POS tags, and Bunsetsu[8] tags in a window size 2. Moreover, with *beginning* predictor, we used a feature for checking whether this position is the beginning of the sentence or not. Similarly, with *end* predictor, we use a feature for checking whether this position is the end of the sentence or not.

With each logical part candidate, we extract following kinds of features:

1. Length of the part
2. Internal structure: this feature is the concatenation of the top logical parts, punctuation marks, parenthesis, and quotes inside the candidate. An example about internal structure may be $(A+, +C+.)$ (plus is used to concatenate items)
3. Word (POS) uni-gram, word (POS) bi-gram, and word (POS) tri-gram.

4.3.2 Experimental Results

In our experiments, we focus on paragraphs in Type A, B, and C defined in (Takano et al., 2010). In these types, the first sentence is the main sentence, which usually contains more logical parts than other sentences. The other sentences often have a few logical parts, and in most cases these logical parts only appear in one layer. The first

[7]We re-implement the FR-perceptron algorithm by ourself.

[8]In Japanese, a Bunsetsu is an unit of sentence which is similar to a chunk in English.

Table 1: Statistics on logical parts of the JNPL corpus

Logical Part	C	A	T_1	T_2	T_3	EL	ER	Ob	RepO	RepR
Number	248	286	0	114	12	55	57	9	12	14

Table 2: Experimental results for Sub-task 1 on the JNLP corpus(W:Word; P: POS tag; B: Bunsetsu tag)

Model	Prec(%)	Recall(%)	F_1(%)
Baseline	**79.70**	52.54	63.33
W	79.18	69.27	73.89
W+P	77.62	68.77	72.93
W+B	79.63	**69.76**	**74.37**
W+P+B	77.89	69.39	73.39

sentences usually contain logical parts in two layers.

We divided sentences into two groups. The first group consists of the first sentences in paragraphs, and the second group consists of other sentences. We set the number of layers k to 2 for sentences in the first group, and to 1 for sentences in the second group. To learn sequence labeling models, we used CRFs (Lafferty et al., 2001; Kudo, CRF toolkit).

Experimental results on the JNPL corpus are described in Table 2. We conducted experiments with four feature sets: words; words and POS tags; words and Bunsetsu tags; and words, POS tags, and Bunsetsu tags. To extract features from source sentences, we used the CaboCha tool (Kudo, Cabocha), a Japanese morphological and syntactic analyzer. The best model (word and Bunsetsu tag features) achieved 74.37% in F_1 score. It improves 11.04% in F_1 score (30.11% in error rate) compared with the baseline model.

Table 3 shows experimental results of our best model in more detail. Our model got good results on most main parts: C(78.98%), A(80.42%), and T_2(82.14%). The model got low results on the other types of parts. It is understandable because three types of logical parts C, A, and T_2 make up more than 80%, while six other types only make up 20% of all types.

Table 3: Experimental results in more details

Logical Part	Prec(%)	Recall(%)	F_1(%)
C	**83.41**	**75.00**	**78.98**
EL	76.74	60.00	67.35
ER	41.94	22.81	29.55
Ob	0.00	0.00	0.00
A	**80.42**	**80.42**	**80.42**
RepO	100	16.67	28.57
RepR	100	28.57	44.44
T_2	**83.64**	**80.70**	**82.14**
T_3	60.00	25.00	35.29
Overall	**79.63**	**69.76**	**74.37**

4.4 Experiments on Sub-Task 2

4.4.1 Baseline: a Heuristic Algorithm

Our baseline is a heuristic algorithm to solve this sub-task on graphs. This is an approximate algorithm which satisfies *minimal*, *complete*, *maximal*, and *significant* constraints. The main idea of our algorithm is picking up as many positive edges as possible, and as few negative edges as possible. We consider two cases: 1) There is no positive value edge on the input graph; and 2) There are some positive value edges on the input graph.

In the first case, because all the edges have negative values, we build logical structures with as few logical parts as possible. In this case, each logical structure contains exactly two logical parts. So we gradually choose two nodes in the graph with the maximum value on the edge connecting them. An example of the first case is illustrated in Figure 8. The maximum value on an edge is -0.1, so the first logical structure will contain node 1 and node 3. The second logical structure contains node 2 and node 4[9].

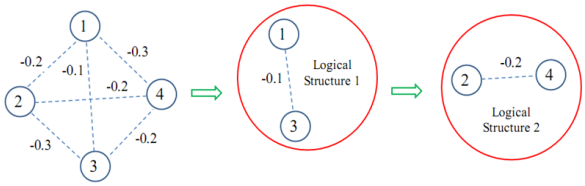

Figure 8: An example of the first case.

In the second case, we first consider the subgraph which only contains non-negative value edges. In this sub-graph, we repeatedly build logical structures with as many logical parts as possi-

[9]If the number of nodes is odd, the final logical structure will consist of the final node and another node, so that the edge connecting them has the maximal value.

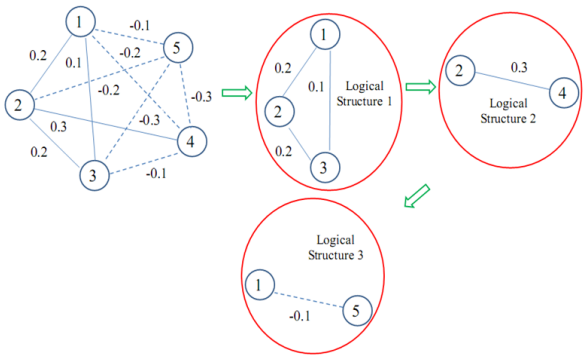

Figure 9: An example of the second case.

ble. After building successfully a logical structure, we remove all the nodes and the edges according to it on the graph. When have no positive edge, we will build logical structures with exactly two logical parts.

An example of the second case is illustrated in Figure 9. First, we consider the sub-graph with positive edges. This sub-graph consists of five nodes $\{1, 2, 3, 4, 5\}$ and four edges $\{(1, 2), (1, 3), (2, 3), (2, 4)\}$. First, we have a logical structure with three nodes $\{1, 2, 3\}$. We remove these nodes and the positive edges connecting to these nodes. We have two nodes $\{4, 5\}$ with no positive edges. Now we build logical structures with exactly two nodes. We consider node 4. Among edges connecting to node 4, the edge $(2, 4)$ has maximal value. So we have the second logical structure with two nodes $\{2, 4\}$. Next, we consider node 5, and we have the third logical structure with two nodes $\{1, 5\}$.

4.4.2 Experimental Results

In our experiments, to learn a maximum entropy binary classification we used the implementation of Tsuruoka (Tsuruoka, MEM). With a pair of logical parts, we extracted the following features (and combinations of them):

- Categories of two parts.
- Layers of two parts.
- The positions of the sentences that contain two parts (the first sentence or not).
- Categories of other parts in the input paragraph.

We conducted experiments on this sub-task in two settings. In the first setting, we used annotated logical parts (gold inputs) as the inputs to the system. The purpose of this experiment is to evaluate the performance of the graph-based method on Sub-task 2. In the second setting, predicted logical parts (end-to-end) outputted by the Sub-task 1 were used as the inputs to the system. The purpose of this experiment is to evaluate the performance of our framework on the whole task.

Table 4: Experiments on Sub-task 2

	Gold Input Setting		
Model	Prec(%)	Recall(%)	F_1(%)
Heuristic	**81.24**	71.19	75.89
ILP	76.56	**82.87**	**79.59**
	End-to-End Setting		
Model	Prec(%)	Recall(%)	F_1(%)
Heuristic	54.88	47.84	51.12
ILP	**57.51**	**54.06**	**55.73**

In the second setting, end-to-end setting, because input logical parts may differ from the correct logical parts, we need to modify the MUC scores. Let $P_1, P_2, \ldots, P_n$ be n predicted logical structures, and $G_1, G_2, \ldots, G_m$ be the gold logical structures. For each gold logical structure $G_i (i = 1, 2, \ldots, m)$, let D_i be the set of logical parts in G_i which are not included in the set of input logical parts. $D_i = \{p \in G_i | p \notin \cup_{j=1}^{n} P_j\}$. Let $k(G_i)$ be the smallest number such that there exist $k(G_i)$ predicted structures $P_1^i, P_2^i, \ldots, P_{k(G_i)}^i$ which satisfy $G_i \subseteq (\cup_{j=1}^{k(G_i)} P_j^i) \cup D_i$.

$recall = \frac{\sum_{i=1}^{m} (|G_i| - |D_i| - k(G_i))}{\sum_{i=1}^{m} (|G_i| - 1)}$.

To calculate the precision, we switch the roles of predicted structures and gold structures.

Table 4 shows experimental results on the second sub-task. The ILP model outperformed the baseline model in both settings. It improved 3.70% in the F_1 score (15.35% in error rate) in the gold-input setting, and 4.61% in the F_1 score (9.43% in error rate) in the end-to-end setting compared with the baseline model (heuristic algorithm).

5 Conclusion

We have introduced the task of learning logical structures of paragraphs in legal articles, a new task which has been studied in research on Legal Engineering. We presented the Japanese National Pension Law corpus, an annotated corpus of

real legal articles for the task. We also described a two-phase framework with multi-layer sequence learning model and ILP formulation to complete the task. Our results provide a baseline for further researches on this interesting task.

In the future, we will continue to improve this task. On the other hand, we also investigate the task of translating legal articles into logical and formal representations.

Abstract

Word ordering remains as an essential problem for translating between languages with substantial structural differences, such as SOV and SVO languages. In this paper, we propose to automatically extract pre-ordering rules from predicate-argument structures. A pre-ordering rule records the relative position mapping of *a predicate word* and its *argument phrases* from the source language side to the target language side. We propose 1) a linear-time algorithm to extract the pre-ordering rules from word-aligned HPSG-tree-to-string pairs and 2) a bottom-up algorithm to apply the extracted rules to HPSG trees to yield target language style source sentences. Experimental results are reported for large-scale English-to-Japanese translation, showing significant improvements of BLEU score compared with the baseline SMT systems.

1 Introduction

Statistical machine translation (SMT) suffers from an essential problem for translating between languages with substantial structural differences, such as between English which is a subject-verb-object (SVO) language and Japanese which is a typical subject-object-verb (SOV) language.

Numerous approaches have been consequently proposed to tackle this word-order problem, such as lexicalized reordering methods, syntax-based models, and pre-ordering ways. First, in order to overcome the shortages of traditional distance based distortion models (Brown et al., 1993; Koehn et al., 2007), phrase dependent lexicalized reordering models were proposed by several researchers (Tillman, 2004; Kumar and Byrne, 2005). Lexicalized reordering models learn local orientations (monotone or reordering) with probabilities for each bilingual phrase from the training data. For example, by taking lexical information as features, a maximum entropy phrase reordering model was proposed by Xiong et al. (2006).

Second, syntax-based models attempt to solve the word ordering problem by employing syntactic structures. For example, linguistically syntax-based approaches (Galley et al., 2004; Liu et al., 2006) first parse source and/or target sentences and then learn reordering templates from the subtree fragments of the parse trees. In contrast, hierarchical phrase based translation (Chiang, 2005) is a formally syntax-based approach which can automatically extract hierarchical ordering rules from aligned string-string pairs without using additional parsers. These approaches have been proved to be both algorithmically appealing and empirically successful.

However, most of current syntax-based SMT systems use IBM models (Brown et al., 1993) and hidden Markov model (HMM) (Vogel et al., 1996) to generate word alignments. These models have a penalty parameter associated with long distance jumps, and tend to misalign words which move far from the window sizes of their expected positions (Xu et al., 2009; Genzel, 2010).

The third type tackles the word-order problem in pre-ordering ways. Through the usage of a sequence of pre-ordering rules, the word order of an original source sentence is (approximately) changed into the word order of the target sentence. Here, the pre-ordering rules can be manually or automatically extracted. For manual extraction of pre-ordering rules, linguistic background and expertise are required for predetermined language pairs, such as for German-English (Collins et al., 2005), Chinese-to-English (Wang et al., 2007), Japanese-to-English (Katz-Brown and Collins, 2007), and English-to-SOV languages (Xu et al., 2009).

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 29–37,
Chiang Mai, Thailand, November 8 – 13, 2011.

Specially, for English-to-Japanese translation, Isozaki et al. (2010b) proposed to move syntactic or semantic heads to the end of corresponding phrases or clauses so that to yield head finalized English (HFE) sentences which follow the word order of Japanese. The head information of an English sentence is detected by a head-driven phrase structure grammar (HPSG) parser, Enju[1] (Miyao and Tsujii, 2008). In addition, transformation rules were manually written for appending particle seed words, refining POS tags to be used before parsing, and deleting English determiners. Due to the usage of the same parser, we take this HFE approach as one of our baseline systems.

The goal in this paper, however, is to learn pre-ordering rules from parallel data in an *automatic* way. Under this motivation, pre-ordering rules can be extracted in a language-independent manner. A number of researches follow this automatic way. For example, in (Xia and McCord, 2004), a variety of heuristic rules were applied to bilingual parse trees to extract pre-ordering rules for French-English translation. Rottmann and Vogen (2007) learned reordering rules based on sequences of part-of-speech (POS) tags, instead of parse trees. Dependency trees were used by Genzel (2010) to extract source-side reordering rules for translating languages from SVO to SOV, etc..

The novel idea expressed in this paper is that, predicate-argument structures (PASs) are introduced to extract fine-grained pre-ordering rules. PASs have the following merits for describing reordering phenomena:

- predicate words and argument phrases respectively record reordering phenomena in a *lexicalized level* and an *abstract level*;
- PASs provide a *fine-grained classification* of the reordering phenomena since they include factored representations of syntactic features of the predicate words and their argument phrases.

The idea of using PASs for pre-ordering follows (Komachi et al., 2006). Several reordering operations were manually designed by Komachi et al. (2006) to pre-ordering Japanese sentences into SVO-style English sentences. For comparison, our proposal 1) makes use of not only PASs but also the source syntactic tree structures for pre-ordering rule matching, 2) extracts pre-ordering rules in an automatic way, and 3) use factored representations of syntactic features to refine the pre-ordering rules.

Following (Wu et al., 2010a; Isozaki et al., 2010b), we use the HPSG parser Enju to generate the PASs of English sentences. HPSG (Pollard and Sag, 1994) is a lexicalist grammar framework. In HPSG, linguistic entities such as words and phrases are represented by a data structure called a *sign*. A sign gives a factored representation of the syntactic features of a word/phrase, as well as a representation of their *semantic content* which corresponds to PASs.

In order to record the relative positions among a predicate word and its argument phrases, we propose a linear-time algorithm to extract pre-ordering rules from word-aligned HPSG-tree-to-string pairs[2]. The syntactic features included in signs and the types of PASs enable us to extract fine-grained pre-ordering rules and thus make it easier to select appropriate rules for given source HPSG trees. We further propose a bottom-up algorithm to apply the extracted rules to HPSG trees to pre-order source sentences. Using the pre-ordered source sentences, we retrain word alignments again.

The remaining of this paper is organized as follows. In the next section, we describe the algorithms guided by using a real example for extracting and applying PAS-based pre-ordering rules. Then, we design experiments on large-scale English-to-Japanese translation to testify our proposal. Employing Moses (Koehn et al., 2007), we show that our proposal can significantly improve BLEU scores of 2.47∼3.15 points compared with using the original English sentences. We finally conclude this paper by summarizing our proposal and the experiment results.

2 Pre-ordering Rule Extraction and Application

2.1 An example

Figure 1 shows a word-aligned HPSG-tree-to-string pair for English-to-Japanese translation. PASs among lexical nodes and their argument nodes in this HPSG tree are described by arrows in thick-lines. For simplicity, we only draw the identifiers for the signs of the nodes in the HPSG tree. Note that the identifiers that start with 'c'

[1] http://www-tsujii.is.s.u-tokyo.ac.jp/enju/index.html

[2] These word alignments are gained by running GIZA++ (Och and Ney, 2003) on the original parallel sentences.

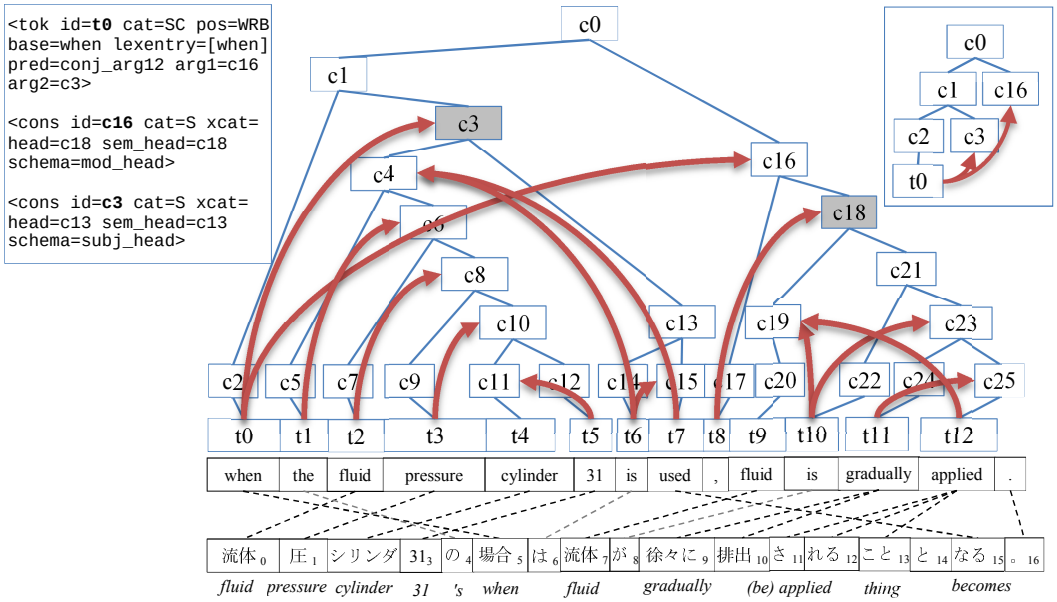

Figure 1: Illustration of a word-aligned HPSG-tree-to-string pair for English-to-Japanese translation.

denote non-terminal nodes (e.g., c0, c1), and the identifiers that start with 't' denote terminal nodes (e.g., t0, t2). In a complete HPSG tree (Wu et al., 2010b), factored syntactic features listed in Table 1 are included in the terminal and non-terminal signs. These features are used by us to sub-categorize pre-ordering rules. As an example of the XML output of Enju, the signs of "when" (t0) and its arguments c16, c3 are shown in the top-left corner of Figure 1.

2.2 Data structures

We define the following data structures for both extracting and applying pre-ordering rules. First, a PAS-based pre-ordering rule is defined to be a four-tuple <*pw*, *args*, srcOrder, trgOrder>. Here, *pw* is the predicate word, *args* are the argument nodes of *pw*, and srcOrder and trgOrder respectively record the relative positions among *pw* and *args* in the source and target language sides.

Then, we suppose an HPSG tree/subtree object contains the following methods:

- localize(): localize syntactic/semantic heads;
- computeSrcSpans(): topologically compute the source span of each node;
- computeSpans(A): topologically compute the source and target spans of each node (Galley et al., 2004). A is the word alignment;
- getArgs(*pw*): return the argument nodes of *pw*;

Name	Description	Examples
WORD	surface word form	"when"
BASE	base word form	"when"
POS	part-of-speech	WRB ("when")
LE	lexical entry	[when] ("when")
PRED	type of predicate argument structure	conj_arg12 ("when")
CAT	syntactic category	SC ("when")
TENSE	tense of a verb (past, present, untensed)	present ("used")
ASPECT	aspect of a verb (none, prefect, progressive, prefect-progressive)	none ("used")
VOICE	voice of a verb (passive, active)	passive ("used")
AUX	auxiliary verb or not (minus, modal, have, be, do, to, copular)	minus ("used")
CAT	syntactic category	S (c16), S (c3)
XCAT	extended category	
HEAD	syntactic head	R (c16), R(c3)
SEM_HEAD	semantic head	R (c16), R (c3)
SCHEMA	schema rule	mod_head (c16)

Table 1: Templates of atomic features included in the predicate node (top size) and its argument nodes (bottom side).

- MCT(*pw*, *args*): return the minimum cover tree (Wu et al., 2010a) of *pw* and *args*.

To implement the localize() method, we use the approach described in (Wu et al., 2010a). That is, we replace the pointer values of HEAD and SEM_HEAD features in non-terminal nodes with three labels: "S" for single daughter, "L" for the left-hand-side daughter, and "R" for the right-

hand-side daughter. For example, for node c16 in Figure 1, its HEAD and SEM_HEAD will change from c18 to "R".

We use the concept of *minimum covering trees* (MCT) defined in (Wu et al., 2010b) to guide the pre-ordering process. A MCT is a subtree of the original HPSG tree that takes a predicate node and its argument nodes as (new) leaf nodes. For example, as shown in the top-right corner of Figure 1, the MCT of "when" (t0) and its argument nodes c3, c16 is "c0(c1(c2(t0)c3)c16)".

Finally, the attributes in the nodes of an HPSG tree include: 1) pred: the PAS of a leaf node, 2) srcSpan: the index set of the source words that current node covers, 3) trgSpan: the index set of the target words that srcSpan aligned to, and 4) srcPhrase that stores the pre-ordered source phrase covered by current node.

2.3 Rule extraction algorithm

We express the idea for extracting PAS-based pre-ordering rules by using the first word "when" of the English sentence in Figure 1. Given the PAS information of "when" (t0) in the English side, we need to determine the target-side-order among t0 and its two arguments c16, c3. To achieve this, we compute the target spans of these three nodes by using current word alignment and then sort their target spans. Through referring to the word alignment shown in Figure 1, we can collect the target spans which are {5}, {4,0,1,2,3,6,15}, and {7,8,9,10,11,12,13} respectively for t0, c3, and c16. However, we cannot sort these three spans since there are overlapping between the first two spans[3]. In order to solve this problem, we sort the spans in a heuristic way. Note that in c3's target span, five indices are smaller than 5 yet only two indices are larger than 5. Thus, we take {4,0,1,2,3,6,15} to be *dominantly smaller* than {5}. Now, we can determine the pre-order rule guided by the PAS of t0 to be "t0 c3 c16 → c3 t0 c16" and formally to be "$t0_0$ $c3_1$ $c16_2$ → 1 0 2". Generally, we use the following heuristic rules to sort two spans, named span A and span B:

- if more than half of numbers in A is bigger than the maximum number in B, or if more than half of numbers in B is smaller than the minimum number in A, then B < A;
- if more than half of numbers in B is bigger than the maximum number in A, or if more than half of numbers in A is smaller than the minimum number in B, then A < B.

In case of a tie (e.g., A={3,4,7,8}, B={5,6}), we keep the original order of A and B in the source-side sentence without any reordering.

Algorithm 1 Pre-ordering Rule Extraction

Input: HPSG tree T_E of an English sentence E, word alignment A
Output: a pre-ordering rule set $\mathcal{R}$

```
1: T_E.localize()
2: T_E.computeSpans(A)
3: for each leaf node t of T_E do
4:     if t.pred is opened and t.trgSpan != NULL then
5:         Node[] args ← T_E.getArgs(t)
6:         if all nodes in args are aligned then
7:             int[] srcOrder ← SORTSPANS(t.srcSpan, srcSpans of args)
8:             int[] trgOrder ← SORTSPANS(t.trgSpan, trgSpans of args)
9:             R.add(< t, args, srcOrder, trgOrder>)
10:        end if
11:    end if
12: end for
```

Algorithm 1 sketches the pre-ordering rule extraction algorithm guided by PASs. The algorithm collect pre-ordering rules through a traversal of the leaf nodes in an HPSG tree. A non-terminal node will not be accessed unless it is an argument of some predicate node(s). Thus, this algorithm runs in a time that is approximately *linear* to the number of leaf nodes in the tree, i.e., the number of words in the source sentence.

We define that a terminal node's PAS is *opened* if at least one of its arguments is neither empty nor unknown. We will not extract a pre-ordering rule if the terminal node is unaligned or any of its argument node is unaligned. These constraints are reflected by Line 4 and 6 in Algorithm 1. After heuristically sorting the source/target spans of a predicate node and its argument nodes, we finally extract a pre-ordering rule.

Table 2 summarizes the PAS-based pre-ordering rules extracted from the example shown in Figure 1. Application of these pre-ordering rules to the original English sentence yields the following Japanese style sentence:

- `the fluid pressure cylinder 31 is used when, fluid is gradually applied.`

2.4 Applying pre-ordering rules

[3]In this example, the overlapping is caused by the wrong/ambiguous alignments between "used" and "$naru_{15}$", and between "is" and "ha_6".

Word	PRED	Pre-ordering Rule
when	conj_arg12	when c3 c16 → c3 when c16
the	det_arg1	the c6 → the c6
fluid	adj_arg1	fluid c8 → fluid c8
pressure	noun_arg1	pressure c10 → pressure c10
cylinder	noun_arg0	-
31	adj_arg1	c11 31 → c11 31
is	aux_arg12	c4 is c15 → c4 is c15
used	verb_arg12	c4 used → c4 used
,	punct_arg1	, c18 → , c18
fluid	noun_arg0	-
is	aux_arg12	c19 is c23 → c19 is c23
gradually	adj_arg1	gradually c25 → gradually c25
applied	verb_arg12	c19 applied → c19 applied

Table 2: PAS-based pre-ordering rules extracted from the example shown in Figure 1. We use real words instead of predicate nodes here for intuitive understanding.

Algorithm 2 Pre-ordering Rule Application

Input: HPSG tree T_E of an English sentence $E[]$, rule set $\mathcal{R}$
Output: srcPhrase in the root node of T_E

```
1: T_E.localize()
2: T_E.computeSrcSpans()
3: mct_rule ← {}
4: for each leaf node t of T_E do
5:     Node[] args ← T_E.getArgs(t)
6:     int[] srcOrder ← SORTSPANS(t.srcSpan, srcSpans of args)
7:     Rule r ←RULEMATCH(R, < t, args, srcOrder>)
8:     if r != NULL then
9:         mct ← T_E.MCT(t, args)
10:        mct_rule.add(<mct, r >)
11:    end if
12: end for
13: for each mct in mct_rule in a bottom-up order do
14:    Rule r ← mct_rule.get(mct)
15:    mct.root().srcPhrase ← '' ▷ root() returns root node
16:    for i from 0 to r.trgOrder.length-1 do
17:        mct.root().srcPhrase += ' ' + mct.leaves()[r.trgOrder[i]].srcPhrase
18:    end for
19: end for
20: for each node n in T_E in a topological order do
21:    if n is a terminal node then
22:        n.srcPhrase ← E[n.srcSpan[0]]
23:    else if n.srcPhrase = NULL then
24:        n.srcPhrase ← CONNECT(n.children().srcPhrase)
25:    end if
26: end for
```

Algorithm 2 sketches the algorithm for applying pre-ordering rules to a given HPSG tree T_E. The algorithm contains three parts: rule matching (Lines 4-12), bottom-up rule applying (Lines 13-19), and sentence collecting (Lines 20-26). We first retrieve available pre-ordering rules from rule set $\mathcal{R}$ by a left-to-right traversal of the leaf nodes of T_E. For each leaf node, we select one pre-ordering rule with the highest frequency. Our experiments testified that this greedy rule selection strategy worked quite well. We selected 93% of the top frequent rule without facing a tie.

The terminal node t, the argument nodes of t, and their source-side ordering are taken as the key for rule matching. Available rules will be assigned to the MCT of t. Then, we apply the available rules to the root nodes of each MCT through a bottom-up traversal of T_E. A competitive problem is that, a non-terminal node can be shared by several MCTs. For example, node c3 and c18 (gray color) in Figure 1 are respectively shared by two MCTs (t6 and t7, t10 and t12). In order to avoid duplicated reordering of these nodes, we first pick the pre-ordering rule in which there are no "gaps" among the predicate words and argument phrases. For example, there is a gap (t6) between t7 and its argument node c4. We then pick a rule by frequency if there are still more than one rule available. Finally, after applying all available rules, we collect the pre-ordered source sentence from the root node of the HPSG tree.

3 Experiments

3.1 Setup

We test our proposal by translating from English to Japanese. We use the NTCIR-9 English-Japanese patent corpus[4] as our experiment set. Since the reference set of the official test set has not been released yet, we instead split the original development set averagely into two parts, named dev.a and dev.b. In our experiments, we first take dev.a as our development set for minimum-error rate tuning (Och, 2003) and then report the final translation accuracies on dev.b. For direct comparison with other systems in the future, we use the configuration of the official baseline system[5]:

- Moses[6] (Koehn et al., 2007): revision = "3717" as the baseline decoder. Note that we also train Moses using HFE sentences (Isozaki et al., 2010b) and the English sentences pre-ordered by PASs;
- GIZA++: giza-pp-v1.0.3[7] (Och and Ney, 2003) for first training word alignment using the original English sentences for pre-ordering rule extraction, and then for retrain-

	Train	Dev.a	Dev.b
# of sent.	2,032,679	1,000	1,000
# of En words	48,322,058	31,890	31,935
Enju suc. rate	99.3%	98.9%	98.7%
parse time (sec./sent.)	0.30	0.38	0.48
# of Jp words	53,865,629	37,066	35,921

Table 3: Statistics of the experiment sets.

ing word alignments using the pre-ordered English sentences;

- SRILM[8] (Stolcke, 2002): version 1.5.12 for training a 5-gram language model using the target sentences in the total training set;
- Additional scripts[9]: for preprocessing English sentences and cleaning up too long (# of words > 40) parallel sentences;
- Japanese word segmentation: Mecab v0.98[10] with the dictionary of mecab-ipadic-2.7.0-20070801.tar.gz[11].

The statistics of the filtered training set, dev.a, and dev.b are shown in Table 3. The success parsing rate ranges from 98.7% to 99.3% by using Enju2.3.1. The averaged parsing time for each English sentence ranges from 0.30 to 0.48 seconds.

3.2 Statistics of PASs and PAS-based pre-ordering rules

Figure 2 shows the number (natural log) of the 40 types of the PASs that appeared in the HPSG trees of the three experiment sets. Top five types of opened PASs include adj_arg1, det_arg1, prep_arg12, noun_arg1, and verb_arg12. By comparing the distributions of the number of PASs in the three sets, we can see that the distributions approximately share the same tendency. Thus, the pre-ordering rules learned from the PASs in the training set can be expected to be properly applied in dev.a and dev.b.

Besides, the statistics of the number of arguments for the predicate words is shown in Table 4. From this table, we find that the ratio of the number of arguments in the three sets are approximately similar. In particular, nearly half of the

# of args	Train	Dev.a	Dev.b
0	22.9%	22.4%	22.3%
1	47.0%	47.0%	47.5%
2	29.5%	29.8%	29.4%
3	0.6%	0.8%	0.8%
4	0.0%	0.0%	0.0%

Table 4: Statistics of the number of arguments of the predicate words in the experiment sets.

	Number	Ratio
Parse success	45,617,387	94.4%
Opened	35,004,893	76.7%
Aligned	33,966,923	97.0%
Contiguous	30,256,858	89.1%

Table 5: Statistics of predicate words in the training set for rule extraction.

predicate words have one argument. The number of predicate words that contain two arguments occurs around 30.0% of all the predicate words. Also, we can not extract pre-ordering rules from around 23.0% of the predicate words since they do not contain any arguments. Finally, less than 1% of predicate words contain three arguments and we only find one four-argument example of verb_arg1234 in the training set.

Now, in Table 5, we show the statistics of predicate words in the training set for pre-ordering rule extraction. Of the 48.3 million English words in the training set, there are 45.6 million words (94.4%) that are included in the HPSG trees that were successfully generated. Then, in the PASs of these 45.6 million words, there are 35.0 million words whose PASs are opened. We also list the number (34.0 million) of aligned predicate words, since we only extract pre-ordering rules from predicate words that are aligned to some target word(s) in Algorithm 1. Finally, there are 89.1% of aligned predicate words that are aligned to contiguous target words.

In order to investigate the sub-categorization effectiveness of the syntactic features included in the pre-ordering rules, we pick four subsets of the total feature set (Table 1). These feature subsets, named from PAS-a to PAS-d, are listed in Table 6. Through the comparison of these four feature subsets, we also attempt to investigate the data-sparseness problem of available pre-ordering rules cased by the factored features.

PAS-a includes all the syntactic features listed in Table 1. In PAS-b, we only keep three features for the predicate word and one feature for the argu-

ment nodes. We further remove one feature (CAT) of the predicate word in PAS-c. In the fourth subset PAS-d, we only use two features WORD and PRED in the predicate word for sub-categorizing pre-ordering rules. Thus, PAS-d is only related to PASs (which can be generated by any kinds of parser) since it does not include additional features generated by the typical HPSG parser.

As the number of syntactic features decreases, more rules can be unified together. Thus, the number of pre-ordering rules and reordering rules, as shown in Table 6, also decreases. The number of reordering rules occurs from 25.1% (PAS-d) to 38.2% (PAS-a) in the pre-ordering rules. For each English sentence in the training set, there are averagely 12 *reordering* rules (instead of monotonic

pre-ordering rules) available under either of the four feature subsets. For each English sentence in dev.a and dev.b, the number of available *reordering* rules is averagely 16. Around 99.1%, 99.0%, and 98.6% English sentences were respectively reordered in the training set, dev.a set, and dev.b set.

3.3 Results

Table 7 shows the final translation accuracies under BLEU score (Papineni et al., 2002) and RIBES[12], i.e., the software implementation of Normalized Kendall's τ as proposed by (Isozaki et al., 2010a) to automatically evaluate the translation between distant language pairs based on rank correlation coefficients and significantly penalizes word order mistakes. Making use of our pre-ordered English sentences significantly ($p < 0.01$) improved BLEU scores from 2.47 (PAS-d) to 3.15 (PAS-a) points. The effectiveness of our proposal for tackling word-ordering problem can also be proved by comparing the scores of RIBES.

In addition, the accuracies change slightly among using the four types of pre-ordering rules. Among PAS-a, PAS-b, and PAS-c, we did significant test and could not differ them under $p < 0.01$ or $p < 0.05$. The only significant difference

Table 8: Translation accuracies by combining HFE and PAS based pre-ordering approach.

($p < 0.05$) appeared between PAS-a and PAS-d. Thus, we argue that the factored syntactic features such as WORD, PRED, and CAT are more essential for sub-categorizing pre-ordering rules than the remaining syntactic features.

As former mentioned, we also take the language-dependent HFE approach (Isozaki et al., 2010b) as another baseline. Note that word alignment was retrained using head-finalized English sentences and Japanese sentences in this HFE approach. Through comparing the HFE results listed in Table 8, we observe that the results are comparable between PAS-a and HFE: HFE is slightly better under BLEU score and PAS-a is slightly better under RIBES score.

Since similar HPSG parser (Enju) yet different linguistic information (syntactic head information vs. PASs) are used in HFE approach and our proposal. A straightforward question is whether we can combine these approaches together. Under this motivation, we select a better pre-ordered English sentence generated by the HFE method and our PAS-based method. Following (Genzel, 2010), we use *crossing score* as the metric for sentence selection. Crossing score is the number of crossing alignment links for a given aligned sentence pair. For monotonic alignments without reordering, crossing score is zero. During selection, we found that nearly 10% of the pre-ordered English sentences yielded by head-finalization and PAS-based methods were similar. In addition, among the different sentences, around 30% of PAS-based pre-ordering sentences were selected. Since we can not compute crossing score in the development/test sets, we instead take both kinds of pre-ordered English sentences as inputs and pick one output with a higher translation score.

The translation result based on this reselection approach is shown in Table 8. Compared with HFE approach, the reselection approach significantly ($p < 0.01$) improved BLEU scores of from 1.22 (PAS-d) to 1.68 (PAS-b) points. These interesting results reflect that syntactic head information and PASs describe the linguistic information of an English sentence in different aspects. Furthermore, compared with the single head-finalization rule, the automatically extracted pre-ordering rules kept the variety of word-ordering by dynamically inferring the word order of target sentences and thus enlarged the reordering space.

Source sent.	Averaged τ	$\tau \geq 0.8$
English	0.407	0.106
HFE	0.708	0.487
PAS-a	0.571	0.291
HFE+PAS-a	**0.809**	**0.643**

Table 9: Comparison of Kendall's τ.

3.4 Alignment comparison

In order to investigate how closely the pre-ordered English sentences follow target language word order, we measured Kendall's τ (Kendall, 1948), a rank correlation coefficient, as shown in Table 9. We exactly follow Isozaki et al. (2010b) to compute Kendall's τ. From Table 9, we can see that the quality of word alignments approximately reflects the final BLEU scores listed in Table 7 and 8.

4 Conclusion

We have proposed a pre-ordering approach by making use of predicate argument structures. The pre-ordering rules record the relative source-target position mapping among predicate words and their argument phrases. We first proposed an algorithm for automatically extracting these lexical pre-ordering rules from aligned HPSG-tree-to-string pairs. Then, we apply these pre-ordering rules to HPSG trees to yield pre-ordered source sentences that follow the word order of target sentences. Finally, we do word alignment again by using the pre-ordered source sentences together with the original target sentences.

Employing Moses (Koehn et al., 2007), our proposal significantly improved 2.47∼3.15 BLEU points compared with using the original English sentences. Combining with the HFE approach (Isozaki et al., 2010b), our approach significantly and impressively improved 5.29 points of BLEU score from 0.2773 to 0.3302. We finally argue that our proposal is not difficult to be implemented and can be easily applied to translate English into other languages.

Abstract

How well can a phrase translation model perform if we permute the source words to fit target word order as perfectly as word alignment might allow? And how well would it perform if we limit the allowed permutations to ITG-like tree-transduction operations on the source parse tree? First we contribute oracle results showing great potential for performance improvement by source-reordering, ranging from 1.5 to 4 BLEU points depending on language pair. Although less outspoken, the potential of tree-based source-reordering is also significant. Our second contribution is a source reordering model that works with two kinds of tree transductions: the one permutes the order of sibling subtrees under a node, and the other first deletes layers in the parse tree in order to exploit sibling permutation at the remaining levels.The statistical parameters of the model we introduce concern individual tree transductions *conditioned on contextual features* of the tree resulting from all preceding transductions. Experiments in translating from English to Spanish/Dutch/Chinese show significant improvements of respectively 0.6/1.2/2.0 BLEU points.

1 Motivation

Word order differences between languages are a major challenge in Machine Translation (MT). Phrase-based Statistical Machine Translation (PB-SMT) (Och and Ney, 2004; Zens et al., 2002; Koehn et al., 2003) deals with word order differences in two subcomponents of a translation model. Firstly, using the local word reordering implicitly encoded in phrase pairs. Secondly, using an explicit reordering model which may reorder target phrases relative to their source sides, e.g., as a monotone phrase sequence generation process with the possibility of swapping neighboring phrases (Tillman, 2004).

Arguably, local phrase reordering models cannot account for long-range reordering phenomena, e.g., (Chiang, 2005; Chiang, 2007). Hierarchical models of phrase reordering employ synchronous grammars or tree transducers, e.g., (Wu and Wong, 1998; Chiang, 2005). These models explore a more varied range of reordering phenomena, e.g., defined by at most inverting the order of sibling subtrees under each node in binary source/target trees (akin to ITG (Wu and Wong, 1998)).

Undoubtedly, the word order of source and target sentences is intertwined with the lexical choices on both side. Statistically speaking, however, one may first select a target word order given the source only, and then choose target words given the selected target word order and source words. One application of this idea is known as source reordering (or -permutation), e.g., (Collins et al., 2005; Xia and McCord, 2004; Wang et al., 2007; Li et al., 2007; Khalilov and Sima'an, 2010). Briefly, the words of the source string s are reordered to minimize word order differences with the target string t, leading to the source permuted string $\grave{s}$. Presumably, a standard PBSMT system trained to translate from $\grave{s}$ to t should have an easier task than translating directly from s to t. The source reordering part, s to $\grave{s}$,

[†] Currently, the first author is employed by TAUS B.V., Amsterdam (The Netherlands).

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 38–46,
Chiang Mai, Thailand, November 8 – 13, 2011.

can be realized in various ways and may manipulate morpho-syntactic parse trees of s, e.g., (Collins et al., 2005; Xia and McCord, 2004; Li et al., 2007).

It may seem that source reordering should provide only limited improvement over the standard PBSMT approach. The literature reports mixed performance improvements for different language pairs, e.g., (Collins et al., 2005; Xia and McCord, 2004; Wang et al., 2007; Li et al., 2007; Khalilov and Sima'an, 2010). But what is the *potential improvement* of source reordering? We contribute experiments measuring oracle performance improvement for English to Dutch/Spanish/Chinese translations. Beside string-driven oracles, we report results using ITG-like transductions over a single syntactic parse tree of s. Our results confirm that reordering a single syntactic tree could be insufficient (e.g., (Huang et al., 2009)), yet they show substantial potential.

Our second contribution is a novel source reordering model that manipulates the source parse tree with two kinds of tree transduction operators: the one permutes the order of sibling subtrees under a node, and the other first abolishes layers in the parse tree in order to exploit sibling permutation at the remaining levels. The latter is the opposite of parse binarization using Expectation-Maximization (Huang et al., 2009). We use Maximum-Entropy training (Berger et al., 1996) to learn a sequence of tree transductions, each conditioned on contextual features *in tree resulting from outcome of the preceding transduction*. The conditioning on the outcome of preceding transductions is a departure from earlier approaches at learning independent source permutation steps, e.g., (Tromble and Eisner, 2009; Visweswariah et al., 2010).

The aim for the rest of this paper is firstly, to quantify the potential performance improvement of a standard PBSMT system if preceded by source reordering and secondly, to show that statistical Markov approach to tree transduction, where the probability of each transduction step is conditioned on the outcome of preceding steps, can improve the quality of PBSMT output significantly.

2 Source-Reordering: Framework

We start out from a word-aligned parallel corpus, consisting of triples $\langle s, a, t\rangle$, a source s, target t and word alignment a. Source reordering assumes that a permutation of s, called $\grave{s}$, is first generated with a model $P_r(\grave{s} \mid s)$ followed by a phrase translation model $P_t(t \mid \grave{s})$. The desired permutation $\grave{s}$ is one that has minimum word order divergence from t, i.e., when word-aligned again with t would have least number of crossing alignments.

Practically, the original parallel corpus $\{\langle s, a, t\rangle\}$ is split to two parallel corpora: (1) a source-to-permutation parallel corpus (consisting of $\langle s, a, \grave{s}\rangle$) and (2) a permutation-to-target parallel corpus (consisting of $\langle g\grave{s}, \grave{a}, t\rangle$), where $g\grave{s}$ is the output of a source reordering model (guessing at $\grave{s}$), and $\grave{a}$ results from automatically word aligning $\langle g\grave{s}, t\rangle$. The latter parallel corpus is used for training a phrase-based translation system $P_t(t \mid g\grave{s})$, while the former corpus is used for training a source reordering model $P_r(\grave{s} \mid s)$. The problem of permuting the source string to unfold the crossing alignments is computationally intractable (see (Tromble and Eisner, 2009)). However, various constraints can be made on unfolding the crossing alignments in a. A common approach is to assume a binary parse tree for the source string, and define a set of eligible permutations by binary ITG transductions. This defines permutations resulting from at most inverting pairs of children under nodes of the source tree. Figure 1 exhibits a long-range reordering of the verb in English-to-Dutch translation: inverting the order of the children of the VP node would unfold the crossing alignment. However, crossing alignments represented as non-constituents cannot be resolved. This difficulty can be circumvented by employing multiple alternative parse trees, by applying heuristic transforms (e.g., binarization) to the tree to fit the alignments (Wang et al., June 2010), or by defin-

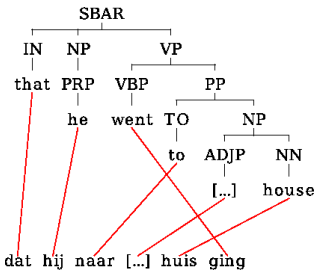

Figure 1: Example crossing alignments and long-distance reordering using a source parse tree.

ing new local transductions, on top child permutation (ITG) as we do next.

3 Existing work on source permutation

Source reordering has been shown useful for PBSMT for a wide variety of language pairs with high mutual word order disparity (Collins et al., 2005; Popovic' and Ney, 2006; Zwarts and Dras, 2007; Xia and McCord, 2004). In Costa-jussà and Fonollosa (2006) statistical word classes as well as POS tags are used as patterns for reordering the input sentences and producing a new bilingual pair.

A rather popular class of source reordering algorithms involves syntactic information and aims at minimizing the need for reordering during translation by permuting the source sentence (Collins et al., 2005; Wang et al., 2007; Khalilov and Sima'an, 2010; Li et al., 2007). Some systems perform source permutation using a set of handcrafted rules (Collins et al., 2005; Wang et al., 2007; Ramanathan et al., 2008), others make use of automatically learned reordering patterns extracted from the plain training data, the corresponding parse or dependency trees and the alignment matrix (Visweswariah et al., 2010).

Inspiring this work, source reordering as a pretranslation step is viewed as a word permutation learning problem in Tromble and Eisner (2009) and Li et al. (2007). The space of permutations is approached efficiently using a binary ITG-like synchronous context-free grammar put on the parallel data. Similarly, a local ITG-based tree transducer with contextual conditioning is used in Khalilov and Sima'an (2010) and Li et al. (2007), and preliminary experiments on a single language pair show improved performance.

Particularly, the model in (Li et al., 2007) is explicitly aimed at long-distance reorderings (English-Chinese), prunes the alignment matrix gradually to fit the source syntactic parse and employs Maximum-Entropy modeling to choose the optimal local ITG-like permutation step of sister subtrees but interleaves that step with a translation step. The model which we present in Section 2 differs substantially from (Li et al., 2007) and other earlier work because it (1) incorporates other kinds of tree transduction operations than those promoted by ITG, and (2) works with the unmodified alignment matrix but learns reorderings only from those alignments that are consistent with the tree, thereby avoiding the effects of heuristics for pruning alignments to fit the tree-structure, e.g., (Li et al., 2007).

In this paper we take the idea of learning source permutation one step further along a few dimensions. We show the utility of other kinds of tree transduction operations, besides those promoted by ITG, stress the importance of using a wide range of conditioning context features during learning, and report oracle and test results on *three* language pairs.

The majority of existing work reports encouraging performance improvements by source reordering. Next we aim at quantifying the potential improvement by oracle source reordering at the string level, if all permutations were to be allowed, and at the source syntactic tree level, by limiting the permutations with two kinds of local transductions.

4 Oracle source reordering results

Source reordering for PBSMT assumes that permuting the source words to minimize the order differences with the target sentence could improve translation performance. However, the question "how much?" is rarely asked. Here, we attempt answering this question with a set of oracle systems[1], in which we perform unfolding operations on the crossing links in alignment a (estimated between corpora s and t) that leads to a more monotone alignment $\grave{a}$ (between $\grave{s}$, which is a permutation of s, and t). We introduce a set of tree-based constraints that control the unfolding of alignment crossings. We measure the impact of (un)folded alignment crossings on the performance of the PBSMT system (see Table 1).

Oracle String. This method scans the alignment a from left-to-right and unfolds all the crossing links between bilingual phrases (*Oracle string*). Figure 2 shows an example of word reordering done on the string level. NULL aligned words do not move from their positions.

Oracle parse tree with permute siblings. The oracle system unfolds an alignment crossing if and

[1] All the source permutation methods presented in this Section are based on automatic alignments, which inevitably contain wrong links. In the future we plan to involve manual alignments to the computation of oracle permutation

only if the source side of the alignment crossing is covered by the same node in the syntactic source tree, and the alignment pair subject to crossing can be unfolded by permuting the order of the sibling nodes. NULL aligned words do not prevent unfolding crossings because we include them with the adjacent words that are involved in the crossings. We call this configuration *Oracle tree*.

Figure 1 shows an example. According to the *Oracle tree* constraint, the word "went" can be placed in the end of the sentence since the replacement can be done as a swapping of "VBP" and "PP" categories. The same happens for the word "reflect" swapping with "S" constituent in Figure 1, but not for the chunks "the positions" and "not properly": this crossing cannot be resolved under the tree constraint since they are not dominated by sibling syntactic categories.

Oracle tree with delete descendants, permute siblings. This oracle implements an additional mechanism of tree modification to increase the number of reordering permutations in comparison with *Oracle tree* algorithm. Here we allow for an additional tree transduction operation that deletes intervening layers before applying sibling permutation. This is illustrated in Figure 3. The word "must" can not be moved to the beginning of the sentence in Figure 3a by *Oracle tree*. Instead, this is done in two steps. Firstly, the VP dominating the words "must" and "apply" is deleted under the current node S, the transformed tree is shown in Figure 3b. Subsequently, the siblings under S in the resulting tree are permuted, "must" is reordered across the whole clause and placed to the first position (see Figure 3c). We call this system *Oracle mod*.
Figure 4 shows an example in which crossing alignment links cannot be unfolded without deleting 4 intervening layers.

Oracle results Table 1 contrasts the oracle results with the performance shown by standard PBSMT systems. The experimental setup is detailed in Section 6. We consider the following baseline configurations: *PBSMT* - Moses-based PBSMT with distance-based reordering model; *PBSMT+MSD* - Moses-based PBSMT with distance-based reordering model and MSD and *Moses-chart* - hierarchical Moses-chart-based PBSMT.

Depending on number of parse tree levels allowed to be deleted, we consider three *Oracle mod* systems: with two (*2lt*), three (*3lt*) and five (*5lt*) levels of descendants allowed to be deleted for a more flat parse tree structure before sibling permutation.

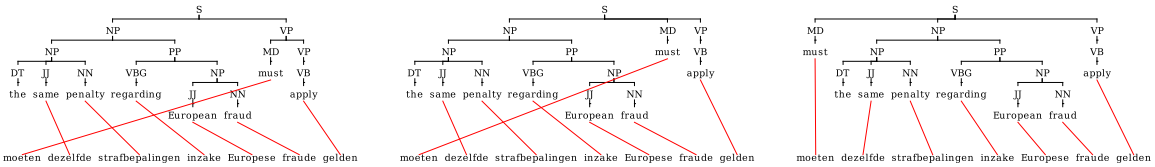
Figure 2: Example of *Oracle string* unfolding.



(a) Original parse tree.

(b) Parse tree with deleted VP category.

(c) Reordered parse tree.

Figure 3: Example of text monotonization with tree transformation.

The impact of corpus monotonization on translation system performance is measured using the final point of weight optimization on the development set (*Dev BLEU*), as well as on the test set (*Test BLEU/NIST*).

The major conclusion that can be drawn from the oracle results is that the source reordering defined in terms of parse tree transduction can potentially lead to increased translation quality (up to 1.2 BLEU points for English-Dutch, 0.5 for English-Spanish and 1.7 for English-Chinese). At the same time, a huge gap between performance shown by *Oracle string* and tree oracle systems (≈2.2 BLEU points for English-Dutch, ≈1.3 for English-Spanish and ≈2.5 for English-Chinese) shows that there are many crossing alignments which cannot be unfolded with simple, local transductions over a single source-side syntactic tree.

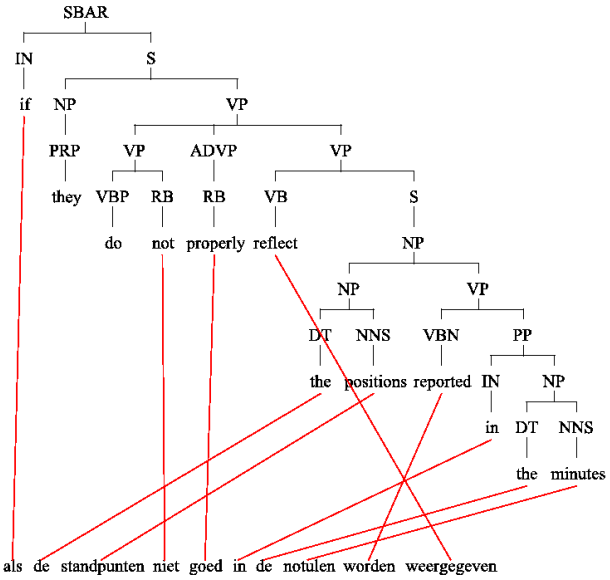


Figure 4: Example of unfoldable alignment crossings.

5 Conditional Tree-Transductions

Our model aims at learning from the source permuted parallel corpus (containing tuples $\langle s, a, \grave{s} \rangle$) a probabilistic optimization ($\arg\max_{\pi(s)} P_r(\pi(s) \mid s, \tau_s)$), where τ_s is the source parse and $\pi(s)$ is some eligible permutation of s. We view the permutations leading from s to $\grave{s}$ as a sequence of local tree transductions $\tau_{\grave{s}_0} \rightarrow \ldots \rightarrow \tau_{\grave{s}_n}$, where $\grave{s}_0 = s$ and $\grave{s}_n = \grave{s}$, and each transduction $\tau_{\grave{s}_{i-1}} \rightarrow \tau_{\grave{s}_i}$ is defined using any of two kinds of local tree transduction operations used in Section 4 or alternatively NOP (No Operation).

The sequence $\tau_{\grave{s}_0} \rightarrow \ldots \rightarrow \tau_{\grave{s}_n}$ is obtained by taking the next node in a top-down tree traversal, then statistically selecting the most likely of three transduction operations and applying the selected operation to the current node. If the current tree is $\tau_{\grave{s}_{i-1}}$, and the current node has address x, is syntactically labeled N_x, directly dominates α_x (the ordered sequence of node labels under x), we approximate the conditional probability $P(\tau_{\grave{s}_i} \mid \tau_{\grave{s}_{i-1}})$ with the transduction operation it employs:

- Permute the children of x in $\tau_{\grave{s}_{i-1}}$ with probability

$$\approx P(\pi(\alpha_x) \mid N_x \rightarrow \alpha_x, C_x) \qquad (1)$$

where $\pi(\alpha_x)$ is a permutation of α_x (the ordered sequence of node labels under x) and C_x is a local tree context of node x in tree $\tau_{s'_{i-1}}$.

- Select a child of x to delete, pull its children up directly under x, effectively changing α_x to some α_x^d, and then permute the children of the latter.

$$\approx P(\alpha_x \rightsquigarrow \alpha_x^d, \pi(\alpha_x) \mid N_x \rightarrow \alpha_x, C_x) \qquad (2)$$

where $(\alpha_x \rightsquigarrow \alpha_x^d$ symbolizes the result of deleting a subtree under a child of x. This operation applies also to subtrees of depth $n \in \{1, 2, 3, 5\}$ under x, i.e., a child is depth 1, a child with its children is depth 2 and so on.

Obviously, the number of possible permutations of α_x is factorial in the length of α_x. Fortunately, the source permuted training data exhibits only a fraction of possible permutations even for longer α_x sequences. Furthermore, by conditioning the probability on local context C_x, the number of permutations is limited to a handful set.

Theoretically, we could define the probability of the sequence of local tree transductions $\tau_{\grave{s}_0} \rightarrow \ldots \rightarrow \tau_{\grave{s}_n}$ as

$$P(\tau_{\grave{s}_0} \rightarrow \ldots \rightarrow \tau_{\grave{s}_n}) = \prod_{i=1}^{n} P(\tau_{\grave{s}_i} \mid \tau_{\grave{s}_{i-1}}) \qquad (3)$$

However, unlike earlier work (e.g., (Tromble and Eisner, 2009)), we cannot afford to do so because every local transduction conditions on context C_x of an intermediate tree, which quickly risks becoming intractable (even when we use packed forests). Furthermore, the problem of calculating the most likely permutation under such a model is made difficult by the fact that different transduction sequences may lead to the same permutation, which demands summing over these sequences (another intractable summation). Earlier work has avoided conditioning context, effectively assuming that the each intermediate permutation is independent from the preceding ones.

Instead, we take a pragmatic approach and greedily select at every intermediate point $\tau_{\grave{s}_{i-1}} \rightarrow \tau_{\grave{s}_i}$ the single most likely local transduction that can be applied to a node in the current intermediate tree $\tau_{\grave{s}_{i-1}}$ using an interpolation of the terms in Equations 1 and 2 with probability ratios of the language model $\grave{s}$ as follows:

$$P(TRANS_i|\ N_x \rightarrow \alpha_x, C_x) \times \frac{P_{lm}(\grave{s}_{i-1})}{P_{lm}(\grave{s}_i)}$$

where $TRANS_i$ is any of the two transduction operations or NOP, and P_{lm} is a language model trained on the $\grave{s}$ side of the corpus $\{\langle s, a, \grave{s}\rangle\}$. The rationale behind this log-linear interpolation is that our source permutation approach aims at finding the optimal permutation $\grave{s}$ of s that can serve as input for a subsequent translation model. Hence, we aim at tree transductions that are syntactically motivated that also lead to improved string permutation. In this sense, the tree transduction definitions can be seen as an efficient and syntactically informed way to define the space of possible permutations.

Estimates. We estimate the string probabilities $P_{lm}(.)$ using 3-gram language models trained on the $\grave{s}$ side of the source permuted parallel corpus $\{\langle s, a, \grave{s}\rangle\}$. We estimate the conditional probability $P_r(TRANS \mid N_x \rightarrow \alpha_x, C_x)$ using a Maximum-Entropy framework, where feature functions are defined to capture the permutation as a class, the node label N_x and its head POS tag, the child sequence α_x together with the corresponding sequence of head POS tags and other features corresponding to different contextual information.

Features in use. We used a set of 15 features to capture reordering permutations from the syntactic and linguistic perspectives: *Local tree topology:* sub-tree instances that include parent node and the ordered sequence of child node labels (1); *Dependency features:* features that determine the POS tag of the head word of the current node (2), together with the sequence of POS tags of the head words of its child nodes (3) and the POS tag of the head word of the parent (4) and grandparent nodes (5); *Syntactic features:* apart from the whole path from the current node to the tree root node (6), we used three binary features from this class describe: (7) whether

the parent node is a child of the node annotated with the same syntactic category, (8) whether the parent node is a descendant of the node annotated with the same syntactic category, and (9) if the current sub-tree is embedded into a "*S-SBAR*" sub-tree[2]; *POS lexical features:* bi- and tri-grams of POS tags of the left- and right-hand side neighboring words (10-13); *Counters:* a number of words covered by a given constituent (14) and a number of children of the given node (15).

6 Translation and reordering experiments

Data. In our experiments we used English-Dutch and English-Spanish European Parliament data and an extraction from the English-Chinese Hong Kong Parallel Corpus. All the sets were provided with one reference translation. Basic statistics of the training data can be found in Table 2, development datasets contained 0.5K, 1.9K and 0.5K lines and test datasets contained 1K, 1.9K and 0.5K for Dutch, Spanish and English, respectively.

Experimental setup. Word alignment was found using GIZA++[3] (Och, 2003), supported by mkcls[4] (Och, 1999) tool. The PBSMT systems we consider in this study is based on Moses toolkit (Koehn et al., 2007). We followed the guidelines provided on the Moses web page[5].

Two phrase reordering methods are widely used in phrase-based systems. A distance-based reordering model providing the decoder with a cost linear to the distance between words that are being reordered. This model constitutes the default for the Moses system. And, a lexicalized block-oriented data-driven reordering model (Tillman, 2004) considers three orientations: monotone (M), swap (S), and discontinuous (D), while the reordering probabilities are conditioned on the lexical context of each phrase pair.

All language models were trained with SRI LM toolkit (Stolcke, 2002). Language models for Dutch, Spanish and Chinese use 5-grams, while the idealized English ($\grave{s}$) is modeled using 3-grams.

We use Stanford parser[6] (Klein and Manning, 2003) as a source-side parsing engine. The parser was trained on the WSJ Penn treebank provided with 14 syntactic categories and 48 POS tags. The evaluation conditions were case-sensitive and included punctuation marks. For Maximum Entropy modeling we used the maxent toolkit[7].

Translation scores. Table 3 shows the results of automatic evaluation using BLEU (Papineni et al., 2002) and NIST (Doddington, 2002) metrics.

MERrd configuration corresponds to the PBSMT system with the source side of the parallel corpus reordered using our Maximum Entropy model, but the transduction operations are limited to permutation of the children only. *MERrd+xlt* configuration refers to the set of systems which, beside child permutation, includes a deletion operation with the maximum number of tree layers that can be deleted set to x. All reordered systems include a MSD model as a supporting reordering mechanism.

BLEU scores measured on the test data, which are statistically significant from the best PBSMT results are marked with bold. The statistical significance calculations have been done for a 95% confidence interval and 1000 resamples, following the guidelines in Koehn (2004).

Analysis. Our results show that source-reordering is beneficial for the language pairs with high mutual word order disparity. In contrast to English-Dutch and English-Chinese translation tasks, the statistical significance test reveals that all but the *MERrd+5lt* English-Spanish PBSMT systems with rearranged input are not different from the translation quality delivered by Moses. This disappointing result for the English-to-Spanish translation task may be explained by the fact that many reordering differences are resolved by standard reordering models (distance-based and MSD).

Table 3 shows the results of automatic translation quality evaluation. A gap between the maximum reachable performance shown by tree transduction systems and the translation quality delivered

[2]The latter feature intends to model the divergence in word order in relative clauses between Dutch and English which is illustrated in Figure 1.

by our model is 0.05-0.29 BLEU points for English-Dutch, 0.01-0.09 for English-Spanish and 0.27-0.76 for English-Chinese. These numbers demonstrate that there are some potentially usable regularities not captured by our current conditional tree-transduction model.

7 Conclusions and future work

We present a source reordering system for PBSMT, in which the reordering decisions are conditioned on features from the source parse tree. Our system allows for two operations over the parse tree: permuting the order of sibling nodes and deleting child nodes in order to make the tree flatter and exploit sibling permutations at the remaining layers.

Our contribution can be summarized as follows: (1) we report detailed results of maximum potential performance that can be achieved with source reordering under different constraints, (2) we define a source-reordering process through an efficient sequence of greedy, context-conditioned transduction operations over the source parse trees.

The method was tested on three different translation tasks. The results show that our approach is more effective for language pairs with significant difference in word order. Another important observation is that our model demonstrate translation quality comparable with the one delivered by SMT systems based on hierarchical phrases.

The introduced reordering algorithm and the results obtained present many opportunities for future work. We plan to perform a detailed analysis of the structure of the extracted phrases to find out the particular cases where the improvement comes from. We also propose to discover other possible transduction operations to better explore the reordering space.

Abstract

Lexicalized reordering models play a central role in phrase-based statistical machine translation systems. Starting from the distance-based reordering model, improvements have been made by considering adjacent words in word-based models, adjacent phrases pairs in phrase-based models, and finally, all phrases pairs in a sentence pair in the reordering graphs. However, reordering graphs treat all phrase pairs equally and fail to weight the relationships between phrase pairs. In this work, we propose an extension to the reordering models, named weighted reordering models, that allows discriminative behavior to be defined in the estimation of the reordering model orientations. We apply our extension using the weighted alignment matrices to weight phrase pairs, based on the consistency of their alignments, and define a distance metric to weight relationships between phrase pairs, based on their distance in the sentence. Experiments on the IWSLT 2010 evaluation dataset for for the Chinese-English language pair yields an improvement of 0.38 (2%) and 0.94 (3.7%) BLEU points over the state-of-the-art work's results using weighted alignment matrices.

1 Introduction

Reordering in Machine Translation (MT) is the task of word-order redistribution of translated words. An early reordering paradigm uses a simple distance based reordering model, which penalizes words that diverge from their original position after being translated (Koehn et al., 2003). This works moderately well for language pairs where reordering distances are small, but performs poorly for language pairs such as Chinese-English, where the opposite occurs. One of many approaches to implement improved reordering models is to use the lexical information during the phrase extraction algorithm to predict reordering orientations, using word-aligned bilingual sentences. However, the fact that spurious word alignments might occur leads to the use of alternative representations for word alignments that allow multiple alignment hypotheses, rather than the 1-best alignment (Venugopal et al., 2009; Mi et al., 2008; Christopher Dyer et al., 2008). More recently, a more efficient representation of multiple alignments was proposed in (Liu et al., 2009) named weighted alignment matrices, which represents the alignment probability distribution over the words of each parallel sentence. The method for building a word-based lexicalized reordering model using these matrices is proposed in (Ling et al., 2011). However, phrase-based reordering models have been shown to perform better than word-based models for several language pairs (Tillmann, 2004; Su et al., 2010; Galley and Manning, 2008), such as Chinese-English and Arabic-English.

In this work, we propose an extension to the phrase-based lexicalized model approach using reordering graphs presented in (Su et al., 2010), which allows phrase pairs to be weighted differently, rather than uniformly as in the original proposal. Then, we will present a phrase-based approach to estimate the orientations of the reordering model from the weighted alignment matrices using this extension.

2 Lexicalized Reordering models

In this section we will present the lexicalized reordering models approaches that are relevant for this work.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 47–55,
Chiang Mai, Thailand, November 8 – 13, 2011.

2.1 Word-based Reordering

The lexicalized reordering model is possibly the most used lexicalized reordering model and it calculates, as features, the reordering orientation for the previous and the next word, for each phrase pair. In the word-based reordering model (Axelrod et al., 2005), during the phrase extraction, given a source sentence S and a target sentence T, the alignment set A, where a_i^j is an alignment from i to j, the phrase pair with words in positions between i and j in S, S_i^j, and n and m in T, T_n^m, can be classified with one of three orientations with respect to the previous word. The orientation is

- Monotonous - if only the previous word in the source is aligned with the previous word in the target, or, more formally, if $a_{i-1}^{n-1} \in A \wedge a_{j+1}^{n-1} \notin A$.
- Swap - if only the next word in the source is aligned with the previous word in the target, or more formally, if $a_{j+1}^{n-1} \in A \wedge a_{i-1}^{n-1} \notin A$.
- Discontinuous - if neither of the above are true, which means, $(a_{i-1}^{n-1} \in A \wedge a_{j+1}^{n-1} \in A) \vee (a_{i-1}^{n-1} \notin A \wedge a_{j+1}^{n-1} \notin A)$.

The orientations with respect to the next word are given analogously. The reordering model is generated by grouping the phrase pairs that are equal, and calculating the probabilities of the grouped phrase pair being associated each orientation type and direction, based on the orientations for each direction that are extracted. Formally, the probability of the phrase pair p having a monotonous orientation is given by:

$$P(p, mono) = \frac{C(p,mono)}{C(p,mono)+C(p,swap)+C(p,disc)} \quad (1)$$

Where $C(p, o)$ is the number of times a phrase is extracted with the orientation o in that group of phrase pairs.

2.2 Word-based Reordering using alignment matrices

The work in (Ling et al., 2011) adapts the word-based reordering model to extract the reordering orientations from the weighted alignment matrices. This is done by changing the $C(p, o)$ from a count function over a given set of phrase pairs P to a weighted sum given by:

$$C(p, o) = \sum_{p \in P} Sc(p) P_c(p, o) \quad (2)$$

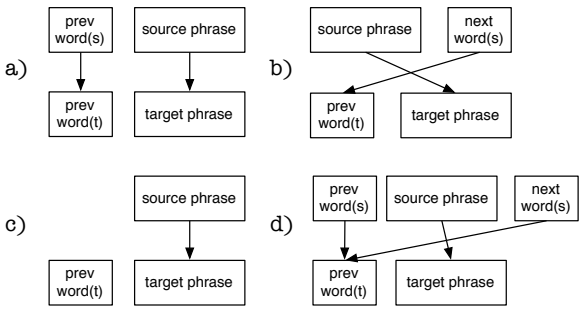

Figure 1: Enumeration of possible reordering cases with respect to the previous word. Case a) is classified as monotonous, case b) is classified as swap and cases c) and d) are classified as discontinuous.

The score $Sc(p)$ of a phrase pair p is given by the algorithm described in (Liu et al., 2009), which is based on its alignments. This score is higher if the alignment points in the phrase pair have high probabilities, and if the alignment is consistent. Thus, if a phrase pair has better quality, its orientation is given more weight than phrase pairs with worse quality. Rather than classifying each phrase pair with either monotonous (M), swap (S) or discontinuous (D), a probability distribution for the orientations is calculated. Thus, for the previous word, given a weighted alignment matrix W, the phrase pair between the indexes i and j in S, S_i^j, and n and m in T, T_n^m, the probability values for each orientation are given by:

- $P_c(p, M) = W_{i-1}^{n-1}(1 - W_{j+1}^{n-1})$
- $P_c(p, S) = W_{j+1}^{n-1}(1 - W_{i-1}^{n-1})$
- $P_c(p, D) = W_{i-1}^{n-1} W_{j+1}^{n-1} + (1 - W_{i-1}^{n-1})(1 - W_{j+1}^{n-1})$

2.3 Phrase-based Reordering

The problem with the word-based lexicalized reordering model is that it is assumed that the adjacent words are translated by themselves, which is not always true in phrase-based SMT. The reordering model presented in (Tillmann, 2004) uses adjacent phrases to generate the phrase orientations. In this model, the previous orientation of a phrase pair p:

- Monotonous if there is a phrase pair with the source S_x^{i-1} that ends at $i-1$ and starts at any x, that is aligned to the target phrase T_y^{n-1}, that ends at $n-1$ and starts at any y. In another words, if there is an adjacent phrase pair

that occurs before p, both in the source and in the target sentences.

- Swap if there is a phrase pair with the source S_{j+1}^{x} that starts at $j+1$ and ends at any x, that is aligned to the target phrase T_{y}^{n-1}, that ends at $n-1$ and starts at any y. In another words, if there is an adjacent phrase pair that occurs before p in the target sentence and after p in the source sentence.

- Discontinuous - if neither of the above are true.

The work presented in (Tillmann, 2004) only considers phrases that are smaller than a fixed size, since the possible phrases for each bilingual sentence are generated and kept in memory making the time and memory needed to store and lookup all possible phrases grows rapidly as the size grows. The work in (Galley and Manning, 2008) implements a shift-reduce parsing algorithm that updates the previously extracted phrase pair orientations when a new phrase pair is extracted, which allows arbitrary sized phrase pairs to be considered.

2.4 Phrase Reordering using Reordering Graphs

The phrase based model considers the existence of a single adjacent phrase, which is not ideal, since many possible adjacent phrases exist for each extracted phrase pair, which can generate different orientations. In work done in (Su et al., 2010) the orientation is computed by considering all possible reorderings of phrase pairs that are extracted in the sentence pair. Once again $C(p, o)$ is given by the weighted count:

$$C(p, o) = \sum_{p \in Ph} P_c(p, o) \quad (3)$$

Where $P_c(p, o)$ is extracted by structuring the extracted phrase pairs into a reordering graph. This graph is created for each sentence pair, using extractable phrase pairs as nodes and connecting adjacent phrase pairs in the target side with an edge. Each edge is associated with a reordering orientation, dependent on the source side of the connected phrase pairs. If these are not adjacent in the source side, the edge is given a discontinuous orientation, otherwise, the edge is given a monotonous or swap orientation depending on whether they are in the same order or not in the source side, respectively.

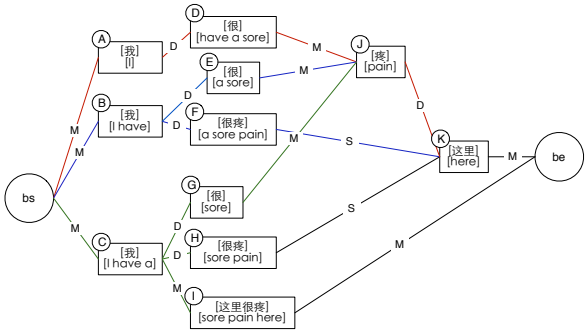

Figure 2: Reordering Graph for the sentence pair with source "我这里很疼 (wo zhe li hen teng)" and target 'I have a sore pain here". Each extracted phrase pair is denoted as a rectangle, with the source and target phrases inside. Each phrase pair is also labeled for reference. The edges are labeled with its orientation (the colors are only for easier visualization).

Furthermore, phrase pairs with no adjacent phrase pairs are linked to the nearest phrase pair. These arcs are also given a discontinuous orientation.

A start node bs is added and is linked to all phrase pairs at the start of the target sentence , and a end node be, which is linked by all phrase pairs that end the target sentence.

For the previous orientation weight, the probability $P_c(p, o)$ of the phrase pair p having a given orientation o, considering the set $Prev(o)$, with all phrase pairs that are linked to p that would lead to a orientation o, is given by:

$$P_c(p, o) = \sum_{p' \in Prev(o)} \frac{\alpha(p')\beta(p)}{\beta(bs)} \quad (4)$$

In this equation, $\alpha(p')$ is the number of paths to the p' node from the first phrase, $\beta(p)$ is the number of paths from p to the last phrase and $\beta(bs)$ results in the number of possible paths. We can see from this equation that $\alpha(p') \times \beta(p)$ results in the number of paths containing the arc from p' to p, thus not only multiple adjacent phrase pairs are considered, but these are also weighted by the number of possible translation segmentations that would use that phrase pair.

An example of a reordering graph is illustrated in figure 2. We can see in that for the phrase pair "这里 (zhe li)"→"here", instead of simply giving the swap orientation due to the adjacent phrase pair "很疼 (hen teng)"→"sore pain", it also considers the case where "疼 (teng)" is translated by itself to "pain", in which case the orientation

would be discontinuous. In this case, the weight is evenly distributed between the 2 orientations since there are 2 paths that contain an edge with each orientation.

3 Phrase-based reordering using Weighted Reordering Graphs

We see in the example given in section 2.4 that the phrase pair "这里 (zhe li)"→"here" is given an equal weight to the swap and discontinuous orientations. However, if we translate "疼 (teng)" by itself, we would have to translate "很 (hen)" without "疼 (teng)". The translation for "很 (hen)" by itself to "sore" is not very probable, since "很 (hen)" without context is generally translated to "very", "much" or "quite". Thus, it is more probable during decoding that the segmentation "很疼 (hen teng)" is used. Although the phrase-based reordering model presented in section 2.3 gives a better reordering estimate in this case, in cases where there is an equal probability of both segmentations the graph-based approach would be better. Hence, we argument that by treating phrase pairs discriminatively, we can improve reordering orientations estimate in both cases. In this work, we propose an extension to the reordering graphs to allow the definition of discriminative behavior during training. We will start by describing our model for the Weighted Reordering Graph and then we proceed into the definition of the algorithm to extract the word orientations from the Weighted Reordering Matrices.

3.1 Weighted Reordering Graph Model

We define a weighted reordering graph for a given sentence pair S as $G_S = (V, E, W_v, W_e)$, where V is the set of all vertices, which are phrase pairs $p_1, p_2, ..., p_n$, and E is the set of all edges and we denote a edge from p_1 to p_2 as $e(p_1, p_2)$. W_v and W_e are functions that map each element in V and E to a weight.

We define a path $PH(bs, p_1, p_2, be)$ as a path starting in bs and through p_1, then p_2 and ending in be. The weight of a path $PH(p_1, p_2, ..., p_{k-1}, p_k)$ is given by the product of the weights of its phrase pairs $W_v(p_1)W_v(p_2)...W_v(p_{k-1}), W_v(p_k)$ and the weights of the edges connecting the phrases in the path $e(p_1, p_2)...e(p_{k-1}, p_k)$. If both weight functions W_v and W_e are set to return 1 we define the same behavior as a reordering graph described in section 2.4, since all paths will have the weight of 1.

Following equation 4, we define the probability of a given orientation, $P_c(p, o)$, for a weighted reordering graph as:

$$P_c(p, o) = \sum_{p' \in Prev(o)} \frac{\alpha_w(p')W_e(e(p',p))\beta_w(p)}{\beta_w(bs)} \quad (5)$$

Where $\alpha_w(p')$ is the sum of weights of paths from bs to p' and $\beta_w(p)$ is the sum of the weights of the paths from p to be. It is also crucial to consider the weight of the edge $e(p', p)$, since it is not weighted in neither $\alpha_w(p')$ nor $\beta_w(p)$. This is not present in equation 4 since all edges are weighted as 1.

The functions α_w and β_w can be defined as:

$$\alpha_w(p) = W_v(p) \sum_{p' \in Prev(p)} \alpha_w(p')W_e(e(p', p)) \quad (6)$$

$$\beta_w(p) = W_v(p) \sum_{p' \in Next(p)} \beta_w(p')W_e(e(p', p)) \quad (7)$$

Where $Prev(p)$ and $Next(p)$ are sets of all phrase pairs that are linked to and linked from p, respectively. We also initiate $\alpha_w(bs) = 1$ and $\beta_w(be) = 1$. These two values can be initialized with any value, as this will not affect the normalized result from equation 5.

The pre-computation of α_w and β_w can be performed using an approach similar to the forward-backward algorithm and calculating the forward probabilities for α_w and backward probabilities for β_w, with time complexity in the order $O(N^2T)$, where N is the number of different phrase pairs and T is the length of sequences. To compute α_w, we need to take into account that the vertices/phrase pairs can be ordered topologically in an array so that a vertice in the index i does not have edges pointing to any vertice at any index at or before $i - 1$. This can be done by ordering the phrase pairs by the ending position of the target phrase n, starting with bs, since we know that the phrase pairs ending at n can only have links to phrase pairs ending at least at $n + 1$, according to the definition of an edge in a reordering graph.

The algorithm for computing β_w can be done analogously, by starting from be and sorting according to the target phrase's starting position.

3.2 Choosing W_v and W_e

In this work, we use the information given by the Weighted Alignment Matrices to define $W_v(p)$. We set $W_v(p)$ using the phrase pair scoring algorithm presented in (Liu et al., 2009), which calculates the weight of a phrase pair based on its alignment points. This weight can be seen as the

Algorithm 1 Compute α_w

Require: sorted phrase pairs P

```
α_w(P) = {0, ..., 0}
for p in P do
    if p = bs then
        α_w(bs) := W_v(bs)
    end if
    for p' in followingNodes(p) do
        w = W_e(e(p, p'))W_v(p')
        α_w(p') := α_w(p') + wα_w(p)
    end for
end for
return extractedPhrasePairs
```

probability of that phrase pair being extractable according to the heuristic proposed in (Koehn et al., 2003).

We also set $W_e(e(p^a, p^b))$ to a distance function between the phrases p^a and p^b in the target, to better cope with the situation where there are no adjacent phrase pairs to a phrase pair and an edge is added to the closest adjacent phrase. An example of such a case instance is displayed in figure 3. In this case, the phrase ending with the target word "wrap" can not be extracted, since it is aligned with "把 (ba)" and "包 (bao)". Thus, consistent phrase pairs that can be extracted must at least contain these 2 words to have "wrap" in the target. Another situation where this might also happen is the case where a phrase is not extracted due to size constraints. In both cases the reordering orientation of the edge is always discontinuous since the target phrases are not adjacent. We find that the reordering orientations that originates from these edges are not very precise. In the first case, the next orientation for the phrase pair "不需要 (bu xu yao)"→"need not" would be divided between monotonous from the edge to the phrase pair "把它包 (ba ta bao)"→"wrap it" and discontinuous from the edge to the phrase pair from "它 (ta)" to "it". However, in an actual translation the only way to translate this sentence correctly would be to treat "把它包 (ba ta bao)" as a segment, which favors the monotonous orientation. Furthermore, even if we could translate "把 (ba)" and "包 (bao)" to "wrap", the orientation would still be monotonous. In the second case, an edge between phrase pairs p^a and p^b that is created because a phrase pair p^c between p^a and p^b was not extracted due to size constraints, would mean that there is a missing edge from p^a to p^c and another

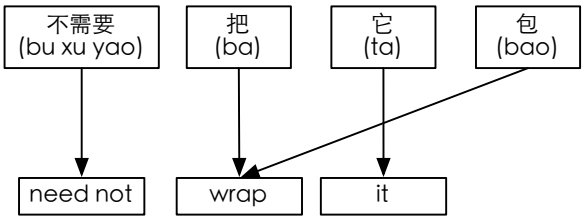

Figure 3: Illustration of a case where no adjacent phrase pairs exits for a phrase pair. In this case, the phrase pair "不需要 (bu xu yao)"→"need not" and the phrase pair "它 (ta)"→"it" are linked by an edge even though they are not adjacent.

from p^b to p^c, and no edge from p^a to p^b. Thus, the orientation of this edge is likely to be spurious, and should be given a lower weight.

This cannot be done by setting this weight to 0 (removing the arc), since it will render all paths that contain that edge to 0. For instance, if we set the maximum phrase pair size to 7 and the first 8 words of the source and target are aligned in a way that no smaller translation units can be extracted, there would be an edge from bs to the 9th word. Therefore, if we set the weight of the edge to 0, any path we take would have 0 weight, rendering the whole sentence pair useless. Hence, we define the W_e function as:

$$W_e(e(p, p')) = \frac{1}{(1+\lambda)^d} \tag{8}$$

Where d is the distance between p and p' defined by the number of words in the target sentence between p and p', and λ is a positive value defining the penalty as d increases. In this work, we empirically set $\lambda = 0.5$, and leave the optimization of this parameter as future work.

3.3 Reordering Model Comparison

In order to illustrate the performance of the different reordering models, we consider two training sentences taken from the IWSLT 2010 DIALOG task. The weighted alignment matrices for these sentences are illustrated in tables 1 and 2. For simplicity in terms of illustration, we assume that algorithms that do not use the alignment matrices, consider all non-zero cells as alignment points. The probability distribution for different previous orientations of each reordering model for the phrase pair "这里 (zhe li)→here" from sentence 1 and the phrase pair "今天 (jin tian)→today" from sentence 2 are calculated in tables 3 and 4, respectively.

Sentence 1	I	have	a	sore	pain	here
我 (wo)	0.90					
这里 (zhe li)						0.75
很 (hen)				0.50		
疼 (teng)					0.80	

Table 1: Weighted alignment matrix for a training sentence pair from DIALOG training corpus from IWSLT 2010.

Sentence 2	Are	there	any	baseball	games	today
今天 (jin tian)						1
有 (you)		0.60	0.90			
棒球 (bang qiu)				1		
比赛 (bi sai)					0.65	
吗 (ma)						

Table 2: Weighted alignment matrix for a training sentence pair from DIALOG training corpus from IWSLT 2010.

We can see that the word-based reordering models classify the word orientation as discontinuous, since the previous word in the target is not aligned to adjacent words in the source. This leads to inaccurate orientations for the first phrase pair, since the words "很 (hen)" and "疼 (teng)" have a high probability of being translated together. In the second phrase pair, it gives a good approximation of the correct orientation, since "棒球 (bang qiu)" and "比赛 (bi sai)" are good translations even when translated without "有 (you)".

The opposite occurs with the phrase-based reordering model, since it considers the source phrase segmentation "很疼 (hen teng)" and "有棒球比赛 (you bang qiu bi sai)", respectively. Thus, the estimation of the orientation is better for the former and worse for the latter phrase pair.

Using the reordering graph, orientations are estimated for different adjacent phrase pairs. In the first phrase pair, both cases where the source phrase "很疼 (hen teng)" and "疼 (teng)" are used as translation units are taken into account, and the same happens with the second phrase pair. As it was already referred in section 3, the problem with this estimation is that it fails to consider that "疼 (teng)" is more likely to be translated with "很 (hen)", otherwise the translation of "很 (hen)" is less likely to be accurate.

Finally, by using weighted-reordering-graph, using phrase scores calculated from weighted alignment matrices, paths in the graph that contain phrase pairs that are better aligned are given more weight.

这里 (zhe li)→here	Mono	Swap	Disc
Word-based	0	0	1
Weighted-Word-based	0	0	1
Phrase-based	0	1	0
Graph-based	0	0.333	0.333
Weighted-graph-based	0	0.271	0.180

Table 3: Previous orientation probabilities for different lexicalized reordering models for the phrase pair "这里 (zhe li)"→"here", taken from sentence 1.

今天 (jin tian)→today	Mono	Swap	Disc
Word-based	0	0	1
Weighted-Word-based	0	0	1
Phrase-based	0	1	0
Graph-based	0	0.166	0.500
Weighted-graph-based	0	0.187	0.416

Table 4: Previous orientation probabilities for different lexicalized reordering models for the phrase pair "今天 (jin tian)"→"today", taken from sentence 2.

4 Experiments

We implemented both word-based and phrase-based lexicalized reordering models described above, and compared the translation results with our algorithm.

4.1 Corpus

Our experiments were performed over two datasets, the BTEC and the DIALOG parallel corpora from the latest IWSLT evaluation in 2010 (Paul et al., 2010). The experiments performed with the BTEC corpus used the French-English subset, while the ones perfomed with the DIALOG corpus used the Chinese-English subset. The training corpora contains about 19K and 30K sentences, respectively.

The development corpus for the BTEC task was the CSTAR03 test set composed by 506 sentences, and the test set was the IWSLT04 test set composed by 500 sentences and 16 references. As for the DIALOG task, we performed 2 tests, one using the evaluation datasets from IWSLT evaluation in 2006 (IWSLT06) and in 2008 (IWSLT08). The development from the IWSLT06 evaluation is com-

posed by 489 sentences, and the test set was composed by 500 sentences and 7 references. The development from IWSLT08 evaluation is composed by 245 sentences, and the test set was composed by 506 sentences and 7 references.

4.2 Setup

We use two setups for the different corpora that are used. Word-based (word-based), phrase-based (phrase-based), and phrase-based using reordering graphs (graph-based) reordering models are generally used with the regular phrase extraction algorithm, with alignment constraints defined in (Koehn et al., 2003). Thus, we compare our method with the methods above in this environment. The weighted word-based reordering model (weighted word-based) described in section 2.2 was tested using the phrase extraction algorithm described in (Liu et al., 2009), where phrase pairs are filtered out based on their scores, which are calculated from their alignment probabilities. So, we also test our algorithm under these conditions. In our work, we set the threshold for filtering out phrase pairs to 0.1, which was the threshold used in (Ling et al., 2011). We also test separately our implementation of W_v (graph-based W_v), which weights phrase pairs according to their scores, and W_e (graph-based W_e), a penalty based on the distance between phrase pairs. Then, we test both approaches combined (graph-based W_vW_e).

The word alignments and the weighted alignment matrices are generated using the Geppetto toolkit[1], using a regular HMM-based word alignment model (V. Graça et al., 2010), without restraints. The optimum alignment is found using posterior decoding, and the weighted alignment matrices are obtained from the same alignment posteriors.

The optimization of the translation model weights was done using MERT tuning. Each experiment was run three times, and the final scores are calculated as the average of the three runs in order to stabilize the results. The results were evaluated using BLEU-4 and METEOR, and computed with 16 references.

4.3 Results

Tables 5, 6 and 7 show the scores using the different reordering models. Consistent improvements

in the DIALOG corpus scores over state-of-the-art reordering models when using the weighted reordering graphs. We can see that both W_v and W_e generate improved results, and their combination generally performs better than both when used individually. The METEOR score is not always higher using our algorithm, but we believe this roots from the fact that the MERT tuning was set to optimize the BLEU score.

For the BTEC corpus, we observe that phrase-based models do not perform as well, although the difference in BLEU is only 0.26 (0.4%) in the weighted case with respect to the weighted word-based model. We believe that this is because a large percentage of translation units that are used during decoding is one-to-one, as it was reported in (Ling et al., 2010). It is highly likely that this roots from the fact that the training set is small, so the probability of finding large sequences of strings in the training set that matches the ones in the test set is rather low. In this case the word-based reordering models yield better reordering estimates, since considering longer training phrase-pairs that will not even be present in the test set will only degenerate the orientation probabilities. This suggests for future work that adding prior knowledge about the probability of a phrase-pair given its size could improve the translation quality. In the extreme case, we can give more weight to phrase pairs with the source that is present in the test set, for estimating the orientations, generating a reordering model that is specific for each test set.

5 Conclusions

In this work, we presented the current state of the art in improving the lexicalized model orientation estimates. The basic word based lexicalized reordering model uses neighboring words to perform the orientation estimates. However, since words are not always translated by themselves, these estimates can be improved by considering neighboring phrases rather than words. Another way to improve the phrase based reordering model is to consider multiple adjacent phrases, which can be done using a reordering graph. Finally, another improvement can be made by addressing the limitations of the lexicalized reordering models extracted from a single alignment, and generate the orientation estimates using weighted alignment matrices.

We extend the reordering graph model to allow the discriminative treatment of different paths. Using scores extracted from weighted alignment matrices to weight phrase pairs and a distance penalty function to penalize paths with phrase pairs that are not adjacent, improvements of 0.38 (2%) and 0.94 (3.4%) in BLEU over the state of the art algorithms using weighted alignment matrices for the Chinese-English language pair can be achieved.

As future work, we will experiment with different types of phrase pair and edge scorers and extending the weighted reordering graphs to allow multiple scorers to be combined and optimized. Additionally, we will evaluate the impact of our algorithm in larger corpora, since we believe that using a larger training corpora will result in bigger improvements over the word-based approaches, since longer sequences of words in the test set will be found in the training set, resulting in longer translation units.

The code used in this work is currently integrated with the Geppetto toolkit[2] , and it will be made available in the next version for public use.

Abstract

Temporal relations between events is a valuable source of information which can be used in a large number of natural language processing applications such as question answering, summarization, and information extraction. Supervised temporal relation classification requires large corpora which are difficult, time consuming, and expensive to produce. Active learning strategies are well-suited to reduce this effort by efficiently selecting the most informative samples for labeling. This paper presents novel active learning strategies based on support vector machines (SVM) for temporal relation classification. A large number of empirical comparisons of different active learning algorithms and various kernel functions in SVM shows that proposed active learning strategies are effective for the given task.

1 Introduction

The identification of temporal relations between events, in texts, is a valuable information for many natural language processing (NLP) tasks, such as summarization, question answering, and information extraction. In question answering, one expects the system to answer questions such as "when an event occurred", or "what is the chronological order of some desired events". In text summarization, especially in the multi-document type, knowing the order of events is important for correctly merging related information.

Most existing algorithms for temporal relation learning are supervised, they rely on manual annotations of corpora. Producing such annotated corpora has shown to be a time consuming, hard, and expensive task (Mani et al., 2006). In this paper we explore active learning techniques as a way to control and speed up the annotation process.

In the active learning framework, the learner has control over choosing the instances that will constitute the training set. A typical active learning algorithm begins with a small number of annotated data, and selects one or more informative instances from a large set of unlabeled instances, named the pool. The chosen instance(s) are then labeled and added to other annotated data, and the model is updated with this new information. These steps are repeated until at least one termination condition is satisfied.

While there have been numerous applications of active learning to NLP researches (Settles and Craven, 2008; Xu et al., 2007), it has not been applied, to our knowledge, to temporal relation classification.

This paper presents a novel active learning strategy for SVM-based classification algorithm. The proposed algorithm considers three measures: *uncertainty*, *representativeness*, and *diversity* to select the instances that will be annotated. The method we propose is generic, it could be applied to any SVM based classification problem. Temporal relation classification has been selected, in this paper, for illustration purpose. Our experiments show that state-of-the-art results can be reproduced with a significantly smaller part of training data.

The remainder of this paper is organized as follows: Section 2 is about temporal relation classification and its related work. Section 3 describes some

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 56–64,
Chiang Mai, Thailand, November 8 – 13, 2011.

of existing active learning methods. Our proposed method will be presented in Section 4. Section 5 briefly presents the characteristics of the corpora that we have used. Section 6 demonstrates the evaluation of the proposed algorithm. Finally, Section 7 concludes the paper and presents some possible future work.

2 Temporal Relation Classification with SVM

For a given ordered pair (x_1, x_2), where x_1 and x_2 are time expressions or events, a temporal information processing system identifies the type of relation that temporally links x_1 to x_2. For example in "If all the debt is converted $(event_1)$ to common, Automatic Data will issue $(event_2)$ about 3.6 million shares; last Monday $(time_1)$, the company had $(event_3)$ nearly 73 million shares outstanding.", taken from document *wsj_0541* of TimeBank (Pustejovsky et al., 2003), there are two temporal relations between pairs $(event_1, event_2)$ and $(time_1, event_3)$. The task of a temporal relation extraction system is to automatically tag these pairs with relations *BEFORE* and *INCLUDES*, respectively.

Several researchers have focused on temporal relation learning (Chklovski and Pantel, 2005; Lapata and Lascarides, 2006; Bethard et al., 2007; Chambers et al., 2007; Bethard and Martin, 2008; Mirroshandel and Ghassem-Sani, 2010; Puscasu, 2007) among which SVM has shown good performances. In this section, we describe two of the most successful SVM-based methods.

Inderjeet Mani was the first to propose an SVM-based temporal relation classification model which is based on a linear kernel (Mani et al., 2006). His system (referred to as (k_{Mani})) uses five temporal attributes that have been tagged in the standard corpora (Pustejovsky et al., 2003) plus the string of words that constitute the events, as well as their part of part of speech tags.

The other successful SVM-based temporal classification method uses a polynomial convolution tree kernel, named argument ancestor path distance kernel (AAPD), and outperforms Mani's method (Mirroshandel et al., 2010). In this model, the algorithm adds event-event syntactic properties to the simple event features described above. In order to use syntactic properties, a convolution tree kernel is applied to the parse trees of sentences containing event pairs. Through this process, useful syntactic features can be gathered for classification by SVM. The two kernels are then polynomially combined.

3 Active Learning

Supervised methods usually need a large number of annotated samples in the training phase. In most applications including temporal relation classification, the preparation of such samples is a hard, time consuming, and expensive task (Mani et al., 2006). On the other hand, all these annotated samples may not be useful, because some samples contain little (or even no) new information. Active learning algorithms overcome this problem by adding only the most informative instances labeled by an oracle (e.g., a human expert) to the learning model. Three scenarios have been proposed for the selection of instances: 1) membership query synthesis, 2) stream-based selective sampling, and 3) pool-based sampling (Settles, 2010).

In membership query synthesis, the model itself generates some instances rather than using real-world unlabeled instances (Angluin, 2004).

In stream-based selective sampling, instances are presented in a stream and the learner decides, based on its specific control measure, whether or not to query its label (Atlas et al., 1990; Cohn et al., 1994).

In pool based sampling, which is the scenario that we have chosen), a large number of unlabeled instances are collected to form the *pool* $\mathcal{U}$. The algorithm begins with a small number of labeled data $\mathcal{L}$, and then chooses one or more informative instances from $\mathcal{U}$. The chosen instance(s) are labeled and added to $\mathcal{L}$. A new model is then learned and the process iterated (Lewis and Gale, 1994).

3.1 Sample Selection Strategies

In all active learning strategies, the informativeness of each unlabeled instance is evaluated by the learner, and the most informative instance(s) are labeled. Different informativeness measures have been proposed: 1) uncertainty sampling, 2) query by committee, 3) expected model change, 4) expected error reduction, 5) variance reduction, and 6) den-

sity weighted methods (Settles, 2010).

Uncertainty sampling is the simplest and the most commonly used selection strategy. In this strategy, instances for which the prediction of the label is the most uncertain are selected by the learner (Lewis and Gale, 1994).

In query by committee, there is a committee of models trained on the current labeled data $\mathcal{L}$ based on different hypotheses. For each unlabeled instance, committee models vote for their label. The most informative instance is one with the largest disagreement on the votes (Seung et al., 1992). In the expected model change, the most informative instance is the one which causes the most change to the model (Settles et al., 2008). In expected error reduction, the learner selects instances which reduce expected error of model as much as possible (Roy and McCallum, 2001). In density weighted methods, selected instances must be both uncertain and representative in order to decrease the effect of outliers which may cause some problems especially in uncertainty sampling and query by committee strategies (Settles and Craven, 2008).

4 Proposed Algorithm

In this section, we present an active learning method based on SVM. There have been other efforts in using active learning in combination with SVM (Brinker, 2003; Xu et al., 2007), our contribution is the design of new uncertainty measures used for sample selection. In addition, the way representativeness and diversity measures are computed and combined are novel.

The algorithm is pool-based. At each iteration, k ($k \geq 1$) instances are selected from a pool $\mathcal{U}$. To select the more informative instance(s), three measures are used: *uncertainty*, *representativeness* and *diversity*. In the next subsections, we begin with an overview of multi-class classification with SVM, then introduce our three measures and describe the active learning algorithm.

4.1 Multi-class classification

In SVM binary classification, positive and negative instances are linearly partitioned by a hyper-plane (with maximum marginal distance to instances) in the original or a higher dimensional feature space. In order to classify a new instance x, its distance to the hyper-plane is computed and x is assigned to the class that corresponds to the sign of the computed distance. The distance between instance x and hyper-plane H, supported by the support vectors $x_1 \dots x_l$, is computed as follows (Han and Kamber, 2006):

$$d(x, H) = \sum_{k=1}^{l} y_k \alpha_k x_k x^T + b_0 \qquad (1)$$

where y_k is the class label of support vector x_k; α_k and b_0 are numeric parameters that are determined automatically.

For multi-class classification with m classes, in one-versus-one case, a set $\mathcal{H}$ of $\frac{m(m-1)}{2}$ hyper-planes, one for every class pair is defined. The hyper-plane that separates class i and j will be noted $H_{i,j}$. We note $\mathcal{H}_i \subset \mathcal{H}$ the set of the $m-1$ hyper-planes that separate class i from the others.

In order to classify a new instance x, its distance to each hyper-plane $H_{i,j}$ is computed and x is assigned to class i or j. At the end of this process, for every instance x, every class i has accumulated a certain number of votes, noted $V_i(x)$ (number of time a classifier has attributed the class i to instance x). The final class of x, noted $C(x)$ will be the one that has accumulated the highest number of votes.

$$C(x) = \arg\max_{1 \leq i \leq m} V_i(x) \qquad (2)$$

4.2 Uncertainty

Uncertainty is one of the most important measures of informativeness of an instance. If the learner is uncertain about an instance, that shows that the learning model is not able to deal with the instance properly. As a result, knowing the correct label of this uncertain instance will improve the quality of learning model.

In the process described in subsection 4.1, there are two places where uncertainty can be measured. In the first case, a decision is taken based on the difference of two distances. The smaller the difference, the less reliable the decision is. In the second case, a decision is taken based on the result of a vote. If the outcome of the vote does not show a clear majority, the decision will be less reliable.

Four measures of uncertainty are presented below, the first and second are based on distances while the third and fourth are based on the result of the vote procedure.

4.2.1 Nearest to One Hyper-Plane (NOH)

Uncertainty of an instance x is defined here as the distance to its closest class separating hyper-planes.

$$\varphi(x) = \min_{H \in \mathcal{H}_{C(x)}} |d(x, H)| \tag{3}$$

4.2.2 Nearest to All Hyper-Planes (NAH)

NAH defines the uncertainty of instance x as the sum of its distances to all its class separating hyper-planes.

$$\varphi(x) = \sum_{H \in \mathcal{H}_{C(x)}} |d(x, H)| \tag{4}$$

4.2.3 Least Votes Margin (LVM)

LVM estimates the uncertainty of an instance by the difference between the two highest votes for this instance.

$$\varphi(x) = V_i(x) - V_j(x) \tag{5}$$

where i is the class that has collected the highest number of votes and j the class that has collected the second higher number of votes.

4.2.4 Votes Entropy (VE)

VE is based on the entropy of the distribution of the vote outcome:

$$\varphi(x) = -\sum_{1 \leq i \leq m} P(V_i(x)) \log P(V_i(x)) \tag{6}$$

where $P(V_i(x))$ is simply estimated as its relative frequency $V_i(x)/m$.

4.3 Representativeness

Representativeness is another important measure for choosing samples in active learning. In figure 1, sample 1 is the nearest instance to decision boundary, it is therefore the instance that will be selected using uncertainty criterion. But it should be clear that this sample is not appropriate for selection, annotation, and addition to the training data, because it is in fact an outlier and non representative instance.

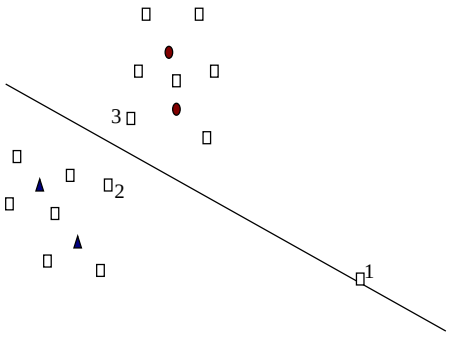

Figure 1: The weakness of uncertainty measure for dealing with outliers. Circles and triangles represent labeled instances while squares represent unlabeled instances.

This simple example shows that uncertainty measure alone is not suited to fight against outliers and noisy samples. In order to prevent the learner to select such instances, a representativeness measure ψ is used. It simply computes the average distance between an instance and all other instances in the pool:

$$\psi(x) = \frac{1}{N} \sum_{x' \in \mathcal{U}} \left| dist(x, x') \right| \tag{7}$$

where N is the number of instances in the pool, and $dist$ is the distance between two samples which can be computed by simply applying a kernel function on them:

$$dist(x_i, x_j) = kernel(x_i, x_j) \tag{8}$$

As it is shown in equation 7, the samples which are more similar to other samples of the pool will be considered to be more representative.

In order to take into account representativeness in the active learning algorithm, the distance between every sample pairs of the pool must be computed. This computation is a costly process, but these distances can be computed only once for the whole active learning algorithm. Algorithm 1 describes how representativeness and uncertainty measures have been combined.

4.4 Diversity

Diversity is the third measure that is used for instance selection. Instances that are both unreliable and representative may be very close to each other

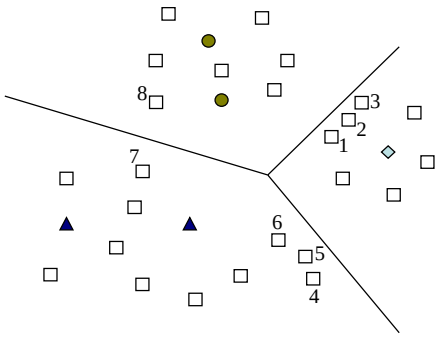

Figure 2: The necessity of applying diversity measure to select samples from the whole problem space.

and it might be interesting, in order to better cover the problem space, to select instances that are different from each other. This is done by taking diversity into account.

Figure 2 illustrates the effect of considering the diversity measure on a simple problem. In this problem, the learner chooses 4 instances for each iteration. Based on uncertainty and representativeness measures, samples 1, 2, 3, and 5 should be selected. However, 1, 2 and 3 are very similar, and only one of such samples may be enough for learning. Besides, selecting 7 and 8 will lead to a better covering of the problem space.

In our algorithm, diversity is taken into account after uncertainty and representativeness were. First, B_I instances are chosen, based on uncertainty and representativeness. A distance matrix is then constructed, based on the distance measure of equation 8. The B_I instances are then grouped into B_F ($B_F < B_I$) clusters, using hierarchical clustering and the centroid of each cluster is selected for labeling. This process is explained in algorithm 1.

4.5 Proposed Algorithm

The pseudo-code of our active learning algorithm is shown in Algorithm 1. This algorithm first trains the model based on the initial labeled data, and applies a combination of uncertainty and representativeness measures to select B_I samples from the pool. Then hierarchical clustering is applied to the extracted samples to select B_F most diverse samples. Chosen samples are then labeled and added to the training labeled set. This process is iterated until at least one termination condition is satisfied. In our experiments, the algorithm stops when all instances of the pool were selected and labeled.

Algorithm 1 THE PROPOSED ACTIVE LEARNING

α: Uncertainty coefficient
$\mathcal{L}$: Labeled set
$\mathcal{U}$: Unlabeled pool
$\varphi(x)$: Uncertainty measure
$\psi(x)$: Representativeness measure
B_I: Initial query batch size
B_F: Final query batch size

while termination condition is not satisfied **do**
  $\theta = train(\mathcal{L})$; $\mathcal{T}_I = \emptyset$;
  for $i = 1$ to B_I **do**
    // Find most uncertain and representative instance
    $\hat{x} = \arg\max_{x \in \mathcal{U}} [\alpha\varphi(x) + (1-\alpha)\psi(x)]$;
    $\mathcal{T}_I = \mathcal{T}_I \cup \{\hat{x}\}$;
  end for
  Apply Hierarchical clustering on $\mathcal{T}_I$ to extract set $\mathcal{T}_F$ of B_F diverse samples;
  $\mathcal{U} = \mathcal{U} - \mathcal{T}_F$;
  $\mathcal{L} = \mathcal{L} \cup \mathcal{T}_F$;
end while

Our algorithm may seem much more costly than the original SVM algorithm. However, it is easy to show, similar to (Brinker, 2003), that it only multiply by a coefficient of N/B_F (N is the final number of labeled instances) the total computational complexity of original SVM.

5 Corpus Description

Two standard corpora were used for our exprimments: TimeBank (v. 1.2)(Pustejovsky et al., 2003) and Opinion (`www.timeml.org`). TimeBank is composed of 183 newswire documents and 64 077 words, and Opinion comprises 73 documents with 38 709 words. These two datasets have been annotated with TimeML (Pustejovsky et al., 2004). There are 14 temporal relation types (*SIMULTANEOUS*, *IDENTITY*, *BEFORE*, *AFTER*, *IBEFORE*, *IAFTER*, *INCLUDES*, *IS_INCLUDED*, *DURING*, *DURING_INV*, *BEGINS*, *BEGUN_BY*, *ENDS*, *ENDED_BY*) in the TLink class of TimeML. Similar to (Mani et al., 2006; Chambers et al., 2007), we used a normalized version of these 14 temporal

relation types, which contains only the following six temporal relations:

SIMULTANEOUS *ENDS* *BEGINS*
BEFORE *IBEFORE* *INCLUDES*

In order to convert 14 relations into 6, the inverse relations were omitted (e.g., *BEFORE* and *AFTER*), and *IDENTITY* and *SIMULTAENOUS*, as well as *IS_INCLUDED* and *DURING* were collapsed, respectively.

Relation Type	**OTC**
IBEFORE	131
BEGINS	160
ENDS	208
SIMULTANEOUS	1528
INCLUDES	950
BEFORE	3170
TOTAL	6147

Table 1: The normalized TLink class distribution in OTC.

In our experiments, as in several previous work, we merged the two datasets to generate a single corpus called OTC. Table 1 shows the normalized TLink class distribution (only for Event-Event relations) for OTC corpora.

6 Experimental Results

The algorithm described above was evaluated on OTC corpus with our four uncertainty measures with and without representativeness and diversity. We used random instance selection (i.e., passive learning) as the baseline strategy.

Several kernels can be used for such experiments. As explained in section 2, we decided to use the kernel proposed in (Mani et al., 2006), which we will refer to as Mani's kernel, and the Argument Ancestor Path Distance (AAPD) polynomial kernel proposed in (Mirroshandel et al., 2010). AAPD polynomial is the state of the art pattern-based algorithm, which exclusively combines gold standard features of events and grammatical structures of sentences.

All evaluations are based on a 5-fold cross validation. The original corpora was randomly partitioned into 5 parts, out of which, a single part was retained for testing the model, and the remaining 4 parts were used for the training and applying our instance selection strategies. This process was then repeated 5 times (the folds), with each of the 5 parts being used exactly once as the test data. To perform the experiments, we started from initial labeled set with 100 randomly selected samples, and in each iteration, 25 samples were selected, labeled, and added to the previously labeled set.

6.1 Uncertainty Measure Alone

Figures 3 and 4 show the result of applying our four uncertainty measures for "instance selection" in OTC, using Mani's (Figure 3) and AAPD kernels (Figure 4).

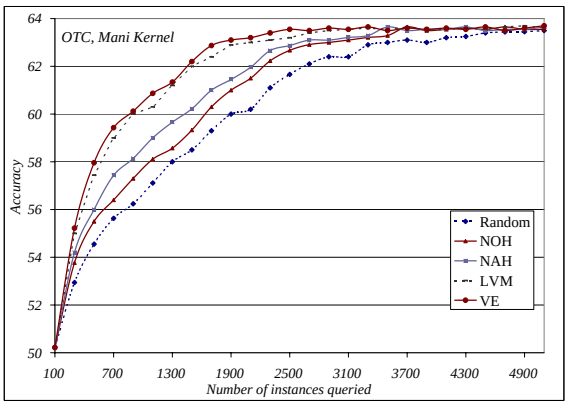

Figure 3: Learning curves for different uncertainty instance selection strategies applied to OTC using Mani's kernel.

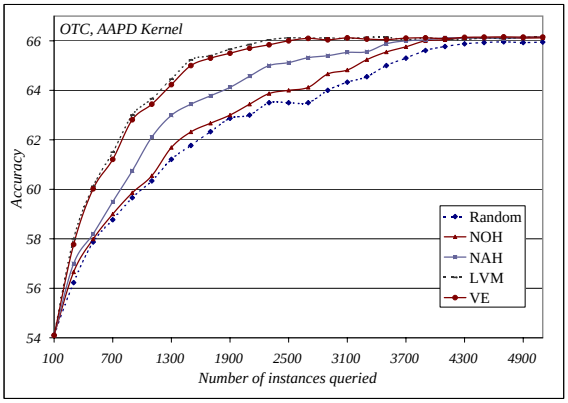

Figure 4: Learning curves for different uncertainty instance selection strategies applied to OTC using AAPD kernel.

The figures show that all proposed uncertainty instance selection strategies are effective and lead to learning curves that are above the baseline. Vote

based measures have outperformed distance based ones. Among the two distance based measures, NAH led to better results than NOH, showing that averaging (aggregation) over the distances to the different separating hyperplanes is more robust than taking into account only the distance to the closest one.

The two vote based methods led to very close results, which seems to indicate that the system usually hesistates between two classes (and not more) when trying to classify an instance.

6.2 Combining Uncertainty and Representativeness Measures

Representativeness has been introduced in order to fight against outliers. Such outliers have two different origins. The first one is data sparseness: some temporal relation events are poorely represented in the data. Eliminating such instances will degrade the results on the corresponding class but will introduce less noise in the data. The second origin of outliers is the difficulty of problem, even for human annotators (Pustejovsky et al., 2003). This causes some mistakes in annotation and generates some outliers.

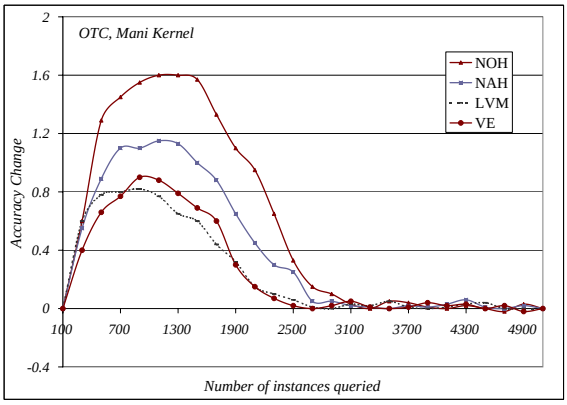

Figure 5: Accuracy improvement when adding representativeness measure to the uncertainty instance selection in Mani's kernel.

In the second series of experiments, we combined a representativeness measure with different uncertainty instance selection strategies to tackle outliers' side effects. In our different experiments, the best value for uncertainty coefficient (α) was 0.65. Figure 5 (resp. 6) shows the accuracy improvement when adding representativeness to uncertainty with Mani's (resp. AAPD) kernel. We have chosen to represent just the improvement rather than the learning accuracy, because the learning curves were not easy to compare.

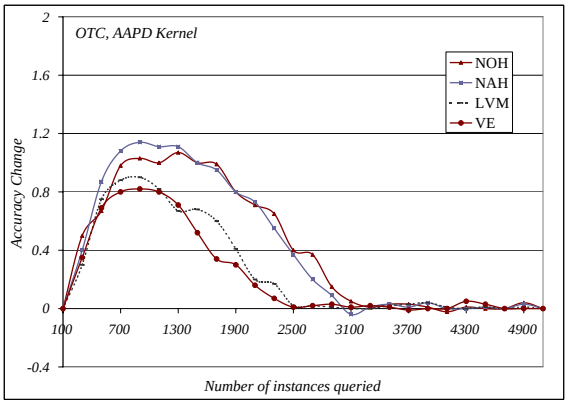

Figure 6: Accuracy improvement when adding representativeness measure to the uncertainty instance selection in AAPD kernel.

The results show that distance based measures are more sensitive to outliers than vote based ones. Figures 5 and 6 also show that the representativeness measure has less impact on AAPD kernel than it has on Mani's kernel. This is because AAPD kernel is more resistant to outliers than Mani's kernel.

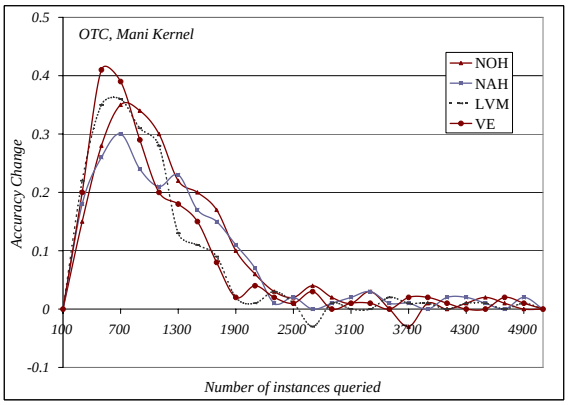

Figure 7: Accuracy improvement when adding diversity in the instance selection with Mani's kernel.

6.3 Combining Uncertainty, Representativeness and Diversity

In the last series of experiments, diversity was added to the instance selection procedure. In each iteration, first 80 instances of the pool were selected by combination of uncertainty and representativeness mea-

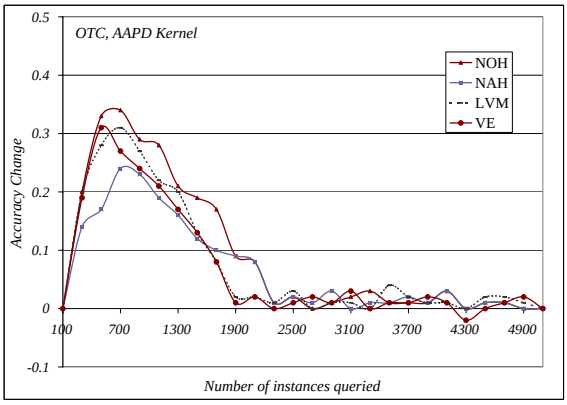

Figure 8: Accuracy improvement when adding diversity in the instance selection with AAPD kernel.

sures. Next, a hierarchical clustering method was used to select the final 25 instances. The accuracy improvement, as it is shown in Figures 7 and 8, is moderate.

The reasons why introducing diversity did not have a greater impact on the results is not clear. That may be due to the way diversity was introduced in our model. It could also come from the distribution of the data: if instances that are both unreliable and representative are not close to each other, selecting instances that are different from each other for better coverage of the problem space is not an issue. More work has to be done to investigate that point.

The final learning curves, when uncertainty, representativeness, and diversity were all considered, are shown in figures 9 and 10. As shown, vote-based uncertainty measures still obtain better results than distance based measures.

7 Conclusion

In this paper, we have addressed the problem of active learning based on support vector machines for temporal relation classification. Three different kind of measures have been used for selecting the most informative instances: uncertainty, representativeness and diversity. The results showed that the three measures improved the learning curve although diversity had a moderate effect.

Future work will focus on three points, the first one is trying other sample selection strategies, as query by committee, the second will focus on combining the two families of uncertainty measures that we have proposed: distance based and vote based. The third one is about diversity. As mentioned above, we do not know if this phenomenon is not well handeled by the model or if it is not an issue for the problem at hand.

Abstract

Sparse learning framework, which is very popular in the field of nature language processing recently due to the advantages of efficiency and generalizability, can be applied to Conditional Random Fields (CRFs) with L1 regularization method. Stochastic gradient descent (SGD) method has been used in training L1-regularized CRFs, because it often requires much less training time than the batch training algorithm like quasi-Newton method in practice. Nevertheless, SGD method sometimes fails to converge to the optimum, and it can be very sensitive to the learning rate parameter settings. We present a two-stage training algorithm which guarantees the convergence, and use heuristic line search strategy to make the first stage of SGD training process more robust and stable. Experimental evaluations on Chinese word segmentation and name entity recognition tasks demonstrate that our method can produce more accurate and compact model with less training time for L1 regularization.

1 Introduction

Conditional Random Fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006) are one of the most widely-used machine learning approach in the field of nature language processing, for their ability to handle large feature sets and structural dependency between output labels. The applications of CRFs cover a wide range of tasks such as part-of-speech (POS) tagging (Lafferty et al., 2001), semantic role labeling (Toutannova et al., 2005) and syntactic parsing (Finkel et al., 2008). CRFs outperform other models like Maximum Entropy Markov models (McCallum et al., 2000), because they overcome the problem of "label bias". Moreover, CRFs can output the probabilistic of labeling result for further use as pipeline or reranking.

For all types of CRFs, the maximum-likelihood method can be applied for parameter estimation, which means training the model is done by maximizing the log-likelihood on the training data. To avoid overfitting the likelihood is often penalized with the regularization term. There were two common regularization methods named L1 and L2 regularization. L1 regularization, also called Laplace prior, penalizes the weight vector with its L1-norm. L2 regularization, also called Gaussian prior, uses L2-form. Based on the work of Gao et al. (2007), there is no significant difference between these two regularization methods in terms of accuracy. But L1 regularization has a major advantage that L1-regularized training can produce models, of which the feature weights can be very sparse, then the size of the model will be much smaller than that produced by L2 regularization. Compact models are more interpretable, generalizable and manageable, require less resources like memory and storage. It is very meaningful especially for the rapid development of mobile application nowadays, which suffer the scarcity of resources. In many NLP tasks, the feature sets can reach the magnitude of several million.

Besides, L1 regularization method can implicitly perform the feature selection, and provide the result for further process such as iterative approach (Vail et al., 2007; Peng and McCallum, 2004). This task requires that we need to train the model as accurate as possible, as to converge to the optimum. The feature selection can be regarded as reliable and unbiased after such a process.

Quasi-Newtion method was successfully and efficiently used in L1-regularized model by Andrew and Gao (2007). They presented an algorithm called Orthant-Wise Limited-memory Quasi-Newton (OWL-QN), which is based on L-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 65–74,
Chiang Mai, Thailand, November 8 – 13, 2011.

BFGS algorithm (Liu and Nocedal, 1989) and achieve better convergence than the method introduced by Kazama and Tsujii (2003).

Stochastic gradient descent (SGD) methods are another kind of L1-regularized training methods. It is a very attractive framework for it often requires much less training time than the batch training algorithm in practice. Tsuruoka et al. (2009) presented a variant of SGD that can efficiently produce compact models with L1 regularization. The main idea is to keep track of the total penalty and the penalty each weight has applied, so that the penalization smooth away the noisy gradient.

Although SGD method with cumulative penalty is very efficient, it sometimes fails to converge to the optimum, because the training process is usually terminated at a certain number of iterations without explicit stop criteria as in quasi-Newton method. Another problem is that the training result of SGD method is very sensitive to the parameter settings of learning rate, therefore we have to tune the values of parameters for different tasks, which is not efficient in practice.

In this paper, we present a two-stage L1-regularized training algorithm to solve these two problems. In the first stage, we use the SGD method to get a relative good solution quickly. In the second stage, we use the OWL-QN method to improve the model which has been dealt with the SGD method. By this means we can fast get the accurate model. The learning rate scheduling in the first stage is done by heuristic line search, which makes the process more robust and stable.

Our experiments are conducted on two tasks, Chinese word segmentation and name entity recognition. We show that our method can produce more accurate and compact model with less training time for L1 regularization. We also verify that the result of SGD training method will be more robust when using the heuristic line search strategy.

The rest of the paper is organized as follows. Section 2 introduces the basics of CRFs. Section 3 describe the two-stage algorithm for L1-regularized models. Experimental results are shown in Section 4. We conclude the work in Section 5.

2 Conditional Random Fields

In this section, we briefly describe the basics of conditional random fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006) and introduce the definition of some concepts and parameters.

2.1 Linear-chain CRFs

CRFs defines the conditional probabilistic distribution over possible output sequences $\mathbf{y}$ for observation $\mathbf{x}$ as following:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left\{\sum_{k=1}^{K} \lambda_k F_k(\mathbf{x}, \mathbf{y})\right\}, \quad (1)$$

where $F_k(\mathbf{x}, \mathbf{y})$is equal to $\sum_{t=1}^{T} f_k(\mathbf{x}, y_{t-1}, y_t, t)$. $\{f_k\}$ is a set of feature function and λ_k is the weight of the feature, and $Z(\mathbf{x})$ is the normalization factor defined by

$$Z(\mathbf{x}) = \sum_{\mathbf{y}} \exp\left\{\sum_{k=1}^{K} \lambda_k F_k(\mathbf{x}, \mathbf{y})\right\}. \quad (2)$$

The feature function can be divided into unigram features and bigram features, here we simply rewrite $f_k(\mathbf{x}, y_t, t)$ as $f_k(\mathbf{x}, y_{t-1}, y_t, t)$ for convenient.

2.2 Training

The maximum-likelihood method is a commonly used way applied for parameter estimation, which means we train the model by minimize the negated conditional log-likelihood $L(\lambda)$ on the training data:

$$\begin{aligned} L(\lambda) &= -\sum_{(\mathbf{x},\mathbf{y})} \log p(\mathbf{x}, \mathbf{y}) \quad (3) \\ &= \sum_{(\mathbf{x},\mathbf{y})} \left\{\log Z(\mathbf{x}) - \sum_{k=1}^{K} \lambda_k F_k(\mathbf{x}, \mathbf{y})\right\}. \end{aligned}$$

To avoid overfitting, the likelihood is often penalized with the regularization term, which we will talk about in the later sections.

The partial derivative of $L(\lambda)$ by the feature weights λ_k are given by

$$\begin{aligned} \frac{\partial}{\partial \lambda_k} L &= \sum_{(\mathbf{x},\mathbf{y})} \sum_{t=1}^{T} E_{p(\mathbf{y}|\mathbf{x})} f_k(\mathbf{x}, y_{t-1}, y_t, t) \\ &\quad - \sum_{(\mathbf{x},\mathbf{y})} \sum_{t=1}^{T} f_k(\mathbf{x}, y_{t-1}, y_t, t) \quad (4) \end{aligned}$$

where $E_{p(\mathbf{y}|\mathbf{x})}$ denotes the conditional expectation under the model distribution:

$$E_{p_(\mathbf{y}|\mathbf{x})} f_k(\mathbf{x}, y_{t-1}, y_t, t) = \sum_{(y',y)} f_k(\mathbf{x}, y', y, t) P(y_{t-1} = y', y_t = y|\mathbf{x}) \quad (5)$$

Computing the conditional expectation directly is impractical for the large number of possible tag sequences, which is exponential in the length of the observation. Thus, a dynamic programming approach known as the Forward-Backward algorithm originally described for Hidden Markov models (Rabiner, 1989), is applied in a slightly modified form. For the forward recursions, we have

$$\alpha_0(\perp) = 1$$
$$\alpha_{t+1}(y) = \sum_{y'} \alpha_t(y') \exp\left\{\sum_{k=1}^{K} \lambda_k f_k(\mathbf{x}, y', y, t)\right\}$$

and for the backward recursion, we have

$$\beta_{T+1}(\top) = 1$$
$$\beta_t(y') = \sum_{y} \beta_{t+1}(y) \exp\left\{\sum_{k=1}^{K} \lambda_k f_k(\mathbf{x}, y', y, t)\right\}$$

for $0 \leq t \leq T$ and $y \in Y$, where $\perp$ and $\top$ are defined as special states for the begin and end of the sequence. Then the normalization factor is computed by

$$Z(\mathbf{x}) = \beta_0(\perp), \tag{6}$$

and the conditional probabilities $P(y_{t-1} = y', y_t = y|\mathbf{x})$ are given by

$$\alpha_t(y') \exp\left\{\sum_{k=1}^{K} \lambda_k f_k(\mathbf{x}, y', y, t)\right\} \beta_{t+1}(y)/Z(\mathbf{x})$$

3 L1 Regularization in CRFs

3.1 Regularization

The logarithmic loss function $L(\lambda)$ defined by (3) is usually penalized with an additional regularization term, which prevents the model from overfitting the training data. There are two common regularization methods named L1 and L2 regularization, in the case of L1 regularization, the term is defined as:

$$R(\lambda) = C \sum_{k} |\lambda_k|, \tag{7}$$

where C is the regularization parameter that controls the trade-off between fitting exactly the observations and the L1-norm of the weight vector. This value is usually tuned by cross-validation or using the heldout data.

Now we can redefine the objective loss function as

$$L(\lambda) + R(\lambda). \tag{8}$$

3.2 Orthant-Wise Limited-memory Quasi-Newton

It is not easy to use some common numerical optimization strategies such as limited memory BFGS (Liu and Nocedal, 1989) directly with L1 regularization, because the regularization term is not differentiable when the weight is zero.

A very efficient strategy called Orthant-Wise Limited-memory Quasi-Newton (OWL-QN) method is introduced in (Andrew and Gao, 2007). This algorithm is motivated by the observation that the L1 regularization term is differentiable when restricted to a set of points in which each coordinate never changes sign (called its "orthant"). Furthermore it is a linear function of its argument, which means the second-order behavior of the regularized objective function on a given orthant is determined by the log-likelihood component alone. Only a few steps of the standard L-BFGS algorithm have been changed in the OWL-QN method, and these differences are listed below:

1. The "pseudo-gradient" is used in place of the gradient.
2. The resulting search direction is constrained to match the sign pattern of the negated pseudo-gradient.
3. Each parameter is projected back onto the initial orthant of the previous value during the line search.

Andrew and Gao (2007) proved that OWL-QN method is guaranteed to converge to a globally optimal result.

3.3 Stochastic Gradient Descent

Stochastic gradient approaches use a small batch of the observations to get a crude approximation of the gradient of the objective function given by (3). The small batch size makes us possible to update the parameters more frequently than the origin gradient descent and speed up the convergence. Only considering the log-likelihood term, the updates have the following form

$$\hat{\lambda}_k^j = \lambda_k^j + \eta_j \left.\frac{\partial L(\lambda)}{\partial \lambda_k}\right|_{\lambda=\lambda^j} \tag{9}$$

where j is the iteration counter and η_j is the learning rate. It should be noted that the partial derivative we presented here is not the true gradient

but the crude approximation from small randomly-selected subset of the training samples. In (Tsuruoka et al., 2009), a variant of SGD that can efficiently train L1-regularized CRFs was presented. The main idea can be concluded as follows:

1. Only update the weights of the features that are used in the current observation, called "lazy update".

2. "Clip" the parameter value when it crosses zero.

3. Keep track of the cumulated penalty that the weights of features should been received if the fluctuationless gradient were used, and use this value to the update.

Let z_j be the total L1-penalty that each weight should been received, it is simply accumulated as:

$$z_j = \frac{C}{N} \sum_{t=1}^{j} \eta_t. \tag{10}$$

Then the process of regularization can be formalized as follows

$$\lambda_k^{j+1} = \begin{cases} \max(0, \hat{\lambda}_k^j - (z_j + q_k^{j-1}) & \hat{\lambda}_k^j > 0 \\ \min(0, \hat{\lambda}_k^j + (z_j - q_k^{j-1}) & \hat{\lambda}_k^j < 0 \end{cases}$$

where q_k^j is the total L1-penalty that λ_k has actually received:

$$q_k^j = \sum_{t=1}^{j} (\lambda_k^{t+1} - \hat{\lambda}_k^t). \tag{11}$$

Tsuruoka et al. (2009) demonstrated that this algorithm can be much more quickly than the OWL-QN method and yield a comparable performance, while the value of objective function and the number of active features are not as good as OWL-QN. The reason is that we usually terminated the training process at a certain number of iterations, because there are no explicit stop criteria for SGD.

Another issue is that the scheduling of learning rates can be very tricky. Tsuruoka et al. (2009) suggest that exponential decay is a good choice in practice compared with the method used in (Collins et al., 2008). This kind of scheduling of learning rates have the following form:

$$\eta_j = \eta_0 \alpha^{j/N}, \tag{12}$$

where η_0 and α are both constant. We name η_0 the initiation learning rate parameter and α the descent learning rate parameter. These learning rate parameters have a great influence on the result of SGD training, and they need to be tuned for different tasks, which is not very efficient in practice.

3.4 Two-stage L1-regularized Training

Based on what we have mentioned above, we know that the SGD method sometimes fails to converge to the global optimal solution, for it does not have the explicit stop criteria as in the quasi-Newton method. Although the scheduling of learning rate found in (Collins et al., 2008):

$$\eta_j = \frac{\eta_0}{1 + j/N} \tag{13}$$

guarantees ultimate convergence theoretically. Its actual convergence speed is poor in practice (Darken and Moody,1990). We have to take quite a number of iterations if we need the result close enough to the best solution. This contradicts to the main motivation we use SGD method for parameter estimation that can speed up the training process.

On the other hand, based on the work of Andrew and Gao (2007), we know that OWL-QN method guarantees the convergence. And we can test the relative change in the objective function value averaged over the several previous iterations for stop criteria.

Tsuruoka et al. (2009) demonstrated that SGD method converges much faster than OWL-QN method especially in the first few iterations. This fact motivates us to use a two-stage training strategy. In the first stage, we use the SGD method to quickly get a relative good solution. In the second stage, we use the OWL-QN method to improve the model which has been dealt with the SGD method.

This method can be also driven from an alternative view. In the theory of convex optimization (Boyd and Vandenberghe, 2004), the asymptotic convergence rate of Newton's method is quadratic if we start at a point close enough to the global optimum.[1] In fact, the iterations in Newton's method can fall into two stages. The second stage, which occurs once the searching point is quite close to the optimum solution, is called "quadratically convergent stage". The first stage is usually referred as the "damped Newton phase", because the algorithm may choose a step size that is different from the exact Newton step to satisfy the backtracking

[1] Quasi-Newton method shares many properties with Newton's method, though its convergence rate is generally superlinear but not quadratic.

condition.[2] The quadratically convergent stage is also called the "pure Newton phase" since the full Newton step is always chosen in these iterations . This fact demonstrates that if we can find a solution close to the global optimum, it will not only increase the average convergence rates, but also reduce the time consuming needed for backtracking line search. This is what we achieved by the first stage of SGD training method.

3.5 Heuristic Line Search

Another problem of SGD method is the troublesome learning rate parameters tuning, and these parameters have a significant influence on the result of SGD training. No matter which way to set the learning rate, if it is fixed without taking the actual effect of the current training sample update into consideration, it may be too large or too small for some situation. In order to get a more robust and stable method for learning rate scheduling, we present a heuristic line search strategy inspired by the implementation of CRFsgd (Bottou, 2007) for learning rate calibration.

For the purpose of convenience, we define the objective function for a single sample as

$$l(\lambda, \mathbf{x}) = -\log p(\mathbf{x}, \mathbf{y}) + \frac{C}{N} \sum_{\lambda_k \in \mathbf{x}} |\lambda_k|. \quad (14)$$

Notice here we only use these active features in the current sample as the L1 regularization term, for we only update these associate parameters in a lazy fashion.

Now we try to find the learning rate that decrease the value of this objective function as much as possible without consuming too much search time. We simply use a heuristic line search strategy as follows: (1) We use the learning rate calculated by Eq.12 as initiation and get the initial value of Eq.14. (2) Then we go on to increase the learning rate until the maximum number of trials for search is reached or the value of Eq.14 is worse than the initial value, we just decrease the learning rate from the initiation if the latter situation happens. (3) At last we just use the learning rate that yields the best result of Eq.14 during the search. For the calculation of Eq.14 only needs the weights of the features that are used in the current sample, so it will still be very efficient. The whole algorithm in pseudo-code was showed in Algorithm 1.

[2]To ensure the objective function decrease a certain value and guarantee the convergence.

Algorithm 1 SGD heuristic line search

1. **for** k = 0 to MaxIterations
2. Select sample j
3. $bestr \leftarrow$ LearningRate(k)
4. UpdateWeights (j,$bestr$)

5. **procedure** LearningRate(k)
6. $r(0) \leftarrow$ initialed by Eq.12
7. $init\_obj \leftarrow$ initialed by Eq.14
8. **for** i = 0 to MaxTrialTime
9. UpdateWeights(j,$r(i)$)
10. $obj(i) \leftarrow$ Eq.14
11. Recover weights before update
12. **if** $obj(i)$ is worse than $init\_obj$ **then**
13. label $flag$
14. **if** $flag$ status is changed **then**
15. $r(i+1) \leftarrow r(0) * decay$
16. **else**
17. **if** $flag$ is not set **then**
18. $r(i+1) \leftarrow r(i)/decay$
19. **else**
20. $r(i+1) \leftarrow r(i) * decay$
21. $bestr = argmin_{r(i)} obj(i)$
22. **return** $bestr$.

It should be noted that we need not set a large number for maximum trial time, because it will generally take a lot of search time and may not yield a good result but arrives at the local optimum, for we only optimize the objective value of a single training sample. Here we set the value to 3 empirically. The changing rate for line search can be any positive number that smaller than 1, it is set to 0.5 as mostly accepted.

4 Experiments

We evaluate the effectiveness and performance of our training algorithm using two NLP tasks that includes Chinese words segmentation and name entity recognition, which are very typical problems in the field of NLP.

To show the improvement of our algorithm, we compare it with the OWL-QN algorithm and SGD algorithm on the same data sets. For the purpose of run-times comparison, we implemented all the algorithm in a quite similar way, especially in feature extraction and gradient computation. For example, we compute the forward/backward scores in logarithm domain instead of scaling

Table 1: Feature templates for Chinese word segmentation task.

(1) $c_{i-1}y_i$, c_iy_i, $c_{i+1}y_i$
(2) $c_{i-1}c_iy_i$, $c_ic_{i+1}y_i$, $c_{i-1}c_{i+1}y_i$
(3) $y_{i-1}y_i$

method, though the latter method was claimed faster (Lavergne et al., 2010). All experiments were performed on a server with Xeon 2.66GHz.

4.1 Chinese Word Segmentation

The first set of experiments used the Chinese word segmentation corpus from the Second International SIGHAN Bakeoff data sets (Emerson, 2005), provided by Peking University. The training data consists of 19,054 sentences, 1,109,947 Chinese words, 1,826,448 Chinese characters and the testing data consists of 1,944 sentences, 104,372 Chinese words, 172,733 Chinese characters. We separated 1,000 sentences from the training data and use them as the heldout data. The test data was only used for the final accuracy report.

The feature templates we used in this experiment were listed in Table 1, where c_i denotes the i^{th} Chinese character in an instance, y_i denotes the i^{th} label in the instance. Based on the work of Huang and Zhao (2007), it was shown that 6 label representation is a better choice in practice. Compare with the origin 2 label representation or 4 label representation, it can represent richer label information. We did not use any extra knowledge such as Chinese and Arabic numbers.

For OWL-QN method and SGD method, we followed the experiment settings in (Tsuruoka et al., 2009). The meta-parameters for OWL-QN method were the same with the default settings of the optimizer developed by Andrew and Gao (2007), the convergence tolerance was 1e-4; the L-BFGS memory parameter was 10. The regularization parameter C was tuned in the way that it maximized the log-likelihood of the heldout data when using the OWL-QN algorithm. We also used this value as the regularization parameter in the SGD method. The learning rate parameters for SGD were tuned in the way that they maximized the value of the objective function in 30 passes. We first set the initiation learning rate parameter (η_0) by testing 1.0, 0.5, 0.2, and 0.1, then we set the descent learning rate parameter (α) by testing 0.9, 0.85, and 0.8 with the fixed initiation learning rate parameter.

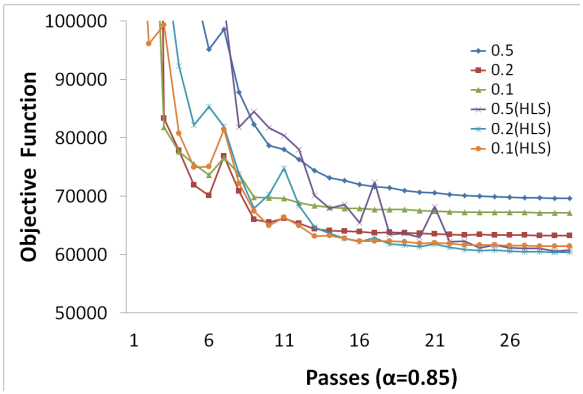

Figure 1: Bakeoff 2005 Chinese word segmentation task: Objective function with fixed α.

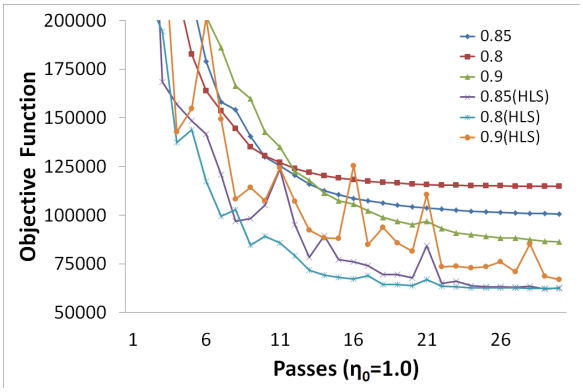

Figure 2: Bakeoff 2005 Chinese word segmentation task: Objective function with fixed η_0.

For our method, we first measured the progress of the SGD algorithm with heuristic line search we presented against the origin SGD method. We use the same parameters settings with the former method including both regularization parameter and learning rate parameters. The number of passes performed over the training data was also set to 30. Then we compare the results of both methods during the training process of the model with the same parameters, and they were shown in Figure 1 and Figure 2.

Figure 1 shows how the value of the objective function changed as the training proceeded with the same descent learning rate parameter ($\alpha = 0.85$), the figure contains six curves representing the results of SGD method with heuristic line search and the origin SGD method with different initiation learning rate parameter settings (η_0). "HLS" stands for the heuristic line search strategy. The results shows SGD method with heuristic line search shows better convergence and more robust

Table 2: Bakeoff 2005 Chinese word segmentation task. Accuracy of the model on the testdata.

	$L+R$	# Features	F score
OWL-QN	56451.8	114,942	94.81
SGD	61398.6	232,585	94.92
Ours	56481.9	117,374	94.78

Table 3: Bakeoff 2005 Chinese word segmentation task. Training time of the model on the testdata.

	Passes	Time
OWL-QN	141	2h59min
SGD	30	58min
Ours	5 + 88	2h06min

result than the origin SGD method when using the same learning rate parameter settings. Figure 2 shows the results with different settings of learning rate parameters (fixed $\eta_0 = 1$), and it demonstrates the same trend as Figure 1.

Then we trained the models with the training data and evaluated the accuracy of the Chinese word segmenter on the test data. The number of passes performed over the training data in SGD was also set to 30. In our method, we set the SGD iteration times to 5. It is worth noting that we didn't spend much time in tuning the value of this parameter. Based on a cursory view of the training process, we found that it converge to a relative "good" result after the first 5 iteration. We used this value throughout all the experiments. Because we would take the OWL-QN method to guarantee the final convergence, and the SGD method with heuristic line search strategy is insensitive to the learning rate parameters, this value would not have a significant influence on the performance.

The results are shown in Table 2 and Table 3. In Table 2, the second column shows the final value of the objective function. The third column shows the number of active features in the final resulting model. The fourth column shows the F score of the Chinese word segment results, which is the harmonic mean of precision P (percentage of output Chinese words that exactly match the golden standard Chinese words) and recall R (percentage of golden standard Chinese words that returned by our system). In Table 3, the second column shows the number of passes performed in the training, in our method, this value includes the the number of passes both in the first stage of SGD and the second stage of OWL-QN process. The third column shows the training time.

Table 4: Feature templates for name entity recognition task.

(1) $c_{i-2}y_i$, $c_{i-1}y_i$, c_iy_i, $c_{i+1}y_i$, $c_{i+2}y_i$
(2) $c_{i-1}c_iy_i$, $c_ic_{i+1}y_i$
(3) $y_{i-1}y_i$

In the terms of accuracy, there was no significant difference between all the models, the origin SGD method yield the slightly better result, probably due to the model has larger features sets. This doesn't contradict to our original purpose, for we have got a substantial improved result in both the final value of the objective function and the number of active features compared with the origin SGD method, and to the same level as OWL-QN method. Notice the origin feature sets are over 6 millon, L1 regularization methods produced the models which are compact indeed. The official best result in the closed test achieved an F score of 95.00, and our result is quite close to that, ranked 4th of 23 official runs.

On the other hand, our method took about 30% less than the OWL-QN method in the training time. Our method only needs 88 passes over the whole training data in the second stage for convergence compared with 141 in the OWL-QN method, which shows a significant improvement in training time consuming, for we have used the first stage of SGD method to get a nearly optimal and stable result beforehand.

4.2 Name Entity Recognition

The second set of experiments used the name entity recognition corpus from the Fourth International SIGHAN Bakeoff data sets (Jin and Chen, 2008), provided by Microsoft Research Asia. The training data consists of 23,182 sentences, 1,089,050 Chinese characters and the testing data consists of 4,636 sentences, 219,197 Chinese characters. We separated 1,000 sentences from the training data and use them as the heldout data. The training data is annotated with the "IOB" tags representing name entities including person, location and organization.

The feature templates we used in this experiment were listed in Table 4. Notice we did not change the label representation made by the origin

Table 5: Fourth SIGHAN Bakeoff name entity recognition task. Training time of the model on the testdata.

	$L+R$	Passes	Time
OWL-QN	11247.1	219	5h26min
SGD	13993.3	30	1h08min
Ours	11245.5	5 + 122	3h10min

Table 6: Fourth SIGHAN Bakeoff name entity recognition task. Accuracy of the model on the testdata.

	# Feat.	LOC	ORG	PER
OWL-QN	34,579	89.94	82.61	90.65
SGD	113,005	89.39	82.75	90.78
Ours	36,709	90.05	82.25	90.49

training data for convenient. Again a richer label representation may yield a better performance.

The other experiment settings are the same with the experiment on Chinese word segmentation. The comparison results are shown in Table 5, Figure 3 and Figure 4. The trend in the results is the same as that of the Chinese word segmentation task. SGD method with heuristic line search strategy produced more stable and robust result than the origin SGD method. Although there will have fluctuations sometimes (in Figure 4), the line search strategy shows the ability to find an appreciate step size in that case. Again our method converged to a much better solution against SGD in both the final value of the objective function and number of active features, and took about 40% less training time than OWL-QN.

The accuracy of the results is shown in Table 6, there was no significant difference between all the models as well. The F score of organization name entity recognition was worse than the results in person and location name entity, for organization name entities in Chinese often have a relative long distance dependency, which is not easy to be captured by our local feature templates in the Chinese character level.

5 Conclusion

We have presented a two-stage algorithm that can efficiently train L1-regularized CRFs. Experiments on two NLP tasks demonstrated that our method is effective and efficient by utilizing both the advantages of SGD and OWL-QN.

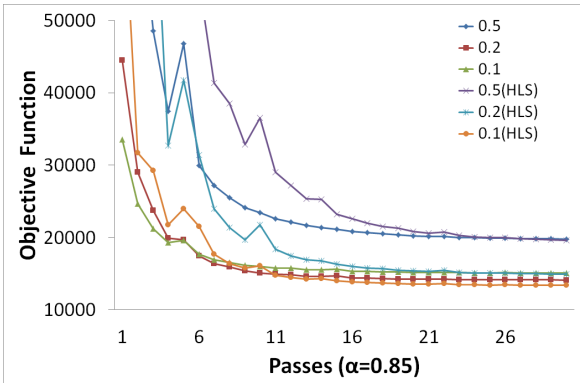

Figure 3: Fourth SIGHAN Bakeoff name entity recognition task: Objective function with fixed α.

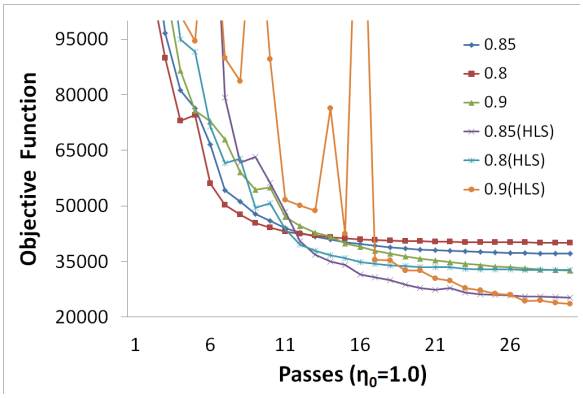

Figure 4: Fourth SIGHAN Bakeoff name entity recognition task: Objective function with fixed η_0.

In the future, we intend to study how to use the results of the first stage of SGD learning to estimate the Hessian information, which can be provided for the second stage of quasi-Newton method to enhance the effectiveness of training. Borders et al. (2009) looked into this problem in a similar way. It is also worthwhile to investigate whether other adaptive learning rate scheduling algorithms can result in fast training with our method, as in (Vishwanathan et al., 2006; Huang et al., 2007).

Automatic Topic Model Adaptation for Sentiment Analysis in Structured Domains

Geoffrey Levine and **Gerald DeJong**
University of Illinois at Urbana-Champaign
Urbana, IL
levine@illinois.edu and mrebl@illinois.edu

Abstract

We present a novel topic modeling approach to sentiment analysis for documents organized into hierarchical categories. In our approach, positive, negative, and subject matter topics are learned and used to infer document labels. A Markov chain Monte Carlo model procedure adapts the number and structure of topics based on a minimum description length objective function. We apply our approach to Yelp.com business reviews and Amazon.com book reviews and demonstrate that 1) the model adaptation procedure selects a high quality model from the space of alternatives, and 2) the resulting model performs well relative to state of the art regression and topic modeling approaches.

1 Introduction

Selecting an appropriate model is an important part of any machine learning endeavor. The model must be chosen in a manner so as to balance two objectives: 1) Be sufficiently rich to capture the relevant patterns in the data, and 2) Be simple enough to avoid spurious patterns in the training data (overfitting). In natural language processing tasks, there are often many modeling choices to be made regarding what feature granularities and interactions to consider. It is important to make these decisions in a manner such that the resulting model strikes a balance between these two somewhat contradictory objectives.

In order to appropriately make these choices, we must consider not only the task involved but also the training data available. With copious data we can reliably calibrate complex models, but with limited data complex models risk overfitting. Many general model selection techniques exist in which each candidate model is fit to the training data and scored with respect to a particular criterion. While these approaches allow us to compare a small number of models in order to select the most appropriate, they require calibrating each model's parameters to the training data. However, when there are many modeling choices to be made and thus a large space of alternative models, fitting all of them to the training data is computationally prohibitive.

In this paper, we present a novel topic modeling approach for structured sentiment analysis domains and an automatic model adaptation approach that takes advantage of categorical metadata. This model adaptation approach resolves the structure of the metadata with the significant patterns in the training data to determine the number and range of latent topics.

We demonstrate our approach on Yelp.com business reviews as well as Amazon.com book reviews. We show that our model adaptation approach selects an appropriate model given a particular amount of training data, and the resulting model is high quality relative to alternative regression and topic modeling approaches.

2 Background

Sentiment analysis, in which the opinion of the author is estimated from a document, has recently grown in popularity. Many works have explored unigram models (Pang and Lee, 2005; Snyder and Barzilay, 2007). Higher-order n-gram models are explored in (Pang and Lee, 2008; Baccianella et al., 2009). In order to combat the high dimensional feature space that accompanies such models, models restricting features based on part of speech patterns (Baccianella et al., 2009) or opinion templates (root, modifiers, negation words) (Qu et al., 2010) have been introduced.

Topic models are generative models in which the words in a document are assumed to be asso-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 75–83,
Chiang Mai, Thailand, November 8 – 13, 2011.

ciated with one of a number of abstract "topics." Latent Dirichlet allocation (Blei et al., 2003) is a popular topic model in which the topic distribution per document is assumed to have a Dirichlet prior. In supervised LDA (Blei and McAuliffe, 2007), the distribution of document topics is used to produce a document label. (Zhao et al., 2010; Titov and McDonald, 2008b; Titov and McDonald, 2008a) focus on topic modeling based approaches to aspect-based sentiment summarization, identifying product features and the opinion associated with each.

Model selection is the act of using data to choose a statistical model from a set of candidates. Often, this task is performed by fitting each candidate model to the training data and using a criterion to score the models and select one. Popular criteria include the Akaike information criterion (AIC) (Akaike, 1974), the Bayesian information criterion (BIC) (Schwarz, 1978), and the minimum description length principle (MDL) (Rissanen, 1978; Grunwald, 2007). Structural Risk Minimization (Vapnik, 1995) defines a general framework in which a nested hierarchy of hypotheses can be defined based on prior knowledge of the domain, such that a hypothesis balancing goodness of fit with simplicity can be identified. The work presented in this paper is closely related to the model adaptation procedure presented in (Levine et al., 2010), in which a hill-climbing approach is used to explore a large space of generative models.

3 Topic Modeling for Sentiment Analysis in Structured Domains

Our approach takes advantage of hierarchical categorical metadata. Formally, this hierarchy forms a tree structure, which we refer to as $\mathcal{C}$ (See Figure 1). Individual nodes in the tree are called *categories*, for which we use notation c. A *categorization*, $\mathbf{c}$, is a set of categories, $\mathbf{c} = \{c_{d,1}, c_{d,2}, ...\}$. $\mathbf{c}$ can be thought of as metadata about a product/service being reviewed. For example, with regard to a book review, $\mathbf{c}$ could equal {"Fiction", "Fiction\Drama", "Fiction\Drama\Romance", ... }. $\mathbf{c}$ must be well formed. That is, if a node $c \in \mathcal{C}$ appears in categorization $\mathbf{c}$, all ancestors of c (in the tree $\mathcal{C}$) must also appear in $\mathbf{c}$. $\mathbf{c}$ can contain multiple distantly related categories. For example, a particular book could belong to both "Fiction\Poetry" and "Children\Humor."

Documents, or examples, are denoted $d = \langle \mathbf{x_d}, \mathbf{c_d}, y_d \rangle$. $\mathbf{x_d} = [w_{d,1}, w_{d,2}, ..., w_{d,|\mathbf{x_d}|}]$ is a vector of *words*. Each word is an element from the *vocabulary*, $V = \{w_1, w_2, ..., w_{|V|}\}$. $\mathbf{c_d}$ is the document's categorization. y_d is a numeric *rating* from a discrete space ({1,2,3,4,5} for our domains). The rating is an overall score given by the document's author to the product or service being reviewed.

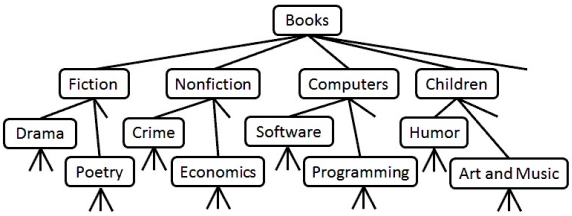

Figure 1: A subtree of the category tree, $\mathcal{C}$, corresponding to the Amazon Books domain.

We are given a collection of documents, $\mathcal{D}$, and our goal is to learn a function $f(\langle \mathbf{x}, \mathbf{c} \rangle)$ to predict rating $\hat{y}$ from an *unlabeled document* so as to minimize the expected loss over the unknown distribution of documents:

$$E\left(\text{loss}(y, f(\langle \mathbf{x}, \mathbf{c} \rangle))\right) \quad (1)$$

We use the squared error loss function.

3.1 Model Structure

We will start by presenting our generative document topic model. In this model, each review is composed of a mixture of topics, and each topic is associated with a distribution over words. We use $t \in T$ to denote a topic, and P_t to denote t's word distribution. Within a document, each word is assumed to be generated from a particular topic, although which topic is unobservable. In many topic model approaches, such as latent Dirichlet allocation (Blei et al., 2003), topics are learned in an unsupervised or weekly supervised fashion (as is the case with supervised LDA).

In our model, we assume each document is generated according to a rigid topic distribution (more similar to labeled LDA (Ramage et al., 2011)). Each document is a mixture of three topics: 1) a *positive* topic (+), in which the reviewer is speaking favorably about the product/service, 2) a *negative* topic (-), in which the reviewer is speaking unfavorably, and 3) a *subject* topic (s_i) corresponding to general text about the content/features of the product.

The proportion of positive words to negative words is a function of the rating score. Subject topics reflect the language used when discussing a particular product or group of products, and do not directly influence a document's rating. Still, learning these topics appropriately is crucial to the performance of the model. When a word is indicative of either the positive or negative topic, it is important to account for its probability in the subject topic. For example, the word "good" may be less indicative of a book review's rating if the review discusses a book about ethics. Furthermore, if subject topics are not learned appropriately, words related to the subject matter of products/services with a disproportionate number of positive training reviews would be attributed to the positive word topic. This will lead to poor performance on unseen data. On the other hand, if these words are correctly attributed to the subject topic, then the high ratings will appropriately be attributed to the unconditional positive words appearing in the reviews.

What constitutes a subject worthy of having its own topic? For books, should we only make broad distinctions such as fiction vs. non-fiction? Should we learn a unique subject topic for each book? Should we use something in between these two extremes? In answering these questions, we need to balance goodness of fit to the training data with model simplicity. There is no optimal answer, it is a function both of the domain (in that we need to make the most "significant" distinctions), and the amount of training data available to calibrate our model (more training data allows us to reliably learn the additional parameters introduced by making additional distinctions).

There exists a many-to-one relationship between documents and subject topics. The mapping from document to subject topic is a function of the document's categorization, $s_i = g(\mathbf{c_d})$, $s_i \in T$. We call the function g the *topic mapping function*. The range of g is the set of subject topics, $\{s_1, s_2, ..., s_N\} \subset T$. In Sections 3.1.1 and 3.1.2 we assume that g is fixed. In Section 3.2, we consider exploring the space of alternative topic mapping functions.

We assume that in expectation, a fixed but unknown fraction, α of each document is composed of the subject topic. The remainder of the review is composed of the positive and negative topics, and the positive/negative ratio is related to the document's rating. Let y_{min} and y_{max} represent the minimum and maximum scores in the rating scale. For document d with score y_d the expected fractional breakdown into topics is as follows:

$$\begin{aligned}
\texttt{Positive:} \quad f_+(y_d) &= (1-\alpha)\frac{y_d - y_{min}}{y_{max} - y_{min}} \\
\texttt{Negative:} \quad f_-(y_d) &= (1-\alpha)\frac{y_{max} - y_d}{y_{max} - y_{min}} \\
\texttt{Subject:} \quad f_s(y_d) &= \alpha
\end{aligned} \tag{2}$$

In total, a model M is composed of the topic mapping function, the value α, and the word distributions associated with each topic. $M = (g, \alpha, P_+, P_-, P_{s_1}, P_{s_2}, ..., P_{s_N})$.

3.1.1 Training

Expectation maximization (Hastie et al., 2001) can be used to train our topic model. The procedure works by iteratively updating 1) the assignment of words in each document to latent topics (Expectation Step), and 2) the word distributions associated with each topic (Maximization Step). EM proceeds as follows:

Expectation Step

Each word is assigned an expected topic distribution. For word i in document d:

$$\begin{aligned}
q_{d,i}(+) &= \frac{f_+(y_d)P_+(w_{d,i})}{Z_{d,i}} \\
q_{d,i}(-) &= \frac{f_-(y_d)P_-(w_{d,i})}{Z_{d,i}} \\
q_{d,i}(g(\mathbf{c_d})) &= \frac{f_s(y_d)P_{g(\mathbf{c_d})}(w_{d,i})}{Z_{d,i}} \\
Z_{d,i} &= \sum_{t \in \{+,-,g(\mathbf{c_d})\}} f_t(y_d)P_t(w_{d,i})
\end{aligned} \tag{3}$$

Maximization Step

Topic word distributions are updated so as to maximize the likelihood of the training data. For each topic t:

$$P_t(w) = \frac{\sum_{d \in \mathcal{D}} \sum_{i=1}^{|\mathbf{x_d}|} \mathbf{I}_w(w_{d,i}) q_{d,i}(t)}{\sum_{d \in \mathcal{D}} \sum_{i=1}^{|\mathbf{x_d}|} q_{d,i}(t)} \tag{4}$$

where

$$\mathbf{I}_w(w_{d,i}) = \begin{cases} 1 & \text{if } w_{d,i} = w \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

3.1.2 Inference

Given the trained topic models we use Bayes' theorem to compute the probability that an unlabeled document $\langle \mathbf{x_d}, \mathbf{c_d} \rangle$ is associated with a particular rating. Let $T_d = \{+, -, g(\mathbf{c_d})\}$:

$$P(y|\mathbf{x_d}, \mathbf{c_d}) = \frac{P(y)P(\mathbf{x_d}, \mathbf{c_d}|y)}{P(\mathbf{x_d}, \mathbf{c_d})}$$
$$= \frac{P(y)\prod_{i=1}^{|\mathbf{x_d}|}\left(\sum_{t\in T_d} f_t(y)P_t(w_{d,i})\right)}{\sum_{y'} P(y')\prod_{i=1}^{|\mathbf{x_d}|}\left(\sum_{t\in T_d} f_t(y)P_t(w_{d,i})\right)} \quad (6)$$

For evaluation purposes, we output the expected value of y and compute the squared error to the true value.

3.2 Model Adaptation

In this section we introduce a Markov chain Monte Carlo approach to selecting a topic mapping function g. Here, we stochastically explore the space of topic mapping functions, driven by the minimum description length principle and estimates of the effect of modifications to g. This approach resists local minima and efficiently finds a high quality topic mapping function.

3.2.1 Minimum Description Length Objective

Our goal is to find a model that balances fit to the training data with simplicity, and concentrates its flexibility where most useful to capture relevant patterns in the domain. We accomplish this by utilizing a two part minimum description length objective function. The objective is the sum of 1) the description length (in bits) required to encode the model and 2) the description length of the data given the model.

$$\mathrm{L}(M, \mathcal{D}) = \mathrm{L}(M) + \mathrm{L}(\mathcal{D}|M) \quad (7)$$

where $\mathrm{L}(M)$ is a function of the number of model parameters ($\approx$ the product of the number of topics and the vocabulary size) and $\mathrm{L}(\mathcal{D}|M)$ is the negative log likelihood of the data given the model. Thus the goal is to jointly minimize the complexity of the model and maximize the likelihood of the data given the model, and the objective can be rewritten as:

$$\mathrm{L}(M, \mathcal{D}) = \beta(N+2)|V| + -log\left(l(\mathcal{D}|M)\right) \quad (8)$$

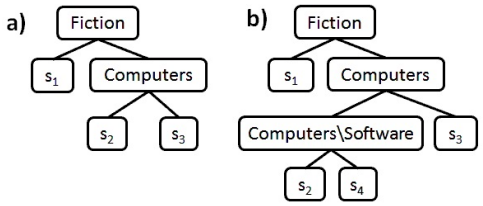

Figure 2: Two possible partitioning trees for the Amazon.com Books category tree (Figure 1). Tree b) is formed by splitting s_2 in a) based on membership in the "Computer\Software" category.

where β is a complexity penalty constant, which is selected via cross-validation.

3.2.2 Topic Mapping Functions

The topic mapping function g maps from categorization $\mathbf{c}$ to a subject topic $s_i \in T$. We select a particular g from the space of *binary partitioning trees*, G. In a binary partitioning tree, each internal node references a category c, and each leaf node references a subject topic s_i. See Figure 2. Starting at the root, a categorization, $\mathbf{c}$ is recursively assigned by each internal node to 1) the left subtree if the referenced category c is in $\mathbf{c}$, and 2) the right subtree otherwise, until a leaf (with associated subject topic) is reached. For example, within the book review domain, a node may reference the category "Computers." In this case, computer books are recursively assigned a subject topic by the left subtree, and all others by the right subtree. We allow only well formed partitioning trees: Any node in g that references a category c with parent category $parent(c) \in \mathcal{C}$ must have an ancestor that references $parent(c)$. For example, we do not allow a node in g to reference "Computers\Software", unless we have already conditioned on the "Computers" category. This constraint guarantees that we partition the space of categorizations into coherent regions (we would never assign "Computer\Hardware" and "Fiction" books to the same subject topic while assigning "Computer\Software" to a different topic).

3.2.3 Adjacent Model Estimation

In order to guide the search through G, we consider 2 types of modification operations: We can 1) Split a leaf based on category $c \in \mathcal{C}$, splitting one partition into two, adding an additional subject topic to the model, or 2) Merge two leaves with the same parent, combining two partitions into one, removing a subject topic from the model.

Given a particular g, there are a finite number of possible merge and split operations to the leaves. Key to our search is the fact that we can estimate the change to the description length objective that each possible modification will cause, using the latent topic distributions assigned to each topic during expectation maximization. Consider merging two subject topics s_i and s_j:

$$\widehat{\Delta L} = -\beta|V| - \sum_{t\in\{s_i,s_j\}}\sum_{w\in V} \#_t(w) log\frac{P_{m_{i,j}}(w)}{P_t(w)} \tag{9}$$

where

$$\#_t(w) = \sum_{d\in\mathcal{D}}\sum_{i=1}^{|\mathbf{x_d}|}\mathbf{I}_w(w_{d,i})q_{d,i}(t)$$

$$P_{m_{i,j}}(w) = \frac{\sum_{t\in\{s_i,s_j\}}\#_t(w)}{\sum_{t\in\{s_i,s_j\}}\sum_{d\in(D)}\sum_{i=1}^{|\mathbf{x_d}|}q_{d,i}(t)} \tag{10}$$

Now consider splitting subject topic s_i based on category c:

$$\widehat{\Delta L} = \beta|V| - \sum_{t\in\{s_{i,c},s_{i,!c}\}}\sum_{w\in V} \#_t(w) log\frac{P_t(w)}{P_{s_i}(w)} \tag{11}$$

where

$$\#_{s_{i,c}}(w) = \sum_{\substack{d=(\mathbf{x},\mathbf{c},y)\in\mathcal{D}\\ s.t. c\in\mathbf{c}}}\sum_{i=1}^{|\mathbf{x_d}|}\mathbf{I}_w(w_{d,i})q_{d,i}(s_i)$$

$$P_{s_{i,c}}(w) = \frac{\#_{s_{i,c}}(w)}{\sum_{\substack{d=(\mathbf{x},\mathbf{c},y)\in\mathcal{D}\\ s.t. c\in\mathbf{c}}}\sum_{i=1}^{|\mathbf{x_d}|}q_{d,i}(s_i)}$$

$$\#_{s_{i,!c}}(w) = \sum_{\substack{d=(\mathbf{x},\mathbf{c},y)\in\mathcal{D}\\ s.t. c\notin\mathbf{c}}}\sum_{i=1}^{|\mathbf{x_d}|}\mathbf{I}_w(w_{d,i})q_{d,i}(s_i)$$

$$P_{s_{i,!c}}(w) = \frac{\#_{s_{i,!c}}(w)}{\sum_{\substack{d=(\mathbf{x},\mathbf{c},y)\in\mathcal{D}\\ s.t. c\notin\mathbf{c}}}\sum_{i=1}^{|\mathbf{x_d}|}q_{d,i}(s_i)} \tag{12}$$

These estimates are upper bounds on the change to the description length objective function. Incorporating these changes (and the associated word distributions) and then retraining the model with expectation maximization may further reduce the objective. These bounds serve as a guide to estimate the objective for models that have *not* been fit to the training data, which will drive our search through G for the optimal topic mapping function.

3.2.4 MCMC exploration

Markov chain Monte Carlo (Gilks et al., 1996) stochastically steps through the space of alternative topic mapping functions. At each iteration of MCMC, the topic model with the current topic mapping function is fit to the training data and the objective change associated with all possible merges and splits is estimated. We then construct a proposal distribution for alternative models that can be reached with these operations. Limiting the proposal distribution to these candidate models, as in (Titov and Klementiev, 2011) and (Singh et al., 2011) induces a decomposable, feasible computation. A model is sampled from this distribution and adopted if certain criteria on its fitness are met.

MCMC will converge to a probability distribution over models. By making better models (those with a lower objective) more probable, the MCMC chain will be driven towards higher quality models. We use an exponential distribution over models:

$$P(M) = \frac{e^{-L(M,\mathcal{D})}}{Z_P} \tag{13}$$

with normalization factor Z_P.

The proposal distribution, Q assigns some probability to all candidate models that can be reached by a single merge or split to each of the leaves in the current partitioning tree. In Q, splits and merges to leaves without a common parent are independent by construction. Now, consider a particular leaf, l, that has the following possible splits, $S = \{c_1, c_2, ..., c_l\}$, and cannot be merged with another leaf. For example, in Figure 2a, the leaf corresponding to s_1 meets this condition as it cannot be merged to another leaf and has possible splits {"Fiction\Drama", "Fiction\Poetry", "Nonfiction", "Computers", "Children", ... }. Let M_l represent the subset of models where l is not split, and M_{l,c_i} represent the subset of candidate models where l has been split with respect to category c_i.

$$Q(M_l) = \frac{e^{-\tau L(M,\mathcal{D})}}{Z_l}$$

$$Q(M_{l,c_i}) = \frac{e^{-\tau \widehat{L}(M_{l,c_i},\mathcal{D})}}{|S|Z_l}$$

$$Z_l = \left(e^{-\tau L(M,\mathcal{D})} + \sum_{c\in S}\frac{1}{|S|}e^{-\widehat{L}(M_{l,c},\mathcal{D})}\right) \tag{14}$$

$0 < \tau \leq 1$ controls a balance between having the proposal distribution completely influenced by

the estimated objectives vs. a uniform proposal distribution.

For all pairs of leaves that share a common parent, we entertain a merge operation. In Figure 2a the leaves corresponding to s_2 and s_3 meet this criteria. Suppose two leaves, l and l' have possible splits $S = \{c_1, c_2, ..., c_l\}$ and $S' = \{c'_1, c'_2, ..., c'_{l'}\}$ respectively. In addition to the one merged alternative, there are $w = (|S|+1)(|S'|+1)$ alternatives that involve only splits to the two leaves. Let $M_{l,l'}$ represent the subset of candidate models where l and l' are merged

$$Q(M_{l,l'}) = \frac{w^{-\frac{1}{2}} e^{-\tau \widehat{L}(M_{l,l'},\mathcal{D})}}{w^{-\frac{1}{2}} e^{-\tau \widehat{L}(M_{l,l'},\mathcal{D})} + (Z_l)(Z_{l'})} \quad (15)$$

The factor of $w^{-\frac{1}{2}}$ accounts for the difference between the number of neighbors that the models with l and l' merged vs. split have. If the two leaves are not merged, then the conditional probability for each of the $(|S|+1)(|S'|+1)$ remaining structural alternatives is computed in Equation 14.

A new topic mapping function g' is sampled from Q and fit to the training data via the expectation maximization presented in Section 3.1.1. If a random value sampled uniformly from $\mathcal{U}[0, 1)$ is less than

$$\frac{P(M_{g'})Q(g|g')}{P(M_g)Q(g'|g)} \quad (16)$$

then g' is accepted as the new topic mapping function g^{t+1}. This guarantees that the Markov chain will converge to the distribution P as $t \to \infty$. Because the ratio $P(M_{g'})/P(M_g)$ appears in Equation 16, the normalization factor Z_P in Equation 13 cancels out and does not need to be computed.

4 Empirical Evaluation

We perform a set of experiments to demonstrate the following:

1) Given the topic model structure outlined in Section 3.1, the model adaptation procedure in section 3.2 selects a high performing topic mapping function while only evaluating a small fraction of the total number of funtions.

2) The topic model resulting from model adaptation is high quality relative to alternative state-of-the-art approaches.

4.1 Data

We demonstrate our approach to two structured sentiment analysis datasets. First, we gathered a collection of approximately 8,000 Yelp.com business reviews from the greater New York area. For this data, businesses are assigned into categories and subcategories based on the Yelp.com business hierarchy. There are 22 primary categories {Arts and Entertainment, Education, Financial Services, Restaurants,...}, each with 6 to 100 subcategories (restaurants have the most subcategories, {Japanese, Barbeque, Cafe, Fast Food, Burgers, Ultra High Enc, Formal, Full Bar,...}). Businesses can be assigned to multiple categories and subcategories within the hierarchy.

Second, we utilize 20,000 Amazon.com book reviews, extracted from the data set first presented in (Qu et al., 2010). Categorical distinctions in these domains are related to the Amazon.com product hierarchy. A small portion of the product hierarchy appears in Figure 1. Books can be assigned to multiple distantly related categories. For example, the book *Six Wives of Henry VIII* belongs to "History\Europe\England\Tudor and Stuart," "Biographies and Memoirs\Specific Groups\Women" and three other categories

For each domain, we have at most one review corresponding to any particular business/book. This allows for a broad coverage of the space of categorizations.

4.2 Results and Discussion

To compensate for extreme variations in the training data we apply two smoothing steps. First, we found that for longer reviews, the assumption that each word is drawn independently from the document's topics is too strong, and so for reviews with more than 35 words, we scale the term counts such that the total is 35. Second, because of the large size of the vocabulary, after training, some rare words have zero or near zero probability in some of the topics. When these words are observed during inference, they have a very strong effect on the document's expected rating. We found that smoothing the subject topics with the overall word distribution across topics stabilizes the predicted ratings and improves performance. The amount of smoothing could be optimized to maximize the likelihood of the test data, but we found that performance varied little for a wide range of values and so we choose a 1 to 1 smoothing.

From each dataset, we sample a subset of size 1000 for cross validation parameter tuning and use the remaining examples for experimentation.

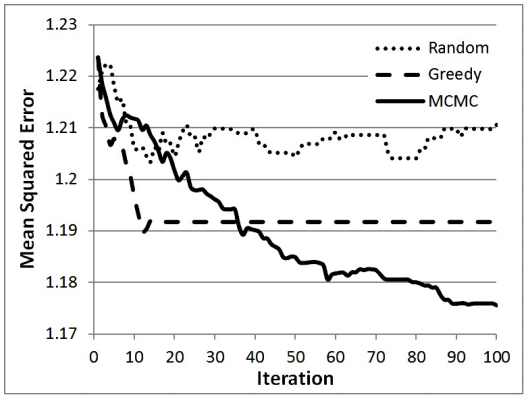

Figure 3: Learning curves for three model sampling approaches on Yelp.com test data with 500 training examples (averaged over 20 trials).

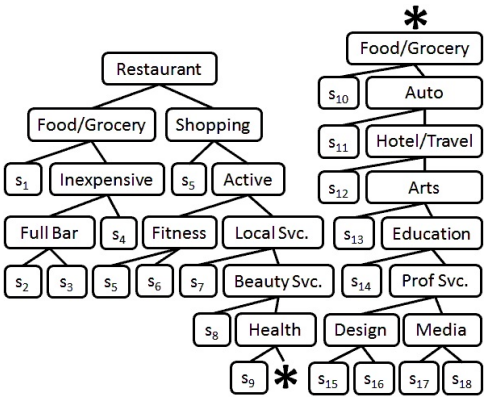

Figure 4: A representative partitioning tree learned from 500 training examples on the Yelp.com data.

The validation data is used to learn the values of α, the subject topic fraction, and β, the complexity penalty. We found that setting τ, the MCMC smoothing factor, equal to .1 worked well across our datasets. For each trial, then, disjoint training and test sets are sampled from the remaining data.

First, we apply our Markov chain Monte Carlo model adaptation procedure along with greedy and random alternatives to demonstrate the necessity of a directed and stochastic approach. In the greedy approach, at each iteration we estimate the objective for all candidate models that can be reached with a single split/merge to each subject topic and adopt the model with the minimum estimate. For the random approach, at each iteration we start with the simplest topic mapping function (mapping all categorizations to one subject topic), and uniformly at random add distinctions until the model has the same number of subject topics as the optimal model found by the MCMC approach. We choose this instead of sampling at random from all possible topic mapping functions as the vast majority of such functions have nearly as many subject topics as training examples. For each approach, at iteration i, we chart the test mean squared error for the best (lowest objective) model observed during training in iterations 1 to i.

Figure 3 charts the per iteration mean squared error on the Yelp test data for the three model adaptation approaches. The greedy approach initially makes the fastest progress, but it is susceptible to local minima, and it levels off before being overtaken by the MCMC approach. As the random approach does not leverage the data in determining what distinctions to make, it fails to make progress at the rate of the other approaches. Its poor performance is indicative of the importance of having an efficient directed model adaptation approach, as high performing models are few and far between, even if we limit our search to models of the appropriate complexity level (number of subject topics). Figure 4 shows a representative partitioning tree learned from the Yelp.com dataset.

Next we compare our approach to alternative regression and topic modeling approaches. In order to implement regression, we 1) Form a vector of unigram (and optionally bigram) occurrences normalized to length 1 (which we found to work better than unnormalized or frequency vectors), and 2) Form a vector corresponding to categorical membership with one element for each node in category tree $\mathcal{C}$. For each example, we set each element in the vector to value γ if the example belongs to the corresponding category, and 0 otherwise. The feature vector is the concatenation of these two vectors. We tested three regression approaches: ridge regression, lasso, and ϵ-support vector regression with a quadratic kernel (Chang and Lin, 2001). In each case, the cross validation dataset is used to tune the value of γ and the regularization parameter (for ridge regression and lasso) or ϵ and the cost parameter (for ϵSVR). We found that in all cases, lasso and ϵSVR were ouperformed by ridge regression, and so omit their results.

For the supervised latent Dirichlet allocation approach, as the space of labels is numeric and discrete, we can treat the task either as a regression problem (Blei and McAuliffe, 2007), or as a multiclass classification problem (Wang et al., 2009).

	Yelp.com Data					Amazon.com Data				
	Training Examples					Training Examples				
	500	1000	2000	4000	6000	500	1000	2000	4000	6000
TMSD, MCMC	**1.207**	**1.062**	**.983**	**.915**	**.870**	**1.243**	**1.161**	**1.090**	**1.019**	**.981**
TMSD, Simple	1.252	1.108	1.017	.951	.893	1.300	1.256	1.158	1.075	1.027
TMSD, Complex	1.284	1.123	—-	—-	—-	1.281	1.198	—-	—-	—-
RR, Uni	1.319	1.182	1.103	1.020	.949	1.337	1.265	1.145	1.081	1.033
RR, Uni/Bi	1.285	1.164	1.059	.971	.903	1.310	1.237	1.119	1.041	1.001
SLDA	1.664	1.649	1.606	1.556	1.479	1.621	1.632	1.607	1.581	1.555

Figure 5: Mean Squared Error for 1) the presented topic model for structured domains (TMSD) using MCMC Model Adaptation (MCMC), the simplest topic mapping function (Simple), or the most complex topic mapping function (Complex), 2) ridge regression (RR) with unigrams (Uni) or unigrams and bigrams (Uni/Bi), and 3) multiclass supervised latent Dirichlet allocation (SLDA). Results are averaged over 10 trials, each with 1000 test examples. The MCMC approach significantly outperforms all other approaches for each training set size (Yelp.com: $p < .01$, Amazon.com: $p < .05$).

We used an open source implementation of each approach, (Chang, 2010) and (Wang, 2009), and found that utilizing the multiclass approach and predicting the expected rating based on the posterior likelihood of each class outperformed the regression approach, so we present these results. The cross validation data is used to learn the number of latent topics and Dirichlet distribution parameter.

For the Markov chain Monte Carlo approach, in order to hasten learning for this comparison, starting from the simplest topic mapping function, we perform a greedy model adaptation until reaching an estimated local minimum, and then apply 50 additional iterations of MCMC model adaptation.

Figure 5 shows the average mean squared error for each approach for various amounts of training data. Our topic model with model adaptation has lower error than each of the alternatives. Paired t-tests reveal that the differences are statistically significant in all cases ($p < .01$ for all Yelp.com and $p < .05$ for all Amazon.com tests). Using MCMC model adaptation also outperforms using either the simplest topic mapping function or the most complex mapping function (which maps each distinct training categorization to a different subject topic).

Ridge regression with unigrams uses the same word and categorical representations as our approach. However, it is unable to entertain the nonlinear relationships between document categorizations and words and is outperformed in all cases. Bigrams improve the performance of ridge regression, especially for larger amounts of training data. This suggests that accounting for word ordering could potentially improve the performance of our topic model as well. sLDA is unable to take advantage of the categorical information during topic construction, and with the limited training data available, its performance is marginally better than guessing the mean label (MSE: 1.675 for Yelp.com data and 1.660 for Amazon.com data).

5 Conclusion

We present an approach to sentiment analysis for structured domains. In our approach, positive, negative, and subject topics are learned and used to infer document labels. Partitioning tree based topic mapping functions define the number and structure of subject topics. A Markov chain Monte Carlo model adaptation procedure explores the space of topic mapping functions based on a minimum description length objective. We demonstrate the approach on two sentiment analysis domains and show that the model adaptation procedure efficiently finds a high performance model that leverages the categorical structure of the documents to outperform other regression and topic modeling approaches.

Abstract

This paper focuses on examining the effect of extra-linguistic information, such as eye gaze, integrated with linguistic information on multi-modal reference resolution. In our evaluation, we employ eye gaze information together with other linguistic factors in machine learning, while in prior work such as Kelleher (2006) and Prasov and Chai (2008) the incorporation of eye gaze and linguistic clues was heuristically realised. Conducting our empirical evaluation using a data set extended the REX-J corpus (Spanger et al., 2010) including eye gaze information, we examine which types of clues are useful on these three data sets, which consist largely of pronouns, non-pronouns and both respectively. Our results demonstrate that a dynamically moving visible indicator within the computer display (e.g. a mouse cursor) contributes to reference resolution for pronouns, while eye gaze information is more useful for the resolution of non-pronouns.

1 Introduction

The task of reference resolution has received much attention because it is important for applications that require interpreting text. In recent work on reference resolution within a text, several machine learning-based approaches have been proposed (McCarthy and Lehnert, 1995; Ge et al., 1998; Soon et al., 2001; Ng and Cardie, 2002; Iida et al., 2003; Yang et al., 2003; Denis and Baldridge, 2008), each of which mainly exploits linguistic clues motivated by the Centering Theory (Grosz et al., 1995) to model the discourse salience of all candidate antecedents. For instance, Yang et al. (2003) and Iida et al. (2003) presented machine learning-based reference resolution models where a pairwise comparison of candidate antecedents, in line with the basic idea of the Centering Theory, leads to the selection of the candidate with the highest salience for a given context. Denis and Baldridge (2008) extended the model by integrating the set of pairwise comparisons into ranking candidates to directly learn which clues of antecedents are useful.

Through the empirical evaluations using the data sets provided by the Message Understanding Conference (MUC)[1] and the Automatic Content Extraction (ACE)[2], which consist of newspaper articles and transcripts of broadcasts, linguistically motivated approaches have achieved better performance than state-of-the-art rule-based reference resolution systems (e.g. Soon et al. (2001) and Ng and Cardie (2002)).

In contrast to this research paradigm (i.e. research focusing on only the linguistic aspect of reference), research in the area of multi-modal interfaces has focused on referring expressions used in multi-modal conversations, in other words, identifying referents of referring expressions in a static scene or a situated world (e.g. objects depicted in a computer display), taking extra-linguistic clues into account (Byron, 2005; Prasov and Chai, 2008; Prasov and Chai, 2010; Schütte et al., 2010, etc.). For instance, Kelleher and van Genabith (2004) used the centrality and size of a object in the display to determine its visual salience. Prasov and Chai (2008) and Prasov and Chai (2010) exploited eye fixations to detect users' focus of attention in terms of visual prominence; their research has been motivated by work in the cognitive sciences (Tanenhaus et al., 1995; Tanenhaus et al., 2000; Hanna et al., 2003; Hanna and Tanenhaus, 2004; Hanna and Brennan, 2007; Metzing and Brennan, 2003; Ferreira and Tanenhaus, 2007; Brown-Schmidt et al., 2002).

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 84–92,
Chiang Mai, Thailand, November 8 – 13, 2011.

These previous studies have shown how promising using eye gaze information for multi-modal reference resolution can be. However, they rely on heuristic techniques for determining visual salience. Hence, there is still room for improvement by introducing eye gaze information in a more systematic and principled manner[3]. This paper, therefore, focuses on a multi-modal reference resolution model that integrates eye gaze and linguistic information by using a machine learning technique. Adapting a ranking-based anaphora resolution model, such as was proposed by Denis and Baldridge (2008), we integrate extra-linguistic information with other linguistic factors for more accurate reference resolution. With the above as a suitable background, this paper focuses on the issue of how to effectively combine linguistic and extra-linguistic factors for multi-modal reference resolution, taking collaborative task dialogues in Japanese as our target data set.

This paper is organised as follows. We first explain related work and our stance on multi-modal reference resolution in Section 2; we then present which multi-modal task we chose and how we merge eye gaze information into the predefined multi-modal task in Section 3. Section 4 introduces what types of information are used in the experiments shown in Section 5. We finally conclude this paper and discuss future directions in Section 6.

2 Related work

Within the field of computational linguistics, researchers have focused on developing computational models of reference resolution, taking into account various linguistic factors, such as grammatical, semantic and discourse clues mainly acquired from the relationship between an anaphor and any candidate antecedents (Mitkov, 2002; Lappin and Leass, 1994; Brennan et al., 1987; Strube and Hahn, 1996, etc.). Research trends for reference resolution have shifted from handcrafted rule-based approaches to corpus-based approaches due to the growing success of machine learning algorithms (e.g. Support Vector Machines (Vapnik, 1998)). For instance, an approach to coreference resolution proposed by Soon et al. (2001), in which the problem of reference resolution is decomposed into a set of binary classification problems of whether a pair of markables (e.g. NP) are anaphoric or not, achieved performance comparable to the state-of-the-art rule-based system, even though they used only a limited number of simple features. Researchers' concerns in this area cover a broad range of research topics from modeling the coreferential transitivity of a set of markables, to integrating discourse salience motivated by the Centering Theory (Grosz et al., 1995). This research area has continued to produce novel reference resolution models over the years, but the target of reference resolution is limited to only written texts or transcripts of speech.

In contrast to the above research area, researchers in the multi-modal community also have paid attention to reference resolution because it is also a crucial task for realising interaction between humans and computers. In this area, the evaluation is typically conducted in the situation where a set of objects (i.e. candidate referents) are depicted within a computer display. For instance, Stoia et al. (2008) designed an experiment where two participants controlled an avatar in a virtual world for exploring hidden treasures. In this case, the task of reference resolution is to identify an object shown on the computer display as referred to by a referring expression used by the participants during dialogue. The task becomes more complicated than typical coreference resolution for written texts because a referent is considered as either *anaphoric* (i.e. it has already appeared in the previous discourse history) or *exophoric*, (i.e. the reference resolution system needs to search for the referent from the set of objects shown in a computer display).

In order to capture the characteristics of exophoric cases, extra-linguistic information acquired from participants' eye gaze data and the visual prominence of each object are also exploited together with linguistic information. A series of research by Kelleher and his colleagues (Kelleher and van Genabith, 2004; Kelleher et al., 2005; Kelleher, 2006; Schütte et al., 2010) tackled the problem of modeling visual salience of objects in situated dialogue. In their algorithm, the visual salience of each object is estimated based on its centrality within the scene and its size; their hy-

[3] Frampton et al. (2009) employed the incorporation of linguistic and visual features on reference resolution of multi-party dialogues. However, their target was limited to only the expression *you* in dialogues, while our focus is to investigate the use of the expressions bridging between a dialogue and the real world (e.g. expressions referring to puzzle pieces on a computer display).

pothesis was that the salience is higher if a object is larger and is placed nearer the centre of the computer display. In Kelleher (2006)'s approach to reference resolution, linguistic clues such as ranking rules of candidate referents based on the Centering Theory (Grosz et al., 1995) were introduced in addition to using visual salience, but the integration of both clues was done in a heuristic way.

In addition to the visual salience assessed from the characteristics of objects in the world, eye gaze has received much attention as a clue for reference resolution. Prasov and Chai (2008), for example, employed eye gaze on the task of identifying a referent in the situation where objects are placed in a static scene. The time span after a speaker most recently fixates on an object is incorporated into their reference resolution model as well as the information of how recently the object was referred to by a referring expression. Although the results of their evaluation demonstrated that eye gaze significantly contributes to increasing performance, there is still room for improvement by adapting machine learning techniques, because in their work the linguistic and visual attention information was heuristically integrated.

In contrast, our previous work (Iida et al., 2010) employed a machine learning technique to identify the most likely candidate referent, taking into account linguistic features together with cues capturing visual salience found within the situated dialogues contained in the REX-J corpus (Spanger et al., 2010). We reported that extra-linguistic information contributes to improving performance (especially, in pronominal reference). However, in Iida et al. (2010) eye gaze information was not considered, even though in the area of cognitive science researchers have demonstrated that a speaker's eye fixations are strong clues for identifying a referent of a referring expression (Tanenhaus et al., 1995; Tanenhaus et al., 2000; Hanna et al., 2003; Hanna and Tanenhaus, 2004; Hanna and Brennan, 2007; Metzing and Brennan, 2003; Ferreira and Tanenhaus, 2007; Brown-Schmidt et al., 2002). Against this background, we investigate the effect of linguistic and extra-linguistic information including eye gaze on multi-modal reference resolution, extending Iida et al. (2010)'s reference resolution model.

3 Collecting eye gaze data in situated dialogues

In our evaluation of automatic reference resolution, we focus on investigating the interaction between linguistic and extra-linguistic clues including eye fixations on multi-modal reference resolution. Therefore, corpora where participants frequently utter both anaphoric and exophoric referring expressions are preferable for our evaluation.

In recent multi-modal problem settings for data collection, researchers have been concerned with more realistic situations, such as dynamically changing scenes rendered in a 3D virtual world (e.g. (Byron, 2005)). However, if we use data collected from such a scenario, referring expressions will be relatively skewed to exophoric cases because of frequently occurring scene updates. On the other hand, if we adopt the data collected using a static scene, we will have a disadvantage in that the change of visual salience of objects is not observed because the centrality and size of each object is fixed through dialogues.

For these reasons, we adopt the same task setting as introduced in the REX-J corpus (Spanger et al., 2010), which consists of collaborative work (solving Tangram puzzles) by two participants; the setting of this corpus is more suitable for our purposes because of the frequent occurrence of both anaphoric and exophoric referring expressions.

For collecting data, we recruited 18 Japanese graduate students, and split them into 9 pairs[4]. All pairs knew each other previously and were of the same gender and approximately the same age. Each pair was instructed to solve four different Tangram puzzles. The goal of the puzzle is to construct a given shape by arranging seven pieces (of different simple shapes) as shown in Figure 1. The precise positions of every piece and every action that the participants make are recorded by the Tangram simulator in which the pieces on the computer display can be moved, rotated and flipped with simple mouse operations. The piece position and the mouse actions were recorded at intervals of 1/65 msec. The simulator displays two areas: a goal shape area (the left side of Figure 1) and a working area (the right side of Figure 1) where pieces are shown and can be manipulated.

A different role was assigned to each participant

[4]Note that the first pair was used to adjust the settings of our data collection, so 4 dialogues collected from that pair were not included in the evaluation data set used in Section 5.

	time	OP-UT	SV-UT	OP-REX	SV-REX	ERR-OP	ERR-SV
total	4:22:20	2,382	4,613	239 / 270	434 / 1,192	–	–
average	9:43	88.2	170.9	8.85 / 10.0	16.1 / 44.1	14.0%	13.9%
SD	3:32	69.8	86.8	10.2 / 11.3	15.9 / 24.4	9.9	10.4

OP-UT (SV-UT) stands for the number of utterances of operators (solvers). The right side of OP-REX (SV-REX) is the frequency of referring expressions uttered by the operators (solvers), whereas the left side stands for the frequency of pronominal expressions uttered by the operators (solvers). ERR-OP (ERR-SV) is the error rate of measuring the operators' (solvers') eye gaze. SD means the standard derivation.

Table 1: Referring expressions in the extended REX-J corpus

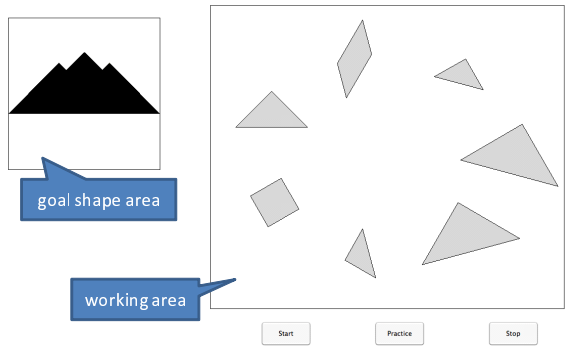

Figure 1: Screenshot of the Tangram simulator

of a pair: a *solver* and an *operator*. Given a certain goal shape, the solver thinks of the necessary arrangement of the pieces and gives instructions to the operator for how to move them. The operator manipulates the pieces with the mouse according to the solver's instructions. During this interaction, frequent uttering of referring expressions is needed to distinguish between the different puzzle pieces. This collaboration is achieved by placing a set of participants side by side, each with their own display showing the work area and the mouse cursor begin manipulated by the operator in real time, and a shield screen set between them to prevent the operator from seeing the goal shape, which is visible only on the solver's screen, and to further restrict their interaction to only speech. We put no constraint on the contents of their dialogues.

In addition to the attributes considered in the original REX-J corpus, we also collected eye gaze data synchronized with speech by using the Tobii T60 Eye Tracker, sampling at 60 Hz for recording users' eye gaze with 0.5 degrees in accuracy. Because the tracking results acquired from Tobii contain tracking errors, 5 dialogues in which the tracking results contain more than 40% errors were removed from the data set used in our evaluation.

Annotating referring expressions and their referents were conducted in the same manner as Spanger et al. (2010), i.e. annotation was conducted using a multimedia annotation tool, ELAN[5]; an annotator manually detects a referring expression and then selects its referent out of the possible puzzle pieces shown on the computer display. Note that only Tangram pieces were tagged as referents of referring expressions, therefore the expressions referring to abstract entities such as an action and event were not annotated. In the corpus multiple pieces were annotated as a single referent, but such referents were excluded in our evaluation because of their infrequent occurrence. Table 1 summarises the statistics of our new version of the REX-J corpus, consisting of 27 dialogues.

4 Multi-modal reference resolution

4.1 Base models

To investigate the impact of extra-linguistic information on reference resolution, we conducted an empirical evaluation in which a reference resolution model chooses a referent (i.e. a piece) for a given referring expression from the set of pieces on the computer display.

As a basis of our reference resolution model, we adopt an existing model for reference resolution. Recently, machine learning-based approaches to reference resolution (Soon et al., 2001; Ng and Cardie, 2002, etc.) focus on identifying anaphoric relations in texts, and have achieved better performance than hand-crafted rule-based approaches. These models for reference resolution take into account linguistic factors, such as relative salience of candidate antecedents, which have been discussed mainly in Centering Theory (Grosz et al., 1995) by ranking candidate antecedents appearing in the preceding discourse (Iida et al., 2003; Yang et al., 2003; Denis and Baldridge, 2008). In order to take advantage of existing models, we adopt the ranking-based approach as a basis for our reference resolution model. More precisely, we em-

eye gaze features		
GZ1:	[0,1]	the frequency of fixating P in the time period $[t-T,t]$, normalised by the frequency of the total fixations during the period.
GZ2:	[0,1]	the length of a fixation on P in the time period $[t-T,t]$, nomalised by T.
GZ3:	[0,1]	the length of a fixation on P in the time period $[t-T,t]$, nomalised by the total length of fixation.
GZ4:	[0,1]	the frequency of fixating P in the time period uttering a referring expression, normalised by the frequency of the total fixations during the period.
GZ5:	[0,1]	the length of a fixation on P in the time period uttering a referring expression, nominalised by T.
GZ6:	[0,1]	the length of a fixation on P in the time period uttering a referring expression, nominalised by the total length of fixation.
GZ7:	yes,no	whether the frequency of fixating P in the time period $[t-T,t]$ is most frequent.
GZ8:	yes,no	whether the frequency of fixating P in the time period $[t-T,t]$ is more than 1.
GZ9:	yes,no	whether the fixation time of P in the time period $[t-T,t]$ is longest out of all pieces.
GZ10:	yes,no	whether there exists the fixation time of P in the time period $[t-T,t]$.
GZ11:	yes,no	whether the frequency of fixating P in the time period uttering a referring expression is most frequent.
GZ12:	yes,no	whether the frequency of fixating P in the time period uttering a referring expression is more than 1.
GZ13:	yes,no	whether the fixation time of P in the time period uttering a referring expression is longest out of all pieces.
GZ14:	yes,no	whether there exists the fixation time of P in the time period uttering a referring expression.

t is the onset time of a referring expression. P denotes a piece, T is a fixed time window (1500ms).

Table 2: Eye gaze features

ploy Denis and Baldridge (2008)'s ranking-based model because they demonstrated their model outperformed the model based on simple pairwise ranking (e.g. Yang et al. (2003)).

In Denis and Baldridge (2008)'s ranking-based model, the most likely candidate antecedent is decided by simultaneously ranking all candidate antecedents. To induce a ranker used in the ranking process, we adopt the Ranking SVM algorithm (Joachims, 2002)[6], which learns a weight vector to rank candidates for a given partial ranking of each referent, while the original work by Denis and Baldridge (2008) uses Maximum Entropy to create their ranking-based model. Each training instance is created from the set of all referents for each referring expression. To define the partial ranking of referents, we simply rank referents of a given referring expression as first place and any other referents as second place.

4.2 Eye gaze features

As we mentioned in Section 2, a speaker's eye gaze contributes to disambiguating referents appearing in the speaker's utterances because the speaker tends to see the target object before it is referred to by a referring expression (Spivey et al., 2002). Several aspects must be considered in order to integrate a speaker's eye gaze data. First, because the eye gaze data includes saccades, the inhibition factor of perceptual sensitivity, we extract only eye fixations as discussed in Richardson et al. (2007). For separating saccades and eye fixations, we employ Dispersion-threshold identification (Salvucci and Anderson, 2001), detecting fixations by using the concentration of eye gaze based on the fact the fixations are relatively slower than saccades. Second, because of the errors in measuring eye gaze by the eye tracker, the fixation data needs to be interpolated by the surrounding data. More specifically, if the error interval is less than 100 msec and the difference of the centers of two fixations is smaller then 16 pixels, these fixations are concatenated according to the work by Richardson et al. (2007).

The clues exploited in this paper are based on the fact that the direction of eye gaze directly reflects the focus of attention (Richardson et al., 2007; Just and Carpenter, 1976) , i.e. when one utters a referring expression, he potentially focuses on the object involved by fixating his eyes on it. Therefore, we use the eye fixations as clues for identifying the pieces focused on using the following criteria: the nearest piece to the eye fixation point is more likely a target of focus over all other pieces. To reflect this, we introduce the feature set shown in Table 2. We henceforth call these features the *eye gaze features*. Note that the parameter T is set to 1,500 ms based on the previous work done by Prasov and Chai (2010).

5 Empirical Evaluation

In order to investigate the effect of extra-linguistic information with or without linguistic factors, we conducted empirical evaluations using the updated version of the REX-J corpus explained in

[6] www.cs.cornell.edu/People/tj/svm_light/svm_rank.html

(a) **Linguistic features**		
L1 :	yes, no	whether P is referred to by the most recent referring expression.
L2 :	yes, no	whether the time distance to the last mention of P is less than or equal to 10 sec.
L3 :	yes, no	whether the time distance to the last mention of P is more than 10 sec and less than or equal to 20 sec.
L4 :	yes, no	whether the time distance to the last mention of P is more than 20 sec.
L5 :	yes, no	whether P has never been referred to by any mentions in the preceding utterances.
L6 :	yes, no, N/A	whether the attributes of P are compatible with the attributes of R.
L7 :	yes, no	whether R is followed by the case marker '*o* (accusative)'.
L8 :	yes, no	whether R is followed by the case marker '*ni* (dative)'.
L9 :	yes, no	whether R is a pronoun and the most recent reference to P is not a pronoun.
L10 :	yes, no	whether R is not a pronoun and was most recently referred to by a pronoun.
(b) **Task specific features**		
T1 :	yes, no	whether the mouse cursor was over P at the beginning of uttering R.
T2 :	yes, no	whether P is the last piece that the mouse cursor was over when feature T1 is 'no'.
T3 :	yes, no	whether the time distance is less than or equal to 10 sec after the mouse cursor was over P.
T4 :	yes, no	whether the time distance is more than 10 sec and less than or equal to 20 sec after the mouse cursor was over P.
T5 :	yes, no	whether the time distance is more than 20 sec after the mouse cursor was over P.
T6 :	yes, no	whether the mouse cursor was never over P in the preceding utterances.
T7 :	yes, no	whether P is being manipulated at the beginning of uttering R.
T8 :	yes, no	whether P is the most recently manipulated piece when feature T7 is 'no'.
T9 :	yes, no	whether the time distance is less than or equal to 10 sec after P was most recently manipulated.
T10 :	yes, no	whether the time distance is more than 10 sec and less than or equal to 20 sec after P was most recently manipulated.
T11 :	yes, no	whether the time distance is more than 20 sec after P was most recently manipulated.
T12 :	yes, no	whether P has never been manipulated.

P stands for a piece of the Tangram puzzle (i.e. a candidate referent of a referring expression) and R stands for the target referring expression.

Table 3: Feature set

Section 3.

5.1 Experimental settings

We employed two models as baselines: a model using only discourse history features, and one using only eye gaze features.

Because the task setting is the same as the evaluation conducted in Iida et al. (2010), we employ the same feature set, consisting of linguistically motivated features, and also features which capture the task specific extra-linguistic information of each object. We call these two kinds of features the *linguistic features* and *task specific features*, respectively. The details of these features are summarised in Table 3.

As reported in Iida et al. (2010), the referential behaviour of pronouns is completely different from non-pronouns. For this reason, we separately create two reference resolution models; one called the *pronoun model*, which identifies a referent of a given pronoun, and another called the *non-pronoun model*, which is for all other expressions. During the training phase, we use only training instances whose referring expressions are pronouns for creating the pronoun model, and all other training instances for the non-pronoun model. We group these two models together, selecting which one to use based on the referring expression. In other words, the pronoun model is selected if a referring expression is a pronoun, and the non-pronoun model otherwise. We will hereafter refer to the selectional model which alternatively picks between the pronoun and non-pronoun models as the *separated model*.

We also train a third model using all training instances without distinguishing between pronouns and non-pronouns. This model we will refer to as the *combined model*.

model	pronoun	non-pronoun
Ling	56.0	65.4
Gaze	56.7	48.0
TaskSp	**79.2**	21.1
Ling+Gaze	66.5	75.7
Ling+TaskSp	79.0	67.1
TaskSp+Gaze	78.0	48.4
Ling+TaskSp+Gaze	78.7	**76.0**

Ling, TaskSp and Gaze stand for the models using the linguistic, task specific and eye gaze features respectively.

Table 4: results in the separated model (accuracy)

5.2 Results

Table 4 shows the accuracy results of our empirical evaluation separately evaluating pronouns and non-pronouns. In reference resolution of pronouns

model	combined	separated
Ling	62.7	61.8
Gaze	51.1	51.2
TaskSp	43.7	42.8
Ling+Gaze	69.9	72.3
Ling+TaskSp	69.9	71.5
TaskSp+Gaze	55.2	59.5
Ling+TaskSp+Gaze	**72.5**	**77.0**

Table 6: 10 highest weights of the features in each model

the results show that the model using only the linguistic features (Ling) achieved performance comparable to the one using only the eye gaze features (Gaze). Moreover, the model using only the task specific features (TaskSp) obtained performance significantly better than the others. This is because a mouse cursor is the only shared visual stimulus between the operator and solver. Therefore, it becomes the most important clue for pronouns, while the eye fixations of a speaker are not necessarily shared between them.

In contrast to pronouns, the non-pronoun model using only the linguistic features (Ling) outperforms the one using either eye gaze features or the task specific features (Gaze and TaskSp). This may be because one linguistic feature (L6) works more effectively than the other features. As shown later (see Table 6), in non-pronoun cases, the feature L6, which is the binary value indicating the compatibility of the attributes between two referring expressions, has the highest feature weight, leading to the best performance out of all three models (Ling, Gaze and TaskSp).

In addition, combining the linguistic and eye gaze features (Ling+Gaze) on non-pronoun reference resolution contributes to increasing performance. This means that these two features work in a complementary manner when a referring expression cannot be judged on a superficial level whether it refers to a discourse referent or a visually focused referent. From these results, we can see that the clues from utterances of participants are also essential for precise reference resolution, while the previous work focusing on eye fixations tends to concentrate on modeling only eye gaze information.

The accuracy results in Table 5 show the performance of the combined and separated models for different settings of feature selection. Table 5 shows that the two models achieved almost the same performance when the linguistic, eye gaze and task specific features are individually used. However, it also shows that the separated model outperforms the combined model when more than two feature types are utilised. This indicates that separating the models with regard to the type of referring expression does make sense even when we employ eye fixations as a clue for recognising referent objects. It also shows that both the combined and separated models obtained the best performance for each model using all the features. In other words, the three types of features work in a complementary manner on multi-modal reference resolution.

We next investigated the significance of each feature for the pronoun and non-pronoun models. We calculate the weight of a feature f shown in Table 6 according to the following formula.

$$\text{weight}(f) = \sum_{x \in SVs} w_x z_x(f) \qquad (1)$$

where *SVs* is a set of the support vectors in a ranker induced by the Ranking SVM algorithm, w_x is the weight of the support vector x, $z_x(f)$ is the function that returns 1 if f occurs in x, respectively.

Table 6 shows the top 10 features with the highest weights of each model. It demonstrates that in the pronoun model the task specific features have the highest weight, while in the non-pronoun model these features are less significant. As shown in Table 4, pronouns are strongly related to the situation where the mouse cursor is over a piece, which is consistent with the results reported in Iida et al. (2010).

In contrast, the highest features in the non-pronoun model are occupied by the eye gaze features, except for L6. This indicates that in the situation where a speaker mentions pieces realised as non-pronouns, the eye fixations become a good clue for identifying the current focus of the

speaker, while the task specific features such as the location of the mouse cursor are less significant. In addition, Table 6 also shows that the discourse feature L6 obtains the highest significance. This means that exploiting the linguistic factors together with eye fixations is essential for more accurate reference resolution.

6 Conclusion

In this paper we focused on investigating the impact of eye fixations on reference resolution compared to using other extra-linguistic information. We conducted an empirical evaluation using referring expressions appearing in collaborative work dialogues from the extended REX-J corpus, synchronised with eye gaze information. We demonstrated that the referents of pronouns are relatively easily identified, as they rely on the visual salience such as is indicated by moving the mouse cursor, and that non-pronouns are strongly related to eye fixations on its referent. In addition, our results also show that combining linguistic, eye gaze and other extra-linguistic factors contribute to increasing the overall performance of identifying all referring expressions.

There are several future directions for making the multi-modal reference resolution more accurate and robust. First, we need to introduce more task dependent information reflecting the characteristics of each multi-modal task. In the Tangram puzzle task, for example, once a piece becomes part of a partially constructed shape, the piece tends to be less salient because a solver typically gives an instruction to move a scattered piece to a partially constructed shape. We expect that introducing such task specific clues into the reference resolution model as features will contribute to improving performance.

Second, in our evaluation we adopted collaborative work dialogues where two participants solve Tangram puzzles. Since all objects (i.e. puzzle pieces) have nearly the same size, this results in explicitly rejecting the factor that a relatively larger object occupying the computer display has higher prominence over smaller objects, which has been considered by Byron (2005). In order to take such a factor into account, we need further data collection and then to incorporate additional factors into the current reference resolution model.

A third possible direction for future work is to examine the relation between linguistic and intentional structures, which are discussed in Grosz and Sidner (1986). In our problem setting, when a solver instructs an operator how to construct a goal shape, a series of utterances by the solver reflects the solver's intentions. As we already mentioned above, objects which a solver wants an operator to manipulate tend to draw a solver's attention, while the other objects (especially, the objects representing the partially constructed shape) are considered less salient. Exploiting the importance of the speaker's intentions also needs to be considered in future work.

Abstract

There is no generally accepted metric for measuring the performance of anaphora resolution systems, and the existing metrics—MUC, B^3, CEAF, Blanc, among others—tend to reward significantly different behaviors. Systems optimized according to one metric tend to perform poorly with respect to other ones, making it very difficult to compare anaphora resolution systems, as clearly shown by the results of the SEMEVAL 2010 Multilingual Coreference task. One solution would be to find a single completely satisfactory metric, but it's not clear whether this is possible and at any rate it is not going to happen any time soon. An alternative is to optimize models according to multiple metrics simultaneously. In this paper, we show, first of all, that this is possible to develop such models using Multi-objective Optimization (MOO) techniques based on Genetic Algorithms. Secondly, we show that optimizing according to multiple metrics simultaneously may result in better results with respect to each individual metric than optimizing according to that metric only.

1 Introduction

In anaphora resolution,[1] as in other HLT tasks, optimization to a metric is essential to achieve good performance (Hoste, 2005; Uryupina, 2010). However, many evaluation metrics have been proposed for anaphora resolution, each capturing what seems to be a key intuition about the task: from MUC (Vilain et al., 1995) to B^3 (Bagga and Baldwin, 1998), from the ACE metric (Doddington et al., 2004) to CEAF (Luo, 2005) to BLANC (Recasens and Hovy, 2011). And unlike in other areas of HLT, none has really taken over. This would not matter so much if those metrics were to reward the same systems; but in fact, as dramatically demonstrated by the results of the Coreference Task at SEMEVAL 2010 (Recasens et al., 2010), the opposite is true—almost every system could come on top depending on which metric was chosen.

It seems unlikely that the field will converge on a single metric any time soon. Given that many of the proposed metrics do capture what would seem to be plausible intuitions, it would seem desirable to develop methods to optimize systems according to more than one metric at once—in particular, according to at least one metric of what we might call the 'link-based' cluster of metrics (e.g., MUC) and at least one of what we will call the 'entity-based' cluster (e.g., CEAF).

As it happens, techniques for doing just that have been developed in the area of Genetic Algorithms: so-called **multi-objective optimization** (MOO) (Deb, 2001) techniques. In this paper, we will show how these techniques can be used to optimize anaphora resolution models (we focused for the time being on feature selection) by looking for a solution in the space defined by a multiplicity of metrics (we used MUC and CEAF (in two variants) as the optimization functions). Perhaps the most interesting result of this work is the finding that by working in such a multi-metric space it is possible to find solutions that are better with respect to an individual metric than when trying to optimize for that metric alone—which arguably suggests that indeed both families of metrics capture some fundamental intuition about anaphora, and taking into account both intuitions we avoid local optima.

The structure of the paper is as follows. We first review the literature on using genetic algorithms for both single function and multi function opti-

[1] We use the term 'anaphora resolution' to refer to the task perhaps most commonly referred to as 'coreference resolution,' which many including us find a misnomer. For the purposes of the present paper the two terms could be seen as interchangeable.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 93–101,

mization. Next, we discuss the particular method of multi-objective optimization we used in this paper, Non-Dominated Sorting Genetic Algorithm II (Deb et al., 2002). After that we discuss how the method was used, and present our results. We then compare our work with other approaches to optimization for anaphora found in the literature.

2 Background: Optimizing for Anaphora Resolution

A great number of statistical approaches to anaphora resolution have been proposed in the past ten years. These approaches differ with respect to their underlying models (e.g., mention pair model (Soon et al., 2001) vs. tournament model (Iida et al., 2003; Yang et al., 2005), vs. entity-model (Luo et al., 2004)), machine learners (e.g., decision trees vs. maximum entropy vs. SVMs vs. TiMBL) and their parameters, and with respect to feature sets used. There have been, however, only few attempts at explicit optimization of these aspects, and in those few cases, optimization tends to be done by hand.

An early step in this direction was the work by Ng and Cardie (2002), who developed a rich feature set including 53 features, but reported no significant improvement over their baseline when all these features were used with the MUC6 and MUC7 corpora. They then proceeded to manually select a subset of features that did yield better results for the MUC-6/7 datasets. A much larger scale and very systematic effort of manual feature selection over the same dataset was carried out by Uryupina (2007), who evaluated over 600 features.

The first systematic attempt at automatic optimization of anaphora resolution we are aware of was carried out by Hoste (2005), who investigated the possibility of using genetic algorithms for automatic optimization of both feature selection and of learning parameters, also considering two different machine learners, TiMBL and Ripper. Her results suggest that such techniques yield improvements on the MUC-6/7 datasets. Recasens and Hovy (2009) carried out an investigation of feature selection for Spanish using the ANCORA corpus.

These approaches focused on a single metric only; the one proposal simultaneously to consider multiple metrics, Zhao and Ng (2010) still optimized for each metric individually.

The effect of optimization on anaphora resolution was dramatically demonstrated by Uryupina's contribution to SEMEVAL 2010 Multilingual Coreference Task (Uryupina, 2010). Uryupina directly optimizes two parameters of her system: the choice of a model (mention-pair vs. ILP with various constraints) and the definition of mention types for training separate classifiers. The optimization is done on the development data in a brute-force fashion, in order to maximize the performance according to a pre-defined metric (MUC, CEAF or BLANC). The results on the SEMEVAL-10 dataset clearly show that existing metrics of coreference rely on different intuitions and therefore a system, optimized for a particular metric, might show inferior results for the other ones. For example, the reported BLANC difference between the runs optimized for BLANC and CEAF is around 10 percentage points.

This highlights the importance of the multi-objective optimization (MOO) for coreference, that suggests a family of systems, showing reliable performance according to all the desired metrics. A form of MOO was applied to coreference by Munson et al. (2005). Their general conclusion was negative, stating that "ensemble selection seems too unreliable for use in NLP", but they did see some improvements for coreference.

3 Optimization with Genetic Algorithms

In this section, we review optimization techniques using genetic algorithms (GAs) (Goldberg, 1989). We first discuss single objective optimization, that can optimize according to a single objective function, and then multi-objective optimization (MOO), that can optimize more than one objective function, in particular, a popular MOO technique named Non-dominated Sorting Genetic Algorithm (NSGA)-II (Deb et al., 2002).

3.1 Genetic Algorithms

Genetic algorithms (GAs) (Goldberg, 1989) are randomized search and optimization techniques guided by the principles of evolution and natural genetics. In GAs the parameters of the search space are encoded in the form of strings (called *chromosomes*). A collection of such strings is called a *population*. Initially, a random population is created, which represents different points in the search space. An *objective* or *fitness* function is associated with each string that represents the degree of *goodness* of the string. Based on the principle of survival of the fittest, a few of the strings are selected and each is assigned a number of copies that go into the mating pool. Biologically inspired op-

erators like *crossover* and *mutation* are applied on these strings to yield a new generation of strings. The processes of selection, crossover and mutation continues for a fixed number of generations or till a termination condition is satisfied.

3.2 Multi-objective Optimization

Multi-objective optimization (MOO) can be formally stated as follows (Deb, 2001). Find the vectors $\overline{x}^* = [x_1^*, x_2^*, \ldots, x_n^*]^T$ of decision variables that simultaneously optimize the *M* objective values

$$\{f_1(\overline{x}), f_2(\overline{x}), \ldots, f_M(\overline{x})\}$$

while satisfying the constraints, if any.

An important concept in MOO is that of **domination**. In the context of a maximization problem, a solution $\overline{x_i}$ is said to dominate $\overline{x_j}$ if $\forall k \in 1, 2, \ldots, M,\ f_k(\overline{x_i}) \geq f_k(\overline{x_j})$ and $\exists k \in 1, 2, \ldots, M,$ such that $f_k(\overline{x_i}) > f_k(\overline{x_j})$.

Among a set of solutions P, the nondominated set of solutions P' are those that are not dominated by any member of the set P. The nondominated set of the entire search space *S* is called the **globally Pareto-optimal set**. In general, a MOO algorithm usually admits a set of solutions not dominated by any solution encountered by it.

3.3 Nondominated Sorting Genetic Algorithm-II (NSGA-II)

Genetic algorithms (GAs) are known to be more effective than classical methods such as weighted metrics, goal programming (Deb, 2001), for solving MOO primarily because of their population-based nature. A particularly popular GA of this type is NSGA-II (Deb et al., 2002).

In NSGA-II, initially a random parent population P_0 is created and the population is sorted based on the *partial order* defined by the non-domination relation. This results in a sequence of nondominated **fronts**. Each solution is assigned a fitness value which is equal to its non-domination level in the partial order. A child population Q_0 of size N is then created from the parent population P_0 by using binary tournament selection, recombination, and mutation operators. In general, in the t^{th} iteration, a combined population $R_t = P_t + Q_t$ is formed. The size of R_t is $2N$, as the size of both P_t and Q_t is N. All the solutions of R_t are sorted according to non-domination. If the total number of solutions belonging to the best nondominated set F_1 is smaller than N, then F_1 is totally included in $P_{(t+1)}$. The remaining members of the population $P_{(t+1)}$ are chosen from the subsequent nondominated fronts in the order of their ranking. To choose exactly N solutions, the solutions of the last included front are sorted using the crowded comparison operator (Deb et al., 2002) and the best among them (i.e., those with lower crowding distance) are selected to fill in the available slots in $P_{(t+1)}$. The new population $P_{(t+1)}$ is then used for selection, crossover and mutation to create a population $Q_{(t+1)}$ of size N.

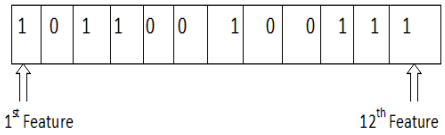

Figure 1: Chromosome representation for GA based feature selection

4 Two Algorithms for Feature Selection in Anaphora Resolution

Below we discuss how single and multi-objective optimization techniques can be used feature selection in the anaphora resolution task.

4.1 Chromosome Representation and Population Initialization

If the total number of features is F, then the length of the chromosome is F. As an example, the encoding of a particular chromosome is represented in Figure 1. Here $F = 12$ (i.e., total 12 different features are available). The chromosome represents the use of 7 features for constructing a classifier (first, third, fourth, seventh, tenth, eleventh and twelfth features). The entries of each chromosome are randomly initialized to either 0 or 1. Here, if the i^{th} position of a chromosome is 0 then it represents that i^{th} feature does not participate in constructing the classifier. Else if it is 1 then the i^{th} feature participates in constructing the classifier.

4.2 Fitness Computation

For fitness computation, the following procedure is executed:

1. Suppose there are N number of features present in a particular chromosome (i.e., there are total N number of 1's in that chromosome).

2. Construct the coreference resolution system (i.e., BART) with only these N features.
3. This coreference system is evaluated on the development data. The recall, precision and F-measure values of three metrics are calculated.

In case of single objective optimization (SOO), the objective function corresponding to a particular chromosome is the F-measure value of a single metric. This objective function is optimized using the search capability of GA. For MOO, the objective functions corresponding to a particular chromosome are F_{MUC} (for the MUC metric), F_{ϕ_3} (for CEAF using the ϕ_3 entity alignment function (Luo, 2005)) and F_{ϕ_4} (for CEAF using the ϕ_4 entity alignment function). These three objective functions are simultaneously optimized using the search capability of NSGA-II.

4.3 Genetic Operators

In case of SOO, a single point crossover operation is used with a user defined crossover probability, μ_c. A mutation operator is applied to each entry of the chromosome with a mutation probability, μ_m, where the entry is randomly replaced by either 0 or 1. In this approach, the processes of fitness computation, selection, crossover, and mutation are executed for a maximum number of generations. The best string seen up to the last generation provides the solution to the above feature selection problem. Elitism has been implemented at each generation by preserving the best string seen upto that generation in a location outside the population. Thus on termination, this location contains the best feature combination.

We use crowded binary tournament selection as in NSGA-II, followed by conventional crossover and mutation for the MOO based feature selection. The most characteristic part of NSGA-II is its elitism operation, where the non-dominated solutions (Deb, 2001) among the parent and child populations are propagated to the next generation. The near-Pareto-optimal strings of the last generation provide the different solutions to the feature selection problem.

5 Methods

5.1 The BART System

For our experiments, we use BART (Versley et al., 2008), a modular toolkit for anaphora resolution that supports state-of-the-art statistical approaches to the task and enables efficient feature engineering. BART implements different models of anaphora resolution (mention-pair and entity-mention; best-first vs. ranking), has interfaces to different machine learners (MaxEnt, SVM, decision trees) and provides a large set of linguistically motivated features, along with the possibility to design new ones. It is thus ideally suited for experimenting with optimization and feature selection.

In this study, we specifically focus on feature selection.[2] The complete list of features currently implemented in BART is listed in Table 1; all were considered in the present experiments. We used a simple mention-pair model without ranking as in (Soon et al., 2001). In the mention-pair model, anaphora resolution is recast as a binary classification problem. Each classification instance consists of two mentions, i.e. an anaphor M_j and its potential antecedent M_i ($i < j$). Instances are modeled as feature vectors (cf. Table 1) and are handed over to a binary classifier that decides, whether the anaphor and its candidate antecedent are mentions of the same entity or not. All the feature values are computed automatically.

We train a maximum entropy classifier and follow the approach of (Soon et al., 2001) to partition mentions into coreference sets given the classifier's decisions.

5.2 The Data Sets

We evaluated our approach on the ACE-02 dataset, which is divided in three subsets: bnews, npaper, and nwire. We provide results for both gold (hand-annotated) versions of the datasets (gbnews, gnpaper, gnwire) and system mentions extracted with CARAFE[3] (cbnews, cnpaper, cnwire).

Table 2 compares the performance level obtained using all the features in Table 1 with that of a loose re-implementation of the system proposed by Soon et al. (2001), commonly used as baseline and relying only on very shallow information. Our reimplementation of the Soon et al. model uses only a subset of features: those marked with an asterisk in Table 1. We also provide in Table 2 typical state-of-the-art figures on the ACE-02 dataset, as presented in an overview by Poon and Domin-

[2] The choice of the best model and the best machine learner, along with its parameters, is the main direction of our future work.

[3] `http://sourceforge.net/projects/carafe`

Table 1: Features used by BART: each feature describes a pair of mentions $\{M_i, M_j\},\ i < j$, where M_i is a candidate antecedent and M_j is a candidate anaphor

Mention types and subtypes	
MentionType*	relevant types of M_i and M_j, as identified in Soon et al.
MentionType_Ante_Salient	M_i is demonstrative; M_i is an NE
MentionType_Ante_Extra	M_i is a pronoun
MentionType_Ana	M_j is a definite, demonstrative or indefinite NP, or pronoun of a specific type
MentionType2	relevant types of M_i and M_j, as identified in Soon et al.
MentionType_Salience	combination of $MentionType$ and $MentionType\_Ana$
FirstSecondPerson	M_i is a pronoun of the 1st/second person, same for M_j
PronounLeftRight	4 possible values for $< M_i$ is a pronoun$> * < M_j$ is a pronoun $>$
PronounWordForm	lemma for M_i if it's a pronoun; same for M_j
SemClassValue	semantic class of M_i, and M_j and the pair
BothLocation	both M_i and M_j are locations or geo-political
Agreement	
GenderAgree*	M_i and M_j agree in gender
NumberAgree*	M_i and M_j agree in number
AnimacyAgree*	M_i and M_j agree in animacy
Aliasing	
Alias*	heuristical NE-matching
BetterNames	heuristical matching for personal names
Syntax	
Appositive*	M_i and M_j are in an apposition
Appositive2	M_i and M_j are adjacent
Coordination	M_i is a coordination; same for M_j
HeadPartOfSpeech	POS of M_i's head; same for M_j and the pair
SynPos	depth of M_i's node in the parse tree
Attributes	M_i and M_j have incompatible premodifiers
Relations	M_i and M_j have incompatible postmodifiers
Matching	
StringMatch*	M_i and M_j have the same surface form after stripping off the determiners
NonPro_StringMatch	both M_i and M_j are non-pronominal and $Stringmatch(M_i, M_j) == 1$
Pro_StringMatch	both M_i and M_j are pronominal and $Stringmatch(M_i, M_j) == 1$
NE_StringMatch	both M_i and M_j are NE and $Stringmatch(M_i, M_j) == 1$
HeadMatch	M_i and M_j have the same head
MinSame	M_i and M_j have the same minimal span
LeftRightMatch	M_j is a prefix or suffix substring of M_i or vice versa
StringMatchExtra	extra string-macthing for bare plurals
StringKernel	approximate matching
Salience	
First_Mention	M_i is the first mention in its sentence
CorefChain	Size of the coreference chain suggested for M_i so far (with a threshold)
NonProSalience	for non-pronominal M_i, number of preceding mentions with the same head lemma
Web	
Wiki	M_i and M_j have the same wikipedia entry
Yago	M_i and M_j are linked in Yago via `means` or `typeof` relation
WebPatterns	specific contexts for co-reference extracted from the web
Proximity	
DistanceMarkable	distance in mentions between M_i and M_j
DistanceSentenceInt*	distance in sentences between M_i and M_j
DistanceSentence	log-distance in sentences between M_i and M_j
DistanceSentence2	log-distance in sentences between M_i and M_j, different formula
DistDiscrete	distance in sentences between M_i and M_j discretized into {0,1,>=2}
Miscellaneous	
Speech	M_i is in quoted speech; same for M_j and the pair

gos (2008). The results clearly show that although even larger sets of features have been proposed (Uryupina, 2007; Bengtson and Roth, 2008), the set of features already included in BART is sufficient to achieve results well above the state of the art on the dataset we used.

The results in Table 2 also confirm the intuition that, contrary to what is suggested by some of the early papers (Soon et al., 2001; Ng and Cardie, 2002) working on smaller datasets, linguistic factors do play a crucial role in anaphora resolution and therefore rich feature sets may lead to performance improvements once larger datasets are considered (a similar result was also obtained by Bengtson and Roth (2008)). Such improvements, however, come at high costs, as both using larger datasets and larger sets of features learning a model becomes slower and requires much more memory.

This suggests that automatic feature selection may be essential not just to improve performance but also to be able to train a model—i.e., that an efficient coreference resolution system should combine rich linguistic feature sets with automatic feature selection mechanisms.

5.3 Genetic Algorithm Parameter Setting

We set the following parameter values for both single (i.e., GA) and MOO (i.e., NSGA-II): population size=20, number of generations=30, probability of mutation $\mu_m = 0.2$ and probability of crossover $\mu_c = 0.9$. Both approaches are executed on devel-

opment data to determine the optimal feature vector(s). Final results are reported on the test data. It is to be noted that GA is a stochastic approach and outputs different results for trials with different seeds and initial populations. Initial seeds and population are chosen randomly. Thus for each data set we executed the proposed single and multi objective based approaches 3 times. Finally, we report the maximum values of these 3 runs.

6 Results

6.1 Single Objective Optimization

Single objective GA based feature selection was executed on the six data sets to determine the appropriate set of features. For each data set three sets of experiments were carried out by optimizing the F-measure values of the three different evaluation metrics. The binary-valued feature vectors identified by the single objective GA based feature selection technique for the six data sets and the corresponding F-measure values are shown in Table 3. The order of the features in the vector corresponds to their order in Table 1; the values of 0's and 1's represent the absence and presence of the corresponding features. Significant improvements over the classifier based on all the features are indicated with † (sign test, $p < 0.05$).

These results show that for all the datasets, the proposed single objective GA-based feature selection technique performs better than the baseline approach of using all features. Moreover, the results show that the technique based on SOO (i.e., conventional GA-based method) with different objective functions provides different evaluation figures. Thus, it is meaningful to optimize each objective function separately.

It is also evident from Table 3 that the optimal feature set obtained by optimizing a single objective function may not be optimal with respect to another objective function. Thus, it is not possible to come up with common patterns in the set of optimal features. For example, in case of *gbnews*, the F-measure value of the first metric, i.e. of MUC corresponding to the optimal feature vector optimizing second metric, i.e. ϕ_3 is 76.7. This is obviously less than the evaluation figure obtained by optimizing the first metric.

6.2 Multi-objective Optimization

Thereafter we apply our proposed MOO based feature selection technique on the six data sets. The MOO approach provides a set of non-dominated solutions on the final Pareto optimal front. All the solutions are equally important from the algorithmic point of view. In Table 4, we show the final solutions obtained by the MOO based approach for all the data sets. Significant improvements over the classifier based on all the features are indicated with † (sign test, $p < 0.05$).

The results in Table 4 indicate that the MOO based technique achieves higher performance than the single objective GA based approach. For the *gbnews* data set, MOO achieves 0.6, 0.3 and 0.8 F-measure points increments for three metrics over the single objective GA based technique. For the *gnpaper* data set, there are increments of 2.5 F-measure points on second metric and 1.0 F-measure point on third metric over the corresponding single objective GA based technique. Similarly, for all other datasets the MOO based approach attains superior performance over the SOO-based approach.

7 Comparison with Related Work

As discussed in Section 2 most work on optimization in anaphora resolution relies on manual optimization; the one significant exception is the work of Hoste (2005).

There are two major differences between the approach of Hoste (2005) and that followed in our study. First, the scope of (Hoste, 2005) is restricted to *single-objective* optimization. As we saw above, this might provide unstable solutions, that are too tailored to a particular scoring metric. Second, the feature set of Hoste (2005) is relatively small and therefore does not provide an efficient test-bed for a feature selection approach. Not surprising, parameter optimization shows a more consistent effect on the overall performance than feature selection in (Hoste, 2005)'s experiments.

8 Discussion and Conclusions

In this paper we showed that it may not be necessary to choose one among the existing metrics for anaphora resolution—in fact, that developing systems attempting to optimize according to a combination of them may lead to better results.

In subsequent work, we plan to expand the optimization technique to consider also learning parameters optimization, classifier selection, and learning model selection.

Abstract

Event coreference is an important and complicated task in cascaded event template extraction and other natural language processing tasks. Despite its importance, it was merely discussed in previous studies. In this paper, we present a globally optimized coreference resolution system dedicated to various sophisticated event coreference phenomena. Seven resolvers for both event and object coreference cases are utilized, which include three new resolvers for event coreference resolution. Three enhancements are further proposed at both mention pair detection and chain formation levels. First, the object coreference resolvers are used to effectively reduce the false positive cases for event coreference. Second, A revised instance selection scheme is proposed to improve link level mention-pair model performances. Last but not least, an efficient and globally optimized graph partitioning model is employed for coreference chain formation using spectral partitioning which allows the incorporation of pronoun coreference information. The three techniques contribute to a significant improvement of 8.54% in B^3 F-score for event coreference resolution on OntoNotes 2.0 corpus.

1 Introduction

Coreference resolution, the task of resolving and linking different mentions of the same object/event in a text, is important for an intelligent text processing system. The resolved coreferent mentions form a coreference chain representing a particular object/event. Following the natural order in the texts, any two consecutive mentions in a coreference chain form an anaphoric pair with the latter mention referring back to the prior one. The latter mention is called the anaphor while the prior one is named as the antecedent.

Most of previous works on coreference resolution such as (Soon et al, 2001; Yang et al, 2006), aimed at object coreference which both the anaphor and its antecedent are mentions of the same real world object such as person, location and organization. In contrast, an event coreference as defined in (Asher, 1993) is an anaphoric reference to an event, fact, and proposition which is representative of eventuality and abstract entities. In the following example:

*"Israel has **[fired]** missiles on the offices of the Palestinian Authority.*
***[It]** has caused 7 deaths with many injuries…*
*Israel helicopter gunships **[fired]** across the Gaza Strip for more than two hours.*
***[The attack]** in Gaza has been said to cause more violence in Gaza and West Bank and terminate the current round of mid-East peace talk in an unexpected way."*

The four mentions here, ***[fired]***, ***[it], [fired]*** and ***[the attack]*** are referring to the same event (an Israel attack in Gaza Strip on Palestinian Authority). The pronouns noun phrases and action verbs are taken as the representation of events which is also in line with OntoNotes 2.0 practices.

Event coreference resolution is an important task in natural language processing (NLP) research. According to our corpus study, 68.05% of articles in OntoNotes 2.0 corpus contain at least one event chain while 15.52% of all coreference chains are event chains. In addition to the significant proportion, event coreference resolution allows event extraction system to acquire necessary details. Considering the previous example, resolving the event chain ***[fired]-[it]-[fired]-[the attack]*** will provide us all necessary details about the "*air strike*" event mentioned in different sentences. Such details includes "Israel/Israel helicopter gunships" as the actuator, "offices of Palestinian Authority" as the target, "7 deaths and many injuries" as the consequence, "Gaza Strip" as the location and "more than two hours" as the duration. Without a successful event coreference resolution such separated pieces of information cannot be assembled properly.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 102–110,
Chiang Mai, Thailand, November 8 – 13, 2011.

On the other hand, event coreference resolution incurs more difficulties comparing to the traditional object coreference from two aspects. In a semantic view, an object (such as a person, location and etc.) is uniquely defined by its name (e.g. Barrack Obama) while an event requires its role[1] information to distinguish it from other events. For example, "the crash yesterday" – "crash in 1968" shares the same event head phrase "crash", but they are distinguished by the time arguments. In a syntactic view, object coreferences only involve mentions from noun category while event coreference involves mentions from different categories. The syntactic differences will cause the tradition coreference features crippled or malfunctioned as reported by (Chen et al, 2010a;b) for Verb-Pronoun/Verb-NP resolution. In addition to their findings, we further find that even the event NP-Pronoun/NP-NP resolution requires more sophisticated feature engineering than the traditional ones. For example, previous semantic compatibility features only focus on measuring the compatibility between object such as "person", "location" and etc. Event cases are generally falls in the "other" category which provides us no useful information in distinguishing different events. These extra syntactic and semantic difficulties make event coreference resolution a more complicated task comparing to object coreferences.

In this paper, we address the various different event coreference phenomena with seven distinct mention-pair resolvers designed with sophisticated features. We then propose three enhancements to boost up performance at both mention pair detection and chain formation level. First, for the mention-pair resolvers, we have proposed the technique to utilize competitive classifiers' results to further boost mention-pair resolvers' performances. Second, a revised instance selection strategy is proposed to avoid mention-pair resolvers from being misguided by locally preferred instances used previously. Last, on top of coreferent pairs identified by the mention-pair resolvers, we have incorporated the spectral partitioning approach to form the coreference chains in a globally optimized way. Especially, we proposed a technique to enhance the chain level performance by incorporating the pronoun information which the previous attempts did not utilized.

The rest of this paper will be organized in the following way. The next section (section 2) will introduce related works. A review on coreference resolution framework and its weaknesses is presented in section 3. After that we will move on to our proposed model to overcome the weaknesses in section 4. Section 5 will present the experiment results with discussions. Last section will wrap up with a conclusion and future research directions.

2 Previous Work

Although event coreference resolution is an important task, it has not attracted much attention. There is only a limited number of previous works related to this task.

In (Asher, 1993) chapter 6, a method to resolve references to abstract entities using discourse representation theory is discussed. However, no computational system was proposed.

Besides linguistic studies, there are only a few previous works attempting to tackle sub-problems of the event coreference resolution. (Byron, 2002; Müller, 2007; Chen et al, 2010a) attempted event pronoun resolution. (Chen et al, 2010b) attempted resolving noun phrases to verb mentions. All these works only focused on identifying pairs of coreferent event mentions in their targeted phenomena. The ultimate goal, which is extracting event chain, is lack of attention.

(Pradhan, et al, 2007) applied a conventional co-reference resolution system to OntoNotes1.0 corpus using the same set of features for object coreference resolution. However, there is no specific performance reported on event coreference. As (Chen et al, 2010b) pointed out, the conventional features do not function properly on event coreference problem. Thus, a thorough investigation on event coreference phenomena is required for a better understanding of the problem.

3 Resolution Framework

Before we introduce our proposed system to event coreference, we would like to revisit the two-step resolution framework to understand some of its weaknesses. Most of previous coreference resolution system employs a two-steps approach as in (Soon et al, 2001; Nicolae & Nicolae, 2006) and many others. The first step identifies all the pairs of coreferent mentions. The second step forms coreference chains using the coreferent pairs identified from the first step.

[1] Event roles refer to the arguments of the event such as actuator, patient, time, location and etc.

Although a handful of single-step frameworks were proposed recently such as (Cai & Strube, 2010), two-step framework is still widely in use because it has been well-studied. Conceptually, the two-step framework adopts a divide-and-conquer strategy which in turn, allows us to focus on different sub-problems at different stages. The mention-pair detection step allows us to employ many features associated with strong linguistic intuitions which have been proven useful in the previous linguistic study. The chain formation step allows us to leverage on efficient and robust graph partitioning algorithms such spectral partitioning used in this paper. Practically, the two-step framework is also more mature for practical uses and has been implemented as a number of standard coreference resolution toolkits widely available such as RECONCILE in (Stoyanov et al, 2010) and BART in (Versley et al, 2008). Performance-wise, two-step approaches also show comparable performance to single step approaches on some benchmark datasets[2].

In this paper, we are exploiting a brand new type of coreference phenomenon with merely previous attempts. Therefore, we employed the much matured two-step framework with innovative extensions to accommodate complicated event coreference phenomena. Such a divide-and-conquer strategy will provide us more insight for further advancements as well.

3.1 Mention-Pair Resolution Models

Most of mention-pair models adopt the well-known machine learning framework for object coreference as proposed in (Soon et al, 2001).

Instances Generation

In this learning framework, a training/testing instance has the form of $fv(cand_i, ana)$, where *ana* is the anaphor and $cand_i$ is the i^{th} candidate of the given anaphor. During training, we employed the widely used instance selection strategy described in (Ng & Cardie, 2002). In brief, only the closest antecedent of a given anaphor is used as positive instance while only candidates in between the anaphor and its closest antecedent are used as negative instances. During testing, an instance is generated in a similar manner with an additional constraint that the candidate must be within n sentences from the anaphor.

An obvious weakness of such an instance selection strategy is the representation power of the selected instances. Ideally, the selected instances should represent the coreferent status between any two mentions. However this strategy turns the selected set into a local preference representation. The positive instance is the closest preferred mention while the negatives are local non-preferable ones. Such an instance set may help in locally choosing a preferable candidate. But it may be harmful if we want to use the classifier's results in a global approach such as graph partitioning. In the section 4, we will propose a revised instance selection strategy to overcome such a weakness.

SVM with Tree-Kernel

In such a learning framework, many well-known learning models can be applied to the coreference resolution task. In this paper, support vector machine (SVM) is employed for its robust performance in high dimensional space.

In addition to the traditional SVM, we incorporate the syntactic structures through a convolution tree kernel. Tree kernel is used to capture the implicitly structural knowledge embedded in the syntax tree. Effectiveness of various structures was investigated in (Yang et al, 2006; Chen et al, 2010a;b). Based on their findings, we choose minimum-expansion for this paper. In brief, it contains only the path in the parse tree connecting an anaphor and its antecedent. The convolution tree kernel and traditional flat kernel are combined to form a composite kernel.

3.2 Coreference Chain Formation

After the coreferent mention pairs are identified, coreference chains are formed based on those coreferent pairs. There are two major ways to form coreference chains in the literature, best-link heuristic and graph partitioning.

Best-Link Heuristics Approach

The best-link heuristic selects the candidate with highest confidence for each anaphor and forms a "best-link" between them. After that, it simply joins all the mentions connected by "best-links" into the same coreference chain. The best-link heuristic approach is widely used as in (Soon et al, 2001; Yang et al, 2006) because of its simplicity and reasonably good performance.

[2] (Stoyanov et al, 2010) reported RECONCILE(two-steps) achieving 74.25% B^3 f-score on ACE 2005. (Haghighi & Klein, 2010) using single-step approach reported 75.10% B^3 f-score on the same dataset with same train/test-splitting. According to our experiences, such a 0.95% difference is not statistically significant. Other single-step works as (Rahman & Ng, 2009) and (Poon & Domingo, 2008) reported clearly lower B^3 f-score than RECONCILE using same datasets but different train/test-splitting.

The major critics of best-link heuristic fall on its lack of global consideration when forming the coreference chains. The mentions are only joined through locally selected "best-links". Thus the chain consistency is not enforced. Remedies to such a critic are proposed such as best-cut in the next subsection and our proposed method.

Graph Partitioning Approach

Graph partitioning approaches are proposed by various researchers to form coreference chains with global consideration. Here we take Best-Cut proposed in (Nicolae & Nicolae, 2006) as a representative of graph partitioning approaches. Best-Cut is a variant from the well-known minimum-cut algorithm. A graph is formed using all the mentions as vertices. An edge is added between two mentions if a positive output from the mention-pair model. Then the set of edges are iteratively cut to form the coreference chains.

According to (Nicolae & Nicolae, 2006), best-cut does not utilize coreferent pairs involving pronouns. However, event coreference chains contain a significant proportion of pronouns (18.8% of event coreference mentions in the OntoNotes2.0 corpus). Leaving them untouched is obviously not a preferable choice. In the next section, we will propose an alternative chain formation method to incorporate coreferent pronouns into the graph partitioning to accommodate its intensive occurrences in event chains.

4 Our Proposed Model

Our proposed resolution framework follows a similar system flow as the two-step framework which is illustrated in figure 1 for an overview of our resolution system. A brief discussion on various types of event coreference is given in the first subsection 4.1. Each type corresponds to a distinct mention-pair resolver. New features are proposed to capture 3 newly encountered phenomena. After that, we proposed two techniques to improve the mention-pair performance, namely a revised instance selection strategy and utilizing competing classifiers' results. At chain formation step, we also proposed the alternative method, spectral graph partitioning to utilizing pronoun coreferent information.

4.1 Seven Distinct Mention-Pair Models

As we mentioned, one major difficulty of event coreference lies in the gap between different syntactic types of mentions (e.g. nouns, verbs and pronouns). As discussed in (Chen et al, 2010a;b), different syntactic types of coreferent mentions behave differently which requires different features to resolve them. Following this insight, we have built five distinct resolution models for event coreferences involving noun phrases (NP), pronouns and verbs. They are Verb-Pronoun, Verb-NP, Verb-Verb, NP-NP and NP-Pronoun

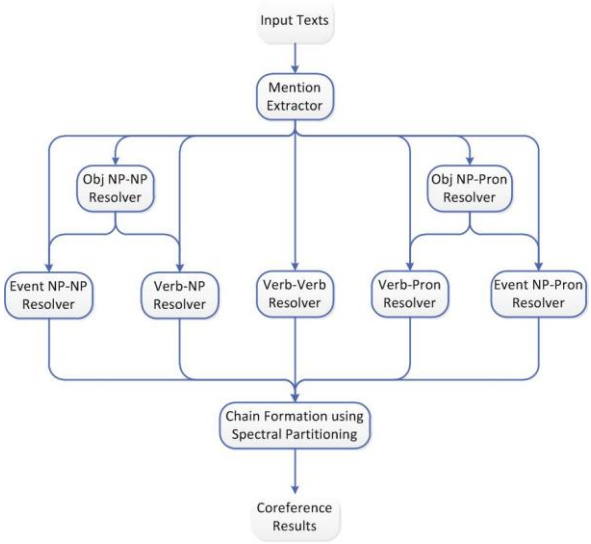

Figure 1: System Overview

resolver. Conventionally, pronouns can only appear as anaphor but not antecedent. Therefore we do not train Pronoun-Pronoun resolvers.

In addition to the syntactic difference, we find event NPs have different behaviors from the object NPs. Event NPs require the event roles to distinguish it from other events while the object NPs are quite self-explaining. The conventional features such as string-matching and head-matching will not work properly when handling cases like "confliction in Mid-East" vs. "confliction in Afghanistan". In our approach, a sophisticated argument matching feature is proposed to capture such information. The arguments information is extracted automatically from the premodifiers and propositional phrase attachments.

Similarly, conventional features try to match mentions into semantic categories like person, location and etc. Then it evaluates the semantic-matching features to pair-up mentions from the same semantic type. However, event NPs exhibit a very different hierarchy in WordNet from the object NPs. A dedicated event hierarchy matching feature is proposed to match event of the same type. With respect to the differences between object NPs and Event NPs, we train two distinct models to handle object NP-NP and event NP-NP resolution separately with distinct features. Similarly, we train separate resolvers

with distinct features for event/object NP-Pronoun. In total we have seven distinct mention-pair resolvers for different syntactic and semantic types of mentions. Five of them focus on event coreference while the other two aim at object coreference. Object coreference results are used to enhance event coreference performance by rule out in appropriate anaphors. All the features we incorporated are tabulated below.

Features	Detail	Used In
Distance	Sentence Distance, Word Distance, Phrase Distance and etc.	All
String-Matching	Full-Match, Partial-Match, Head-Match, Contained-In, Similarity Measures and etc.	eNN oNN VV
Argument-Matching	Event arguments from pre-modifiers and PP-attachments	VN VV eNN
Contexts-Matching	Non-stop-words near the anaphor and antecedent	eNN VN
NP Type	Definite / Indefinite / Proper Name	oNN eNN VN NP
Verb Type	Predicative / Model / Passive / Common	VN VP VV
Pronoun Type	Possessive/Reflexive/Common	oNP VP NP
NE-Semantic	Named entity semantic type	oNN
WN-Event-Semantic	WordNet semantic types of event	eNN eNP
WN-Object-Semantic	WordNet semantic types of object	oNN oNP
Grammatical Roles	Subject/Object in main/sub clauses	All
Synonymic Relation	If anaphor and antecedent share synonym list	eNN VV VN
Morphological Relation	If anaphor and antecedent are morphological	VN
Structural Information	Minimum-Expansion	Except o/eNN

Table 1: Feature List (e:Event; o:object; N:NP; P:Pronoun; V:Verb)

Besides the new features we proposed above (e.g. Event-Semantic and Argument-Matching), the other features we used in the seven mention pair resolvers are employed from a number of previous works such as (Soon et al, 2001; Yang et al, 2008) for object coreference feature, (Chen et al, 2010a;b) for features involving verbs.

Utilizing Competing Classifiers' Results

For the same mention, different mention-pair resolvers will resolve it to different antecedents. Some of these resolution results contradict each other. In the following example:

"USA Today reports ***{some evidence}*** *that has been uncovered shows Bin Laden financed* ***[the attack]*** *and assigned one of his top assistants to supervise* ***[it]****."*

For the anaphor ***[it]***, event NP-Pronoun resolver may pick ***[the attack]*** as antecedent while object NP-Pronoun resolver may pick ***{some evidence}*** as antecedent. Instead of choosing one as the final resolution result from these contradicting outputs, we feed the object resolver results into the event resolvers as a feature and re-train the event resolvers. The idea behind is to provide the learning models with a confidence on how likely the anaphor refers to an object.

Revised Training Instances Selection Strategy

As we mentioned previously, the traditional training instance selection strategy as in (Ng & Cardie, 2002) has a significant weakness. The original purpose of mention pair resolvers is to identify any two coreferent mentions (not restricted to the closest one). By using the previous training instance selection strategy, the selected training instances actually represent a sample space of locally closest preferable mention vs. locally non-preferable mentions. In most of previous works, it shows a reasonably good performance when using with "best-link" chain formation technique. Our investigation shows it actually misguided the graph partitioning methods. Therefore, we propose a revised training instance selection strategy which reflects the true sample space of the original coreferent/non-coreferent status between mentions. In brief, our revised strategy exhaustively selects all the coreferent mention-pairs as positive instances and non-coreferent pairs as negative instances regardless of their closeness to the anaphor. Considering the following example,

"…linking ***{Saudi terrorist Osama Bin Laden}*** *to* ***[the bombing]****.* ***{USA Today}*** *reports* ***{some evidence}*** *that has been uncovered shows* ***{Bin Laden}*** *financed* ***[the attack]*** *and assigned one of his* ***{top assistants}*** *to supervise* ***[it]****."*

The traditional instance selection scheme will only select ***[the attack]–[it]*** as positive instance and ***{top assistants}–[it]*** as negative instance. Our revised instance selection scheme will select an additional positive instance ***[the bombing]–[it]*** and additional negative instance as ***{Bin Laden}–[it]***, ***{USA Today}–[it]*** and other curly brackets NP mentions. Thus the full sample

space is represented using our training instances selection strategy.

4.2 Spectral Graph Partitioning

After deriving the potential coreferent mention pairs, we further use spectral graph partitioning as described in (Ng et al, 2002) to form the globally optimized coreference chains. As we mentioned previously, traditional chain formation technique suffers from a local decision (as in best-link approaches) or failure to incorporate pronoun information (as in best-cut approaches). Spectral graph partitioning shows its advantages over previous approaches. Spectral graph partitioning (aka. Spectral clustering) has made its success in a number of fields such as image segmentation in (Shi & Malik, 2000) and gene expression clustering in (Shamir & Sharan, 2002).

Compared to the "traditional algorithms" such as k-means or minimum-cut, spectral clustering has many fundamental advantages. Results obtained by spectral clustering often outperform the traditional approaches, spectral clustering is very simple to implement and can be solved efficiently by standard linear algebra methods. More attractively, according to (Luxburg, 2006), spectral clustering does not intrinsically suffer from local optima problem. In this paper, the similarity graph is formed in similar way as in (Nicolae & Nicolae, 2006) using SVM confidence[3] outputs.

Utilizing Pronoun Information

Besides the simplicity and efficiency of spectral graph partitioning, one particular reason to employ spectral partitioning is that the previous best-cut approach failed to incorporate pronoun information in their similarity graph. It may not be an issue in object coreference scenario as pronouns are only a relatively small proportion (9.78% of object mentions in OntoNotes). However, in event cases, pronouns contribute 18.8% of the event mentions. As we further demonstrated in our corpus study, event chains are relatively more sparse and shorter than object chains. Removing pronouns from the similarity graph will break a significant proportion of the event chains. Thus we propose this spectral graph partitioning approach to overcome this weakness from the previous models.

Instead of re-implementing the minimum-cut algorithm, we apply the spectral partitioning to a similarity graph without pronoun information. This setting is based on two considerations. Firstly, spectral partitioning is theoretically equivalent to minimum-cut partitioning which means they can handle the same problem set. Secondly, by using the same model, we can eliminate any empirical difference in these two partitioning algorithms and show the true contribution from incorporating pronoun information.

[3] Confidence is computed from kernel outputs using sigmoid function.

5 Experiment Settings and Results

In this section, we present various sets of experiment results to verify the effectiveness of our proposed methods individually and collectively.

5.1 Corpus Study

The corpus we used is OntoNotes2.0 which contains 300K of English news wire data from Wall Street Journal and 200K of English broadcasting news from various sources including (ABC, CNN and etc.). OntoNotes2.0 provides gold annotation for parsing, named entity, and coreference. The distribution of event coreference is tabulated below.

	# of Articles	# of Chains	# of Mentions
Event	1033	2693	7314
Object	1511	14655	54753
Total	1518	17348	62067

Table 2: Event Coreference Distribution in OntoNotes2.0

The distribution of event chains is quite sparse. In average, an article contains only 2.6 event chains comparing to 9.7 object chains. Furthermore, event chains are generally shorter than object chains. Each event chain contains 2.72 mentions comparing to 3.74 in the object chains.

5.2 Performance Metrics & Experiment Settings

In this work, we employ two performance metrics for evaluation purposes. At mention-pair level, we used the standard pair-wise precision/recall/f-score to evaluate the seven mention-pair resolvers. At coreference chain level, we use B-Cube (B^3) measure as proposed in (Bagga & Baldwin, 1998). B^3 provides an overall evaluation of coreference chains instead of coreferent links. Thus it is widely used in previous works.

For each experiment conducted, we use the following data splitting. 400 articles are reserved to train the object NP-Pronoun and NP-NP resolvers. (400 news articles are sufficient for object coreference training, comparing with other data sets used for both training and testing such as 519 articles in ACE-02, 60 articles in MUC-6 and 50 articles in MUC-7.) Among the remaining 1118 articles, we random selected 894 (80%) for

training the 5 event resolvers while the other 224 articles are used for testing.

In order to separate the propagated errors from preprocessing procedures such as parsing and NE tagging, we used OntoNotes 2.0 gold annotation for Parsing and Named Entities only. Coreferent mentions are generated by our system instead of using the gold annotations.

In order to test the significance in performance differences, we perform paired t-test at 5% level of significance. We conduct the experiments 20 times through a random sampling method to perform meaningful statistical significance test.

5.3 Experiment Results

In this section, we will present the experiment results to verify each of the improvements we proposed in previous sections.

Mention-Pair Models Performances

The first set of experiment results presented here is the seven mention-pair resolvers using all conventional settings without any proposed methods.

The Verb-Verb resolver performance is particularly low due to lack of training instances where only 48 positive instances available from the corpus. Our Mention-pair models are not directly comparable with (Chen et al, 2010a;b) which used gold annotation for object coreference information while we resolve such coreferent pairs using our trained resolvers. There are also a number of differences in the preprocessing stage which makes the direct comparison impractical.

Mention-Pair Score	Precision	Recall	F-Score
Event Resolvers			
Verb-Pronoun	32.34	68.32	43.90
Verb-NP	54.22	68.56	60.55
Verb-Verb	22.47	83.33	35.40
NP-Pronoun	46.62	70.47	56.12
NP-NP	48.83	60.08	53.88
Object Resolvers			
NP-NP	58.89	66.04	62.26
NP-Pronoun	61.37	84.33	71.04
Event Chain B^3	**Precision**	**Recall**	**F-Score**
BL	26.67	68.09	38.33

Table 3: Mention-Pair Performance in %

The coreference chains formed using spectral partitioning without any proposed improvements yields a B^3 f-score of 38.33% which serves as our initial baseline (BL) for further comparisons.

Utilizing Competing Classifiers' Results

Since object resolver results are in general better than event resolver, we propose to utilize competing object classifiers' results to improve event resolvers' performance. The experiment results are tabulated below. The "BL+CC" row presents the performance when utilized competing classifiers' results into the baseline system.

Mention-Pair	Precision	Recall	F-Score
Event Verb-Pronoun Resolver			
w/o object info	32.34	68.32	43.90
with object info	45.09	64.73	53.00
Event Verb-NP Resolver			
w/o object info	54.22	68.56	60.55
with object info	56.67	67.61	61.66
Event NP-Pronoun Resolver			
w/o object info	46.62	70.47	56.12
with object info	57.83	69.15	62.99
Event NP-NP Resolver			
w/o object info	48.83	60.08	53.88
with object info	51.35	59.20	55.00
Event Chain B^3	**Precision**	**Recall**	**F-Score**
BL	26.67	68.09	38.33
BL + CC	32.33	67.08	43.61

Table 4: Performance in % using competing classifiers' results

By incorporating the object coreference information, we manage to improve the event coreference resolution significantly, more than 9% F-score for Verb-Pronoun resolver and about 7% F-score for event NP-Pronoun resolver. Object coreference information improves pronoun resolution more than NP resolution. This is mainly because pronouns contain much less information than NP. Such additional information will helps greatly in preventing object pronouns to be resolved by event resolvers mistakenly. Although object coreference is incorporated at mention-pair level, we still measures its contribution to B^3 score at chain level. It improves the B^3 f-score from 38.33% to 43.61% which is a 5.28% improvement. This observation also shows the importance of collective decision of multiple classifiers.

Revised Instance Selection

The second technique we proposed is a revised training instances selection strategy. Table 5 shows improvement using revised instance selection strategy. We refer the traditional instance selection strategy as "BL+CC" and our proposed instance selection strategy as "BL+CC+RIS" (Revised Instance Selection). At mention-pair level we take event NP-Pronoun resolver for demonstration. Similar behaviors are observed in all the mention-pair models. In order to demonstrate power of revised instance selection scheme, we evaluate the mention-pair results in two different ways. The best-candidate evaluation follows the traditional mention pair evaluation. It firstly groups mention-pair predictions by

anaphor. Then an anaphor is correctly resolved as long as the candidate-anaphora pair with highest resolver's score is the true antecedent-anaphor pair. The correct/wrong of other candidates' resolution outputs are not counted at all. The coreferent link evaluation counts each candidate-anaphor pair resolution separately. Intuitively, best-candidate evaluation measures how good a resolver can rank the candidates while the coreferent link evaluation measures the how good a resolver identifies coreferent pairs.

An interesting phenomenon here is the performance evaluation using the best candidate actually drops 3.26% in f-measure when employing the revised instance selection scheme. But when we look at the coreferent link results, the revised instance selection scheme improves the performance by 2.84% f-measure. As a result, our revised instance selection scheme trains better classifier with higher coreferent link prediction results. Since this coreferent link information is further used in the final chain formation step. Our revised scheme contributes an improvement on the final event chain formation by 2.02% F-Score in B^3 measure.

Mention-Pair Score	**Precision**	**Recall**	**F-Score**
Event NP-Pronoun using **Best Candidate** Evaluation			
BL+CC	57.83	69.15	62.99
BL+CC+RIS	52.05	67.11	58.63
Event NP-Pronoun using **Coreferent Link** Evaluation			
BL+CC	39.96	64.03	49.21
BL+CC+RIS	43.33	65.47	52.15
Event Chain B^3	**Precision**	**Recall**	**F-Score**
BL+CC	32.33	67.08	43.61
BL+CC+RIS	35.21	64.74	45.63[4]

Table 5: Performance in % using revised instance selection

This observation shows that the traditional mention-pair model should be revised to maximize the coreferent link performance instead of the traditional best-candidate performance. Because the coreferent link performance is more influential to the final chain formation process using graph partitioning approach.

Spectral Partitioning Utilizing Pronoun Information

The third improvement we proposed is the spectral partitioning with pronoun information. The performance improvement is demonstrated in table 6. In order to separate the contribution from incorporating pronouns and revising instance selection, we conducted the experiment using traditional training instance selection.

B^3 Performance	**Precision**	**Recall**	**F-Score**
BL	26.67	68.09	38.33
BL+CC	32.33	67.08	43.61
BL+CC+Pron	34.14	69.65	45.82[5]
BL+CC+RIS+Pron	35.27	70.02	46.91

Table 6: Performance in % using pronoun information

By incorporating the coreferent pronoun information, the performance is significantly improved by 2.19% in f-measure. By further incorporating the revised instance selection scheme, we achieve B^3-Precision/Recall/F-Score as 35.27 / 70.02 / 46.91% respectively which is an 8.54% F-score improvement from the initial resolution system. 46.91% F-score is the highest performance we achieved in this event coreference resolution work.

6 Conclusion and Future Works

This paper presents a unified event coreference resolution system by integrating multiple mention-pair classifiers including 3 new mention-pair resolvers. Furthermore, we proposed three techniques to enhance the resolution performance. First, we utilize the competing classifiers' results to enhance mention-pair model. Then we propose the revised training instance selection scheme to provide better coreferent link information to graph partitioning model. Lastly, we employ spectral partitioning method with pronoun information to improve chain formation performance. All the three techniques contribute to a significant improvement of 8.54% over the initial 38.33% in B^3 F-score. In future, we plan to incorporate more semantic knowledge for mention-pair models such as semantic roles and word senses. For chain formation, we plan to incorporate domain knowledge to enforce chain consistency.

[4] The B^3-F-Score difference between RIS and Baseline is statistically significant using paired t-test at 5% level of significance

[5] The B^3-F-Score difference between Baseline and Baseline+Pronoun is statistically significant using paired t-test at 5% level of significance

Handling verb phrase morphology in highly inflected Indian languages for Machine Translation

Abstract

The phrase based systems for machine translation are limited by the phrases that they see during the training. For highly inflected languages, it is uncommon to see all the forms of a word in the parallel corpora used during training. This problem is amplified for verbs in highly inflected languages where the correct form of the word depends on factors like gender, number and tense aspect. We propose a solution to augment the phrase table with all possible forms of a verb for improving the overall accuracy of the MT system. Our system makes use of simple stemmers and easily available monolingual data to generate new phrase table entries that cover the different variations seen for a verb. We report significant gains in BLEU for English to Hindi translation.

1 Introduction

Data driven approaches have become widely popular as they use little or no language specific knowledge. The main drawback of these approaches is the need for large amounts of data. (Koehn et al., 2003) have shown that the quality of the translations produced by data driven approaches mainly depends on the amount of parallel data available for the language-pair under consideration. Creation of a large bilingual corpus is expensive and time consuming if high quality manual translations are required. Hence, building MT systems for language-pairs with limited amounts of data is a big challenge.

Approaches have been suggested in the past to mine the world-wide-web to automatically obtain large amounts of parallel data. For example, news articles in two different languages describing the same event can be sentence-aligned to obtain a parallel corpus. Although this approach has shown improvements, this cannot be extended to languages that have little or no data on the world wide web.

The situation gets worse for languages that are rich in morphology. Clearly large amounts of parallel data are required to observe all variations of a word. Popovic and Ney (2004) applied transformations to verbs to reduce the number of out-of-vocabulary words and showed improvements in translation quality when morphemes were considered.

Yang and Kirchhoff (2006) used a back off model in a Phrase-based SMT system which translated word forms in the source language by hierarchical morphological abstractions. Unknown words in the test data were stemmed and phrase-table entries were modified such that words sharing the same root were replaced by their stems. Freeman et al. (2006) and Habash (2008) find in-vocabulary words for OOV words that could be morphological variants of the OOV words. Phrases in the phrase table containing these invocabulary words are then replaced by OOV words to create new entries. Vilar et al. (2007) used a letter-based MT system that treated the source and target sentences as a string of letters for translating unknown words.

All the above approaches handled OOV issues that arise when the source language is morphologically rich. Generation of the target sentence when the target language is morphologically rich from a source language that is not rich in morphology is non-trivial as the source language does not contain all the information for inflecting the target words. Minkov et. al (2007) predicted inflected forms of a sequence of word stems on languages that are morphologically rich using syntactic and rich morphological sources. This inflection generation model was then applied in MT by (Toutanova et al., 2008) while translating English into morphologically complex languages and showed improve-

Chiang Mai, Thailand, November 8 – 13, 2011.

ment in translation quality. Their methods require a syntactic analyzer and a very rich morphological analyzer which may not be available for many rare or low-density languages. Also, their feature set includes bilingual features that require expensive and difficult to get bilingual corpora. We rely more on monolingual data and a small amount of parallel data. In cases of multi word compound words (explained in section 1.1) , since inflections on the light verb might change with change in the root verb compounding with it, we need to predict these verbs together and not as separate words.

In this paper, we consider Indian languages which are considered as low density languages as they do not have rich knowledge sources such as parsers or complex morphological analyzers. These languages also suffer from data sparsity and hence form ideal languages for the analysis of our proposed method. We also consider only various forms of verbs and do not consider other words such as noun phrases and adjectives affected by inflections.

1.1 Background on Indian Languages

India has fifteen official languages which originated from the Indo-Iranian branch of the Indo-European language family, the non-Indo-European Dravidian family, Austro-Asiatic, Tai-Kadai and the Sino-Tibetan language families (Microsoft Encarta Online Encyclopedia, 1997). The languages that stem from the Dravidian family, are - Tamil, Kannada, Malayalam and Telugu, spoken in the South Indian states. Languages in North India, such as Hindi, Urdu, Punjabi, Gujarati, Bengali, Marathi, Kashmir, Sindhi, Konkani, Rajasthani, Assamese and Oriya, stem from Sanskrit and Pali.

Indian languages are verb final i.e., verbs are placed at the end of the sentences. Verbs in these languages are inflected to contain information about gender (masculine and feminine), tense, aspect and number of the subject (singular or plural). A few examples showing inflections on the verbs in Hindi are shown below:

वो(he) साफ कर रहा (cleaning) हैं (is)
[vo saapha kara rahaa hai.n]
वो(she) साफ कर रही (cleaning) हैं (is)
[vo saapha kara rahI hai.n]
वो (she) साफ (clean) करेगी (will)
[vo saapha karegI]

These languages also contain compound verbs (multi-word compound representing a single verb). They contain a light verb which receives inflections and another component that can be a noun or a verb responsible for conveying the meaning. For example, in Hindi, most commonly used light verbs are “karna” (to make), “lena” (to take), “hona” (to happen) and “dena” (to give).

2 Motivation

When translating from a morphologically poor language such as English to any of the Indian languages, finding the right translation along with the inflections on the verbs becomes difficult, especially when the amount of bilingual data available is scarce. We try to use the pattern behavior of verbs to tackle this problem. Table 1 gives an example of hindi verbs classified according to their light verbs. Hindi side is transliterated for the sake of clarity. It shows how the verb phrase of one compound verb (clean) can generate verb phrase for words in the same group (help and forgive) just by replacing the corresponding source and target root words. The suffixes (shown in bold) are separated from the word to show how the actual process takes place. This paper tries to automatically group the different kinds of verbs occurring in the language based on their light verbs and generates the variation for all the verbs in one group by looking at the variations of any one member.

Karna	Lena	Dena
saaph (clean)	sokh (absorb)	saaza (punish)
maaph (forgive)	bhaag (participate)	jawab (answer)
madad (help)	goad (adopt)	anumati (allow)

he will be *clean* **ing** -> vo *saaph* kar **egaa**
he will be *forgive* **ing** -> vo *maaph* kar **egaa**
he will be *help* **ing** -> vo *madad* kar **egaa**

Table 1: Example of verbs belonging to different groups based on their light verb

The novel concept of this paper is generation of verb phrases on the source side and their translations using a) source and target monolingual data, b) simple morphological segmentation on source and target side and c) Small amount of manual translations or d) Word alignments of parallel corpora. We have described two methods of generating these verb phrase translations in the following sections.

3 Manual Generation

The idea here is to get the manual translations of source and target verb pairs which could capture the entire range of variations seen in the source and the target verb phrases. These translations can then be used to generate the variations for rest of the verb pairs. The entire flow of the method is shown in Figure 1.

3.1 Verb Phrase Chunking

Given a language pair (e,f), we extract all verb phrases that occur in the source monolingual data using a verb phrase chunker. Part of speech (POS) tags can be used to extract verb phrases for languages having a good POS tagger. In our experiments for English-Hindi language pair, POS tags were used for English verb phrase chunking. Modals in English were included as a part of the verb phrase since their counterparts in Hindi appear as verbs. For Hindi, the verb phrase chunker was trained on a small set of 6000 sentences, where the reference markings were obtained by projecting the verb phrases from English. The 6000 sentences were hand aligned with the corresponding English sentences, hence helping with the accuracy of the projected verb phrases. On this data, we built a CRF based chunker (Lafferty et al., 2001) using word and POS tag features.

3.2 Verb Classing

Using a segmenter, the root verb is separated from its inflected suffix for all the extracted verb phrases. These extracted verb phrases are then clustered based on the root verb so that all the variations of a root verb '<verb>' are grouped together into one cluster. As an example, a part of the verb cluster for 'play' is shown below. Note that all possible variations of each verb (both source and target side) are under one cluster.

play
was play +ing
should have play +ed
ought be played
would have been play +ed
is play +ed
cannot be play +ed
is being play +ed

The different variations within each verb cluster are normalized by replacing the root verb by a normalization tag '<verb>' so that similar root verb clusters now contain exactly the same variations and can be aggregated together easily. These clusters are put in N different 'verb classes' so that all verbs occurring with the same variations are under a single class and those with different variations are put in separate classes. For instance, since 'play' and 'help' have the same variations, they would belong to the same class. Choosing any one member of the class will cover all the variations of that class and by choosing one member from each of the N classes, all possible variations of all verbs in a given language are covered.

Class	Verb Class	**No of words**
AH	No Auxiliary	854
BH	'karna' as Auxiliary	1772
CH	'dena' as Auxiliary	212
DH	'lena' as Auxiliary	90
EH	'hona' as Auxiliary	242
	Rest	309

Table 2: Count of verbs belonging to different classes in Hindi

For English, we used morphA, (Minnen et al., 2000) an open source stemming package, to get the root form of the head verb in the extracted English verb phrases. It was observed that all the root verb clusters had the same variations of verb phrases and hence all belonged to the same class. Thus, from the source (English) side, only one verb could be picked up to cover all the variations, which could be then replicated for all the others verbs. We call that class 'AE'.

In Hindi, as explained in section 1.1, many verbs occur as compound verbs where a noun followed by a light verbs is considered as a verb and hence we also included these for our clustering and classification. The extracted verb phrases were segmented using a stemmer similar to one in (Ramanathan et al., 2003). After clustering the verb phrases based on their root verbs into groups and classing them based on the different variations, the main classes depended on the a) whether the verb has a light verb or not and b) the type of light verb attached. Table 2 shows the different classes found along with the number of verbs within each class.

There were more classes with a different auxiliary verb but we neglected them since the frequency of verbs in those classes was insignificant. 'lena' and 'dena' verb forms take the same vari-

ations (differing only in one character), we could easily generate one from another. Overall, only 3 classes were used for manual translation on the Hindi side(AH,BH and CH). Note that we allow a verb to belong to more than one class, suggesting that a word can be used in more than just one way depending on the context.

3.3 Root verb translation pairs

Given a parallel corpus, it is possible to extract source root verb to target root verb translation. Since a parallel corpus will contain the inflected form of a verb, it is necessary to stem them to their root form before calculating the word translation probabilities. Hence, given a parallel corpus, sentences are machine aligned by a maxent model as described in (Ittycheriah and Roukos, 2005) and then the verbs on both the source and target side are stemmed to the respective root forms using a suitable stemmer. Given the list of possible source verbs and target words from the previous clustering step, the forward and reverse translation probabilities for these verbs is calculated from the alignments using by relative frequency:

$$P(f_i/e_j) = count(f_i, e_j)/\sum_f count(f, e_j) \quad (1)$$

$$P(e_i/f_j) = count(e_i, f_j)/\sum_e count(e, f_j) \quad (2)$$

Using these forward and reverse probability, a mapping file that maps the source root verb to the corresponding target root verb(s) is created by empirically combining the two probabilities.

$$P_{tot}(e_i/f_j) = 0.5*P(e_i/f_j)+0.5*P(f_j/e_i) \quad (3)$$

We allow one source verb mapping to multiple target verb, since the meaning can change due to context in the test sentence. TopM translations of source word are selected for translations, provided $P_{tot} > P_{thresh}$. We empirically found the P_{thresh} = 0.2 and M=4 to work reasonably well. Two or more worded root verb, such as phrasal verbs 'take off', 'figure out', were not considered while creating the mapping since the meaning is often different that the individual words and the generation of verb phrases from these root verbs is more tricky. Such constructions, where one word verb may translate to multiple words, occurred for only 3% of the verbs in the test data and hence could be ignored without any significant loss in improvement.

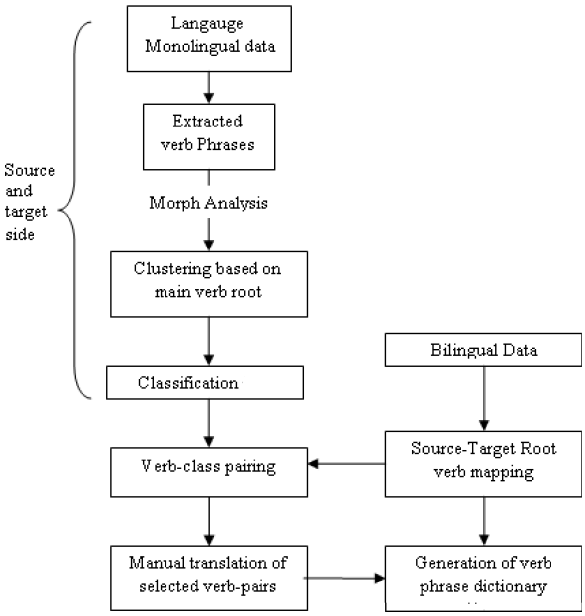

Figure 1: Steps involved in manual generation of verb phrases

3.4 Generation of Verb Phrase Dictionary

Given the root verb mapping and the classes to which these source and target root verb belong to, we create a 'source class' to 'target class' mapping, or a 'verb-pair class', by replacing the root verbs with their corresponding verb classes. This causes each of the verb pair to fall under some particular verb-pair class. If there are n classes in the source side and m on the target side, the maximum number of verb-pair classes are

N = m*n

By picking any one root verb pair from each of these verb-pair classes, we can cover all the possible variations of verb phrase translation pairs. These pairs can then be given for human translation, by creating all possible variations of either the source side or target side and asking humans to translate to the other.

Templates for each of the N verb-pair class are created from the manually translated data by segmenting the verb phrase pairs on both sides and replacing the root verb by the '<verb>' tag. An example of such translation pair for English-Hindi is shown

was <verb> +ing == <verb> raha tha [Class AH-AE]
was <verb> +ing == <verb> kar raha tha [Class BH-AE]

Picking root verb pairs from each verb-pair class and replacing the <verb< tag with corresponding verbs, these templates are used to create new verb phrases which may not be present in the parallel data to a large extent. A reverse morphological tool or joiner is used to recombine the segmented verb phrases and create a verb phrase dictionary.

In our paper, English had one class and Hindi had 3. Thus, only 3 Hindi-English verb pairs needed to be translated, one from each of the verb-pair classes AH-AE, BH-AE, and CH-AE. We created different variations of the English verbs, since it had only one class and could be easily generated using manually built rules. Grammar rules contain number (singular/plural), tense and aspect agreement between different auxiliary forms (for example: was, is, were, can, might, could not, wouldn't, etc) and verbs (for example: answer, punishing, cleaned, etc.). A unique Hindi-English verb pair is picked from each of the verb-pair classes obtained earlier and their English verbs are used in generating the English verb forms. For example, "saaf" belonged to the "karna" cluster, so its English translation, "clean" is used for creating verb forms. Gender information is also added to the Verb forms which will be required for the Hindi counterparts. About $\approx$ 970 verb forms were generated for each of the 3 verbs. Examples of a few Verb forms are given below:

[he] will clean
[we] will clean
[I(he)] will clean
[he] may not have been cleaning
[she] could have been cleaning
[we] may have been cleaning
[I(she)] may have cleaned

'Not' is included as a part of the extracted verb phrases since it is the most common adverb that occurs within the verb phrases. Other adverbs such as 'now', 'also' have not been dealt with in this paper. These variations, along with the mapping of the English-Hindi root verb was given to the annotators for translation. The subject information within '[]' helps the annotators to decide on the number and gender inflections on the target (Hindi) side. These are removed before using in the machine translation system. The reverse morphology of the generated verb phrases is done using MorphG (Minnen et al., 2000) for English and a simple suffix joiner for hindi.

4 Automatic generation

Although manual translation is a clean and effective way of generating these verb phrases, a human is still required in the loop to complete the setup. Instead, both side monolingual data can be employed to extract all the variations for each root verb, parallel corpus can be used to get the source-verb to root-verb pairs, and finally a model can be learnt to align the source verb phrase to target verb phrase using the verb alignments from the hand alignments and machine alignments.

4.1 Verb pairs

Using the technique described in section 3.3, a source to target root verb mapping are obtained.

4.2 Clustering

Clustering of verb phrases on source and target side is done as explained in section 3.2 so that each cluster contains different variations of the same root verb form. The phrases within each cluster are segmented on both sides using the techniques described section 3.2 and are generalized by replacing the root verb in the segmented verb phrase by a '<verb>' tag as this will help while aligning the source verb phrase to its corresponding target verb phrase.

4.3 Verb Phrase Translations

In order to learn a verb phrase alignment model, we need good quality verb phrase alignments from the parallel corpora. We concentrate on hand aligned data and accurate machine alignments. Machine aligned verb phrases that occurred less than three times were treated as inaccurate. The source side verb phrases are extracted using the scheme similar to one in section 3.1, and by looking at the target words they align to, verb phrase alignments are obtained. The aligned verb phrases are segmented on both the target and the source side using the strategy described in section 3.2 and then normalized by replacing the head word for both the source side verb phrase and the target side verb phrase by a '<verb>' tag. The '<verb>' tagged verb phrases act as templates for verb alignments. Since all the root forms of verb will not occur in the extracted verb alignments, it's necessary to normalize them to be able to learn a general model. This way, if the translation of a particular source verb phrase variation is known, its generalized form can be used to get the trans-

lation of a different root verb for the same variation. This is similar to our claim in section 3.4 that translation of one root verb can generate translations for all other verbs belonging to the same class.

A simple word alignment model is used to learn the word translation probabilities. Please note that the suffixes of the verbs are also treated as words since they contain important information about tense, gender and number. We used GIZA++ model 4 to learn P(V_{si}/V_{tj}), which is the probability of the i^{th} source word/segment aligning to the j^{th} target word/segment.

4.4 Automatic Alignment and Generation

From the root-verb pairs obtained in section 4.1, each verb pair is picked and the best translation for a source verb phrase in source-side verb cluster is searched for in the target verb cluster. If a cluster for the source or target verb does not exist, that pair is ignored. Both the source and the target verb clusters contain the generalized verb phrase of the form '... aux_{-1} <verb> aux_1 aux_2.. '. First, a perfect match of a source phrase and target verb phrase is searched in the hand aligned and machine aligned verb phrase pairs. If found, that phrase pair is treated as a valid verb phrase pair. If no perfect match is found, word alignment probabilities obtained in previous section are use to get the source to target verb phrase alignments. Any verb phrase alignment pair with score lower than a threshold score of 0.5 is ignored.

After obtaining all the valid verb phrase pairs, the tag <verb> is replaced by their corresponding root verbs and as in section 3.4 and the suffixes are joined to the root verb to get the automatically generated verb phrase dictionary which can be used in the MT system.

5 Experiments

In this section, we report our experimental results on English - Hindi language pair. We first report on the coverage ratio, which gives an estimate of number of exact verb phrases covered by the baseline system and our method. In addition, we also report on English to Hindi Machine translation results for phrase based systems.

5.1 Discovery of new data

The data used for clustering and classification on source and target side, the parallel corpora and the test set details are shown in table 3.

Data	No of Sentences
English Monolingual	6 million
Hindi Monolingual	1.4 million
Test set 1	4000
Test set 2	715
Training Data	280k

Table 3: Data used for experiments

The Hindi monolingual data was used to collect 4320 Hindi verb clusters belonging to 3 different classes (section 3.2) and the English monolingual yielded 4872 clusters. Many of these clusters were false positives due to the bad quality of verb phrase chunker but were eliminated in the subsequent steps. The parallel data was aligned using a maxent model (Ittycheriah and Roukos, 2005) and gave us 2944 verb-pairs.

For manual generation method, 3 verb pairs were given to annotators for translation, with about 972 different English verb forms in each. The generated dictionary from the manual translations had 2.7 million verb phrases. The automatic method aligned the corresponding clusters of the 2944 verb-pairs and produced about 300k new verb phrases. The considerably lesser size of the automatically created verb phrase dictionary compared to the manual dictionary can be attributed to the fact that the manual dictionary contains variations that are not seen in our monolingual data.

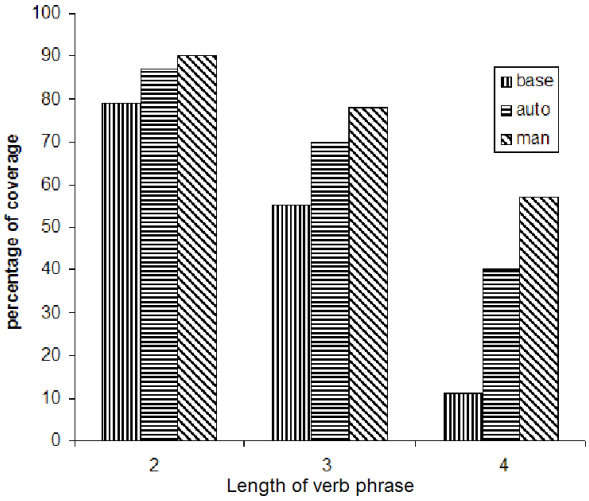

Figure 2: Coverage percentage for different settings

We claim that the manually and automatically

created verb phrase dictionaries add new data to the system and have a higher chance of finding a matching source verb phrase in a given corpus than our phrase based system. We verify this claim by extracting verb phrases from two test sets and searching for them in:

1. Baseline Phrase table
2. Base+Manual generated Dictionary
3. Base+Auto generated Dictionary

Figure 2 shows the ratio of the number of verbs phrases found in the three cases to the total number of verbs searched. We call this as coverage ratio. The verb phrases are divided based on their lengths. The plot clearly shows that the coverage increases considerably by the addition of these generated verb phrases which may or may not be seen in the training data, especially as the length of the verb phrase increases. Verb phrases of length 1 are not shown since the coverage was almost same for the 3 settings.

5.2 Machine translation Results

Table 3 shows the training data and the two test sets used for evaluation. The bilingual parallel data is split into training data and Test set 1. Test set 2 is a generic test set. All the data (training and test) used is predominately contains news. We report are results on BLEU (Papineni et al., 2002).

The verb phrase pairs were generated as explained in manual generation section and then added to the baseline system as a part of corpus(Base+manVPcorp). To emphasis on the improvement from generated verb phrases, an experiment where only the human translated verb phrases are added to the baseline corpus was also conducted(Base+humanVPcorp).

Table 4 shows the results on Moses - a state of the art phrase based system, and on a phrase based system (PBMT) similar to (Tillman et al., 2006) on test sets 1 and 2. Both systems were trained on 280k parallel sentences. On the in-domain data, we had an improvement of 4.8 BLEU points for Moses and 0.9 for PBMT. On the more generic test set, Moses gave a BLEU score improvement of 1.1 whereas the PBMT performance was comparable. One reason for this difference in the BLEU score jumps is the better alignments in the PBMT system, aligned by a maxent model as described in (Ittycheriah and Roukos, 2005). The PBMT system thus has a higher chances of having a good verb phrase in the baseline system than Moses and hence on adding generated verb phrases, we would see a lesser gain. Since the PBMT system had comparable results on the in-domain data with Moses and performed better on the out of domain (more generic) test set, the remaining experiments have been conducted with the PBMT system.

	Moses		**PBMT**	
	Set 1	Set2	Set 1	Set2
Baseline	13.5	08.6	13.4	**16.1**
Base+humanVPcorp	14.1	08.6	14.0	16.1
Base+manVPcorp	**18.3**	**9.7**	**14.3**	16.0

Table 4: BLEU score on test set 1 and 2 for different settings on moses and PBMT

Adding the generated phrases as a parallel corpus can alter the translation probabilities of individual words and sub-phrases. This is one of the reasons for no improvement in the bleu score of the PBMT system when the generated verb phrases are added as corpus. A better method would be to add the verb phrases directly to the phrase table. We added the manual dictionary to the PBMT system and the results are tabulated in table 5.

	Set 1	**Set2**
Baseline	13.4	16.1
Base+humanVP-PT	14.0	16.1
base+manVP-PT	**14.9**	**16.5**
base+autoVP-PT	14.8	16.3

Table 5: BLEU score for PBMT system after adding verb phrases directly to Phrase Table (PT)

Adding the verb phrases directly to the system keeps the rest of the phrases and their scores intact. Only phrases with matching source side phrase need to be re-normalized to adjust the translation probabilities. This would mean that the probability of only the verb phrases we add to the baseline phrase table would be affected while the rest of the translation model would be the same. Table 5 shows that addition of manually generated data to the phrase table(Base+manVP-PT), gives a good improvement of 1.5 points on the in-domain data and 0.4 on the out of domain data. A significant improvement of 1.4 BLEU points is seen even when the automatically generated verb phrases are added (Base+autoVP-PT), which was not seen when these were added as a corpus to the system.

Figure 3 shows the variation of BLEU score

with change in the corpus size. We should expect that the gain be higher in the case of low corpus size. However, note that the verb-pair list used to generate the verb phrases also changes with the change in corpus size, since decreasing the corpus size would decrease the quality of the overall alignments and the number of verbs seen. Thus, while the verb-pair list using 160k sentences had a total of 2499 verb pairs, the 20k corpus produced only 1347 verb pairs. So, for a smaller corpus size, the number of new verb phrases added to the table would also be lesser. This explains the rather constant gain in BLEU score throughout the graph.

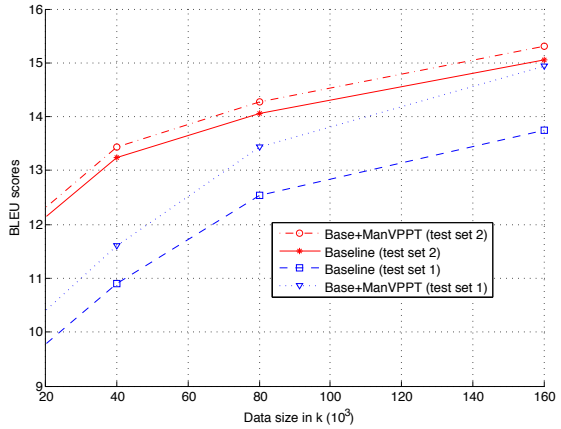

Figure 3: Change in BLEU for different corpus sizes

6 Conclusion and Future Work

We showed an improvement of up to 1.5 bleu points on the in domain data set and an improvement of 0.4 bleu on the generic test set. However, there are still some errors in respect to the morphology of the verb phrases, which the Language Model is unable to tackle. These are primarily the long range dependencies which includes determining the gender and number of the subject or object to get the appropriate inflection. Having a dynamic feature based system, which does not require rich morphological resources, and predicts the suffixes and inflections would be able to solve this problem. Also, when a verb has more than one meaning, the contextual information is not captured efficiently in the current method and often produces a more literal translation than the the reference.

Apart from adding the verb phrases to the phrase table, filtering of poor verb phrase pairs from the original phrase table is another approach to consider. The two methods together can give a higher boost to the translation than just one of them. A more language independent method of extraction of verb phrases also needs to be constructed, which does not require building language dependent stemmers and verb phrase chunkers.

Abstract

This paper addresses the problem of predicting the pronunciation of Japanese text. The difficulty of this task lies in the high degree of ambiguity in the pronunciation of Japanese characters and words. Previous approaches have either considered the task as a word-level classification problem based on a dictionary, which does not fare well in handling out-of-vocabulary (OOV) words; or solely focused on the pronunciation prediction of OOV words without considering the contextual disambiguation of word pronunciations in text. In this paper, we propose a unified approach within the framework of phrasal statistical machine translation (SMT) that combines the strengths of the dictionary-based and substring-based approaches. Our approach is novel in that we combine word- and character-based pronunciations from a dictionary within an SMT framework: the former captures the idiosyncratic properties of word pronunciation, while the latter provides the flexibility to predict the pronunciation of OOV words. We show that based on an extensive evaluation on various test sets, our model significantly outperforms the previous state-of-the-art systems, achieving around 90% accuracy in most domains.

1 Introduction

This paper[1] explores the problem of assigning pronunciation to Japanese text, which consists of a mixture of ideographic and phonetic characters. The task is naturally important for the text-to-speech application (Schroeter et al., 2002), and has been researched in that context as letter-to-phoneme conversion, which converts an orthographic character sequence into phonemes. In addition to speech applications, the task is also crucial for those languages such as Chinese and Japanese, where users generally type in the pronunciations of words, which are then converted into the desired character string via the software application called input methods (e.g. Gao et al. (2002a); Gao et al. (2002b)).

Predicting the pronunciation of Japanese text is particularly challenging because the word and character pronunciations are highly ambiguous. Japanese orthography employs four sets of characters: *hiragana* and *katakana* (called generally as *kana*), which are syllabary systems and thus phonemic; *kanji*, which is ideographic and consists of several thousand characters; and Roman alphabet. Out of these, kanji characters typically have multiple possible pronunciations[2]; especially those in frequent use tend to have many — between 5 and 10, sometimes as many as 20. This yields an exponential number of pronunciation possibilities when multiple kanji characters are combined in a word. Also, the pronunciation of a word is frequently idiosyncratic.

This idiosyncratic property of the word pronunciation naturally motivates us to take a dictionary-based approach. Traditionally, most approaches to Japanese pronunciation prediction have regarded the problem as a word pronunciation disambiguation task. Since there are no white spaces between words in Japanese text, these approaches first segment an input sentence/phrase into words, and then select a word-level pronunciation among those defined in a dictionary (Nagano et al., 2006; Neubig and Mori, 2010). For example, given a word "人気", these methods try to select the most appropriate pronunciation out of the three dictionary entries: *ninki* (popularity), *hitoke* (sign of life) and *jinki* (people's atmosphere), depending on the context. However, in these approaches, seg-

[1]This work was conducted during the first author's internship at Microsoft Research.

[2]In UniDic (Den et al., 2007), the average number of pronunciations per kanji character is 2.3.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 120–128,
Chiang Mai, Thailand, November 8 – 13, 2011.

mentation errors tend to result in the failure of the following step of pronunciation prediction. Moreover, since the dictionary-based approach is inapplicable to those words that are not in the dictionary, there needs to be a separate mechanism for handling out-of-vocabulary (OOV) words.

Nonetheless, the problem of OOV words has received little attention to date. Traditional systems either bypass this problem completely and assign no pronunciation to OOV words, as Mecab (Kudo et al., 2004), a Japanese morphological analyzer, does; or use a simple model to cover them (e.g. Neubig and Mori (2010) uses a noisy-channel model with a character bigram language model). Our previous work (Hatori and Suzuki, 2011) explicitly addresses the problem of predicting the pronunciation of OOV words, but focuses solely on predicting the pronunciation of nouns that are found in Wikipedia in isolation, and does not address the contextual disambiguation of pronunciation at the sentence level.

In this paper, we propose a unified approach based on the framework of phrasal statistical machine translation (SMT), addressing the whole sentence pronunciation assignment while integrating the OOV pronunciation prediction as part of the whole task. The novelty of our approach lies in using word and single-character pronunciations from a dictionary within the SMT framework: the former captures the idiosyncratic properties of word pronunciation, while the latter provides the flexibility to predict the pronunciation of OOV words based on the sequence of pronunciations at the substring level.

In addressing the pronunciation disambiguation problem within the framework of phrasal SMT, we extend the use of composed operations, which were applied in a limited manner in Hatori and Suzuki (2011). Within our dictionary-based model, the composed operations are able to incorporate the composition of dictionary words (i.e. phrases) as well as substrings of the character sequence (i.e. (partial) words). In this sense, our approach is more like a standard monotone phrasal SMT, rather than the substring-based string transduction. We also propose to use the joint n-gram model as a feature function, which has been proven to be effective in the letter-to-phoneme conversion task (Bisani and Ney, 2008; Jiampojamarn et al., 2010). In the context of our current task, this feature not only incorporates smoothed contextual information for the purpose of pronunciation disambiguation, but also captures the dependency between single-kanji pronunciations, which is effective for predicting the pronunciation of OOV words.

We collected an extensive evaluation set for the task, including newswire articles, search query logs, person names, and Wikipedia-derived instances. Using these test sets, we show that our model significantly outperforms the previous state-of-the-art systems, achieving around 90% accuracy in most test domains, which is the best known result on the task of Japanese pronunciation prediction to date. We also give a detailed analysis of the comparison of the proposed model with an SVM-based model, KyTea (Neubig and Mori, 2010), through which we hope to shed light on the remaining issues in solving this task.

2 Background

2.1 Pronunciation Prediction: Task Setting

We define the task of pronunciation prediction as converting a string of orthographic characters representing a sentence (or a word or phrase) into a sequence of hiragana, which corresponds to how the string is pronounced. For example, given a Japanese sentence "東京都美術館の狩野探幽展に行った。" ("I went to the Exhibition of Tanyu Kano at the Tokyo Metropolitan Art Museum."), the system is expected to output a sequence of hiragana, "とうきょうとびじゅつかんのかのうたんゆうてんにいった。", pronounced as *tookyoo to bijutsukan no kanoo tanyuu ten ni itta*. The task involves two sub-problems: (a) contextual disambiguation of a word pronunciation, e.g., 行った can be pronounced either as いった *itta* "went" or おこなった *okonatta* "did" depending on the context; (b) pronunciation prediction of OOV words, e.g., in the above example, 狩野探幽展 ("the Exhibition of Tanyu Kano") is not likely to be in the dictionary, so the pronunciation must be reasonably guessed based on the possible pronunciations of individual characters.

2.2 Related Work

Our research on pronunciation prediction is inspired by previous research on string transduction. The most directly relevant is the work on letter-to-phoneme conversion. Previous approaches to this task include joint n-gram models (e.g., Bisani and Ney (2002); Chen (2003); Bisani and Ney (2008)) and discriminatively trained substring-based models (e.g., Jiampojamarn et al. (2007); Jiampojamarn et al. (2008)). This task is typically evaluated at the word level, and therefore does not include contextual disambiguation.

Similar techniques to the letter-to-phoneme task

have also been widely applied to the transliteration task (Knight and Graehl (1998)). The most relevant to the current task include an approach based on substring operations in the SMT framework (e.g., Sherif and Kondrak (2007), Cherry and Suzuki (2009)), and those that use joint n-gram estimation method for the task of transliteration (e.g., Li et al. (2004); Jiampojamarn et al. (2010)). However, similarly to the letter-to-phoneme task, the contextual disambiguation of the words has not received much attention.

The task of Japanese pronunciation prediction itself has been a topic of investigation. Sumita and Sugaya (2006) proposed a method to use the web for assigning word pronunciation, but their focus is limited to the pronunciation disambiguation of known proper nouns. Kurata et al. (2007) and Sasada et al. (2009) discuss the methods of disambiguating new word pronunciation candidates using speech data. Nagano et al. (2006) and Mori et al. (2010b) investigated the use of the joint n-gram estimation to this task.

More recently, Neubig and Mori (2010) proposed a classifier-based system called KyTea, which is one of the current state-of-the-art systems for the task of Japanese pronunciation prediction. As we use this system as one of our baseline systems, we describe this work in some detail here. KyTea exploits an SVM-based two-step approach, which performs a word segmentation step, followed by a pronunciation disambiguation step for each word segment. In the pronunciation prediction step, if the word in question exists in the dictionary, KyTea uses character and character-type n-grams within a window as features for the SVM classifier. For OOV words, a simple OOV model based on a noisy channel model with a character bigram language model is used. While KyTea uses the discriminative indicator features, our model instead uses character/joint n-gram language models and composed operations (to be explained in Section 3.3.2) to capture the context for the purpose of pronunciation disambiguation. The use of the indicator features essentially requires probabilistic optimization of a large number of weights, making the training less scalable than our model, which only requires frequencies of operations and phrases in the training data.

In our previous work (Hatori and Suzuki, 2011), we addressed the pronunciation prediction of Japanese words in a semi-supervised, substring-based framework, using word-pronunciation pairs automatically extracted from Wikipedia. Though we obtained more than 70% accuracy on

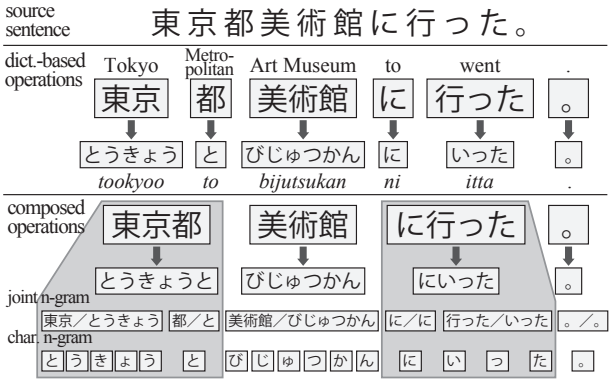

Figure 1: Overview of the model.

Wikipedia data, the model is quite specific to handling the noun phrases in Wikipedia, and it is not clear if the approach can handle the pronunciation assignment of a general text, which includes the pronunciation prediction and disambiguation of the words of all types at the sentence level. Since our current work is an extension of this approach, we also adopt our previous work as one of our baseline models in Section 4.4.

3 Pronunciation Prediction Model

This section describes our phrasal SMT-based approach to pronunciation prediction, which is an extension of our previous work (Hatori and Suzuki, 2011). We assume that the task of translating a Japanese orthography string to a hiragana string is basically monotone and without insertion or deletion. The overview of our model is given in Figure 1. The components of the model will be explained below.

3.1 Training and Decoding

As is widely used in SMT research (Och, 2003), we adopt a discriminative learning framework that uses component generative models as real-valued features (Cherry and Suzuki, 2009). Given the source sequence s and the target character sequence t, we define real-valued features over s and t, $f_i(s,t)$ for $i \in \{1,\ldots,n\}$. The score of a sequence pair $\langle s,t\rangle$ is given by the inner product of the weight vector $\boldsymbol{\lambda} = (\lambda_1,\ldots,\lambda_n)$ and the feature vector $\mathbf{f}(s,t)$.

For the training of model parameters, we use the averaged perceptron (Collins and Roark, 2004): given a training corpus of transduction derivations, each of which describes a word/substring operation sequence converting s into t, the perceptron iteratively updates the weight vector every time it encounters an instance for which the model outputs a wrong sequence. For decoding, we use a

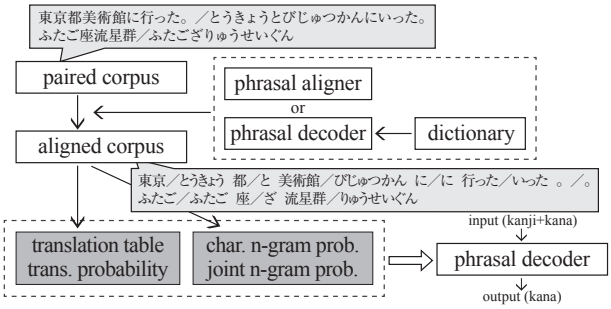

Figure 2: Overview of the training.

stack decoder (Zens and Ney, 2004).

3.2 Features

For our baseline model features, we first use those from Hatori and Suzuki (2011): the bidirectional translation probabilities, $P(t|s)$ and $P(s|t)$, the target character n-gram probability, $P(t)$, the target character count, and the phrase count. In addition, we incorporate the joint n-gram probability, $P(s,t)$, as a feature (described in Section 3.2.1). The estimation of the translation and joint/character n-gram probabilities requires a set of training corpus with source and target alignment at the word/substring level. Once these probabilities have been estimated by using the frequency of (the sequences of) operations in the training set, we only need a small tuning set to adjust the feature weights of the model. This makes online training and domain adaptation easy, and makes our model more scalable compared to fully discriminative systems with indicator features, such as KyTea.

3.2.1 Joint n-gram Language Model Feature

Motivated by the success in the transliteration task (Jiampojamarn et al., 2010), we incorporate the joint n-gram language model into our SMT-based framework. The joint n-gram sequence is the sequence of operations used in the transduction: for example, when a paired sentence "床屋に行く／とこやにいく" is decomposed into three operations "床屋→とこや, に→に, 行く→いく", the corresponding joint n-gram sequence is "⟨ 床屋, とこや ⟩ ⟨ に, に ⟩ ⟨ 行く, いく ⟩". The effectiveness of this feature is confirmed in our experiments in Section 5.2.

3.3 Translation Table

The corpora we use are a collection of pairs of a Japanese sentence and its hiragana sequence, as described as "paired corpus" in Figure 2. These are just like bilingual corpora if we regard the hiragana sequence as monotonically translated from Japanese text. Since the original corpora do not have any word segmentation or word/substring alignments, we first need to obtain them to construct the translation table for the decoder. In previous work, KyTea used a corpus that is manually aligned using words as a unit of alignment, while Hatori and Suzuki (2011) used an unsupervised substring-based alignment. The former is not scalable easily, while the latter cannot take advantage of existing dictionaries. In this work, we use a novel application of dictionary-based phrasal decoder in order to create an aligned corpus, which allows us to use dictionary information while learning substring-based alignments for handling OOV pronunciation prediction.

3.3.1 Dictionary-based model

In the dictionary-based model we propose, alignments are obtained using a phrasal decoder which is based on a dictionary. This essentially treats the dictionary entries as the minimal unit of substring operations, instead of using single-kanji pronunciations estimated from training corpora as in the case of the substring-based model (Hatori and Suzuki, 2011). We first build a simple dictionary-based decoder with only two features: the forward translation probability and the phrase count; and then use it to decode a paired corpus to obtain the alignments between the source and target strings. In this process, instances including any operation that is not defined in the dictionary are discarded; this is a major difference with the substring-based model of Hatori and Suzuki (2011), which uses all instances of training data.

Since Japanese dictionaries typically include single-kanji entries as well as word entries[3], dictionary-based substring operations actually consist of both single-kanji (that is not a word per se) and word pronunciations. This is why our dictionary-based model is still able to handle OOV words. We show in Section 5 that the benefit of removing noisy training samples by this process outweighs the risk of discarding infrequent or non-standard pronunciations that do not exist in the dictionary.

3.3.2 Composed operations

Our previous work (Hatori and Suzuki, 2011) exploits composed operations in order to include local contextual information in the substring-based model. Given a paired corpus, they use an aligner to obtain single-character alignments, which maps

[3]This is because each kanji character is a morpheme representing a meaning, and is worth an entry in dictionaries.

one kanji to one or more kana characters, which are then composed into larger operations. This procedure makes it possible to obtain longer alignments with limited memory, rather than using the source phrase length larger than one. In the current work, we extend the use of composed operations so that they work properly with the joint n-gram estimation.

The composed operations are beneficial for capturing contextual information. For example, the phrase "行った" can be pronounced in two ways: *itta* "went" and *okonatta* "did", which cannot be distinguished without any context. However, if this phrase is preceded by a hiragana particle に *ni* "to", we can assume that the correct pronunciation is most likely *itta*, because the pronunciation *ni okonatta* is unusual (行った *okonatta* is seldom preceded by に *ni*). The composed operations are also useful in capturing the pronunciation of compound nouns: for example, due to the phonological process called *rendaku* (sequential voicing) (Vance, 1987), 食器-棚 "plate rack" is pronounced as *shokki-dana*, while the components of this word are individually pronounced as *shokki* ("plate") and *tana* ("rack"). By considering the compositions of operations, we can capture the pronunciation in the context of a compound word. Our phrasal decoder considers all (i.e. composed and non-composed) operations during the decoding, but longer (composed) operations are generally preferred when available because the phrase count feature usually receives a negative weight.

However, the simultaneous use of these operations of different size may cause a problem when the joint n-gram estimation is applied: because composed operations include multiple non-composed operations, they break the independence assumption of n-gram occurrences in the language model. For example, given a parallel phrase "展覧会に行った／てんらんかいにいった" (went to an exhibition), which is decomposed into "展覧会／てんらんかい, に／に, 行った／いった" by dictionary-based alignments, the joint n-gram language model expects that the occurrence of "に／に" (non-composed operation) is independent of that of "に-行った／に-いった" (composed operation), but this is not the case. To avoid this, we let the model retain the original operations even after they are composed. As shown in Figure 1, even after the two operations "に→に" and "行った→いった" are merged into a composed operation "に-行った→に-いった", the joint n-gram probability is still estimated based on the original (non-composed) operations. For efficiency purposes, we only retain the decomposition of the first appearance of each composed operation even if multiple different decompositions are possible.

4 Experiments

4.1 Dictionary

In the dictionary-based framework, we need a dictionary based on which we obtain the alignments. We use a combination of three dictionaries: UniDic (Den et al., 2007), Iwanami Dictionary, and an in-house dictionary that was available to us of unknown origin. UniDic is a dictionary resource available for research purposes, which is updated on a regular basis and includes 625k word forms as of the version 1.3.12 release (July 2009). Iwanami Dictionary consists of 107k words, which expands into 325k surface forms after considering *okurigana* (verb inflectional ending) variants. The in-house dictionary consists of a total of 226k words and single-kanji pronunciations. After removing duplicates, the combined dictionary consists of 770k entries. Note that these dictionaries are also used as part of training data.

4.2 Training and Test Data

As described in Section 3, we need word/substring-aligned parallel corpora to train the models. We used three different sources of training data in our experiments. First, following Hatori and Suzuki (2011), we used Wikipedia: following the heuristics described in the paper, we extracted about 460k noisy word-pronunciation pairs from Japanese Wikipedia articles as of January 24, 2010. Of these pairs, we set aside 3k instances for use in development and evaluation, and used the rest for training (referred to as "Wiki-Train"). Secondly, since word-pronunciation pairs extracted from Wikipedia are noisy[4] and mostly consist of noun phrases, we also used a newspaper corpus, which is comprised of 1.4m sentence pairs, referred to as "News-Train". Finally, for the comparison with KyTea, we use a publicly available corpus, the Balanced Corpus of Contemporary Written Japanese (Maekawa (2008)). Specifically, we use the 2009 Core Data of this corpus, which consists of 37k sentences annotated with pronunciations (referred to as "BCCWJ").

Our test data consist of six datasets from various domains. Table 1 shows the statistics of these corpora, with the OOV rate estimated using KyTea[5]

[4]We have found that roughly 10% of these instances are invalid word-pronunciation pairs.

[5]We ran KyTea 0.13 with the built-in default model. For

Test set	#Instance	Avg. len.	OOV rate
News-1 (N1)	867	51.8	0.3%
News-2 (N2)	739	44.9	0.3%
Query-1 (Q1)	1,049	3.8	3.5%
Query-2 (Q2)	3,078	5.7	12.7%
Name (PN)	9,170	3.0	23.4%
Wiki (WP)	2,000	4.1	13.7%

Table 1: Statistics of test sets, where "Avg. len." is the average length of an instance in the number of characters.

- **News-1**(N1) and **News-2**(N2): collections of newswire articles available as Microsoft Research IME Corpus (Suzuki and Gao, 2005). These articles are from different newspapers from the news corpus we used in training. In preparing these test sets, instances including Arabic and kanji numerals (0,1,⋯,9, ○, 一,⋯, 九), or Roman alphabets are excluded[6].
- **Query-1**(Q1) and **Query-2**(Q2): query logs from a search engine (source undisclosed for blind reviewing). These sets consist of various instances ranging from general noun phrases to relatively new proper nouns.
- **Name**(PN): a collection of difficult-to-pronounce words, mostly consisting of person names.
- **Wiki**(WP): manually-cleaned word-pronunciation pairs from Wikipedia, which consists mostly of proper nouns including names of people and locations as well as terms that are difficult to pronounce.

For the tuning of the weights of the model, we used 200 held-out instances for each test domain, except that the development set of Query-1 is also used for the tuning for Query-2, and the set of Wiki is used for the tuning for Name.

4.3 Experimental settings

We use our original implementation of the phrasal aligner and decoder, which is also used as our implementation of the substring-based model of Hatori and Suzuki (2011). An ITG-based aligner with EM algorithm (Zhang et al., 2008) is used with monotonic setting; we set the source (kanji) and target (kana) phrase length limits to 1 and 4, and prohibit alignments to a null symbol in either source or target side. The decoder runs with the beam size of 20. The maximum number of composed operations is 4 for the substring-based model of Hatori and Suzuki (2011), and 3 for the proposed dictionary-based model. In the substring-based model, character 5-gram and joint 4-gram language models with Kneser-Ney smoothing and the BoS (beginning-of-string) and EoS (end-of-string) symbols are used; in the dictionary-based model, character 5-gram and joint 3-gram models with the same settings are used. We did not use the infrequent operation cut-off. All of these parameters and settings are set based on the preliminary experiments. As the evaluation measure, we use instance-level accuracy, which is calculated based on the percentage of the outputs that exactly match the gold standard: instances correspond to sentences in News-1/2, and to words or phrases in all other test domains. The statistical significance of the results is given using McNemar's test.

4.4 Baseline Models

We describe three baseline models that we use as reference in our experiment.

- **Mecab**: *Mecab* version 0.98[7], which is the state-of-the-art morphological analyzer for Japanese that also outputs pronunciations of words (Kudo et al., 2004), with the off-the-shelf IPA Dictionary containing 392k word entries provided at the author's page.
- **KyTea**: *KyTea* version 0.13[8], which is described in Section 2.2. In our comparison experiment, we run KyTea version 0.13 both as is (using their pre-trained model), and as trained by us to allow the comparison of the framework using the same publicly available training data.
- **HS11**: *HS11* is our reimplementation of the substring-based model by Hatori and Suzuki (2011), which was shown to outperform the substring-based joint trigram model on a Wikipedia test set.

5 Results and Discussion

5.1 Main Results

Table 2 shows the performance of the proposed model along with various baseline models. The first two lines are the result of the off-the-shelf, pre-trained systems. Mecab achieves around or above 80% accuracy on five out of six test sets, although the result on Wiki is below 60% because

News-1/2, the OOV rate in the table is the OOV word rate based on the KyTea's output. For the other test sets, the figures show the rate of the instances (words or phrases) that contain any OOV word, again based on the KyTea's output

[6]This is because there exist different standards in how to pronounce them. For example, the literal pronunciation is preferred for text-to-speech applications, whereas just outputting numerals as such suits better for the training of Japanese input methods.

[7]http://mecab.sourceforge.net/

[8]http://www.phontron.com/kytea/

Model	N1	N2	Q1	Q2	PN	WP
Mecab	78.8	79.7	88.0	79.8	79.8	55.9
KyTea	83.6	85.9	92.9	85.6	52.9	62.9
HS11	23.3	31.8	87.7	73.3	83.9	64.5
HS11+	37.6	31.8	93.3	82.7	90.5	**72.9**
Proposed	**89.7**	**88.6**	**95.5**	**87.8**	**92.9**	70.2

Table 2: Instance-level accuracy (in %) of pronunciation prediction models. The upper two models use the off-the-shelf models; the lower three models are trained using the same resources: Wiki-Train, News-Train, and the combined dictionary.

the system does not have a mechanism to handle OOV words. The second row shows the result of KyTea using the off-the-shelf "full SVM model"[9], which is trained on several resources including BCCWJ and UniDic. It generally does better than Mecab, but the accuracies on the high OOV rate domains (i.e. Name and Wiki) are still quite low.

The bottom three models are all trained with the same resources: Wiki-Train and News-Train with all the three dictionaries. "HS11" is the substring-based model proposed by Hatori and Suzuki (2011), while "HS11+" is the model enhanced with two additional features: the joint n-gram feature (as described in Section 3.2), and the dictionary feature, whose value is the total length (in souce characters) of words matching any dictionary entry.[10] By comparing these two models, the effectiveness of these features over the model "HS11" is quite clear. However, the accuracy is below 40% on newswire test sets, where each instance is a full sentence. We assume that this is because the substring-based model cannot capture the contextual information that is broad enough, and also is easily affected by noise in the training data. Our proposed model, corresponding to the last line in the table, overcomes this problem and achives the best accuracy in all but one test domain (Wiki), showing the effectiveness and robustness of the dictionary-based approach. We lags behind "HS11+" on Wiki, probably because the dictionary-based model discards many operations that are uncommon, but are still useful for the pronunciation of OOV words in Wikipedia.

Table 3 shows the direct comparison between KyTea and the proposed model trained[11] with exactly the same datasets: BCCWJ, Wiki-Train, and UniDic, all of which are from publicly available resources. Whereas "KyTea (w/noise)" uses all the instances for training, "KyTea (wo/noise)" uses only the instances that are filtered using dictionary-based operations[12]. Note that this cleaning process is also a novel contribution of our work. As is observed from Table 3, this cleaning process resulted in a large improvement in accuracy, with the exception of the Name and Wiki sets. After inspecting the errors manually, we have found that this is because the UniDic-based operations do not include many single-kanji pronunciations that are commonly used in person's names, such as "美 *mi*" and "人 *to*". However, this problems seems negligible when a larger dictionary including common pronunciations for person's names is available. In the comparison in Table 2, where the models use a combination of three dictionaries, the dictionary-based model "Proposed" performs better than the substring-based model "HS11+" even on the Name set.

Model	N1	N2	Q1	Q2	PN	WP
KyTea (w/noise)	68.5	65.3	88.0	79.5	**67.9**	**65.8**
KyTea (wo/noise)	**75.3**	**75.5**	91.5	83.4	61.7	64.1
Proposed	73.8	75.4	**92.8**†	**84.9**†	62.8	64.3

Table 3: Instance-level accuracy (in %) of the models trained on Wiki-Train and BCCWJ with UniDic. "†" denotes a statistically-significant ($p < 0.01$) difference between "KyTea (wo/noise)" and "Proposed".

Overall, the proposed model outperforms "KyTea (wo/noise)" in four out of six test sets, and the differences in the remaining two sets (News-1/2) are not statistically significant. Considering also that the training data is relatively small in this comparison experiment[13], we can conclude that our model has at least a comparable performance to KyTea for the task of pronunciation disambiguation, while achieving a superior performance on the task of pronunciation prediction for OOV words. A manual analysis of the results also showed that our model indeed has an advantage in outputting phonetically natural pronunciation sequences, partially resolving problems related to *on/kun*[14] and *rendaku*, as in 契約-切れ *keiyaku-*

[9] We could not train KyTea with the same dataset as the proposed model uses due to memory limitation.

[10] The dictionary is also used as the training data.

[11] Our training of KyTea is performed as follows: we first train a segmentation model for KyTea using BCCWJ and UniDic, and use this model to segment the substring-aligned Wiki-Train instances to obtain a corpus with consistent segmentation, which is then used to train the final model.

[12] 27.6% of the instances in Wiki-Train is filtered out. This percentage is larger than the noise rate of 10% in this corpus, which Hatori and Suzuki (2011) reported, because the sole use of UniDic does not cover many single-kanji pronunciations, as mentioned later in this paragraph.

[13] Since the translation probabilities in our model are based on unregularized frequency, our model is less powerful with small training data, while it is more scalable.

[14] Pronunciations of kanji are classified into *on* and *kun* pronunciations (corresponding to their origin, Chinese and

Model	N1	N2	Q1	Q2	PN	WP
Proposed (D)	89.7	88.6	95.5	87.8	92.9	70.2
- wo/joint n-gram	-5.5	-3.3	-1.5	-3.8	-4.4	-4.2
- wo/composed op.	-3.9	-4.0	-2.6	-1.2	-1.8	-2.9

Table 4: Feature ablation results for the dictionary-based model trained with Wiki-Train, News-Train and the combined dictionary. All the losses in accuracy were statistically significant ($p < 0.01$).

gire (individually pronounced as *keiyaku* and *kire*; "contract expiration"). Although KyTea wrongly output *keiyaku-kire* to this instance, the proposed model was able to output the correct pronunciation by learning that the pronunciation of 切れ tends to be *gire* after the pronunciation *ku*, from other instances such as 句-切れ *ku-gire* (segments in haiku). On the other hand, KyTea is better at capturing generalized context by using a character-type feature, resolving instances such as "ブランド-米" (katakana + *mai*; "brand rice"), while the proposed model wrongly output the most frequent pronunciation *bei* for 米.

5.2 Feature Ablation Experiments

Table 4 shows the results of the feature ablation experiment of the proposed model. As we mentioned in Section 3.2.1, the advantage of the joint n-gram language model is twofold: incorporating smoothed context into word pronunciation disambiguation (which is the dominant problem in News-1/2), as well as incorporating single-kanji pronunciation dependencies into pronunciation prediction for OOV words (considered to be common in Name and Wiki). The improvement observed in these domains suggests that the joint n-gram probability successfully captured these two aspects. The use of composed operations showed large improvement particularly on News-1/2, proving its utility for the pronunciation disambiguation aspect of this task.

5.3 Data Ablation Experiments

Figure 3 shows the performance of the proposed model with respect to the number of News-Train sentences used for training. In this experiment, the model is first trained only with Wiki-Train; then, sentences from News-Train are incrementally added. This can be seen as a process for adapting a word-based model to a fully sentential, disambiguation-capable model. As expected, the accuracy is consistently improved in the news domain as more sentences are added, while the accuracy remains almost unchanged in the rest of the domains, without showing any negative effect by the additional out-of-domain training data. These results suggest that our model is robust and can adapt to new domains with a simple addition of training data.

Japanese), each of which tends to be used consecutively.

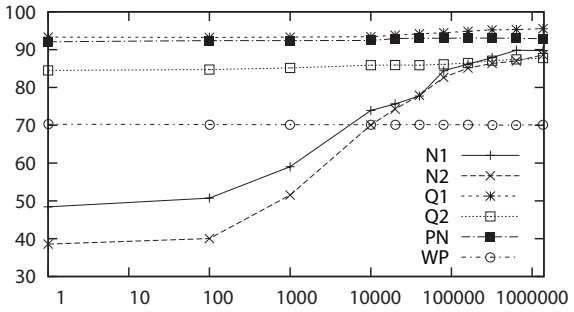

Figure 3: Performance (accuracy in %) of the proposed model with respect to the log of the number of additional training sentences from News-Train.

6 Conclusion

We have presented a unified approach to the task of Japanese pronunciation prediction. Based on the framework of phrasal SMT, our model seamlessly and robustly integrates the task of word pronunciation disambiguation and pronunciation prediction for OOV words. Its basic components are trained in an unsupervised manner, and work in the presence of noise in training data. The model also has potential to adapt to a new domain when additional training data is available. We have performed an extensive evaluation on various test sets, and showed that our model achieves the new state-of-the-art accuracy on the task of Japanese pronunciation prediction.

Looking into the future, we would like to see if the proposed model is effective in a general task of transliteration within a sentential context, which is conceivable as an application of phonetic input (e.g., inputting Arabic using Roman text and converting it automatically into Arabic scripts). On the task of Japanese pronunciation prediction, we are also interested in incorporating class-based features, such as character type information and on/kun dependencies, by using both existing resources and clustering methods.

Comparing Two Techniques for Learning Transliteration Models Using a Parallel Corpus

Hassan Sajjad **Nadir Durrani** **Helmut Schmid** **Alexander Fraser**
Institute for Natural Language Processing
University of Stuttgart
{sajjad,durrani,schmid,fraser}@ims.uni-stuttgart.de

Abstract

We compare the use of an unsupervised transliteration mining method and a rule-based method to automatically extract lists of transliteration word pairs from a parallel corpus of Hindi/Urdu. We build joint source channel models on the automatically aligned orthographic transliteration units of the automatically extracted lists of transliteration pairs resulting in two transliteration systems. We compare our systems with three transliteration systems available on the web, and show that our systems have better performance. We perform an extensive analysis of the results of using both methods and show evidence that the unsupervised transliteration mining method is superior for applications requiring high recall transliteration lists, while the rule-based method is useful for obtaining high precision lists.

1 Introduction

Urdu and Hindi are closely related languages which have a similar phonological, semantic and syntactic structure. Hindi is derived from Sanskrit and Urdu is a mixture of Persian, Arabic, Turkish and Sanskrit. Both share closed class vocabulary which they inherit from Sanskrit. They differ however in the open class vocabulary and in the writing script used. Hindi is written in Devanagari script and borrows most of the open class vocabulary from Sanskrit. Urdu is written in Perso-Arabic script and borrows most of the open class vocabulary from Persian, Arabic, Turkish and Sanskrit. Both languages have lived together for centuries and now share a large part of their vocabulary with each other. In an initial study on a small parallel corpus, we found that both languages share approximately 82% (tokens) and 62% (types) of the vocabulary. Transliterating overlapping words will help to bridge the scripting gap between Hindi and Urdu. The remaining words must be converted into the other language with a bilingual dictionary which is beyond the scope of this work.

In this paper, the term *transliteration pair* refers to a word pair where the words are transliterations of each other and the term *transliteration unit* refers to a character pair where the characters are transliterations of each other. We are interested in building joint source channel models for transliteration. Because we do not have a list of transliteration pairs to use as training data in building such a transliteration model, we use two methods to extract the list of transliteration pairs from a parallel corpus of Hindi/Urdu. The first method uses the transliteration mining algorithm of Sajjad et al. (2011) to automatically extract transliteration pairs. This approach does not use any language specific knowledge. The second method uses handcrafted transliteration rules specific to the mapping between Hindi and Urdu to extract transliteration pairs. We automatically align the two lists of extracted transliteration pairs at the character level and learn two transliteration models. We compare the results with three other transliteration systems. Both of our transliteration systems perform better than the other systems.

The 1-best output of the transliteration system built on the list extracted using the rule-based method is better than the 1-best output of the system built on the automatically extracted list. The rule-based extraction method is focused on obtaining a high precision list as compared to the automatic method which obtains a higher recall list. The 10-best and 20-best output of the transliteration system built on the automatically extracted list is better than the N-best outputs of the system built on the list extracted using the rule-based method. The wide coverage of transliteration units in the automatically extracted list helps the

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 129–137,
Chiang Mai, Thailand, November 8 – 13, 2011.

transliteration system to produce difficult transliterations which are hard to learn using the rule-based list.

The transliteration task between Hindi and Urdu is non-trivial. The missing short vowels in the writing of Urdu and a missing short vowel in the writing of Hindi are a particular problem, and we identify other areas of difficulty. We provide a detailed error analysis to account for the complexities in Hindi to Urdu transliteration motivated by linguistic phenomena.

The paper is organized as follows. Previous work on transliteration is summarized in Section 2. The two methods used to extract lists of transliteration pairs are described in Section 3. The joint probability model for transliteration is explained in Section 4. The evaluation and the results in comparison with three other transliteration systems are presented in Section 5. A detailed discussion and error analysis is presented in Section 6. Section 7 concludes.

2 Previous Work

Transliteration can be done with phoneme-based or grapheme-based models. Knight and Graehl (1998), Stalls and Knight (1998), Al-Onaizan and Knight (2002) and Pervouchine et al. (2009) use the phoneme-based approach for transliteration. Kashani et al. (2007) and Al-Onaizan and Knight (2002) use a grapheme-based model to transliterate from Arabic into English. Al-Onaizan and Knight (2002) compare a grapheme-based approach, a phoneme-based approach and a linear combination of both for transliteration. They build a conditional probability model. The grapheme-based model performs better than the phoneme-based model and the hybrid model. This motivates our use of grapheme-based models.

In this paper, we use a grapheme-based approach for transliteration from Hindi to Urdu. The phoneme-based approach would involve the conversion of Hindi and Urdu text into a phonemic representation which is not a trivial task as the short vowel 'a' is not written in Hindi text and no short vowels are written in Urdu text. The difficulty of this additional step would be likely to lead to additional errors.

Malik et al. (2008) and Malik et al. (2009) work on transliteration from Hindi to Urdu and Urdu to Hindi respectively. They use the rules of SAMPA (Speech Assessment Methods Phonetic Alphabets) and X-SAMPA[1] to develop a phoneme-based mapping scheme between Urdu and Hindi (J C. Wells, 1995).

Hindi	SAMPA	Urdu			
ज़	z	ز	ض	ظ	ذ
स	s	س	ص	ث	
ह	h	ہ	ھ	ح	
त	t_d	ت	ط		

Table 1: Ambiguous Hindi characters (characters which can transliterate to many different Urdu characters)

Malik et al. (2008) reported an accuracy of 97.9% for transliterating Hindi to Urdu. However, this number is not comparable to ours. Some Hindi characters can be ambiguously transliterated to several Urdu characters (see Table 1). Malik et al. (2008) do not deal with these ambiguous characters and count any occurrence of an ambiguous character as a correct transliteration in all scenarios. We discuss this further in Section 6.

In the previous work, a transliteration system is built on transliteration units learned either automatically from a list of transliteration pairs (Li et al., 2004), (Pervouchine et al., 2009) or using a heuristic-based method (Ekbal et al., 2006). We do not have a list of transliteration pairs for the training of our Hindi to Urdu transliteration system. Therefore we use two methods to extract transliteration pairs from parallel data of Hindi/Urdu. In the first approach, we use the transliteration mining algorithm proposed by Sajjad et al. (2011) to extract transliteration pairs. This method does not use any language dependent information. In the second approach, we use a rule-based method to extract transliteration pairs. Both processes are imperfect, meaning that there is noise in the extracted list of transliteration pairs. We build a joint source channel model as described by Li et al. (2004) and Ekbal et al. (2006) on the extracted list of transliteration pairs. The following sections describe the two mining approaches and the model in detail.

3 Extraction of Transliteration Pairs

We automatically word-align the parallel corpus and extract a word list, later referred to as *"list of word pairs"* (see Section 5, for details on training data). We use two methods to extract transliteration pairs from the list of word pairs. In the first

[1]SAMPA and XSAMPA are used to represent the IPA symbols using 7-bit printable ASCII characters.

approach, we automatically extract transliteration pairs using the transliteration mining algorithm as proposed in Sajjad et al. (2011). We align the transliteration pairs at character level using a character aligner. In the second approach, we use an edit distance metric and handcrafted equivalence rules to extract transliteration pairs from a parallel corpus. We align the list of transliteration pairs at character level using the edit distance metric. The transliteration system is then trained on these character aligned transliteration pairs which is described in Section 5. The following subsections describe the extraction methods in detail.

3.1 Automatic Extraction of Transliteration Pairs

In this section, we review the transliteration mining approach described by Sajjad et al. (2011) to automatically extract the transliteration pairs from the list of word pairs. The approach consists of two algorithms, Algorithm 1, which performs an iterative filtering of the word pair list, and Algorithm 2, which determines when Algorithm 1 should be stopped. The details of this process follow.

Algorithm 1 is based on an iterative process. In each iteration, it first builds a joint transliteration model using g2p (grapheme-to-phoneme converter (Bisani and Ney, 2008)) on the current list of word pairs. It then filters out 5% of the word pairs which are least likely to be transliterations according to their normalized joint probability, resulting in a reduced word pair list, after which the next iteration begins. In each iteration the word pair list is reduced by 5%.

Algorithm 2 is used to select the optimal stopping iteration for Algorithm 1. Algorithm 2 is an extension of Algorithm 1. It divides the original list of word pairs into two halves which are used as training and held-out data. The division is done using a special splitting method which keeps the morphologically related word pairs from the list of word pairs either in the training data or in the held-out data. It builds a joint sequence model on the training data (approximately half of the list of word pairs) and filters out those 5% word pairs which are least likely to be transliteration pairs. Then it builds a transliteration system using the Moses toolkit (Koehn et al., 2003) on the filtered data and tests it on the source side of the held-out data. It repeats this process for 100 iterations. The iteration which best predicts the held-out data is selected as the stopping iteration for the transliteration mining algorithm.

We first ran Algorithm 2 on the list of word pairs for 100 iterations. It returned the 45th iteration as the best stopping iteration for Algorithm 1. Then we ran Algorithm 1 for 45 iterations and obtained a list of 2245 transliteration pairs. Due to data sparsity, there were two Hindi characters which were missing in the extracted list of transliteration pairs. We could either add complete word examples or just transliteration units of the missing Hindi characters to the list of transliteration pairs. Adding examples will provide context information which may bias the results of the evaluation. Thus we added only the two missing 1-to-1 transliteration units to the list of transliteration pairs.

We align the list of transliteration pairs at the character level using a character aligner[2]. The aligner uses the Forward-Backward algorithm to learn the character alignments between the transliteration pairs. It allows only 0 or 1 character on either side of the transliteration unit. So, a source character can align either to a target character or to $\emptyset$ and a target character can align either to a source character or to $\emptyset$. We get three kinds of alignments of Hindi characters to Urdu characters i.e. $\emptyset \rightarrow 1$, $1 \rightarrow \emptyset$ and $1 \rightarrow 1$. We modify the $\emptyset \rightarrow 1$ alignments by merging the Urdu character with the left neighboring aligned pair. If it is the left-most character, then it is merged with the right neighboring aligned character pair. Table 2 shows the alignment of Hindi characters with Urdu characters before and after the merging of unaligned Urdu characters.

a)	Hindi	$\emptyset$	b	c	$\emptyset$	e	f
	Urdu	A	X	C	D	$\emptyset$	F
b)	Hindi		b	c		e	f
	Urdu		AX	CD		$\emptyset$	F

Table 2: Hindi-Urdu alignment pairs for transliteration where a) shows initial alignment with NULL alignments and b) shows final alignments after merging of NULL alignments

3.2 Rule-based Extraction of Transliteration Pairs

As an alternative to automatic extraction of transliteration pairs, we use our own knowledge

[2]We were unable to get character alignments from g2p. We use a separate character aligner to align the list of transliteration pairs at the character level.

of the Hindi and Urdu scripts to make the initial transliteration units. The rules are further extended by looking into available Hindi-Urdu transliteration systems and other resources (Gupta, 2004; Malik et al., 2008; Jawaid and Ahmed, 2009). Table 3 shows some examples of equivalence rules. Each transliteration unit is assigned a cost. A Hindi character which is always mapped to the same Urdu character is assigned zero cost. In some cases, a Hindi character, say H_1, can be mapped to several different Urdu characters, say U_1, U_2 and U_3. We assign an equal cost of 0.3 to all three mappings H_1 to U_1, H_1 to U_2 and H_1 to U_3 as shown in the last three rows of Table 3.

Hindi character	SAMPA	Urdu character	Cost
ब	b	ب	0
ल	l	ل	0
ज़	z	ض	0.3
ज़	z	ظ	0.3
ज़	z	ذ	0.3

Table 3: Hindi-Urdu handcrafted equivalence rules

The edit distance metric allows insert, delete and replace operations. The handcrafted rules define the cost of replace operations as shown in Table 3. Each insert and delete operation costs 0.6, except for the deletion of Hindi diacritics where the cost is 0.

If two identical characters occur next to each other in an Urdu word then either only one character is written with a shadda sign ّ after it or both characters are written next to each other. The shadda sign is treated as a diacritic by most Urdu writers and is thus frequently omitted in Urdu text. We deleted all shadda characters in a preprocessing step in order to obtain a consistent representation. Hindi, on the other hand, uses a special joining symbol between two characters to write conjuncts. If the joining symbol is used between two identical characters then it will be transliterated with a shadda in Urdu. Assume the joining symbol is "z" and L is a character in Hindi.

The occurrence L"z"L in Hindi will be transliterated as L ّ in Urdu. In the handcrafted rules, we add separate entries mapping Hindi L"z"L to Urdu L.

Urdu and Hindi differ in their word definition for some particular categories. For example, in Hindi the case marker is always attached to the pronoun, whereas in Urdu, the case marker can be written either as a separate token after the pronoun or can be attached to the pronoun. The edit distance metric was modified to avoid penalizing spaces in Urdu text.

The raw list of word pairs contains translations (that are not transliterations), transliterations and alignment errors. We apply the edit distance metric to the list of word pairs and extract the list of transliteration pairs. We optimized the costs on a held-out set. We filter out word pairs with a cost of more than 0.6 thus allowing only one deletion/insertion or at most three ambiguous replacements in the Hindi-Urdu pairs (Table 3). If we decrease the filtering threshold or increase the replacement cost, the number of types extracted reduces significantly. We obtained 1695 types in the list of transliteration pairs. Due to data sparsity, there were about 5 Hindi characters which were not covered in the list of transliteration pairs. We added transliteration units for the missing Hindi characters to the list of transliteration pairs.

We align the list of word pairs at the character level using the same handcrafted equivalence rules and the edit distance algorithm. We get three kinds of alignments of Hindi characters to Urdu characters i.e. $\emptyset \rightarrow 1$, $1 \rightarrow \emptyset$ and $1 \rightarrow N$. The character alignments produced using the edit distance metric differ from those produced using the character aligner (Section 3.1). The character aligner allows only one character on the source and the target side. The edit distance metric allows a Hindi character to align to more than one Urdu character. We postprocess the alignment $\emptyset \rightarrow 1$ as described in Section 3.1.

4 Transliteration Model

The character-based translation probability $p_{char}(H, U)$ is defined as follows:

$$p_{char}(H,U) = \sum_{a_1^n \in align(H,U)} p(a_1^n) \quad (1)$$

$$= \sum_{a_1^n \in align(H,U)} \prod_{i=1}^{n} p(a_i | a_{i-k}^{i-1}) \quad (2)$$

where a_i is an aligned pair consisting of the i-th Hindi character h_i and a sequence of 0 or more Urdu characters. Usually a Hindi character is aligned with one Urdu character, but some

Hindi characters map to zero or two Urdu characters. The short vowels except the short vowel 'a' are always written in Hindi while in Urdu short vowels are usually not written. Hence, Hindi short vowels should be aligned to zero Urdu characters. $align(H, U)$ is the set of all possible alignments between the characters of U and H.

During transliteration we need to maximize $P(H, U)$ over all possible sequences U but we can not efficiently compute the sum over all possible different alignment pairs in equation 1. Therefore we resort to the Viterbi approximation and extract the most probable alignment.

The parameter k in equation 2 indicates the amount of context used (e.g. if $k = 2$, we use a trigram model on character pairs). A good value of k for our transliteration system is 4. Table 5 (Section 5) shows the variation of results on different values of k.

The SRILM-Toolkit (Stolcke, 2002) was applied in the implementation. Add-one smoothing was used for unigrams and Kneser-Ney smoothing was used for order > 1.

5 Evaluation Setup

5.1 Training and Test Data

We use a Hindi-Urdu parallel corpus taken from the EMILLE corpus[3]. In both Urdu and Hindi, there are cases where one character can be represented either as one Unicode character or as a combination of two Unicode characters. These characters are normalized to have only one representation. In Urdu, short vowels are represented with diacritics which are usually missing in written text. In order to keep the corpus consistent, all diacritics were removed from the Urdu corpus.

A Hindi news corpus of 5000 tokens (1330 types) was randomly selected from BBC News. The tokens that can be transliterated into Urdu were manually extracted and a test corpus of 819 transliteration pairs was obtained.

5.2 Word Alignment

We automatically generate two word alignments using GIZA++ (Och and Ney, 2003), and refine them using the grow-diag-final-and heuristic (Koehn et al., 2003). We extracted a total of 107323 alignment pairs from the sentence aligned parallel corpus of 7007 sentences. The M-N and N-1 alignment pairs were ignored as they are unlikely to be transliterations. Most of the 1-N alignment pairs are cases where the Urdu part of the alignment actually consist of two (or three) words which are sometimes written without a space because of lack of standard writing convention in Urdu. For example جا سکتے (can go ; d_ZA s@kt_de) is alternatively written as جاسکتے (can go ; d_ZAs@kt_de) , i.e., without a space before the "s" sound. These are always written as a single token in Hindi. We drop 1-N alignments with gaps, but keep alignments with contiguous words. We refer to the word-aligned corpus generated from 1-1 and 1-N alignments as "list of word pairs" later on.

5.3 Baselines

5.3.1 Phrase-based MT

Our first baseline is a phrase-based machine translation system (PSMT) for transliteration built using the Moses toolkit. We use the default settings but the distortion limit is set to zero (no reordering). Minimum error rate training (MERT) is used to optimize the parameters. The list of transliteration pairs is divided into 90% training and 10% development data (used for MERT).

5.3.2 External Transliterators

We also compare our systems with three Hindi-Urdu transliteration systems, HUMT[4] , CRULP[5] and Malerkotla[6] (MAL), available on the internet. HUMT is based on finite state transducers. It implements a phoneme-based mapping scheme between Hindi and Urdu. The HUMT system is described in Section 2 (Malik et al., 2008). CRULP is a rule-based transliterator which uses a direct orthographic mapping between Hindi and Urdu. Little information is available on the method of the Malerkotla transliterator. If there are two legal transliterations of a Hindi word, it transliterates it to the most frequent Urdu word. We suspect that Malerkotla may use a bilingual word list to override the basic transliteration scheme.

5.4 Experiments

Phrase-based MT: We first build a PSMT system on the list of word pairs. Due to the amount of noise in the training data, it shows 45.9% accuracy. The low score of the PSMT system supports our

Table 4: Results of Phrase-based MT

work of extracting the transliteration pairs from the list of word pairs to build a transliteration system.

The PSMT is then trained on the transliteration pairs extracted using the automatic method and the rule-based method. The purpose of this experiment is to compare the quality of the extracted lists by building an identical model on them. The PSMT shows best accuracy on the transliteration pairs extracted using the rule-based method (Table 4). The rule-based extraction method is based on high precision and thus extracted fewer transliteration pairs than the the automatic method. The list extracted using the automatic method contains close transliterations as well, which are word pairs which only differ by one or two characters from correct transliterations. The close transliteration pairs help to learn transliteration information but also add noise to the system.

Our systems: We build two versions of our system, using the list of transliteration pairs extracted in Section 3.1 (AUTO) and using the list of transliteration pairs extracted in Section 3.2 (RULE). We use a context size of $k = 4$ (see eq. 2) for our systems. The results of our transliteration system RULE with different context sizes are shown in Table 5. The accuracy of the transliteration system is stable at context sizes greater than three.

1	2	3	4	5
64.5%	76.3%	80.7%	81.6%	81.6%

Table 5: Accuracies of RULE for different context sizes

AUTO shows an accuracy of 76% on the test data of 819 types as shown in Table 6. It could not learn certain language specific phenomena due to data sparsity. The system had problems to learn the mapping of a Hindi character to an Urdu conjunct. The system could not learn the shadda cases (see Section 3.2). There are 18 types (2% of the test data) with shadda phenomena. AUTO correctly transliterates only 28% of these types. This might be due to the character aligner which can not capture the information where a Hindi character can be aligned to more than one Urdu character and vice versa. The other factor is the preprocessing step where we delete diacritics and the character joiner from the Hindi word aligned corpus.

AUTO	RULE	MAL	CRULP	HUMT
76%	81.6%	73.4%	69.8%	69.5%

Table 6: Accuracies of the joint model built on lists from AUTO and RULE, compared with the three baseline transliterators

The rule-based system (RULE) shows the best results of 81.6%. It obtains 100% accuracy in transliterating the shadda cases. Due to the inclusion of transliteration units in the training data (Section 3.2), it contains at least one entry of every transliteration unit in its training corpus.

Results of other transliteration systems: We test three other transliterators (HUMT, CRULP and MAL) on the test corpus of 819 types. The results are shown in Table 6. The HUMT system performs worst with an accuracy of 69.5%. The HUMT system does not handle ambiguous characters as mentioned in Section 2. It maps each ambiguous Hindi character to the most frequent matching Urdu character without taking into account the transliteration context. CRULP has difficulty in disambiguating Hindi characters which map to several different Urdu characters. Table 11 shows some examples of such transliteration units. The ambiguous Hindi characters (Table 1) can not be predicted correctly on the basis of the neighboring characters but these Hindi characters (Table 11) can be predicted correctly by looking at the context. MAL mostly performs well on ambiguous Hindi characters. The results of MAL are discussed in detail in the next section.

6 Discussion & Error Analysis

In this section, we discuss the errors made by the transliteration systems by dividing the test data into different subclasses. The transliteration between Hindi and Urdu is strongly motivated by the language of origin and script of the word to be transliterated.

Proper nouns: The test corpus contains a large number of words borrowed from other languages which are differently transliterated to Hindi and to Urdu. Words borrowed from Arabic contain ambiguous characters which make the transliteration task more challenging. Proper nouns form 19% of the test corpus. In a second set of experiments, we evaluated only on the proper nouns from the test corpus. All five transliterators perform poorly in transliterating proper nouns as shown in Table 7.

AUTO	RULE	MAL	CRULP	HUMT
59.1%	65.6%	56.5%	56.5%	57.1%

Table 7: Accuracies of AUTO, RULE and three baseline transliterators on proper nouns

Most of the proper nouns were names borrowed from English and other languages. We observed that there is sometimes a difference between the pronunciation of borrowed words in Hindi and Urdu. Consider the English name "Donald": the character "a" in "Donald" is transliterated using a long vowel into Hindi as डोनाल्ड (donAld) and using a short vowel into Urdu as ڈونلڈ (don@ld). There are some foreign words which are directly transliterated in Hindi and borrowed from another language in Urdu. Consider the word "America" which is transliterated as अमेरिका (@"mErIk@) in Hindi but borrowed from Arabic as امریکہ (A@mrikA) in Urdu. Table 7 shows the results of our transliterators in comparison with other transliterators.

Ambiguous characters: The ambiguous characters frequently occur in Hindi text and are found in 52% of the types in the test corpus. There are four ambiguous characters as shown in Table 1. For each such character, we extract the tokens containing this character from the test corpus. There were 15%, 19%, 13% and 3.8% occurrences of words with ह (h), स (s), त (t_d) and ज़ (z) respectively. Table 8 shows the results of the three baseline transliterators on these four cases.

	MAL	CRULP	HUMT
ह (h)	74.4%	60.8%	60%
स (s)	69.8%	62.9%	66%
त (t_d)	76.4%	66%	66%
ज़ (z)	32.3%	41.9%	3.2%

Table 8: Results of the baseline transliteration systems on words containing ambiguous characters

Malerkotla shows poor results on words containing ज़ (z). These words form only 3.8% types of the test corpus and thus do not substantially affect the overall accuracy achieved by Malerkotla. Table 9 shows the results of Malerkotla and our transliteration systems. RULE performs best on all cases of ambiguous characters.

Sometimes, the use of several ambiguous characters in a string leads to two legal Urdu words as shown in Table 10. The disambiguation between two legal Urdu words requires word context.

Ambiguous transliteration units: There are some characters in Hindi that may map to different Urdu characters depending on the context. Table 11 shows some examples. In the first column, the Hindi characters may map to any of the three Urdu characters in the same row. Sometimes, there is no phonological difference between the Urdu characters but conventionally they are written in one way or the other.

	AUTO	RULE	MAL
ह (h)	69.6%	78.4%	74.4%
स (s)	69.8%	74.8%	69.8%
त (t_d)	77.4%	79.3%	76.4%
ज़ (z)	64.5%	74.2%	32.3%

Table 9: Results of Malerkotla and our transliteration systems on words containing ambiguous characters

Hindi	SAMPA	Urdu-1	Urdu-2
बाज़	bAz	بعض Some	باز Eagle
असरार	A@srAr	اصرار Insist	اسرار Israr
सहरा	s@hrA	صحرا Desert	سہرا Credit

Table 10: Highly ambiguous words in Urdu that have the same sound but that are written with different characters and represent different meanings

Hindi	SAMPA	Urdu		
◌ा	A	ا	ہ	ع
आ	A	ا	آ	ع
ऊ	AU	ا	او	و

Table 11: Some ambiguous transliteration units

Pronunciation differences between Hindi and Urdu speakers: Different pronunciations of Hindi and Urdu speakers also cause confusion for the transliteration systems. For example, the English word "bazaar" is written in Hindi as बाजार (bAd_ZAr) and in Urdu as بازار (bAzAr). The transliteration system has to disambiguate by mapping the character representing "d_Z" in Hindi to either the "d_Z" sound or the "z" sound in Urdu. Table 12 shows some of these examples.

N-best analysis of RULE and AUTO: The transliterators show poor performance on words containing ambiguous characters. In the 20-best output, we find the correct solution for many words with ambiguous characters as shown in Table 13. However, if a word contains two ambigu-

Hindi	Urdu
बाजार (bAd_ZAr)	بازار (bAzAr)
फोल (fol)	پھول (p_hul)
श्रीलंका (SIril@nkA)	سری لنکا (sIril@nkA)

Table 12: Pronunciation differences between Hindi and Urdu

ous characters, it was difficult for the transliterator to transliterate it correctly. We hope that the tokens with ambiguous characters can be correctly transliterated using context by a statistical machine translation system. The unknown transliterations in the 20-best output will get lower scores from the language model as compared to known words. If two words in the 20-best output are known, the language model helps to choose the right output based on the word context.

The 10-best and 20-best results of AUTO are competitive with RULE[7]. The automatically extracted list obtains high recall and thus contains close transliterations which RULE's list does not contain. Close transliterations are word pairs which only differ by one or two characters from correct transliterations. The close transliteration pairs are useful for the transliteration system as they provide information about transliteration units and help avoid the problem of data sparseness. However, the transliteration system also learns noise from them and might not produce correct 1-best output. Table 14 shows two examples which are correctly transliterated by AUTO but are wrongly transliterated by RULE in the 10-best output. These examples are difficult to transliterate as most of the characters are ambiguous and have more than one possible transliteration. The system built on AUTO is able to transliterate them correctly as it contains more instances of infrequent ambiguous characters. For the incorporation of a transliteration model in a machine translation system, AUTO would be a better option as it is language independent and has better 10-best and 20-best scores.

7 Conclusion

We have implemented a joint source channel model to transliterate Hindi words into Urdu

[7]We also aligned AUTO with the edit-distance based aligner to verify that alignments differences were not important. The results dropped a little less than 1-point for 1-best, 10-best and 20-best, which is still better than RULE for 10-best and 20-best, so the differences in alignment did not unduly influence the results.

	AUTO	RULE
1-Best	76%	81.6%
10-Best	93.8%	91.5%
20-Best	95.1%	92.3%

Table 13: Comparison of 1-Best, 10-Best and 20-Best outputs of our transliteration systems

Hindi	Urdu	SAMPA
अफ़ीका	افریقہ	AfrIcA
आउट	آؤٹ	OUT

Table 14: In the 10-best output, these examples are correctly transliterated by AUTO but are wrongly transliterated by RULE

words. We have used two approaches to extract transliteration pairs from a parallel corpus of Hindi/Urdu – an unsupervised transliteration mining method and a method based on handcrafted rules. We then built models on the automatically aligned orthographic transliteration units of the extracted Hindi/Urdu transliteration pairs. Our best transliteration system achieved an accuracy of 81.6% which is 8% better than the best of three other systems. The 10-best and 20-best results of our transliteration system built on the automatically extracted transliteration pairs showed that it is suitable for integration with machine translation which will allow the use of translation context to choose the best transliteration (Hermjakob et al., 2008; Durrani et al., 2010).

A Semantic-Specific Model for Chinese Named Entity Translation

Abstract

We observe that (1) it is difficult to combine transliteration and meaning translation when transforming named entities (NE); and (2) there are different translation variations in NE translation, due to different semantic information. From this basis, we propose a novel semantic-specific NE translation model, which automatically incorporates the global context from corpus in order to capture substantial semantic information. The presented approach is inspired by example-based translation and realized by log-linear models, integrating monolingual context similarity model, bilingual context similarity model, and mixed language model. The experiments show that the semantic-specific model has substantially and consistently outperformed the baselines and related NE translation systems.

1 Introduction

Named entity (NE) translation, which transforms a name entity from source language to target language, plays a very important role in translingual language processing tasks, such as machine translation and cross-lingual information retrieval.

Generally, NE translation[1] includes transliteration and meaning translation. Recently, many researches have been devoted to NE transliteration (most person names) or NE meaning translation (organization names) individually. However, there are still two main challenges in statistical Chinese-English (*C2E*) NE translation.

(1) The combination of transliteration and meaning translation. Either transliteration or meaning translation is only a subtask of NE translation. There has been less work devoted to the combination of transliteration and meaning translation for translating NEs.

(2) The selection of NE translation variations. Segments in different NEs could be translated differently due to NEs' origins and enrich language phenomenon (Huang et al., 2005). As shown in Table 1, the same Chinese character "金" is translated into different English variations (highlighted in aligned parts).

Transliteration variations
金炳华 —— **Jin** Binghua
金成勋 —— **Kim** Sung-Hoon
何塞 华**金** 布伦纳 —— Jose Joa**quin** Brunner

……

Table 1. *C2E* Translation variations of a character "金" in different instances

Furthermore, we randomly extract 100 Chinese characters from the person names of LDC2005T34 corpus, and find out all the characters have more than one translation variations. And each character has about average 7.8 translation variations. Also, (Li et al., 2004) have indicated that there is much confusion in *C2E* transliteration and Chinese NEs have much lower perplexity than English NEs.

According to the above two problems, we find that a crucial problem of *C2E* NE translation is selecting a correct syllable/word at each step,

[1] NE translation referred to in this paper denotes bilingual NE transformation (either transliteration or meaning translation), and meaning translation is proposed as distinct from transliteration.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 138–146,
Chiang Mai, Thailand, November 8 – 13, 2011.

unlike traditional Statistical machine translation (SMT), which mainly focuses on (word, phrase or syntax) alignment and reordering. The selection in NE translation is much related to its *semantic information*, including NE types, origins, collocations of included Chinese characters, and position-sensitive etc. We want the translation model could automatically learn the semantic information. However, this semantic information for translation is various and difficult to classify.

Given an input "卡科夫**金**(Kakov**kin**)", how to identify the translation of "金"? Only selecting high probable translation across the training set is not reliable in this case. After simply comparing "卡科夫金" with the instances in Table 1, we find that the input is much relevant to "卡列伊**金**(**kin**)", since both of them include "金" at the end position, and their contexts are much related (they share a common Chinese character usage mainly due to the same origin (Russia), such as "卡", "列", and "夫" etc., according to clues supplied by global context). If we only considers the left/right context of "金", "卡科夫金" would have been related to "阿利亚夫**金**(**din**)" wrongly. From this view, this strongly suggests using a global context as the knowledge base for the final translation decision.

Therefore, we propose a semantic-specific NE translation model, which makes use of those related instances in the training data (defined as *global context*), to capture semantic information. The main idea is: for each input Chinese NE segment, it is assumed that its correct translation exists somewhere in the instances of the training set. What we need to do is to find out the correct answers based on semantic clues. It is achieved by selecting relevant instances, of which the semantic information is much relevant with the input. In other word, we choose those relevant instances from corpus to imitate translation. Here, semantic information is not directly learned, but is used as a bridge to measure the relevance or similarity between the input and those instances.

The proposed semantic-specific model has two advantages. Firstly, traditional translation approaches only exploit a general model to transform a source name into the target name with the same rules or distributions. Whereas our model could capture the transformation differences by measuring semantic similarity among different instances (global context). Secondly, we do not need define exact semantic labels for translation, such as various origins or NE types.

2 Framework

Formally, given a source (Chinese) name $C = c_1,...,c_k,...c_K$, which consists of K Chinese segments, we want to find its target (English) translation $E = e_1,...e_k,...e_K$ of the highest probability. Here, it is assumed that an NE is literally translated, without insertion or deletion during the transformation. Within a probabilistic framework, a translation system produces the optimum target name, *E**, which yields the highest posterior probability given the source Chinese name.

$$E^* = \arg\max_{E \in \Phi_E} P(E \mid C) \quad (1)$$

where Φ_E is the set of all possible translations for the Chinese name. In order to incorporate enrich language phenomenon of NEs (i.e. origins or other semantic information that affect NE translation) for capturing more exact translation, $P(E \mid C)$ is rewritten as:

$$\begin{aligned} P(E \mid C) &= \sum_S P(E, S \mid C) \\ &\cong \max_S P(E, S \mid C) \end{aligned} \quad (2)$$

where S is the semantic-specific information for C and E. Inspired by example-based machine translation model (Nagao, 1984; Sato and Nagao, 1990), we assume that certain mappings in the training set are identical with the transformation of the input NE. Thus we materialize the semantic information as a set of *C2E* mappings coming from the training set $S = s_1^K = s_1,...,s_k,...s_K$. A mapping s_k is defined as a segment [2] pair $[sc_k, se_k]$, where sc_k is similar to the input NE segment c_k on the source side, while se_k is the corresponding transformation of sc_k on the target side. Such as [金, Jin], [金, din], or [基金, Fund]. Therefore,

$S = [sc_k, se_k]_1^K = \{[sc_1, se_1],...,[sc_k, se_k],...,[sc_K, se_K]\}$.

For example, given an input NE "日本松山芭蕾舞团 (Japanese Matsuyama Ballet Troupe)", one of its mapping sets would be {[日本, Japanese],[松山, Matsuyama],[芭蕾舞团, Ballet Troupe]}, or {[日本, Japanese],[松, Matsu], [山, yama],[芭蕾, Ballet], [舞团, Troupe]} and so on. Therefore, the semantic-specific translation model incorporates semantic information by finding out the most likely mappings coming

[2] The source side of one mapping could be a character, a word or several words. The target side of one mapping could be several syllables or words. Therefore one mapping is defined as a segment pair.

from the training set to capture the semantic structure. If the mappings are known, the translation is achieved. Thus the semantic-specific model is further derived as:

$$\begin{aligned} & P(E,S|C) \\ &= P(E,[sc_k,se_k]_1^K|C) = P(E,sc_1^K,se_1^K|C) \\ &= P(sc_1^K|C)\times P(E,se_1^K|sc_1^K,C) \\ &= P(sc_1^K|C)\times P(se_1^K|sc_1^K,C)\times P(E|se_1^K,sc_1^K,C) \\ &\cong P(sc_1^K|C)\times P(se_1^K|sc_1^K,C)\times P(E) \end{aligned} \quad (3)$$

where $P(sc_1^K|C)$ is the probability to segment the input C into several source parts sc_1^K. And $P(se_1^K|sc_1^K,C)$ is used to assign preference to target segments se_1^K across global context given the input and the source segments sc_1^K. Finally, $P(E)$ is the probability to connect the target segments as the final translation E .Therefore, in our semantic-specific model, the traditional NE translation problem is transferred as searching the most probable (higher semantic similarity) mappings from the training data and then constructing the final translation.

In the proposed model (Eq (3)), those features are equally weighted. However, they should be weighted differently according to their contributions. Considering the advantages of the maximum entropy model (Berger et al., 1996) to integrate different kinds of features, we use this framework to model the probability $P(E,S|C)$. Suppose that we have a set of M feature functions $h_m(C,E,S)$, $\mathrm{m}=1,...M$. For each feature function, there exists a model parameter λ_m, $\mathrm{m}=1,...M$ .The decision rule is used to choose the most probable target NE (Och and Ney, 2002):

$$(\hat{E},\hat{S}) = \arg\max_{E,S}\left\{\sum_{m=1}^{M}\lambda_m h_m(C,E,S)\right\} \quad (4)$$

Here, the feature functions $h_1^M(C,E,S)$ are modeled by the probabilities of $P(sc_1^K|C)$, $P(se_1^K|sc_1^K,C)$, and $P(E)$ respectively. Next, we discuss these three features in detail.

3 Feature Functions

3.1 Monolingual Similarity Model

The First feature $P(sc_1^K|C)$ segments the source into several related segments assumed independence.

$$h_1(C,E,S) = P(sc_1^K|c_1^K) \approx \prod_{k=1}^{K} P(sc_k|c_k) \quad (5)$$

The probability $P(sc_k|c_k)$ describes the relationship of sc_k and the source NE segment c_k . Since sc_k and c_k are on the same language side, $P(sc_k|c_k)$ can be commonly measured by the frequency of sc_k . However, this measurement usually produces short and high frequent segments, which is not really suitable for NE translation with multiple variations.

To better estimate the distribution $P(sc_k|c_k)$, this paper proposes a much more generic model called monolingual similarity model, which captures phonetic characteristics and corpus statistics, and also removes the bias of choosing shorter segment.

$$\begin{aligned} & P(sc_k|c_k) \\ &\cong sim_l(sc_k,c_k)\times tf(sc_k)\times idf(sc_k)\times\log(|sc_k|+1) \end{aligned} \quad (6)$$

Here we first adopt a local similarity function $sim_l(sc_k,c_k)$ to measure the relationship of the input Chinese segment c_k and a possible Chinese segment sc_k . It is measured on literal level (shallow level based on Chinese character and phonetic similarity).

$$sim_l(sc_k,c_k) = \begin{cases} 1.0, & \text{if } sc_k = c_k \\ \frac{1}{I}\sum_{i=1}^{I} P(e_i|sc_k)\times P(e_i|c_k), & \text{otherwise} \end{cases} \quad (7)$$

If all the characters of the two segments are identical ($sc_k = c_k$), their similarity is assigned as a high score 1.0. However, many phonetically similar segments are usually translated into a same syllable, such as “肯” and “坎” could align to a same syllable “cam”. So we use NE alignment result to evaluate the phonetic similarity of two segments by $\frac{1}{I}\sum_{i=1}^{I} P(e_i|sc_k)\times P(e_i|c_k)$, where e_i denotes the same syllables they aligned in the training set.

On the other hand, a global concept, which is borrowed from tf×idf scheme in information retrieval (Chen et al., 2003), is used in Eq (7). Term frequency (tf) of a Chinese segment $tf(sc_k)$ denotes the number of occurrences of sc_k . Document frequency (df) of sc_k is the number of English segments that sc_k is translated to. And $idf(sc_k)$ is formulated as $\log(N/df(sc_k))$. Here, it is assumed there are totally N English segments according to *C2E* NE alignment result.

Therefore, Eq (7) prefers Chinese segments that occur frequently, but rarely have different English transformations. Besides, since a longer segment has less disambiguation of its translation variations, we also favor longer Chinese segments, so that the length of a Chinese segment, i.e., $|sc_k|$, is also considered.

3.2 Bilingual Similarity Model

The second feature is formulated as follows:

$$h_2(C,E,S) = P(se_1^K \mid sc_1^K, c_1^K) \approx \prod_{k=1}^{K} P(se_k \mid sc_k, c_k) \quad (8)$$

The probability $P(se_k \mid sc_k, c_k)$ identifies the target segment se_k, of which the semantic information is consistent with the input c_k. This distribution estimates the bilingual similarity of se_k and c_k, thus is formulated as follows:

$$\begin{aligned} & P(se_k \mid sc_k, c_k) \\ & \cong \sum_{sc_k \in KNN} sim_s(sc_k, c_k)\, y(sc_k, se_k) \end{aligned} \quad (9)$$

Here, we borrow the idea of KNN (K Nearest Neighbor) algorithm. Translation variations for each c_k could be seen as different categories. To classify c_k into a correct translation, we could find the instance sc_k in the training set that is most semantically similar to c_k, and then assign the translation (category) se_k of this nearest neighbor to c_k. Since there would be $K(K>1)$ nearest neighbors for c_k, we generalize the nearest neighbor to K nearest instances of c_k. If the translation of sc_k in the instance is se_k, $y(sc_k, se_k) = 1$, otherwise $y(sc_k, se_k) = 0$.

On the other hand, $sim_s(sc_k, c_k)$ measures the semantic consistency between sc_k and c_k, which ensures the two have the same translation. Note that $sim_s(sc_k, c_k)$ is different from $sim_l(sc_k, c_k)$, which only measures the literal similarity based on characters or syllables as shown in Eq (7). Because it is difficult to measure the semantic similarity of two segments directly, we quantify their similarity in terms of their specific contexts. The context of c_k is the input NE C, while the context of sc_k is an instance SC that includes sc_k in the training set. For example: given an input NE "日本松山芭蕾舞团" that acts as a context, we want to find the translation of a segment "松", the segment "松" in the training data have different global contexts, such as "斯文**松** (Sven**sson**)", "亚**松**森 (A**sun**cion)", and "赤**松**广隆 (Aka**matsu** Hirotaka)" and so on.

To address this problem, we adopt a vector space model that describes the context of c_k and sc_k. Some notions are defined here. A term set $T = \{t_{-n}, ..., t_{-1}, t_1, ..., t_n\}$ is an orderly character set of the context of c_k, where $[-n, n]$ is a Character-based n-range context window for c_k. This term set not only represents the character set of the context, but also presents the position information of the context. The similar action is applied to SC (the context of sc_k). Therefore, the context of c_k (the input Chinese NE) and each instance that includes sc_k would be transformed into vectors. For example, given a segment "松" in the input NE "日本松山芭蕾舞团", its term vector is {/s, 日, 本, 山, 芭, 蕾} when $n=3$, "/s" denotes the start position. While "松" in the instance "赤松广隆", its vector is {/, /s, 赤, 广, 隆, /e}, where "/" denotes a valid character and "/e" represents the end position.

We don't use Boolean weighting or tf/idf conceptions as traditional information retrieval (IR) to calculate the terms' weight, due to the sparse data problem. The mutual information is adopted to calculate the weight of t, which expresses the relevance between the context of c_k and the context of sc_k.

$$t_{weigh} = MI(t_C, t_{SC}) = \log \frac{p(t_C, t_{SC})}{p(t_C) \times p(t_{SC})} \quad (10)$$

After transferring the contexts into general vectors, the similarity of two vectors is measured by computing the cosine value of the angle between them. This measure, called cosine-similarity measure, has been widely used in information retrieval tasks (Baeza-Yates and Ribeiro-Neto, 1999), and is thus utilized here.

$$sim_s(sc_k, c_k) = \frac{V_C \bullet V_{SC}}{\|V_C\| \times \|V_{SC}\|} \quad (11)$$

The numerator is the inner product of two vectors. The denominator is product of the length of V_C and the length of V_{SC}. If an instance SC (including the segment sc_k) is much related to the input NE C (including the segment c_k), this case suggests that the semantic similarity between c_k and sc_k is much high. In other words, the two probably have the same translation se_k. Here sc_k

acts as a bridge to realize the transformation from c_k to se_k.

3.3 Mixed Language Model

The probability $P(E)$ in Eq (3) encodes the popularity distribution of an English NE E, i.e. English language model. As mentioned above, there are two transformation styles for NEs: transliteration and meaning translation. Hence the glue rules for the final result are different. Transliteration is syllable-connecting without space on the English side, such as "Matsu (松)" and "yama (山)" are connected as "Matsuyama (松山)", its language model can be defined as a syllable-based n-gram model $P_{LM}(E_{tl}) = \prod_{k=1}^{K} \prod_{j=1}^{J} P(e_{k,j} \mid e_{k,j-n+1}^{k,j-1})$ (suppose there are j letters in the k segment). In contrast, the output of meaning translation is chained word by word with spaces, for example, "Wuyi (武夷)" and "Mountain (山)" are connected as "Wuyi Mountain", of which the language model is presented as a general word-based n-gram model $P_{LM}(E_{ts}) = \prod_{k=1}^{K} P(e_k \mid e_{k-n+1}^{k-1})$. For some NEs (most organization names), transliteration and meaning translation coexist. Hence we denote E_{tl} as the included transliteration part, while E_{ts} as the meaning-translation part. Intuitively, the whole language model is estimated as follows.

$$h_3(C,E,S) = P(E) = P_{LM}(E_{tl}) \times P_{LM}(E_{ts}) \quad (12)$$

Moreover, the language models $P_{LM}(E_{tl})$ and $P_{LM}(E_{ts})$ could be further normalized for removing the bias induced by different word/syllable lengths.

4 Training and Search

Without Chinese word segmentation, we have to calculate every possible mapping to determine the most probable one in a large corpus, which will make the search space significantly huge. Therefore, we only measure those instances that including at least one character of the input NE. And the candidates, of which the feature values are below a threshold, are discarded.

4.1 ME Parameter Training

The weighting coefficients for the three features in Eq (3) can be learned from the development set via Maximum Entropy (ME) training.

One way to get the associated weighting coefficients for those log-probability-factors adopted in the model is to regard each of them as real-valued features, and then use ME framework to find their corresponding lambda values, which are just the weighting coefficients that we look for. Following (Och et al. 2002; Liu et al. 2005), we use the GIS (Generalized Iterative Scaling) algorithm (Darroch and Ratcliff, 1972) to train the model parameters $\lambda_1,...\lambda_M$ of the log-linear models according to Eq (4). In practice, YASMET[3] package is adopted here to train the model parameters $\lambda_1,...\lambda_M$. In our case, $M = 3$.

4.2 Search

We use a greedy search algorithm to search the translation with highest probability in the space of all possible mappings. A state in this space is a partial mapping. A transition is defined as the addition of a single mapping to the current state. Our start state is the empty translation result, where there is no selected mapping. A terminal state is a state in which no more mappings can be added to increase the probability of the current alignment. Our task is to find the terminal state with the highest probability.

We can compute *gain*, a heuristic function, to figure out a probability when adding a new mapping, which is defined as follows:

$$gain(S, s_k) = \frac{\exp[\sum_{m=1}^{M} \lambda_m h_m(C, E, S \cup s_k)]}{\exp[\sum_{m=1}^{M} \lambda_m h_m(C, E, S)]} \quad (13)$$

where $S \cup s_k$ means a single mapping s_k is added to S. Since we have assumed that NE is literally translated in our model, there is a restriction: no overlap is allowed between the mapping s_k and the mapping set S.

The greedy search algorithm for general log-linear models is formally described as follows:

Input: C **and aligned training set**
Output: E **,** S

1. Start with $S = \phi$;
2. Do for each s_k and $s_k \cap S = \varnothing$:
   Compute $gain(S, s_k)$;
3. Terminate if $\forall s_k, gain(S, s_k) \le 1$ or sc_1^K covers all segments in C;
4. Add s_k with the maximal $gain(S, s_k)$ to S;
5. Go to 2.

[3] http://www.fjoch.com/YASMET.html

The above search algorithm generates the final translation result by adding one mapping for each time.

5 Experiments

The training-set, testing-set, and development-set all come from Chinese-English Named Entity List v1.0 (LDC2005T34). The training-set consists of 218,172 proofread bilingual entries: 73,052 person name pairs, 76,460 location name pairs and 68,660 organization name pairs. Besides, 300 person names, 300 organization names, and 300 names of various NE types (including person names, location names and organization names) are used as three testing-sets respectively. Development-set includes 500 randomly selected name pairs of various NE types. There is no overlap between the training set, the development set and the open test sets.

Note that in the training set, the included transliterated parts and the meaning translated parts, which have been manually labeled, are trained separately. 218,172 NE pairs are split into 185,339 transliterated pairs (*TL-training set*) and 62,453 meaning translated pairs (*TS-training set*) (since transliteration and meaning translation would occur in one NE pair, so 185,339+62.453>218,172).

In the TL-training set, the Chinese name of an NE pair is transformed into a character-based sequence and its aligned English name is split into syllables, of which the split rules are described in (Jiang et al., 2007). Afterwards, GIZA++[4] tool is invoked to align characters to syllables. On the other hand, for TS-training set, the Chinese part of an NE is also treated as a character-based sequence, while the English part is regarded as a word-based sequence. The alignment between Chinese characters and English words are achieved by GIZA++ toolkit as well.

We use the recall of top-N hypotheses (Yang et al, 2008) as the evaluation metrics, and also adopt the Mean Reciprocal Rank (MRR) metric (Kantor and Voorhees, 2000), a measure that is commonly used in information retrieval, assuming there is precisely one correct answer. Each NE translation generates at most top-50 hypotheses for each input when computing MRR.

First, we will show the experimental results when setting different parameters for the semantic similarity model, which is done on the development set with equal feature weightings. We set different ranges of the context window (the parameter n) to find which range could get the best performance. Figure 1 illustrates the effect of the range parameter n for the final translation result (by MRR metric). From Figure 1, we could find that when n=3, the proposed model gets the best performance (MRR value=0.498). Therefore, n=3 is chosen for further study.

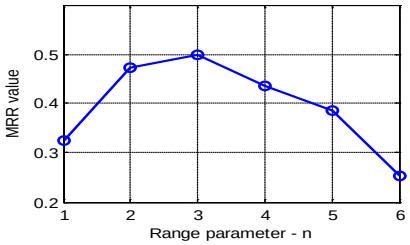

Figure 1. Effects of different context ranges (n) on translation results (by MRR metric)

Because the proposed three features cannot be used separately, we do not compare their individual effectiveness. Those normalized weighting coefficients (i.e., normalized lambda-values) obtained from YASMET package is 0.248, 0.565 and 0.187 (we all use 3-gram in the mixed language model). It is not surprising to find that λ_2 (corresponding to the bilingual similarity feature) receives the highest value. This clearly indicates that the bilingual similarity model plays a critical role in our semantic-specific translation model.

5.1 Semantic-Specific Model Vs. Baselines

We adopt a traditional statistical translation model (a phrase-based machine translation model, Moses[5] decoder) to process transliteration, meaning translation, and their combination as three baselines respectively. All of the baselines generate Top-50 candidates for each input. Table 2 shows their different settings comparing the proposed semantic-specific (SS) model.

Setting	SS-model	Baseline I	Baseline II	Baseline III
Input	Un-segmented	Character-based	Word-based	Character-based
Training data	TL-training set + TS-training set	TL-training set	TS-training set	TL-training set + TS-training set
Language model	Mix of syllable-based and word-based	Syllable-based	Word-based	Word-based

Table 2. The experiment configurations of baselines

[4] http://www.fjoch.com/GIZA++.html

[5] http://www.statmt.org/moses/

Note that baseline III combines transliteration and meaning translation only by training TL training set and TS training set individually, and then directly integrating generated syllable-based alignment and word-based alignment into a whole translation table.

Firstly, Table 3 compares the semantic-specific model (*SS-model*) with three baselines for the translation of person names. From Table 3, we find that the proposed model raises the recall of top-50 6.2% over Baseline I. It proves that our proposed model is effective for the transliteration of person names, and outperforms the traditional transliteration model. Baseline II can not output result due to its used TS-training set is out of the range of transliterating. It is interesting that the performance of baseline III even deteriorates after combing TS and TL training sets. One explanation might be that the language model of baseline III is only trained on word level, so that there is a severe data sparse problem.

Metric	SS-model	Baseline I	Baseline II	Baseline III
Top1	25.6%	17.7%	0%	14.2%
Top10	44.9%	28.2%	0%	23.7%
Top50	62.5%	56.3%	0%	39.8%
MRR	0.348	0.229		0.197

Table 3. Semantic-specific model vs. baselines for person names' translation

Metric	SS-model	Baseline I	Baseline II	Baseline III
Top1	34.4%	0%	26.5%	30.8%
Top10	38.7%	0%	29.8%	36.4%
Top50	46.9%	0%	35.2%	40.2%
MRR	0.381		0.297	0.336

Table 4. Semantic-specific model vs. baselines for organization names' translation

Secondly, the comparison between SS-model and three baselines for translating organization names are shown in Table 4. Baseline III outperforms baseline II for combining both TL-training set and TS-training set. Also SS-model has substantially raised the Top-N recall and MRR value over the baselines. Intuitively, we might expect that SS model could play a greater advantage on translating organization names, because organization names usually combine transliteration and meaning translation. However, comparing Table 3 with Table 4, the performance gaps between SS-model and baselines for organization names is smaller than that for person names. After checking those errors, this phenomenon is probably due to the word reordering problem, which usually occurs in the translation of organization names, but has not been considered by SS-model. Further study would be required for this problem.

Thirdly, we measure the overall effect of SS-model in Table 5. Evidently, the proposed SS-model yields significantly better results than the three baselines at all aspects. It is not surprising to find that the proposed SS-model is effective in translating various NEs of different NE types.

Metric	SS-model	Baseline I	Baseline II	Baseline III
Top1	30.7%	9.5%	11.8%	22.4%
Top10	36.2%	14.2%	16.7%	30.8%
Top50	55.3%	23.5%	32.8%	42.3%
MRR	0.337	0.139	0.142	0.256

Table 5. Semantic-specific model vs. baselines for various names' translation

5.2 Semantic-Specific Model Vs. Joint Transliteration Model

Actually, the proposed semantic-specific model captures semantic information by incorporating the global context information in the corpus, which is similar to the joint transliteration model proposed by (Li et al., 2004). However, the joint model only utilized the local context of the input (joint n-gram model of transliteration pairs) $P(E \mid C) = \prod_{k=1}^{K} P(< e, c >_k \mid < e, c >_{k-n+1}^{k-1})$, whereas our model measures the similarity of the global context amongst corpus. Table 6 gives the comparison of the joint model and SS-model for person names' transliteration. Here previous used training-set I and 300 person names are adopted for training and testing here. Also we use 3-gram in both of the two models. As shown in Table 6, even though the performance gap of Top1 (+0.8%) is not much obvious, the performance gap gets larger when the top-N hypotheses increase. This evidently proves the superiority of the proposed model on selecting the correct translation variation from global context.

System	Top1	Top10	Top50	MRR
Joint model	24.8%	40.2%	54.2%	0.319
SS-model	25.6 % (+0.8%)	43.9% (+3.7%)	61.4% (+7.2%)	0.348

Table 6. Semantic-specific model vs. joint model for person names' translation

5.3 Semantic-Specific Model Vs. Origin-Based Model

To further validate the capability of our proposed model, we measure its sensitivity to NE origin

information. Thus we compare it with a well-known semantic transliteration model (Li et al., 2007), which only deals with transliteration. Li's semantic transliteration model, called *origin-based model* here, firstly identifies the NE's origin O by $O = \arg\max_O P(O|C)$, and then uses its corresponding trained model, which is trained on instances all from origin O. The training and decoding process also use the Moses decoder.

In this experiment, we adopt training-set II, which includes 7,021 person names from USA, Japan and Korea (International *whoswho* corpus in LDC2005T34). And then we randomly select 100 person names from USA, Japan and Korea respectively (also in *whoswho* corpus) as our test data. Also, there is no overlap between the training set II and those test data. Here, baseline I is also the transliteration model, but trained on training set II, and we use the MRR criterion as well.

Test data	Baseline I	SS-model	Origin-based model
Origin=USA	0.289	0.417	0.335
Origin=Japan	0.257	0.473	0.489
Origin=Korea	0.213	0.406	0.368

Table 7. Semantic-specific model vs. origin-based model for person names' translation

Considering Table 7, though there is a slight drop comparing our model with origin-based model for the Japanese person names, the translation improvements on the person names of the other two origins show the superiority of our semantic-specific translation model. Actually, there would be much more origins to classify. For instance, there are more than 100 origins in *whoswho* data; it is tedious to train a large number of models in practice. And the origin labeled data for person names is hard to acquire. By using semantic-specific model, we could directly cluster instances of similar origin, and generate final translation result for origin consistency. The experiments prove that the SS-model is effective on capturing NE origin information to assist NE translation, and it could further accommodate more different semantic information.

6 Related Work

There are two strategies for NE translation. One is to extract NE translation pairs from the Web or from parallel/comparable corpora. This is essentially the same as constructing NE-pair dictionary (lee et al., 2006; Jiang et al., 2009), which is usually not a real-time translation model and is limited by the coverage of the used corpus and the Web resource.

The other is to directly translate an NE phonetically or according to its meaning. For transliteration, several transliteration approaches have been applied to various language pairs (Knight and Graehl, 1998; Tsuji 2002; Li et al. 2004; Oh and Choi, 2005; Pervouchine et al., 2009; Durrani et al., 2010). In contrast, for NE meaning translation, (Zhang et al., 2005; Chen and Zong, 2008; Yang et al., 2009) have proposed different statistical translation models only for organization names.

So far, semantic transliteration has been proposed for learning language origin and gender information of person names (Li et al., 2007). However, semantic information is various for NE translation. It is complicated to define different semantic types, and is tedious to train a large number of models used for different semantic information. Moreover, a semantically labeled training corpus is hard to acquire. Hence this paper does not directly learn NE semantic information, but measures the semantic similarity between the input and global context to capture exact NE translation.

7 Conclusion

In this paper, we present a novel semantic-specific model which could adaptively learn semantic information via instance-based similarity measurement from global context. Accordingly, this model combines transliteration and meaning translation, and automatically selects most probable translation candidates on the basis of the NE semantic-specific information. In summary, our experiments show that the semantic-specific model is much more effective than the traditional statistical model for named entity translation, which achieves a remarkable 31.6% relative improvement in MRR (Table 5). Furthermore, the proposed model yields a comparable result with the joint transliteration model (also using context) and the origin-based model, which shows its advantage on capturing semantic information from global context, such as origin information.

It is expected that the proposed semantic-specific translation model could be further applied to other language pairs, as no language dependent linguistic feature (or knowledge) is adopted in the model/algorithm used.

Abstract

We present an attempt to extract a large-scale Japanese learners' corpus from the revision log of a language learning SNS. This corpus is easy to obtain in large-scale, covers a wide variety of topics and styles, and can be a great source of knowledge for both language learners and instructors. We also demonstrate that the extracted learners' corpus of Japanese as a second language can be used as training data for learners' error correction using an SMT approach. We evaluate different granularities of tokenization to alleviate the problem of word segmentation errors caused by erroneous input from language learners. Experimental results show that the character-wise model outperforms the word-wise model.

1 Introduction

The number of Japanese language learners around the world has increased more than 30-fold in the past three decades. The Japan Foundation reports that more than 3.65 million people in 133 countries and regions are studying Japanese in 2009 [1]. However, there are only 50,000 Japanese language teachers overseas, and thus it is in high demand to find good instructors for writers of Japanese as a Second Language (JSL).

Recently, natural language processing research has begun to pay attention to second language learning (Rozovskaya and Roth, 2011; Park and Levy, 2011; Liu et al., 2011; Oyama and Matsumoto, 2010; Xue and Hwa, 2010). However, most previous research for second language learning deals with restricted types of learners' errors. For example, research for JSL learners' errors mainly focus on Japanese case particles (Oyama and Matsumoto, 2010; Imaeda et al., 2003; Nampo et al., 2007; Suzuki and Toutanova, 2006), however they focus only on case particles whereas we attempt to correct all types of errors.

However, real JSL learners' writing contains not only errors of Japanese case particles but also various other errors including spelling and collocation errors. For instance, a Japanese language learner who speaks Chinese may write:

何で日本語はこんなに難しいなの？
(Why does Japanese are so difficult?)

which has a grammatical error of inserting 'な' due to literal translation from Chinese. Park and Levy (2011) proposed an EM-based unsupervised approach to perform whole sentence grammar correction, but the types of errors must be predetermined to learn the parameters for their noisy channel model. It requires expert knowledge of L2 teaching, which is often hard to obtain.

One promising approach for correcting unrestricted errors of JSL learners is Brockett et al. (2006)'s automated error correction method using statistical machine translation (SMT). The advantage of their method is that it does not require expert knowledge. Instead, it learns a correction model from sentence-aligned corrected learners' corpora. However, it is not easy to acquire large-scale learners' corpora. In fact, Brockett et al. (2006) used regular expressions to automatically create erroneous corpora from native corpora.

To solve the knowledge acquisition bottleneck, we propose a method of mining revision logs to create a large-scale learners' corpus. The corpus is compiled from error revision logs from a language learning social network service (SNS), which covers a wide variety of topics and styles. The main advantage of using revision logs is three-fold: (1) it benefits from the wisdom of crowds, (2) it can be obtained in large-scale, and (3) it is a great source

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 147–155,
Chiang Mai, Thailand, November 8 – 13, 2011.

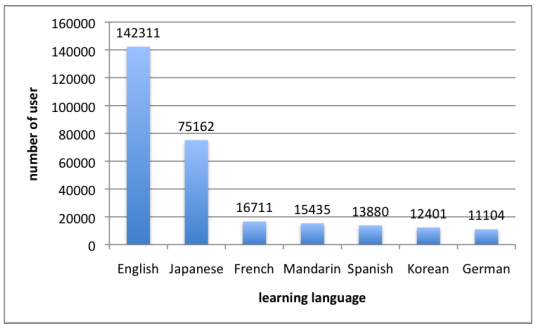

Figure 1: Number of users for each learning language in Lang-8

of knowledge not only for learners but also for language teachers. In this paper, we show that the method using SMT techniques with a large-scale learners' corpus can correct JSL learners' error with reasonable accuracy.

The rest of this paper is organized as follows. Section 2 describes the JSL corpus created from revision logs of a language learning SNS. Section 3 explains an SMT-based approach to JSL error correction. In section 4, we report the experimental results of SMT-based JSL error correction using large-scale real corpus. In section 5, we conduct error analysis and discuss issues of the proposed method. Section 6 concludes this work and presents future direction.

2 A Large Scale Japanese Language Learners' Corpus from Revision Logs

Recent growth of the web has opened the possibility of using the internet to break the barriers of space and time. Specifically, social network service (SNS) has begun to receive a lot of attention recently. There are a number of SNS sites that help language learners across the world, including smart.fm, Livemocha and Lang-8, to name a few. We will look briefly at each SNS below.

First, smart.fm [2] (formerly iKnow!) is a SNS-based language learning service that helps learners practice language learning. Smart.fm provides a tailored curriculum for each user to memorize learning content through simple exercises.

Second, Livemocha [3] is also a language learning SNS that offers course of grammar instructions, reading comprehension exercises and practice for both writing and speaking. Users can submit a free composition on a subject and receive feedbacks from other users of the native language. However, they are not able to write about arbitrary topics.

Third, Lang-8 is a "Multi-lingual language learning and language exchange Social Networking Service" [4] , which has over 200,000 registered members at the moment. As soon as the learners write a passage, mostly a part of a diary, in a language they are learning, native speakers of the language correct it for them. The learners in turn are encouraged to correct other members' composition errors according to their first language (L1). Hence, the SNS is called "language exchange". It supports 77 languages, facilitating multilingual communication.

2.1 Japanese Language Learners' Corpora

One of the most famous learners' corpus is Teramura Error Data [5]. The corpus was mainly collected in 1986 from Japanse compositions written by foreign students, mostly from Asian countries. The corpus consists of several styles including free composition, cloze (gap filling) test, and pattern composition. Unlike this data, JSL learners in Lang-8 encompass the whole world. Also, Lang-8 offers a wide variety of free compositions of the learner's choice, and the size of the data is orders of magnitude (448MB without all the tags) larger than Teramura's data (420KB, 4,601 sentences written by 339 students). Also, although Teramura Error Data is annotated with error types, the correct words or strings are not often provided, which makes it difficult to use it for automatic correction of learners' errors.

Ohso [6] created a database of Japanese compositions by JSL learners. It is annotated with error types with correct forms to allow error analysis. However, similar to Teramura Error Data, the corpus does not cover many topics because it was collected at only four institutions. In addition, it is limited in size (756 files, average file size is 2KB).

The corpus most related to ours is the JSL learners parallel database of Japanese writings and their translation of learners' L1 [7] created by National Institute for Japanese Language and Linguistics. It collects 1,500 JSL learners' writings and their

[7] http://jpforlife.jp/taiyakudb.html

self-translations. There are around 250 writings corrected with error types by several Japanese language teachers. The advantage of this corpus is that some of the texts are annotated by professional language teachers and can be used as a source of error correction. However, again, the size of this corpus is limited since it is hard to obtain annotations from language teachers. Our approach differs from them in that we employ the wisdom of crowds of native speakers, not necessarily language teachers, to compile a large-scale learners' corpus.

2.2 Features of Lang-8 Data

We created a large-scale language learners' corpus from error revision log of Lang-8. Figure 1 shows that approximately 75,000 users are learning Japanese [8]. Table 1 shows the top seven languages in the corpus. There are 925,588 sentences of JSL learners [9]. Out of 925,588 sentences, 763,971 (93.4%) sentences are corrected by human annotators. A sentence written by JSL learners might have two or more revision sentences in Lang-8 by different voluntary reviewers [10]. Therefore, the total number of corrected sentences amounts to 1,288,934. In other words, one sentence gets corrected approximately 1.69 times on average.

There are several distinguishing features of the data obtained from Lang-8. First, since Lang-8 is a language learning SNS, we can obtain pairs of learner's sentence and corrected sentence. Using this data, it is possible to collect the learner's errors. We will describe how to build a learners' corpus from revision logs later in this section.

Second, Lang-8 data may have more than one correction for the same sentence. We could exploit this feature to acquire paraphrases in a similar way to (Barzilay and McKeown, 2001). Table 2 shows an example of multiple correction. Two annotators correct the same learner's sentence. In this example, one can infer that "なりの表現で (in one's own expressions)" and "なりに (in one's own way)" are paraphrases of each other.

Third, we could obtain multi-lingual parallel sentences. Figure 2 shows examples of parallel

Figure 2: Parallel sentence in Lang-8

sentences in Lang-8. In this example, the JSL learner writes two Japanese sentences and their translation for each sentence to tell what he or she wants to say. Although the sentences written in the learning language may contain errors and mistakes, we can align the English translation to the corrected Japanese sentence. The parallel corpus created from the revision log of SNS would be a remarkable source of colloquial expressions ideal for translating consumer generated media such as blogs and SNS.

Fourth, annotators of Lang-8 sometimes add inline comments to the corrected sentences. It is often written in parentheses to indicate that the string is a comment, but not always. Depending on the first language of the language learner, annotators put comments in either the learning language or the learner's L1. This can be a great source of extracting useful information for language learning, since the comment itself explains pitfalls that the language learners often come across.

2.3 Extracting corrected sentence from HTML

All the error revisions are made through a web-based editing interface that allows annotators to delete, insert or change any character sequence of the learner's text by any sequence. Table 3 illustrates an example of the HTML generated from Lang-8's revision editor. The tag `<span class="sline">` shows that the characters within the tags should be removed. The color tags `<span class="red">` and `<span class="f_blue">` are used somewhat arbitrarily by annotators. In general, they indicate correct strings. In the example, the annotator used delete line and red color to point out and correct the first error, and blue color to indicate inserted characters.

From this observation, we apply simple

[8] We counted learning language in user profile. Some learners register two or more learning languages.

[9] We counted learning language written for each journal because learners may write in different languages.

[10] The correction of a new review might be affected by the previous corrections by others.

Table 1: Number of sentences for each language in Lang-8

Language	English	Japanese	Mandarin	Korean	Spanish	French	German
Number of sentences	1,069,549	925,588	136,203	93,955	51,829	58,918	37,886

Table 2: An illustraive example of multiple correction

Sentence written by a JSL learner	三人はそれぞれ自分 の方式で 感情を表 れ ます。
Sentence corrected by an annotator1	三人はそれぞれ自分 なりの表現で 感情を表 し ます。 (Each of three expresses their feelings in their own expressions.)
Sentence corrected by an annotator2	三人はそれぞれ自分 なりに 感情を表 し ます。 (Each of three expresses their feelings in their own way.)

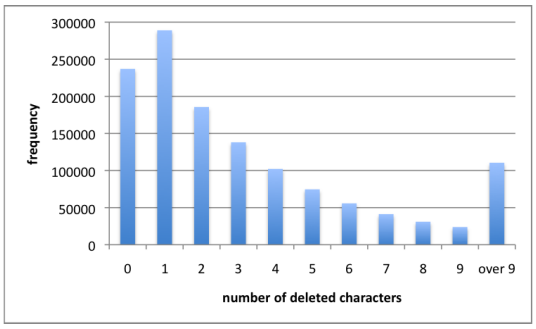

Figure 3: Summary of number of deletion

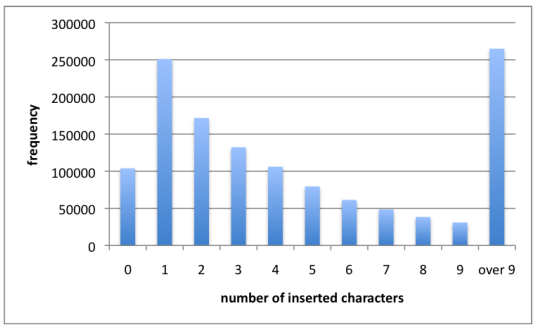

Figure 4: Summary of number of insertion

heuristics to extract corrected sentences from Lang-8. First, we remove all the `<span class="sline">` tags and characters within them. Then, we discard other tags, retaining the characters surrounded by the tags. After this rule, we obtain the corrected sentence shown in the bottom row in Table 4.

2.4 Data Statistic and Filtering by Edit Distance

In an actual correction, it is expected that annotators do not completely rewrite the original sentence and most character strings remain the same as the original sentence. Thus, we investigated the quantitative distribution of Lang-8 data by breaking down the sentences according to the edit distance between the original and corrected sentences (number of deletion / number of insertion of characters in revision log).

Figures 3 and 4 summarize the numbers of deleted and inserted characters. These figures reveal that both distributions of deletion and insertion are comparable. On the other hand, they differ in the absolute frequency of deletion and insertion. For example, the number of cases with no deletion is considerably more than the number with no insertion. Also, the frequency of sentences with more than nine insertions is higher than that for deletions. This reflects the fact that there are many sentences with comments (insertions) and that people tend not to remove too many characters to keep the information of the original sentence written by the learner.

From observations of the created corpus, a correction can be divided into two types: (1) a correction by insertion, deletion, or substitution of strings, (2) a correction with a comment. Table 4 shows examples of correction from Lang-8. The first example is a sentence written by JSL learners containing an error, and is corrected by inserting a character. In the second example the learner's sentence is correct; in addition the annotator writes a comment [11]. Besides, there exist "corrected" sentences to which only the word "GOOD" is appended at the end. In this case, original sentence is not modified at all by the annotator. The inserted comment merely informs the learner that there is no mistake in the learner's writing.

To handle these comments, we conduct the following three pre-processing steps: (1) if the corrected sentence contains only "GOOD" or "OK", we do not include it in the corpus, (2) if edit dis-

[11] Some annotator erase a learner's original sentence and rewrite it to "OK".

Table 3: Extracting corrected sentence from HTML

Sentence written by a JSL learner	去年は参加してなかった、見るだけ。 (I was not participating last year, just watching.)
Corrected sentence with tags	去 年 は 参 加し て な かったせ ず に、見るだけだった。
Seen on the browser	去年は参加~~してなかった~~せずに、見るだけだった。
Corrected sentence	去年は参加せずに、見るだけだった。 (I did not participate but watched last year.)

Table 4: Examples of correction in Lang-8

Sentence written by a JSL learner	ビデオゲームをやました (Video games Yamashita.)
Sentence corrected by an annotator	ビデオゲームをや り ました (I played video games.)
Sentence written by a JSL learner	銭湯に行った。 (I went to a public bath.)
Sentence corrected by an annotator (with comment)	銭湯に行った。 いつ行ったかがある方がいい (I went to a public bath. It is better to say when you went.)

tance between the learner's sentence and corrected sentence is 5, we simply drop the sentence for the corpus, and (3) if the corrected sentence ends with "GOOD" or "OK", we remove it and retain the sentence pair. As a result, we obtained a corpus of 849,894 corrected and aligned sentence pairs by JSL learners.

Another notable issue is that annotators may not correct all the errors in a sentence. Table 5 shows an example of JSL learner's sentence for confusing case markers of "が" (NOM) and "は" (TOP). In this example, "は" and "が" should be corrected to "が" and "は", respectively. However, the annotator left the second case markers "は" unchanged. Because the number of these cases seems low, we regard it as safe to ignore this issue for creating the corpus.

3 Error Correction Using SMT

In this study, we attempt to solve the problem of JSL learners' error correction using the SMT technique. The well-known SMT formulation using the noisy channel model (Brown et al., 1993) is:

$$\hat{e} = \arg\max_{e} P(e|f) = \arg\max_{e} P(e)P(f|e) \quad (1)$$

where e represents target sentences and f represents source sentences. $P(e)$ is the probability of the language model (LM) and $P(f|e)$ is the probability of the translation model (TM). TM is learned from sentence-aligned parallel corpus while LM is learned from target language corpus.

To adapt SMT to error correction, f can be regarded as the sentences written by Japanese learners, whereas e represents the manually-corrected Japanese sentences. TM can be learned from the sentence-aligned learners' corpus. LM can be learned from a monolingual corpus of the language to be learned. Once we obtain a manually-corrected corpus of language learners, it is possible to translate erroneous sentences into correct sentences using SMT.

The use of SMT for spelling and grammar correction has the following three advantages. (1) It does not require expert knowledge. (2) It is straightforward to apply SMT tools to this task. (3) Error correction using SMT can benefit from the improvement of SMT method.

Related work on error correction using phrase-based SMT includes research on English and Japanese (Brockett et al., 2006; Suzuki and Toutanova, 2006). Brockett et al. (2006) proposed to correct mass noun errors using SMT and used 45,000 sentences as training sets randomly extracted from automatically created 346,000 sentences. Our work differs from them in that we (1) do not restrict ourselves to a specific error type such as mass noun; and (2) exploit a large-scale real world data set. Suzuki and Toutanova (2006) proposed a machine learning-based method to pre-

Table 5: Problem of correction in Lang-8

Sentence written by a JSL learner	この４つ が 僕 は 少年のころに発売されて (As for me, these four were sold when I was a kid.)
Sentence corrected by an annotator	この４つ は 僕 は 少年のころに発売されて (As for these four, I was sold when I was a kid.)
Corrt sentence	この４つ は 僕 が 少年のころに発売されて (As for these four, they were sold when I was a kid.)

dict Japanese case particles using a monolingual corpus in the context of SMT.

3.1 Statistical Error Correction with Different Granularity of Tokenization

When translating a sentence from Japanese to another language with SMT, one usually performs word segmentation as a pre-processing step. However, JSL learners' sentences contain a lot of errors and hiragana (phonetic characters), which are hard to tokenize by traditional morphological analyzer trained on newswire text. Suppose we want to tokenize into words the following real sentence written by a JSL learner:

でもじょずじゃりません

The correct counterpart would be:

でもじょう ずじゃあ りません
(But I am not good at it.)

The corrected sentence has "う" and "あ" inserted [12]. These sentences written by a learner and corrected by a native speaker are tokenized as follows by MeCab [13], which is one of the most popular Japanese Morphological Analyzer:

でも じ ょずじゃりません
(but (fragment) (garbled word))

でも じょうず じゃ あり ません
(but good at be not)

These examples illustrate the difficulty of correcting JSL learners' sentence using word-wise SMT.

To alleviate this problem, we propose to build a character-wise segmented corpus with phrase-based SMT. Character-wise model is not affected by word segmentation errors, thus it is expected to be more robust for the task of correcting JSL errors. For the above-mentioned two example sentences, we split sentences into characters rather than words:

This enables the phrase-based SMT to learn the alignment between "じょず" and "じょうず", resulting in a more robust model to correct JSL errors than word-wise model.

4 Experiments on JSL Learner's Error Correction with SMT

We carried out an experiment to see (1) the effect of granularity of tokenization as described in Section 3.1; (2) the effect of corpus size; (3) the difference of L1 model. We used Moses 2.1 [14] as a decoder and GIZA++ 1.0.5 [15] as an alignment tool. We used Japanese morphological analyzer MeCab 0.97 with UniDic 1.3.12 [16] for word segmentation.

We created a word-wise model as baseline. Hereafter, we refer to this as W and also constructed model with entries from UniDic for better alignment, denoted as W+Dic. We used word trigram as LM for W and W+Dic. We built two character-wise models: character 3-gram and 5-gram represented as C3 and C5, respectively. We also conducted minimum error rate training (MERT) (Och, 2003) in all experiments [17].

4.1 Experimental Data

All the data was created from 849,894 Japanese sentences extracted from revision logs of Lang-8 crawled in December 2010. To see the difference of errors stemming from L1, we carried out an experiment with two L1s: English and Mandarin. ALL extracts training data from the entire corpus for the translation model. There are 320,655 Japanese sentences whose L1 is English

[12] It is hard for JSL learners of certain L1 to distinguish Japanese short and long vowels.

[13] http://mecab.sourceforge.net/

[16] http://www.tokuteicorpus.jp/dist/

[17] We performed minimum error rate training to maximize BLEU (5-gram).

and 186,807 Japanese sentences whose L1 is Mandarin. For each L1 JSL corpus, we split the corpus into two parts: 500 sentences for testing and development, and the rest for training.

We shuffled the training data to prepare the corpus for learning LM and TM. We manually reannotated 500 sentences to make gold-standard data and used 200 sentences for testing, and 300 sentences for development.

4.2 Evaluation Metrics

As evaluation metrics, we use automatic evaluation criteria. To be precise, we used recall (R) and precision (P) based on longest common subsequence (LCS) (Mori et al., 1999; Aho, 1990) and character-based BLEU (Papineni et al., 2002).

Park and Levy (2011) adopted character-based BLEU for automatic assessment of ESL errors. We followed their use of BLEU in the error correction task of JSL learners. Since we perform minimum error rate training using BLEU we can directly compare each model's performance.

Recall and precision based on LCS are defined as follows:

$$Recall = \frac{N_{LCS}}{N_{SYSTEM}}, \quad Precision = \frac{N_{LCS}}{N_{CORRECT}}$$

where N_{LCS}, N_{SYSTEM}, and $N_{CORRECT}$ denote the number of character containing longest common subsequences of system results and corrected answers, the number of character containing system results, and the number of character containing corrected answer, respectively. Also, F-measure is the harmonic average between R and P. To illustrate recall and precision based on LCS, let us consider the following example:

CORRECT: 私 は 学生 です
(I am a student)

SYSTEM: 私 わ[18] 学生
(I ring student)

LCS consists of three characters "私 学 生", and $N_{LCS} = 3$. Number of characters in the corrected sentence is six and that in the system is four, so $N_{CORRECT} = 6$ and $N_{SYSTEM} = 4$. Thus, $Recall = 3/4$ and $Precision = 3/6$.

4.3 Experimental Results

Comparison of granularity of tokenization Table 6 illustrates the performance with different methods (Training Corpus: L1 = ALL; Test Corpus: L1 = English; TM: 0.3M sentences; LM: 1M sentence). The character-wise models outperform the word-wise model in both recall and precision. C5 achieved the best precision, F and BLEU, while C3 obtained the best recall.

Table 6: Comparison of the performance (recall, precision, F, BLEU) of error correction for each system with different granularity of tokenization (TM: 0.3M sentences, LM: 1M sentence)

	W	W+Dic	C3	C5
R	0.9043	0.9083	**0.9089**	0.9083
P	0.9175	0.9210	0.9234	**0.9243**
F	0.9109	0.9146	0.9161	**0.9162**
B	0.8072	0.8101	0.8163	**0.8181**

Effects of corpus size We varied the size of TM while fixing the size of LM to 1M sentences to see the effect of corpus size on the performance. Figure 5 shows the performance (BLEU) with different TM size (Training Corpus: L1 = ALL; Test Corpus: L1 = English). The larger the size of the TM, the higher the BLEU. This confirms that the large scale JSL learner's corpus extracted from Lang-8 is a great source of learning learners' errors. Although TM trained on 0.85M sentences exhibits lower performance than TM trained on 0.3M sentences, the difference is not statistically significant.

Comparison of L1 of the training model Table 7 shows result for each L1 trained translation model [19].

Basically, performance was better when TM was trained with the same L1 as the test set. In the case where L1 of test data is English, the model trained from ALL is comparable to L1 English. This is because the model trained from ALL includes many sentence written by learners whose L1 is English.

5 Discussion

As we discussed in Section 2, the extracted corpus still contains comments in the corrected sentences. However, it does not greatly affect the performance of the JSL learner's error correction, demonstrating that we were able to build a large-scale JSL learners' corpus from revision logs. Moreover, we have checked all the output of

[18] The pronunciation of "わ" is the same as "は".

[19] Note that LM was trained from the whole training corpus. We did not change L1 for LM.

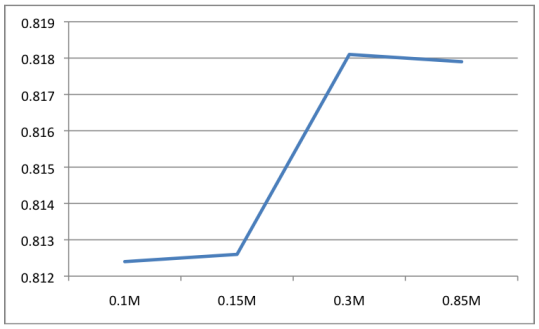

Figure 5: Comparison of the performance (BLEU) of error correction for different size of TM (fixing the size of LM to 1M sentence)

our SMT-based error correction system, but none of the errors of the system derive from the annotators' comments.

Here are some examples illustrating the difference of the scale of the training corpus.. We compared translation models TM trained on 0.1M sentences and 0.3M sentences in Figure 5. Note that the model trained on 0.1M sentences gave the worst result, wheares model trained on 0.3M sentences achieved the best. All the models were trained on 1M sentence for LM. Both models corrected the examples below:

Original: またど もう ありがとう
(Thanks, Matadomou (OOV))

Correct: またど うも ありがとう
(Thank you again)

Also, both of them corrected a case marker error frequently found in JSL learners' writing as in:

Original：TRUTHわ 美しいです
(TRUTH wa beautiful)

Correct：TRUTHは 美しいです
(TRUTH is beatiful)

On the other hand, the model trained on 0.3M sentences corrected the following example:

Original: 学生な る たら学校に行ける
(the learner made an error in conjugation form.)

Correct: 学生な った ら学校に行ける
(Becoming a student, I can go to school.)

0.1M: 学生な るため 学校に行ける
(I can go to school to be student)

0.3M: 学生な った ら学校に行ける
(Becoming a student, I go to a school)

Table 7: Comparison of the performance (recall, precision, F, BLEU) of error correction trained on different first language (L1). (TM: 0.18M sentences, LM: 1M sentences)

			L1 of test data	
			English	Mandarin
L1 of training data	English	R	0.9079	0.9339
		P	0.9241	0.9387
		F	0.9159	0.9363
		B	**0.8148**	0.8573
	Mandarin	R	0.9063	0.9357
		P	0.9169	0.9388
		F	0.9116	0.9373
		B	0.8083	**0.8589**
	ALL	R	0.9099	0.9349
		P	0.9183	0.9367
		F	0.9141	0.9358
		B	0.8121	0.8553

This example also illustrates the fact that there remains uncorrected errors (missing "ni" case marker after "学生" *student*) as we discussed in Section 2.4.

Another remaining issue is evaluation metric. We have used character-based BLEU, recall and precision based on the longest common subsequence. These methods have the advantage of allowing automatic system evaluation, but they do not reflect the importance of the errors that language learners make. There is still much room for improvement in the evaluation metric for error correction of language learners.

6 Conclusions

We proposed to extract a large-scale learners' corpus from the revision log of a language learning SNS. This corpus is easy to obtain in a large-scale, covers a wide variety of topics and styles, and can be a great source of knowledge for both language learners and instructors. We adopted phrase-based SMT approaches to alleviate the problem of erroneous input from language learners. Experimental results show that the character-wise model outperforms the word-wise model. We plan to apply factored language and translation models incorporating the POS information of the words on the target side, while learners' input is processed by a character-wise model.

Abstract

This paper presents a new method for Authorship Attribution (AA) on online forum posts. The idea behind the method is to generate meta features that capture modality specific similarity relations among texts from different authors. Each modality represents a particular linguistic dimension (syntactic, lexical, stylistic). To evaluate this approach we measure prediction accuracy on data from an online forum with up to 100 candidate authors. We also compare our results with a state of the art approach that has shown to perform well across different genres. We have found the meta features to be especially helpful in the online forum domain, where the documents are very short, showing this to be a very promising direction for AA on a realistic web forum scenario.

1 Introduction

Authorship attribution (AA) refers to the task of analyzing a document to identify the potential author who wrote the text. Earlier work on this problem involved gathering statistics about the frequency of words with specific length, together with other stylistic characteristics extracted from written samples that were in most cases an entire book or volume (Mendenhall, 1887; Mosteller and Wallace, 1964). Current approaches to AA relay on casting this problem as a text classification task, where instead of aiming to do a thematic classification of documents the goal is to have the models learn the distinguishable characteristics in the written work of authors. The focus of analysis on more recent work has also shifted from book-length pieces to documents with length ranging from a couple of blocks (Hirst and Feiguina, 2007) to samples with at most 140 characters (Layton et al., 2010).

AA can help settle disputes over the original creators of a given piece of text. But other practical applications include using AA for building a prosecution case against an online abuser. This is an important application, especially when we consider the raising trends in cyber-bullying and other electronic forms of teen violence[1].

Achieving good accuracy in AA on spontaneous online data is, however, far more challenging than the typical scenario for AA. One of the major complicating factors involves the limited amount of training data. In the typical scenario, we may have an entire document (several pages long), or even an entire book, while in the case of online data from social media we will have very short texts that are a couple of sentences long. Another challenge related to online data from social media is the number of potential authors that the model will need to learn. Consider aiming to do AA for data of online web forums, which is the goal in our work. In this case the potential author of a given post is one out of the thousands of registered users in that forum. In contrast, the majority of the text classification problems have a small number of classes. Lastly, we have to consider the problems with processing spontaneous written

[1] http://cyberbullying.us/index.php

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 156–164,
Chiang Mai, Thailand, November 8 – 13, 2011.

language, and in particular, from informal interactions of web forum posts. The fact that the written fragments are informal is not by itself a complicating factor. We can argue that because they are informal they allow the writer to express more freely and thus they may contain more revealing information. But if we are to use syntactic analyzers to extract features for our learning model, as previous work in AA has done, then these informal and spontaneous samples can cause the analyzers to break, or output very noisy information.

This paper presents a new approach for AA on web forum data that generates informative meta features that can help discriminate the posts from different authors. The meta features in our work are derived from clustering of the feature vectors. However, different from distributional clustering and related approaches such as (Baker and McCallum, 1998; Slonim and Tishby, 2001; Dhillon et al., 2003), we do not cluster the features, but the instances in an unsupervised fashion. The goal of the meta features is to encode high level relations of similarities among posts from different authors, and not to reduce the feature set or find semantically related features as in the work listed above. Moreover, another difference and contribution of our work is the idea of generating modality specific meta features. This modality specific framework allows to reach higher AA accuracy on short texts than that achieved by the standard approach using only first level features and competitive state of the art approaches.

The question we aim to answer here is whether generating these metafeatures, which contribute to the computational cost, are indeed helpful in the scenario of AA on web forum posts. Our experiments are done on a much smaller scale than that of the real scenario, with data sets of up to 100 authors and in a closed-class setting. However, they represent the best results reported so far under similar conditions and thus they show promise to scale up. The results we present show that the modality specific meta features are indeed helpful for short online data, and outperform accuracy of previous work.

The next section reviews related work on AA. Then in Section 3 we discuss our approach to generating meta features from clustering the instances using different "views" of the posts. A discussion of the first level features is presented in Section 4. Section 5 presents the data sets used in our experiments. The evaluation of our approach is outlined in Section 6, where we also discuss our baseline system and results. The last section summarizes our findings and outlines our research goals for the immediate future.

2 Related Work

Authorship Attribution (AA) and related author analysis tasks, such as plagiarism detection and author profiling, have received a lot of attention recently, but most of the evaluation sets have a small number of authors. Here we highlight previous work that involves a large number of authors (at least 50) and refer the reader to the survey by (Stamatatos, 2009).

Luyckx and Daelemans studied the impact on accuracy of the number of potential authors and the size of the training data per author (Luyckx and Daelemans, 2010). They measured classification accuracy of a memory-based learner on three datasets with up to 145 candidate authors for one of them. The features used in their experiments include lexical features, such as word and lemma n-grams, type/token ratio, and readability measures; the syntactic features include Parts-of-Speech (POS), grammatical relations, chunk n-grams, and tokens with POS attached. They also used character n-grams, features that have been found to work well for AA (Peng et al., 2004; Plakias and Stamatatos, 2008). As expected, accuracy reported for 145 authors ($\tilde{1}2\%$) was considerably lower than that achieved when the number of authors was smaller. An important characteristic of Luyckx and Daelemans work is that the 145 author set has only one document per author. In the experimental setup they partitioned each document into 10 fragments and used 9 of these fragments for training their model while testing on the remaining one. We believe that training a model on pieces of the same document used for testing is not exactly the task of AA, at least not in a realistic scenario. However, we recognize that the limited training data is an important constraint.

(Layton et al., 2010) shows results from using the Source Code Authorship Profile (SCAP) method on Twitter data where the microblogs are restricted to a maximum of 140 characters. The SCAP method, as developed by (Frantzeskou et al., 2007), determines authorship by measuring the overlap in character n-grams from the text document to the concatenated documents of each au-

thor. On a set with 50 authors, the SCAP method reached an accuracy of 55%, although when the `@username` was included in the text their accuracy increased to little over 70%. As the authors suggest, expecting to have this `@username` information from an author that wants to remain anonymous is not realistic.

Koppel *et al.* (2011) present a study of AA using blog data crawled from `blogger.com`. The approach used by them is based on computing cosine similarity from vectors of character 4-grams, and the number of candidate authors is by far the largest reported in the literature: for some experiments they trained on 10,000 authors and tested on 1,000. Precision and Recall in this setting were reported at 87.9% and 28.2%, respectively. However, we should also note that in these experiments text was also fragmented into snippets, and similar to what Luyckx and Daelemans did, the similarity model uses fragments of the same source text to predict authorship. In our opinion, the task resembles more a data provenance problem than an AA one. Moreover, because the blog data used in this work was not controlled for topic, and given that they used character 4-grams as features in a similarity based approach, we speculate that in the Koppel *et al.* setting there is more risk to bias the task from AA to a semantic or topic categorization and the only way to disentangle the two is by controlling for topic variation.

In another interesting recent work on AA, Probabilistic Context-Free Grammars (PCFGs) were proposed for AA (Raghavan et al., 2010). The number of authors in the evaluation data sets was rather small (3 to 6) but it included different domains, such as poetry, football, business, travel, and cricket, and all the data was harvested from the Internet. Raghavan et al. trained a PCFG for each author independently and authorship on the test data was assigned by taking the highest likelihood score from these grammars. To overcome the data sparseness problem, they mixed treebanked data from the Wall Street Journal (WSJ). They also enriched this mostly syntactic models with lexical information by combining the output with a bag-of-words Maximum Entropy classifier and a word-based n-gram language model. In their case, the combined model performed better than the baseline and the other machine learning approaches for most of the datasets. What is very interesting from this previous work is the fact that the same inexpensive PCFG-based approach worked reasonably well on all the data sets tested. In our experiments we evaluate this approach on the web forum data and the results show this to be a competitive method, even though the number of potential authors increased by a large margin and the documents are shorter than those used in (Raghavan et al., 2010).

3 Modality Specific Meta Features for Authorship Attribution

The standard formulation of text classification considers having a set of labeled examples, l, where each document is represented by a feature vector $\mathbf{x} \in R^n$ and their corresponding labels y, where $y_i \in \{0, 1\}$ in a binary classification. The feature vectors and their true class values are then input to a learning algorithm that will then build a model to predict the class of new instances. In contrast, we extract a set of smaller feature vectors that are then the basis for generating meta features, or more concretely, meta feature vectors.

Our approach starts with the extraction of first-level features to generate a feature vector representation for each instance. However, in our framework instead of having a single feature vector for $\mathbf{x}$, we generate m smaller vectors that contain complementary types of features, or views, describing the instances. We call these different views multimodal because they represent different characteristics of the text. More formally, an instance $\mathbf{x}$ is now represented as $\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_m\}$ where each $\mathbf{x}_i$ is a vector with $|\mathbf{x}_i|$ features in modality i. Note that $\textbf{union}(\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_m) = \mathbf{x}$ and $\textbf{intersection}(\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_m) = \emptyset$ since we are only generating sub vectors (or complementary views) from the original feature set.

The generation of meta features uses these m different vectors to produce m clustering solutions for the training data with k clusters each. That means that we end up with different arrangements of the training instances into clusters, one arrangement per modality. Note that since clustering is performed per modality, k may be different in each clustering solution. From each cluster c_k in each of the m clustering solutions, we compute a centroid by averaging all the feature vectors in that cluster.

$$\textbf{centroid}_{m_i} = \frac{1}{\mid c_{m_i} \mid} \sum_{x_j \in c_{m_i}} \mathbf{x}_j \qquad (1)$$

where i above ranges from 1 to k, the number of clusters. We then measure the *similarity* of each instance to these centroids using the cosine function. These $m \times k$ similarity values are then used as the meta features, x', and we compute them for training and testing instances. Thus, as a result of this step each instance $\mathbf{x}$ is now represented by m tuples of vectors, the first level feature vectors $\langle \mathbf{x}_{i_1}, ..., \mathbf{x}_{i_{|x_i|}} \rangle$ and the newly generated meta feature vectors $\langle \mathbf{x'}_{i_1}, ..., \mathbf{x'}_{i_k} \rangle$ for each modality i.

In our problem of AA, we consider four types of first level features: stylistic features, lexical features, syntactic features, and perplexity values from character 3-gram language models. That is, in these experiments $m = 4$. Therefore, in our problem we have $x = \{\mathbf{x}_{sty}, \mathbf{x}_{lex}, \mathbf{x}_{ppl}, \mathbf{x}_{syn}\}$, where $\mathbf{x}_{sty}$ refers to the feature vector containing only stylistic features, $\mathbf{x}_{lex}$ is the vector for lexical features, $\mathbf{x}_{ppl}$ is the feature vector for perplexity values, and lastly, $\mathbf{x}_{syn}$ is the vector of syntactic features. Section 4 describes the features we are using in more detail.

To summarize, our MSMF approach is different from previous machine learning approaches to AA in that it has an intermediate step where we generate meta features from clustering the training instances per modality. Thus, all the vectors $\mathbf{x}_{sty}$ in the training data are input to a k-means clustering algorithm. Similarly, the set of vectors $\mathbf{x}_{lex}$, $\mathbf{x}_{ppl}$, and $\mathbf{x}_{syn}$ are clustered separately.

We are proposing to generate new meta features from clustering the data that can better represent posts from each author, but more important, the relation, i.e. closeness, to posts from other authors. It should be noted that no class information is used during clustering as the idea is to uncover regularities across the posts from authors on individual modalities as a result of the clustering. New in this work as well is the idea of a multimodal clustering, where each feature modality is clustered separately. Our assumption is that generating clusters by looking at feature sets separately will allow contrasting authors' characteristics in a subdimensional space without the risk of blurring differences, or similarities, across authors that can occur when clustering the entire feature vector at once. For instance, one author may have a similar style on the use of emoticons to a subset of authors while sharing similar syntactic characteristics to a very different subset of authors. This information, we hope, will be captured by the metafeatures, and will yield higher classification accuracy than the first level features by themselves.

4 First Level Features

The previous section motivated and described the use of the meta features. This section describes the first level features, where by first level features we refer to features computed directly from the documents.

Table 1 shows a list of the features used arranged by modality. For the *stylistic* modality we crafted a list of features tuned for written interactions in social networks. Thus, we use percentages of non-alphanumeric characters that are commonly used in emoticons. We also include percentages of capitalized words, use of quotations, and use of signature, that we believe allow writers more freedom to express their unique writing style. The *lexical* modality is the standard bag of words representation used in text classification that has also been commonly used in previous AA work (Argamon and Levitan, 2005; Zhao and Zobel, 2005). In the modality noted as *perplexity* in Table 1 we use perplexity values as computed by character 3-gram language models. We use the training data to train one language model per author and each model generates a perplexity, or cross entropy, value per instance. For training the language models and computing perplexity values we used the SRI-LM toolkit (Stolcke, 2002). Frequencies of character n-grams have also been successfully used to build author profiles (Keselj et al., 2003). However, to the best of our knowledge, this is the first work exploiting character-based language models for AA, although, Raghavan *et al.*'s work on PCFGs is closely related to this. Lastly, in the *syntactic* modality we have unigrams, bigrams, and trigrams of POS tags, and typed dependency relations extracted using the Stanford parser (Marneffe et al., 2006), that have been used before in AA.

5 Data Sets

To test our approach we downloaded posts from the Chronicle of Higher Education (CHE). Because our focus is on evaluating the use of metafeatures for the problem of AA in web forum posts, we need to control potential confounding characteristics in the data. Therefore, for our evaluation we downloaded posts from a single topic and generated 5 data sets with a different number

Modality	Features
Stylistic	Total number of words Average number of words per sentence Binary feature indicating use of quotations Binary feature indicating use of signature Percentage of all caps words Percentage of non-alphanumeric characters Percentage of sentence initial words with first letter capitalized Percentage of digits Number of new lines in the text Average number of punctuations (!?.;:,) per sentence Percentage of contractions (won't, can't) Percentage of two or more consecutive non-alphanumeric characters
Lexical	Bag of words (freq. of unigrams)
Perplexity	Perplexity values from character 3-grams
Syntactic	Part-of-Speech (POS) tags Dependency relations Chunks (unigram freq.)

Table 1: Feature breakdown by modality

of authors each. Table 2 shows some statistics on these data sets.

Because the forum is related to higher education it is expected that users of this forum will be more conscious about their writing and grammar. This is one of the reasons why we decided to start working on this data as a first cut on the problem of AA on online forums. However, it is still a spontaneous and informal setting. Table 3 shows some excerpts from the forum that show this to be a middle ground between carefully edited and written text and typical social media samples.

"OH MY GOD. ARE YOU THE STUPIDEST MAN... WAIT STUPIDEST PERSON ON THE FACE OF THIS EARTH?
"We've been married for xx years and you STILL can't figure it out? Look, here's a quarter. Why don't you call someone and see if they will help you PULL YOUR HEAD OUT OF YOUR A$$."

Table 3: Excerpts from the CHE forums

Our datasets are available to the research community by contacting the authors[2].

6 Empirical Evaluation

For all our experiments we chose a fixed partition of training and testing for all collections. We randomly divided each data set into 80% training and 20% testing. We are presenting results of using Support Vector Machines (SVMs) (Schölkopf and Smola, 2002) as the underlying learner as implemented in WEKA (Witten and Frank, 2005). We report classification accuracy as the evaluation metric.

6.1 Baseline Experiments for AA

The first set of experiments we present are aimed at establishing a good baseline for our approach. Following the baselines presented in previous work, we measure prediction performance for AA on the CHE collection using a bag-of-words approach.

Authors	Baseline
5	51.30
10	44.59
20	36.58
50	29.20
100	27.95

Table 4: Baseline accuracy using SVMs and bag of words for the CHE data set

The results are shown in Table 4. The baselines chosen are strong. Especially for the data set with 100 authors, where SVMs reached an accuracy of close to 30%, much higher than a simple majority predictor (1/100), but also considerably higher than that reported for datasets with a similar number of authors (Luyckx and Daelemans, 2010). As expected, accuracy drops as the number of potential authors increases, with the 100 authors data set posing the greatest challenge for the classifier.

6.2 First Level Features (FLF) for AA

Before we evaluate the meta features approach we want to assess the value of the first level features for this problem. The features described in Section

[2]Because the CHE data set exceeds the 10MB limit we were unable to upload it as supplementary material.

Dataset	Authors	Total Number of Posts	Avg Number of Posts per Author	Avg Number of Words per Author
1	5	2,889	577.8	39,664
2	10	5,579	557.9	40,953
3	20	9,779	488.95	35,838
4	50	15,543	310.86	21,502
5	100	16,171	161.71	11,322

Table 2: Summary of the CHE data set

4 were tailored to the web forum domain, therefore we expect them to be valuable for learning to discriminate the writeprint of each author. We used SVMs as the underlying algorithm. The results are shown in Table 5. In all cases the FLF outperformed the baseline results.

Authors	FLF Accuracy
5	69.21
10	70.81
20	67.06
50	60.12
100	57.78

Table 5: Results using First Level Features (FLF) and SVMs for the CHE data set

These results are higher than what has been reported on AA for a similar number of authors. The FLF have shown to be competitive and in some cases the improvement in accuracy over the baseline reaches 100%. In most cases accuracy decreased with a larger number of potential authors, although, for the data set with 10 authors accuracy was a little bit higher than with 5 authors. Moreover, the drop in accuracy is not as pronounced as in the baseline system, suggesting that BOWs are not sufficient to solve this task and that a combination of features, such as those included in our FLF are more appropriate for this problem.

6.3 Using Modality Specific Meta Features (MSMF)

After establishing the baseline performance in our data set, and the performance of using only FLF, we want to evaluate the idea of generating meta features that are modality specific. As described in Section 3, we cluster each of the four types of feature vectors in the training data set separately. Because we use a k-means clustering algorithm, implemented in CLUTO, the first step is to choose the number of clusters. Determining the optimal number of clusters is challenging and beyond the scope of this exploratory work. But it is still an important parameter in our solution since the value of k determines the number of meta features generated per modality. The role of these meta features is to extract relations among the posts of different authors on a given modality. A reasonable assumption is then to set k as a function of the number of authors. We experimented setting k =number of authors $\times n$, with values of $n = 1, 3, 5, 10, 15$. For example, for the data set with 5 authors we experimented with values of $k = 5, 15, 25, 50, 75$.

Authors	K	MSMF	FLF	MSMF+FLF
5	1×5	45.04	69.21	73.39
	3×5	50.95		74.6
	5×5	53.91		74.08
	10×5	62.60		75.47
	15×5	65.04		**76.17**
10	1×10	37.47	70.81	77.38
	3×10	47.29		75.85
	5×10	50.09		76.3
	10×10	61.16		**77.38**
	15×10	59.54		76.84
20	1×20	35.35	67.06	70.81
	3×20	40.03		71.22
	5×20	43.78		71.37
	10×20	48.40		**71.42**
	15×20	49.58		70.96
50	1×50	32.77	60.12	63.20
	3×50	37.66		62.75
	5×50	39.83		63.72
	10×50	43.50		**63.79**
	15×50	44.53		63.33
100	1×100	33.15	57.78	60.41
	3×100	40.11		60.95
	5×100	42.02		61.17
	10×100	42.52		**62.10**
	15×100	43.34		59.54

Table 6: Accuracy results for AA on the CHE collection when using modality specific metafeatures (MSMF), first level features (FLF) and the combination of both (MSMF+FLF)

Table 6 summarizes our results showing accuracy values. For comparison purposes we include in this table results from using only first level features (FLF), only modality specific meta features (MSMF), and the combination of both (MSMF+FLF). The results show several consistent trends across all 5 data sets. First, meta fea-

tures by themselves are always outperformed by the first level features. This is not surprising since the meta features aggregate posts from different authors depending on similarity and thus predicting authorship only on these features does not work as well as the standard approach of using first level features. However, these meta features do outperform the bag of words baseline results (compare column MSMF in Table 6 with results shown in Table 4), underscoring the fact that the CHE data set is harder than the typical text classification task where the lexical features by themselves can solve the problem with very high accuracy. Moreover, the combination of first level features and meta features (MSMF+FLF) consistently achieves higher accuracy than any of the other two alternatives, this is the second trend and the most relevant to our work. These results show that the modality specific meta features are important and yield improvements of up to 10% in accuracy over the standard approach of using only FLF, and of more than 100% in accuracy over a strong bag of words baseline. Third, with respect to the value of k, the results show that for all values chosen, the MSMF outperforms the baseline results, and that using the combined set of features (MSMF+FLF) will yield a higher accuracy than that of using only the first level features. However, it does seem that higher values of k result in higher accuracy, suggesting that trying to find more clusters, and therefore finer-grained clusters in the data is resulting in the extraction of more meaningful relations among the posts of different authors. The results also show that the best k overall was $k = 10\times$ number of authors. For larger k values only the data set with 5 authors reached better results. Overall, it is interesting to see as well that both types of features yield classifiers that are less affected by the larger number of authors, as the drop in accuracy seems to be less pronounced than in the baseline system (see Table 4).

Our previous results show that the meta features contribute to a better prediction of authorship. But what about the multi modal framework? In order to assess if generating modality specific meta features is helpful we performed additional experiments where all instances are represented by a single vector that concatenates all modality feature vectors. The rest of the meta features approach remains unchanged, the vectors are clustered using k-means clustering and we generate metafeatures for each instance. The results are shown in Table 7 and for all cases we chose k = number of authors$\times 10$. The results under AMMF are the meta features generated without separate processing per modality, AMMF+FLF shows results of combining first level features with "all modalities together" meta features. As we speculated, there is a considerable gain in accuracy from the independent processing per modality. The gain in accuracy of MSMF over AMMF ranges from 73% to $\sim$250%. This gain possibly comes from the ability to aggregate feature vectors that semantically represent the same type of information, which can be difficult to maintain when all modalities are grouped together. Both approaches improve accuracy when they are combined with FLF, but again the combination using modality specific meta features (MSMF+FLF) yields the best results. However, the gain in accuracy observed when going from AMMF+FLF (Column 4 in Table 7) to MSMF+FLF (Column 5 in Table 7) is not as large as that observed when going from using only AMMF (Column 2 in Table 7) to MSMF (Column 3 in Table 7). This is expected since both approaches share the same set of FLF, which we know are by themselves very powerful. Further experiments and analysis are needed to better characterize the advantages of the MSMF approach. We plan to leave this for future work.

6.4 Benchmark Comparisons

To explore further the intuition that our approach is a good alternative for AA on web forum data we performed additional experiments where we evaluated the PCFG-based approaches in (Raghavan et al., 2010). In their experiments they have three systems: one is the standard PCFG approach, noted as PCFG in Table 8, the second version uses treebanked data from the WSJ mixed with the original CHE data. This interpolated version is called PCFG-I in that table. We followed the same approach of training the parser on the first 10 sections of the WSJ. For the interpolation, we added Section 20 of the WSJ and replicated the original author's data twice. The third version, noted as PCFG-E, is the combination of the PCFG with the bag-of-words MaxEnt model, and an n-gram language model. The results in Table 8 show that the best accuracy in the CHE collection is achieved by our method in all four data sets. For comparison purposes we also included here the baseline results

Authors	AMMF	MSMF(% gain)	AMMF+FLF	MSMF+FLF(% gain)
5	36.00	62.60 (73%)	71.47	**75.47**(5%)
10	19.63	61.16 (211%)	70.99	**77.38**(9%)
20	19.63	48.40 (146%)	69.06	**71.42**(3%)
50	12.44	43.50 (249%)	61.65	**63.79**(3%)
100	15.07	42.52 (182%)	59.16	**62.10**(4%)

Table 7: Accuracy comparison on CHE data set between generating modality specific meta features (MSMF) and meta features with all modalities together (AMMF), and the combination of each with first level features (FLF).

Approach	5 Authors	10 Authors	50 Authors	100 Authors
SVM	51.3	44.59	29.20	27.95
PCFG	62.95	58.46	31.41	29.77
PCFG-I	64.17	61.26	46.02	44.43
PCFG-E	64.00	55.85	36.11	34.72
Our Approach	**75.47**	**77.38**	**63.79**	**62.10**

Table 8: Benchmark comparison of AA accuracy on the CHE collection

shown in Table 4. The baseline results are consistently outperformed by all of the PCFG-based approaches, showing yet again PCFGs to be robust to different genres but more important, to scale up well to a larger number of authors. However, the results were considerably lower than those of our method. These results support our hypothesis that the modality specific meta features are appropriate for online forum data where the documents are short, the number of potential authors is larger, the stylistic features are more discriminative, and there are less restrictions with respect to standards of writing. Another interesting finding from these experiments is the fact that the PCFG-I method always reached higher accuracies than the ensemble in the CHE collection. In Raghavan *et al.*'s collection, the ensemble (PCFG-E) was the most accurate model. We believe this difference is because of the fact that the CHE collection is single topic, having a more semantically uniform collection prevented the lexical-based components, such as bag of words and n-gram language models, used in the ensemble to boost accuracy.

7 Concluding Remarks

Following recommendations from previous work in AA, we have gathered a single topic evaluation data set of web forum posts with up to 100 candidate authors. The main contribution of this work is the use of modality specific meta features generated by an unsupervised approach. Previous work has used distributional clustering to aggregate features that share the same relation with the class (Baker and McCallum, 1998; Slonim and Tishby, 2001; Dhillon et al., 2003). Our proposed framework is different, we generate meta features from similarity metrics between centroids from an unsupervised clustering of instances and the instances themselves. The additional cost in clustering instances shows to be valuable for AA as we can gain up to 100% improvements in accuracy over strong baselines. Further analysis of results also showed that treating each modality separately to generate the meta features is also important and can yield gains of close to 10% in accuracy over the standard approach of using only first level features. To the best of our knowledge, this is by far the best result reported for AA in a task having up to 100 authors. The framework is general enough that it can be extended to other classification problems where instances can be represented using different modalities.

The experimental evaluation presented here shows that a relatively inexpensive approach based on PCFGs can scale up to a larger number of authors, even if the documents are only a couple of sentences long. However, this syntactically driven approach is outperformed by our proposed modality specific meta features framework.

The results are very promising although we recognize that this is not yet a real world scenario for web forum data, so we are currently gathering data sets with a larger number of authors. We also want to evaluate this work on different data sets to analyze the robustness and suitability of this method. Lastly, we want to study the effect of having more than one topic in the data set as in the work of (Schein et al., 2010).

{09110240024,qz,xjhuang}@fudan.edu.cn

Abstract

In recent years, keyphrase extraction has received great attention, and been successfully employed by various applications. Keyphrases extracted from news articles can be used to concisely represent main contents of news events. Keyphrases can help users to speed up browsing and find the desired contents more quickly. In this paper, we first present several criteria of high-quality news keyphrases. After that, in order to integrate those criteria into the keyphrase extraction task, we propose a novel formulation which converts the task to a binary integer programming problem. The formulation cannot only encode the prior knowledge as constraints, but also learn constraints from data. We evaluate the proposed approach on a manually labeled corpus. Experimental results demonstrate that our approach achieves better performances compared with the state-of-the-art methods.

1 Introduction

Keyphrase extraction is a long studied topic in natural language processing. A keyphrase, which consists a word or a group of words, is defined as a precise and concise expression of one or more documents. It has been widely used in various applications such as summarization, clustering, categorizing, browsing, and so on. In recent years, keyphrase extraction has received much attention (Witten et al., 1999; Zha, 2002; Hulth, 2003; Tomokiyo and Hurst, 2003; Chen et al., 2005; Medelyan et al., 2009; Liu et al., 2009).

Keyphrases are usually manually chosen by authors, for scientific publications, magazine articles, books, et al. Due to the expensive and time consuming effort of manually assigning keyphrase, web pages and online news rarely contain keyphrases. It should be useful to automatically extract keyphrases from online news to represent their main contents. There are already a number of studies which focus on extracting keyphrases from scientific publications or single news article (Frank et al., 1999; Turney, 2000; Wan and Xiao, 2008; Jiang et al., 2009). We also notice that, currently, many websites provide the service which group related news together to facilitate users' browsing. In this paper, we focus on extracting keyphrases from a group of news articles which describe the same news event by different publishers.

Previous studies on keyphrase extraction can be roughly categorized into two groups: supervised and unsupervised. Unsupervised approaches usually select a set of candidates and use different ranking methods to select the candidates with the highest scores as keyphrases. Most of ranking methods are based on the information extracted from the document, such as TF·IDF, position, syntactic relation with other words, and so on. Supervised methods convert the task into a binary classification problem, which categorizes phrases as keyphrases or non-keyphrases. Similar as other tasks applied by supervised methods, a large amount of domain dependent training data is required. When the domain is changed, the labeled corpus should also be changed. And corpus labeling is a time-consuming and tedious task.

Most of the current methods focus on judging the importance of each phrase, and individually extract phrases with the highest scores. After analyzing the human assigned keyphrases, we observe

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 165–173,
Chiang Mai, Thailand, November 8 – 13, 2011.

that the keyphrases of news should satisfy the following properties:

1. **Relevance**. The keyphrases should be semantically relevant to the news theme. The most important ones should be selected as keyphrases.

2. **Coverage**. The keyphrases should be indicative of the whole news event. The extracted keyphrases should cover most of the aspects of the news event.

3. **Coherence**. The keyphrases should be semantically related to each other, and logically consistent and holding together as a harmonious whole.

4. **Conciseness**. The keyphrases should not contain keyphrases with redundant information.

In order to automatically select keyphrases which can satisfy the above properties, in this paper, we propose a novel formulation which converts keyphrase extraction to a binary integer programming problem (BIP) (Alevras and Padberg, 2001). An objective function and a number of constraints which high-quality keyphrases should satisfy are specified. BIP, which is the special case of integer programming and a well-studied optimization framework, is used to efficiently search the entire space to extract keyphrases. The formulation provides a flexible framework for integrating different criteria as objective functions or constraints.

The major contributions of this work can be summarized as follows: 1) We propose a novel formulation of keyphrase extraction as a binary integer programming problem; 2) Several criteria which high-quality keyphrases should satisfy are converted to the objective function and a set of constraints in order to fit the formulation; 3) Keyphrases are extracted as a set with consideration of their relationships; 4) Experimental results on the dataset consisting of 150 groups of news articles with human annotated keyphrases demonstrate that the proposed method performs better than the state-of-the-art algorithms.

The rest of this paper is organized as follows: Section 2 reviews some related studies. We propose our approach in Section 3. In Section 4, the experimental results are shown and discussed. Finally, we conclude this paper in Section 5.

2 Related Work

As mentioned in the previous section, most of current studies on keyphrase extraction can be roughly divided into two categories: supervised and unsupervised approaches.

Unsupervised approaches usually select general sets of candidates and use a ranking step to select the most important candidates. For example, Mihalcea and Tarau proposed a graph-based approach called TextRank, where the graph nodes are tokens and the edges reflect cooccurrence relations between tokens in the document (Mihalcea and Tarau, 2004). Wan and Xiao expanded TextRank by using a small number of topic-related documents to provide more knowledge, which improved results compared with standard TextRank and a tf.idf baseline (Wan and Xiao, 2008). Tomokiyo and Hurst used pointwise KL-divergence between language models derived from the documents and a reference corpus (Tomokiyo and Hurst, 2003). Matsuo and Ishizuka presented a statistical keyphrases extraction approach that did not make use of a reference corpus, but was based on cooccurrences of terms in a single document (Y.Matsuo and M.Ishizuka, 2004). In this paper the proposed BIP based method can combine those unsupervised methods as assignment value in the objective function. TF·IDF and locality information are used in our approach.

Supervised approaches use a corpus of training data to learn a keyphrase extraction model that is able to classify candidates as keyphrases or non-keyphrases. A well known supervised system is KEA that uses all n-grams of a certain length as candidates, and ranks them based on a Naive Bayes classifier using tf.idf and position as its features (Frank et al., 1999). Then Medelyan and Witten presented the improved KEA++ that selected candidates with reference to a controlled vocabulary from a thesaurus or Wikipedia (Medelyan and Witten, 2006). "Extractor" was another supervised system that used stems and stemmed n-grams as candidates (Turney, 2000). Its features are tuned using a genetic algorithm. Turney introduced a feature set based on statistical word association to ensure that the returned keyphrases set is coherent (Turney, 2003). Experimental results showed that coherence features can significantly improve the performance and they were not domain-specific. Nguyen and Kan presented a keyphrase extrac-

tion algorithm for scientific publications and introduced novel features towards scientific publications such as section information and certain morphological phenomena often found in scientific papers (T.D.Nguyen and Kan., 2007).

Since integer linear programming (Alevras and Padberg, 2001) can be used to incorporate both local features and non-local features, which are difficult to handle with traditional algorithms, it has received much attention in various NLP problems in recent years. Roth and Yih (2005) extended CRF models by applying inference procedure based on ILP to naturally and efficiently support general constraint structures. They applied their model on semantic role labeling (SRL) task. Martin et al. (2009) formulated the problem of nonprojective dependency parsing as a polynomial-sized integer linear program. Woodsend and Lapata (2010) presented a joint content selection and compression model for single-document summarization using an integer linear programming formulation.

3 Keyphrase Extraction Using BIP

The objective of keyphrase extraction is to select the most informative group of phrases, which are relevant to the news event and subject to constraints including the number of phrases, topic/aspect coverage, and coherence. Since these constraints are global, and cannot be adequately satisfied by optimizing each of them individually, our approach uses the BIP formulation, a well-studied optimization framework, which can be efficiently solved using standard optimization tools, to extract keyphrases.

Integer Linear Programming (ILP) denotes a set of constraint optimization problems which have a linear objective function, subject to linear equality and linear inequality constraints, and require the objective variables to be integers. ILP can be expressed in canonical form:

$$\begin{array}{ll} \text{maximize} & c^T x \\ \text{subject to} & Ax \leq b \\ & Gx = d \\ & x \in \mathbf{Z}^n \end{array} \quad (1)$$

Binary Integer Programming (BIP) is the special case of ILP where variables are either 0 or 1.

In this paper, we treat the keyphrase extraction task as a two class labeling problem. Given a group of documents D, for each word $w \in D$, we decide to select this word as a keyphrase (assign label "1" to the word), or non-keyphrase (assign label "0"). We use a vector of binary variables $x = (x_1, x_2, ..., x_n)$ over word $w_i \in D$, to indicate whether the corresponding word should be selected or not. With the objective variables x and word $w_i \in D$, $c = (c_1, c_2, ..., c_n)$ is defined as the assignment value. The variable c_i gives the expected value of labeling w_i as a keyphrase. The basic extraction model is shown in Eq.(2). Our goal is to find the optimal point of weights x^* satisfying the constraints.

$$\begin{array}{ll} \text{maximize} & c^T x \\ \text{subject to} & 0 \leq x_i \leq 1 \\ & x \in \mathbf{Z}^n \end{array} \quad (2)$$

3.1 Objective Function

With the BIP formulation, objective function $c^T x = \sum_k c_k x_k$ denotes the expected informative scores over all the words of a solution x. Maximizing the expected scores biases the words with highest c_i values as keyphrases. Various features can be considered as the values c. In this work, we use two basic features TF·IDF and locality. They have also been widely used in existing keyphrase extraction methods. The objective function is given in the Eq.(3).

$$\begin{aligned} c^T x, \;\; c_i = \;\; & \alpha \cdot \frac{\sum_{d \in D} TF{\cdot}IDF(w_i, d)}{|D|} \\ & + \beta \cdot \mu_i + \gamma \cdot \nu_i \end{aligned} \quad (3)$$

Three parameters α,β, and γ are used to tradeoff among the different parts, $|D|$ is the number of documents in this news group. The latter section provides detailed description of this equation.

3.1.1 TF·IDF

TF·IDF compares the frequency of a phrase in a particular document with that in general corpus. The TF·IDF for word w_i is computed as:

$$TF{\cdot}IDF(w_i, d) = \frac{\text{freq}(w_i, d)}{|d|} \cdot \log_2 \frac{N}{df(w_i)}, \text{ where}$$

freq(w_i, d) is the number of times w_i occurs in d; $df(w_i)$ is the number of documents containing w_i in the global corpus; N is the size of the global corpus; $|d|$ is the length of the document of d..

In this paper, we use the average TF·IDF over all the news articles belonging to the same group. TF·IDF has also been used as features by almost all the keyphrase extraction algorithms.

3.1.2 Locality

The first occurrence position of the candidate phrase is an important feature for keyphrase extraction. It has also been used by many existing methods (Witten et al., 1999; Zha, 2002; Liu et al., 2009). In this paper, we also incorporate the information as parts of objective function.

For the words in the title of news articles, we define a bonus μ for their informative scores. It is the second component in the Eq.(3). The μ_i is defined as follows:

$$\mu_i = \begin{cases} \mu, & w_i \in T \\ 0, & \text{otherwise} \end{cases}$$

, where T represents the set of all the title words.

Similarly, we define ν for those words which occur in the first sentences. It is the third component of the objective function. The ν_i is defined as follows:

$$\nu_i = \begin{cases} \nu, & w_i \in FS \\ 0, & \text{otherwise} \end{cases}$$

,where FS represents the set of words which occur in the first sentences.

3.2 Constraints

One limitation of existing keyphrase extraction methods is that they usually separately make judgment of individual phrase instead of considering the qualities of the set of phrases as a whole. In this section, we define several constraints converted from the coverage and coherence criteria, and the number of extracted phrases.

3.2.1 Coverage

From both observations we make, and the properties proposed by Liu et al.(2009), we believe that high-quality keyphrases should cover the whole document or group of documents well. For example, if we have a document describing "Toyota recalls Prius" from various aspects of "reason", "scope", "influence" and so on., the extracted keyphrases should cover as many aspects as possible.

In order to satisfy this criterion, topic model is used to estimate words distribution over topics. In this paper, we use latent Dirichlet allocation (LDA) (Blei et al., 2003) to do it[1]. LDA is a three-level hierarchical Bayesian model, in which each word is modeled as a finite mixture over an underlying set of topics. Each topic is, in turn, modeled as an infinite mixture over an underlying set of topic probabilities.

From LDA model, we can get $p(w|z)$, which represents aspect distributions over words. It indicates which words are important to an aspect. We use matrix G to represent $p(w|z)$. The vector g_i denote the distribution over words of aspect i. The projection $g_i^T x$ gives us the aspect coverage of topic i under current solution x. We want the coverage of every aspect to exceed the same threshold ζ. The constraint can be expressed as follows:

$$G^T x \succeq \zeta$$

3.2.2 Coherence

According to the properties which high-quality keyphrases should satisfy, the keyphrases should be semantically related and coherent. Turney (2003) also mentioned this issue and pointed out that incoherent keyphrases might highly impact the quality and user experience.

An intuitive method for measuring word relations is based on word cooccurrence relations within the document. It indicates that word pairs with high cooccurrence frequency should be selected together. For instance, the words "economy", "unemployment", and "loan" are likely to cooccur in documents about "financial crisis". And we are aiming to extract them together to ensure coherence property. In this paper, we use mutual information (MI) to measure the word's coherence. MI is a measure of association which quantifies the discrepancy between the dependent joint distribution and the independent individual distributions.

For each word pair $< w_i, w_j >$, whose mutual information $I(w_i, w_j)$ is bigger than a pre-defined threshold ξ, we add the following constraint:

$$x_i - x_j = 0$$

It encodes the fact that keyphrases pairs with high cooccurrence frequency should be selected together.

3.2.3 Number of Extracted Phrases

According to the limitations of space or other constraints given by applications, the number of extracted phrases should also be constrained. Since we use a vector of binary variables $x = (x_1, x_2, ..., x_n)$ over words $w_i \in D$, the constraint

[1] We use MALLET 2.0.6 in the experiments

can be represented as follows:

$$\sum_{i=1}^{n} x_i \leq K$$

,where K is the pre-defined threshold.

3.3 BIP Problem

Putting the objective function and all the constraints together, we obtain the BIP program to extract keyphrases as follows:

$$\begin{aligned} \text{maximize} \quad & c^T x \\ \text{subject to} \quad & G^T x \succeq \zeta \\ & x_i - x_j = 0\ , \ \text{ if } \ I(w_i, w_j) \geq \xi \\ & \sum_{i=1}^{n} x_i \leq K \\ & x_i \in \{0, 1\}\ , \ \ i = 1 \cdots n \end{aligned} \tag{4}$$

Binary integer programming is a popular optimization technique and many effective solvers have been developed. In this paper we use CPLEX solver, which is part of AIMMS[2] system, to estimate the optimal solution from the Eq.(4).

4 Experiments

In this section, we perform evaluations of the proposed method. The data sets we used in the experiments are described in the first part. After that, experimental results are given and detailedly described in the following sections.

4.1 Dataset and Evaluation Metric

There are almost no publicly available datasets with manually annotated gold standard keyphrases for news, due to the high expense of labor and time for manual annotation. In this experiment, we randomly selected 150 groups of online news articles from Goolge News. Three annotators participated in the annotation task. They were asked to manually assign keyphrases for each group of news. The keyphrases which at least two annotators have agreed on are selected as the "Golden" ones. Statistics on the dataset are shown in Table 1. The corpus data is divided into development set and test set. The development set, which contains 50 groups of news, is used to tune the parameters. The other 100 groups of news are used as test set.

We regard an extracted keyphrase as "correct" if it matches one of the ground truth. We measure the performance by Precision (the percentage of correct extracted keyphrases out of all the extracted ones), Recall (the percentage of correct extracted keyphrases out of the ground truth) and F-Measure (the harmonic mean of the precision and recall).

Description	value
# News articles	1103
# Words	345K
# News articles per group	7.35
# Labeled keyphrases per group	5.83

Table 1: Statistics on the dataset

4.2 Comparisons with Other Methods

Since the dataset used in this paper is manually labeled by ourselves, we implement three baseline methods on the same dataset for comparison.

BL-1: The titles of news articles provide a reasonable summary or keyphrase sequence. So baseline 1 is performed based on the titles of news articles. We sort the phrases in multi-news titles according to the TF·IDF scores and select top-k as keyphrases. We assign K to 6 after tuning the parameter.

BL-2: Many existing methods converted the keyphrase extraction as a classification problem. In this paper, we used SVM[3] as baseline 2. The features include TF·IDF, "First occurrence", and "Is in title or not". Those feature sets are similar to our objective function. We divided the dataset into five subsets and conducted a 5-fold cross-validation.

BL-3: We re-implemented the ranking approach proposed by Jiang et al. (2009) as baseline 3. This method employed Ranking SVM (Joachims, 2006), the learning to rank method, to perform keyphrase extraction. Feature sets are the same as the feature sets used in the BL-2. We also conducted a 5-fold cross-validation.

We used the following default values for the parameters of our method: $\alpha = 0.4$, $\beta = 0.3$, $\gamma = 0.3$, $\mu = 0.1$, $\nu = 0.05$, $\zeta = 0.005$, $\xi = 16.5$, and $K = 6$. The meaning of these parameters are described in the previous section. And how to learning the optimal values will be discussed in section 4.4. The test set is used in this experiment. Since the average number of manual-

[2] http://www.aimms.com/

[3] SVM^{light} is used in our experiments, which can be downloaded from http://www.cs.cornell.edu/People/tj/svm_light.

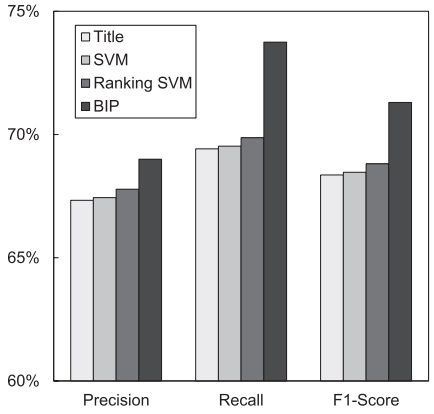

Figure 1: Comparison results of Title, SVM, Ranking SVM and our BIP-based methods .

labeled keyphrases is six, we selected the top 6 ones as keyphrases in all three baseline methods.

Figure 1 shows the performance comparison of BIP-based method with baselines. From the figure, we have the following observations. Firstly, BIP-based method consistantly outperforms all baselines under all evaluation metrics – Precision, Recall, and F1-Score. This indicates the robustness and effectiveness of our method. Furthermore, compared with the supervised methods, BIP-based method does not need any labeled corpus. Secondly, Ranking SVM performs slightly better than SVM. This is congruence with the previous conclusion given by Jiang et al. (2009). However, the improvement of BL-3 over BL-2 is not significant. We also observe that the performances of BL-1 are quite good. The precision, recall, and F1-score achieved by it are comparable with results of SVM and Ranking SVM.

4.3 Contribution of Constraints and Objective Function

To determine the contribution of different components of objective function and individual constraints, we omit components and constraints one by one to identify its contribution to the performance. Table 2 shows the results on development set. The first row represents the performance of the BIP-based method with all constraints and objective function with all three components. The parameters are default ones listed in the previous section.

The contribution of different components in the objective function is shown from the second row to fourth row. From the results we can observe that, TF·IDF is the most important feature in the objective function. Without the feature of TF·IDF, the evaluation metrics drop sharply from 72.68% to 59.82%. The candidate occurs in the title is also an important feature. It is consistent with the observations given by the results of BL-1. It gives about 17.27% relative improvement over the performance without it. Compared with the two features, the occurrence in the first sentence gives less contribution. The improvement given by it is not significant.

Table 2: Contribution of different components of objective function (TFIDF, InTitle, InFirstSenetence) and two constraints (Coverage and Coherence) under Precision, Recall, and F1-Score.

	Pre.	**Rec.**	**F.**
All	**71.45**%	**73.96**%	**72.68**%
All - TF·IDF	58.86%	60.82%	59.82%
All - InTitle	60.96%	62.77%	61.85%
All - InFirstSentence	71.00%	73.20%	72.08%
All - Coverage	68.56%	70.68%	69.60%
All - Coherence	70.67%	72.85%	71.74%

The fifth row shows the results without the coverage constraint. From the result, we observe that the coverage constraint is effective, which can give more than 4.2% relative improvement. The contribution of coherence constraint is shown in the end of the table. Althoug its contribution is less than that of coverage constraint, an outlier keyphrase may highly impact the user experience. Coherence constraint is important to improve user experience.

4.4 Varying Parameters

As we mentioned in the previous section, there are eight parameters which should be adjusted in our method. One may concern the problem of parameters tuning. In order to answer this question, in this section, we explore the impact of different parameters on our approach's performance in the development set. Except the parameter under investigation, the other parameters are set to the default values which are listed in the Section 4.2.

4.4.1 Number of Keyphrases K

Figure 2 presents the performance varying the number of keyphrases, which ranges from 1 to 10. K is one of the most important arguments leading to the trade-off between precision and recall. Larger K increases recall but decreases precision. From this figure, we observe that the best

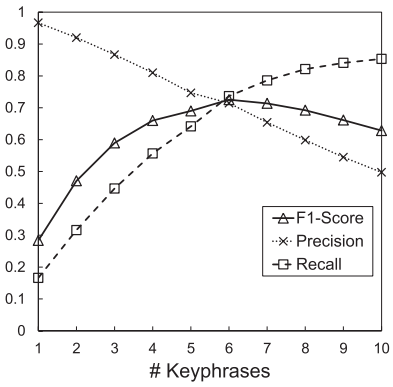

Figure 2: Results of varying the number of extracted keyphrases using the proposed BIP-based extraction method.

result is achieved at the point $K = 6$, which is similar to the average number of manually selected keyphrases. We also observe that the F1-Score drops quickly when K is bigger than 7. The main reason is that only a small number of phrases which should be selected are ranked after the top 10.

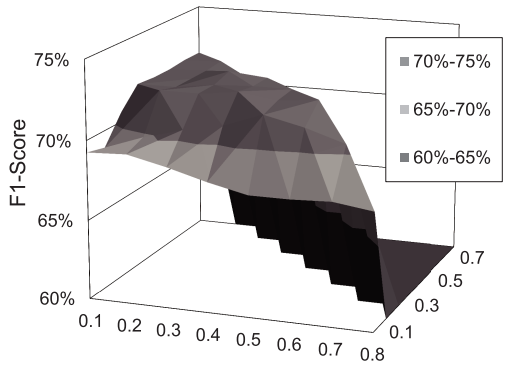

Figure 3: Results of varying the parameters α, β, γ in the objective function.

4.4.2 α, β, γ in the Objective Function

In the objective function, there are three parameters α,β, and γ , which are used to trade off among TF·IDF and two locality features. Figure 3 gives the F1-Score surface varying α and β. Since $\alpha + \beta + \gamma$ equals to 1, α and β are used as x-axis and y-axis in the figure. We have found that the surfaces are almost concave around a number of areas. Therefore, a simple hill-climbing search can be used to optimize F1-Score. Since the surface is almost concave, the global maximum can be easily achieved though a few initial seeds. For example, the optimal parameters for this experiment are $\alpha = 0.4$, $\beta = 0.3$. The γ can be calculated through function $1 - \alpha - \beta$.

Table 3: Influence of the Coverage threshold ζ

ζ	Pre.	Rec.	F.
0.001	69.44%	71.59%	70.50%
0.002	70.33%	72.50%	71.40%
0.003	71.22%	73.43%	72.31%
0.004	71.00%	73.20%	72.08%
0.005	**71.45%**	**73.65%**	**72.53%**
0.006	71.33%	73.54%	72.42%
0.007	71.22%	73.43%	72.31%
0.008	71.11%	73.31%	72.19%
0.009	70.67%	72.85%	71.74%

4.4.3 Coverage threshold ζ

Coverage threshold ζ represents the property that the extracted keyphrases should cover most of the important aspects of a news event. We want the aspect coverage for all topics to exceed the threshold. Table 3 shows the results when ζ ranges from 0.001 to 0.009. All of them perform better than the result without coverage constraint, and the best result is achieved at $\zeta = 0.005$. From the results, we observe that the coverage threshold ζ can also be easily selected. From 0.005 to 0.008, the changes of F1-score are not significant. When the coverage threshold is above 0.02, in order to get the solution of the ILP program, the impact of objective function would be limited. We think that it is the main reason of why best result is achieved at a small value threshold.

4.4.4 Coherence threshold ξ

Finally, we explore the inference of ξ, which is used to represent the word coherence. When the threshold is below 12, there would be too many coherence constraints. More than 30.05% word pairs can satisfy the threshold. Under this condition, no solution can be estimated in some cases. When the threshold is above 32, there are rarely word pairs satisfying the threshold. In other words, there would be no coherence constraints. In table 4 we show the influence of ξ, which ranges from 15 to 18. Similar to the results of coverage threshold, a large range of ξ's value can achieve satisfactory result. $\xi = 16.5$ achieves the best result 72.53%.

Table 4: Influence of the Coherence threshold ξ

ξ	Pre.	Rec.	F.
15.0	68.00%	70.10%	69.04%
15.5	69.89%	72.05%	70.95%
16.0	70.78%	72.97%	71.85%
16.5	**71.45%**	**73.65%**	**72.53%**
17.0	71.22%	73.43%	72.30%
17.5	71.00%	73.20%	72.08%
18.0	71.00%	73.20%	72.08%

4.5 Extracting Example

Table 5 shows examples of extracted keyphrases by different methods from a group of news articles about "Master Kong applies for TDR listing in Taiwan". Top 6 extracted keyphrases for each method are shown in the table, and the correct ones are marked with "(+)". From table 5, we observe that keyphrases extracted through BIP-based method are relevant, coherent, with good coverage. Without the coverage constraint, "Taiwan Depositary Receipt" and it's abbreviation "TDR" are both selected. And, the topic coverage cannot be well satisfied through the top keyphrases. For SVM and Ranking SVM, they separately consider each word, some of the high frequency words are selected as keyphrases, such as "billion", and "issue". However, those words are not meaningful.

Table 5: Example of extracted keyphrases by SVM, Ranking SVM and BIP-based method*.

BIP
Masker Kong(+), Ting Hsin International Group(+), Taiwan Depositary Receipt(+), instant noodle, Taiwan Stock Exchange(+), NT$30 billion
BIP without Coverage constraint
Masker Kong(+), Taiwan Depositary Receipt(+), TDR, lunch, Taiwan Stock Exchange(+), Taiwan
BIP without Coherence constraint
Masker Kong(+), Taiwan Depositary Receipt(+), Taiwanese-invested food producer(+), IPO, issue, Taiwan Stock Exchange(+)
SVM
Taiwan Depositary Receipt(+), Masker Kong(+), China market, TDR, Hong Kong Exchanges, billion
Ranking SVM
Masker Kong(+), China market, TDR, Taiwan Depositary Receipt(+), issue, Taiwan

*The keyphrases are translated from Chinese.

5 Conclusions

In this paper, we have presented a novel keyphrase extraction approach. It adapts the integer linear programming methods to the keyphrase extraction problem by casting features and criteria as objective function and constraints.

By integrating TF·IDF and two locality features as objective function, and the coverage and coherence properties as constraints, the proposed ILP-based unsupervised approach achieves better performance than the state-of-the-art supervised approaches, SVM and Ranking SVM. Contributions of constraints and different components of the object function are experimental evaluated. In the objective function, the TF·IDF is the most important feature. Locality features can further improve the performance. Results also demonstrate that both the coverage and coherence constraints are useful to keyphrase extraction task. We also detail the impact of parameters used in our approach. Through experimental results, we demonstrate that the parameters are not sensitive. The value of them can be easily estimated using simple hill-climbing search methods.

Abstract

This paper describes experiments on the TREC entity track that studies retrieval of homepages representing entities relevant to a query. Many studies have focused on extracting entities that match the given coarse-grained types such as organizations, persons, locations by using a named entity recognizer, and employing language model techniques to calculate similarities between query and supporting snippets of entities from which entities are extracted to rank the entities. This paper proposes three improvements over baseline, i.e., 1) incorporating homepages of entities to supplement supporting snippets, 2) recognizing fine-grained named entities to filter out or negatively reward extracted entities that do not match the specified fine-grained types of entities such as a university, airline, author, and 3) adopting a dependency tree-based similarity method to improve language model techniques. Our experiments demonstrate that the proposed approaches can significantly improve performance, for instance, the absolute improvements of nDCG@R and P@1 scores are 8.4%, and 27.5%.

1 Introduction

Many user information needs would be better answered by presenting a ranked list of entities directly, instead of just a list of relevant documents. Based on this assumption, increasing attention has been devoted to related entity finding tasks that aimed at finding documents representing entities of a correct type that are relevant to a query. The TREC expert finding track (Nick, 2005), for example, focused on creating an ordered list of experts who have skills and experiments on a given topic. The INEX entity ranking task (Vries, 2007) studied at ranking Wikipedia entities given a query, in which target entity types are shifted from a single type of entity (person) to any Wikipedia category. The TREC related entity finding (REF) track (Balog, 2010) started in 2009, is defined as: Given an input entity, by its name and homepage, the type of the target entity[1], as well as the nature of their relation, described in free text, find related entities that are of a target type, standing in the required relation to the input entity. The REF task is also similar to a combination of the TREC list QA (Voorhees, 2003) and homepage finding (Hawking, 2001) tasks. In short, all these entity finding tasks generally aim at performing entity-oriented search tasks on the Web. This paper is concerned with the TREC REF track. Figure 1 shows an example of this.

```
<query>
<num>7</num>
<entity_name>Boeing 747</entity_name>
<entity_URL>clueweb09-en0005-75-02292</entity_URL>
<target_entity>organization</target_entity>
<narrative>Airlines that currently use Boeing 747 planes.</narrative>
</query>
```

Figure 1: Test query in TREC 2009 entity track.

The key challenge in the REF task involves entity ranking, that is, estimating the likelihood of the extracted entities being answer entities for a given query. Many related studies (Bron, 2010; Fang, 2010) have employed language model techniques to estimate the likelihoods of the extracted entities being answer entities via calculating similarities between query and supporting documents/snippets of entities. This technique may fail in cases where supporting documents/snippets of entities do not support their being answer entities.

[1]TREC 2010 limits the track's scope to searches for instances of the organizations, people, locations and product entity types.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 174–182,
Chiang Mai, Thailand, November 8 – 13, 2011.

To improve the above approach, this paper first argues that candidate entities' homepages are important supplements to supporting snippets and should be effectively exploited. Homepage information is, however, ignored by many TREC participants' systems. Second, much of the work to date only extracts coarse-grained types of entities (such as people, organizations, locations and products specified in *target_entity* field as shown in Figure 1) by using entity repositories such as YAGO (Suchanek, 2007) or named entity recognizers (Ratinov, 2009), and then rank them. However, some queries specify fine-grained types of target entities in *narrative* fields, such as airlines in Figure 1. In these cases, fine-grained entity recognition is necessary and helpful for improving performance, which can recognize fine-grained named entities such as airlines, publishers, drivers, or newspapers. Third, a dependency tree-based similarity approach is implemented to substitute language model techniques, which proved superior to the latter.

The contributions of this paper include 1) incorporating homepages of entities, and 2) recognizing fine-grained types of entities for improving entity ranking. Furthermore, we propose an unsupervised method of generating training examples for fine-grained entity recognition and exploit multiple-contexts of entities as classification features. In related studies, only single-contexts of entities are employed. The experimental results in terms of the TREC 2010 entity track test data set demonstrate that the nDCG@R improvements of our three proposals, i.e., dependency-tree similarity, incorporating homepage and recognizing fine-grained named entity components, are 2.3%, 4.1%, and 2.1%, respectively. Compared with baseline, the accumulative improvements of our REF system in terms of nDCG@R, P@1 and P@5 scores are 8.4%, 27.5%, and 12.0%, respectively.

2 Related Work

The TREC REF task is highly related to a combination of the TREC list QA and homepage finding, INEX entity ranking, and TREC expert search tasks. The TREC list QA task (2001-2007) (Voorhees, 2003) required systems to assemble an unordered list of answer strings to factoid questions such as *Who are six actors who have played Tevye in "Fiddler on the Roof"?* The underlying information need is of a more informational nature. However, the REF task is situated in explorative search tasks. Moreover, the list QA task also does not require returning to the homepage for each answer string. In recent years, retrieval-based (Yang, 2003), pattern-based (Ravichandran, 2002), deep NLP-based (Moldovan, 2002; Harabagiu, 2003), and supervised/unsupervised machine learning based approaches (Ittycheriah, 2002; Wu, 2007) have been proposed. The TREC homepage finding task (2001-2003) assumes that incoming queries (like "IJCNLP 2011") are attempts to navigate to the homepage of a particular web site (`http://www.ijcnlp2011.org/`).

The TREC expert search task (2005-2008) (Nick, 2005) focused on creating an ordered list of experts who have skills and experiments on a specific topic with enterprise data. Most of the proposed approaches generally fall into two categories: generative language models and discriminative models. For example, Balog (2006) proposed profile-centric (directly models the knowledge of an expert from associated documents) and document-centric (locates documents on the topic and then finds the associated experts) generative language models (LMs). Cao (2005) proposed a two-stage language model consisting of a document relevance and co-occurrence model. There are many other generative probabilistic models such as (Fang, 2007; Serdyukov, 2008). Fang (2010) proposed a principled relevance-based discriminative model that integrates a variety of document evidence and document candidate association features for improving expert searching.

The INEX entity ranking task (2007-2010) (Vries, 2007) studies ranking of Wikipedia entities to a query topic. Apart from estimating similarities between Wikipedia pages and the given query topic, many systems (Pehcevski, 2008) have exploited Wikipedia link structure and Wikipedia categories, for instance, estimating overlap between the set of categories associated with target Wikipedia pages and the categories specified in a given query topic.

The TREC REF task (2009-2010) (Balog, 2010) aims at entity-oriented search on the Web. The most typical system is a cascade of the following components. (1) Document Retriever retrieves top relevant documents to a given query from the given Clueweb09 collection with 503 million English pages. (2) Entity Extractor extracts candidate entities that match the given target types from the

	Types of Anwers	Source of Answers	Entity Extraction	Main Models used
List QA	Noun phrase	Newspaper texts	Needed	IR-based, NLP-based, and machine learning-based models
Expert Search	Person only	W3C corpus	No	IR-based model
INEX Entity	Any Wikipedia category	Wikipedia data	No	IR-based model with Wikipedia category and link
TREC REF	Location, person, organization, and product	Clueweb09, a snapshot of the Web	Needed	IR-based model due to the task is originally situated in a search problem

Table 1: Comparison of entity ranking tasks. W3C corpus is a simulation of enterprise data crawled from public W3C (*.w3.org) sites in June 2004.

top relevant documents by using entity repositories such as Wikipedia, or using named entity recognizers. (3) Entity Ranker estimates the probabilities of the extracted entities being answer entities by using supporting documents and/or snippets in which entities and queries co-occur. A number of language modeling techniques borrowed from expert search systems were employed (Bron, 2010; Fang, 2010; Li, 2010). (4) Homepage Finder assigns primary homepages for the top ranked entity names by using entity names as queries, or homepage identifiers.

Table 1 compares these tasks from four aspects.

3 Our System

We can see that TREC entity ranking task is very complicated, and each component is an independent research topic in the fields of NLP and IR. This paper cannot cover all of them, and only focuses on Entity Ranker component, that is, given a query Q, and a list of extracted entities $E = \{e_i|i = 1, 2, ...n\}$ associated with their homepages $H = \{h_{e_i}|i = 1, 2, ..., n\}$, how to effectively rank these entities.

The other three components are beyond the scope of this paper. For better understanding of the REF system, we simply introduce them. Our Document Retriever first employs Yahoo! BOSS API[2] to search relevant pages from the Web and then map them to documents in Clueweb09. Since one lesson from TREC 2009 is that commercial search engines such as Yahoo! are generally superior in locating relevant documents for the search engine, we used the Indri tool for building. In Entity Extractor, an NER tool developed at UIUC (Ratinov, 2009)[3] is employed. In particular, phrases/words tagged with PER, ORG, LOC and MISC tags are extracted when the target entities are people, organizations, locations, and products, respectively. For Homepage Finder, the DBpedia homepage data[4] is used to train a binary classifier and features are similar to (Upstill, 2003). It is noted that we reverse the sequence of the Entity Ranker and Homepage Finder to enable incorporating homepage for ranking (introduced in section 3.3), that is, we first assign homepage for each entity, and then rank them.

3.1 Baseline

In the context of expert search, the task is to find out what is the probability of a candidate person being an expert to a query. The REF system can be simply regarded as the task of estimating $p(e_i|Q)$, the probability of an entity e_i being answer entity given a query Q. Therefore, approaches proposed in expert search can be used for entity finding. In TREC expert search, document model (referred as Model 2) (Balog, 2006) turned out to be one of the most prominent and effective models for estimating $p(e_i|Q)$. Model 2 is also used as our baseline, which can be expressed by,

$$p(e_i|Q) \propto \sum_{j=1}^{n} p(Q|es_{ij}) * p(e_i|es_{ij}, Q) \quad (1)$$

In (1) es_{ij} stands for the j-th supporting snippet from which entity e_i is extracted, n is the number of supporting snippets, $p(Q|es_{ij})$ denotes the relevance between query and supporting snippet, and can be relatively easy to determine using a language model (the KL-divergence language model used in this paper), $p(e_i|es_{ij}, Q)$ denotes the co-occurrence of the query and entity in the snippet. Because unique characteristics of the W3C corpus used in expert search, meta-based co-occurrence

[2] http://developer.yahoo.com/

[3] http://l2r.cs.uiuc.edu/~cogcomp

[4] http://dbpedia.org/About

model is commonly used. In entity ranking task, the KL-divergence language model is adopted to calculate $p(e_i|es_{ij}, Q)$. Model 2 can be further improved in the context of REF task as follows.

3.2 Improvement 1: Dependency Tree-based Similarity

To improve unigram KL-divergence language model that can not capture relations between query words, this paper adopts a dependency tree-based similarity algorithm to calculate $p(Q|es_{ij})$, which can be expressed by,

$$p(Q|es_{ij}) \quad \propto \quad \frac{DP_Q \cap DP_{es_{ij}}}{\sqrt{|DP_Q| \times |DP_{es_{ij}}|}} \qquad (2)$$

where DP_Q and $DP_{es_{ij}}$ stand for a set of sub-trees generated from dependency trees of query Q and text snippet es_{ij}, respectively. Dependency trees are obtained by parsing Q and es_{ij} using Lin's dependency parser, Minipar[5], and the subtree is defined as any node up to its two descendants and extracted with the Freqt toolkit[6].

3.3 Improvement 2: Incorporating Homepage

The goal of the REF task is to return homepages representing entities to a query, and homepages sometimes contain valuable information for ranking. Therefore, it is easy and necessary to incorporate homepages of entities in ranking. As input in entity finding, we receive a query Q, a list of candidate entities $E = \{e_i|i = 1, 2, ..., n\}$ associated with their homepages $H = \{h_{e_i}|i = 1, 2, ..., n\}$. The Entity Ranker can be reformulated to estimate a conditional probability $p(e_i, h_{e_i}|Q)$. The top k entities with their homepages are deemed the most probable answer entities.

By assuming entity e_i is independent of its homepage h_{e_i}, we obtain,

$$p(e_i, h_{e_i}|Q) \; = \; p(e_i|Q) \times p(h_{e_i}|Q) \qquad (3)$$

where $p(e_i|Q)$ stands for the probability of entity e_i being an answer given query Q, and can be calculated using Equation (1) and (2), $p(h_{e_i}|Q)$ stands for the probability of homepage h_{e_i} being an answer given query Q.

By applying the Bayes' Theorem and assuming that $p(h_{e_i})$ is uniform for all homepages h_{e_i}, we obtain,

$$p(h_{e_i}|Q) = \frac{p(Q|h_{e_i}) \times p(h_{e_i})}{p(Q)} \propto p(Q|h_{e_i}) \qquad (4)$$

In some cases, homepages such as that of racecar driver Michael Schumacher (`http://www.michael-schumacher.de/`) do not contain any valuable information but intend to greet visitors and provide information about the site or its owner. Thus, we retrieve text snippets hs_{e_i} from a homepage site using query Q to build a back-off model for $p(h_{e_i}|Q)$ built from the homepage (the opening or main page of the homepage site). Finally, we can obtain,

$$p(Q|h_{e_i})' = \alpha \times p(Q|h_{e_i}) + \beta \times p(Q|hs_{e_i}) \qquad (5)$$

where $\alpha + \beta = 1$, $p(Q|h_{e_i})$ and $p(Q|hs_{e_i})$ are estimated using the KL-divergence language model.

In short, conditional probability $p(e_i, h_{e_i}|Q)$ of the likelihood of entity e_i with its homepage h_{e_i} being answer is calculated by using Equation (3), (5), (1) and (2).

3.4 Improvement 3: Fine-grained Entity Recognition

As mentioned, entities are extracted by using NER tool. There exist two problems. First, the NER tool can only identify coarse-grained types of entities such as organizations or locations. However, users' queries sometimes specify fine-grained types of named entities such as airlines, universities, or actresses. Second, many incorrect entities are extracted. The main reason lies in: the NER tool is trained on newspapers, but we use it to tag web data. Therefore, it is necessary to filter out or negatively reward entities that do not match the fine-grained entity types if specified in queries. For example, this step can hopefully remove or negatively reward the extracted entities that are not airlines for the TREC 2009 test query shown in Figure 1.

Many semi-supervised methods have been proposed to recognize fine-grained types of entities. For example, Hearst (1992) used lexical patterns such as "X, such as Y". Fleischman (2002) employed a supervised learning method that considered the local context surrounding the entity as well as global semantic information. Etzioni (2005) started with a set of "*predicates*" and bootstrapped the extraction process from high-precision generic patterns. Oh (2009) exploited

[5] `http://webdocs.cs.ualberta.ca/~lindek`
[6] `http://chasen.org/~taku/software`

Wikipedia structure information and textual context to determine fine-grained types of Wikipedia entities. Generally, these methods mainly exploit the single-context of an entity as classification feature, which may result in errors in cases in which the relation between entity and its fine-grained type is not explicitly expressed.

Our proposal differs: 1) we utilize multiple contexts in which entities and their fine-grained types co-occur, 2) multiple contexts obtained by querying the Web with entities and their fine-grained types are helpful to disambiguate entities, 3) a dependency pattern-based approach is proposed for fine-grained classification of named entities. More specifically, our goal is to assign a class label ("yes" or "no") for each ⟨entity, fine-grained type⟩ pair. A "yes" means the entity belongs to the corresponding fine-grained type. Otherwise, it does not. The details are as follows.

3.4.1 Step-1: Preparation of Training Examples

A certain number of ⟨entity e, its fine-grained type fgt, multi-contexts they co-occur mc⟩ training triples are needed to build a classifier of fine-grained entities. The key challenge here is to prepare positive and negative $\langle e, fgt \rangle$ pairs.

A Wikipedia article usually starts with a definition sentence like "*Continental Airlines is an American airline based and headquartered in Continental Center I in downtown Houston, Texas.*" We find that it is practicable to automatically extract entity ("Continental Airlines" in this example) and its fine-grained type ("airline") from such well-formed sentences. To extract the pairs from these definition sentences, we first use Minipar to parse all Wikipedia definition sentences and then extract the pairs using heuristic rules such as *(be (Wikipedia-entity) (fine-grained-type))*. In this example, ⟨Continental Airlines, airline⟩ is extracted. Finally, 41,495 pairs are generated. These pairs will be used as positive instances. In order to construct negative training pairs, we first adopt the NER tool to recognize named entities in the Wikipedia definition sentences, and then pair the fine-grained type and the identified entities, except for the Wikipedia entity, as negative examples. For example, ⟨Continental Center I, airline⟩, ⟨Houston, airline⟩, and ⟨Texas, airline⟩ pairs are generated. Finally, 122,686 negative pairs are collected from Wikipedia.

Multi-context mc can be easily obtained by querying a search engine with the entity and its type and merging the first k snippets returned. Formally, $mc = \bigcup_{j=1}^{k} s_j$, where s_j denotes the j-th snippet. For ambiguous entities such as "Michael Collins", it is hard to recognize their fine-grained types with fewer frequencies from multiple contexts obtained by querying the Web with entities only. Multiple contexts learned with entities and their fine-grained types can partially solve this problem.

3.4.2 Step-2: Building Classifier

In order to handle long distance relations between words, dependency patterns are extracted as features for classification. First, textual contexts of $\langle e, fgt, mc \rangle$ triples are parsed using Lin's Minipar. Then, the shortest dependency paths between e and fgt are extracted as dependency patterns. Figure 2 shows two examples. To reduce the dimensionality of the feature space, we calculate the precision of each dependency pattern by using the equation, $precison = Cnt_p/(Cnt_p + Cnt_n)$, where, Cnt_p and Cnt_n denote total numbers of patterns occurring in positive and negative triples, respectively. We sort the extracted dependency patterns in deceasing order of precision and empirically select the top 500 patterns as classification features.

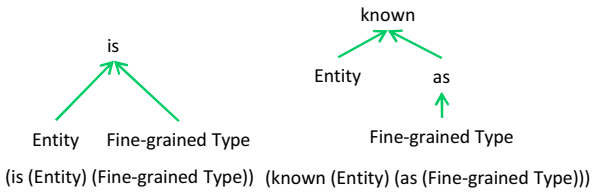

Figure 2: Examples of dependency patterns.

For the classifier, we employ multivariate classification SVMs that can directly optimize a large class of performance measures such as F_1-Score, prec@k and rec@k (the precision and recall of a classifier that predicts exactly k = 100 examples to be positive) (Joachims, 2005). For our experiment we held out 500 pairs from each of the positive and negative instances for testing. The remainder are used for training. Table 2 reports the results on the testing data. These results are quite promising. The classifier optimizing F_1-Score is finally used in our REF system.

3.4.3 Step-3: Using Classifier

To use the classifier in the REF system, we recognize fine-grained type fgt_Q of the target entity

	Rec@k	Prec@k	F1-score
Precision	80.8	89.3	86.4
Recall	97.4	83.6	91.6
F-measure	88.3	86.4	88.9

Table 2: Fine-grained named entity classifiers optimizing different measures.

from the $narrative$ field of query Q according to the predefined heuristic rules such as the head of the first non-stop noun phrase being fine-grained. For exmaple, $gallery$ in "*What art galleries are located in Bethesda, Maryland?*" is identified as fine-grained type.

For each entity e_i extracted via the Entity Extractor, the following steps are performed. (1) obtain textual contexts by querying the Yahoo! search engine with entity e_i and the identified fine-grained type fgt_Q, and merging the Yahoo! snippets returned. (2) parse contexts using Lin's Minipar and extract dependency patterns between e_i and fgt_Q. (3) employ the classifier to determine whether the entity e_i belongs to the fine-grained type fgt_Q, and remove or negatively reward the entities that are not fine-grained type identified from the query.

4 Experiments

Our experiments are conducted in the context of the TREC 2010 REF task. Relevance judgements in the TREC were performed in two stages. In phase one, all participant systems were pooled to a depth of the 20. The submitted homepages were judged on a three-point relevance scale: (2) primary homepage devoted to and in control of the entity, (1) relevant homepage devoted to the entity, but is not in control of the entity, and (0) non-relevant homepage that only mentions the entity but is not about the entity. Note that the Wikipedia page of a given entity is regarded as non-relevant by definition in TREC 2010. In phase two, homepages belonging to the same entity are grouped together. The test set used in the TREC 2010 entity track contains 50 test queries. In the official evaluation, only 47 test queries are used because no answers to the other three queries are found. Among 47 test queries, 31 are for organization, 7 for location, 8 for person, and 1 for product name. The average number of answered homepages per topic is 14 (Balog, 2010).

The TREC metrics are based on the homepages only because the ultimate goal of the REF system is to find the homepages of the entities. The main metric is nDCG@R; that is, the normalized discounted cumulative gain at rank R (the number of primary and relevant homepages for that topic) where a record with a primary gets a gain of 3, and a record with a relevant gets a gain of 1. We also report P@N, that is, the fraction of primary homepages in the first N ranks. Experimental results are computed using the *eval-entity.pl* script released by TREC.

4.1 Overall Performance

Table 3 reports the results of the four runs. Best$_T$ and Median$_T$ denote the best and median scores among all TREC 2010 participants' systems, respectively. Perfect$_O$ means the manual ranking system, which can indicate the performance ceiling that our Entity Ranker can achieve. Our$_{comb}$ denotes the proposed system that negatively reward all entities not belonging to the fine-grained entity type by simply putting them at the end of the ranking list.

	nDCG@R	P@1	P@5	P@10
Our$_{comb}$	.1865	.3404	.20	.1596
Perfect$_O$	.3564	.8298	.5872	.3787
Median$_T$	.12	-	-	-
Best$_T$	.38	-	-	-

Table 3: Comparison of four runs.

The results demonstrate that: i) Our$_{comb}$ significantly improves the median performance of the TREC participant systems from 12% to 18.65% in terms of nDCG@R. However, Perfect$_O$ (the performance ceiling) is much high than our automatic system, Our$_{comb}$. This means that there is still much room for improving the entity ranking component. ii) Figure 3 shows the performance of each target type. Product-type queries achieve a worse score due to poor product (PRO) name recognition of the NER tool. The best P@1 score is obtained for organization (ORG) type queries. The nDCG@R score for the person (PER) type is, however, better than that for ORG-type queries. This is because the average number of answer homepages for the ORG-type (29.5) is significantly larger that that of the PER-type (10.5), and the recall for ORG type queries is relatively poor. iii) The Best$_T$ (Yang, 2010)

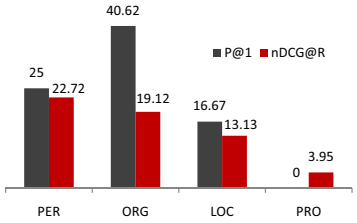

Figure 3: Results per topic type.

is even better than our Perfect$_O$. This indicates that the recall of our entity extraction is unsatisfactory. Note that this paper is mainly concerned with entity ranking, and entity extraction is not the scope of this paper. Yet the proposed methods can be incorporated into Best$_T$ and it can be expected to further improve its performance. Because Best$_T$ only use co-occurrence information between entities in ranking. For better understanding, Table 4 analyzes the recalls of the answer entities in the Document Retriever and Entity Extractor modules. #que represents the number of queries in which at least one answer entity is contained. #ent represents the number of answer entities of all test queries contained. This table indicates that the recall of the Entity Extractor is only 37% (= 266/715).

	Golden Answers [a]	Document Retriever [b]	Entity Extractor [c]
#que	47	45	40
#ent	715	384	266

[a] Golden answers are proved by TREC 2010 `http://trec.nist.gov/data/entity10.html`
[b] No answer entities are retrieved for queries 34 and 44.
[c] No answer entities are extracted for queries 28, 36, 37, 65, and 66.

Table 4: Recalls of answer entities.

The following sections mainly analyze the impacts of the dependency tree-based similarity, incorporating homepage and the fine-grained entity recognition to the REF system; thus, we exclude the queries for which no answer entities are extracted in the Entity Extractor, and the following experiments are based on 40 queries of the TREC 2010 test set.

4.2 Impact of Homepage and Fine-grained Entity Recognition

Table 5 shows the contributions of the dependency tree-based similarity (DTBS), incorporating homepage information (HP), and fine-grained named entity recognition (FG-NER). The baseline is Model 2 discussed in section 3.1. Significance tests are conducted. †: significantly better than the system without this component at the $p = 0.05$ level using two-sided t-tests; $^\flat$: significantly better at the 0.01 level.

	nDCG@R	P@1	P@5	P@10
Baseline	.1336	.125	.115	.1075
+DTBS	.1562†	.25†	.135	.1225
+HP	.1969$^\flat$	.20	.20$^\flat$	.175$^\flat$
+FG-NER	.2181†	.40$^\flat$	.235	.1875

Table 5: Contribution of each component.

The experimental results indicate that: i) the DTBS method can greatly improve Baseline, e.g., the nDCG@R and P@1 scores are significantly improved by 16.9% and 100.0%, respectively. We expect this because the DTBS method considers the relation between words. ii) homepage (HP) can positively impact the REF system in terms of nDCG@R, P@5, and P@10 metrics, which, however, leads to a lower P@1 score. When a non-homepage but one highly-related to the query is assigned as the homepage of an incorrect entity, incorporating homepage information will cause a negative influence. iii) the FG-NER can greatly improve the P@1 score from 20.0% to 40.0% and the P@10 score by 7.1% (not significant). This indicates that the FG-NER on TREC answer entities has nice precision and but poor recall. Table 2, however, shows that our FG-NER can achieve promising precision and recall. It is hard for TREC non-famous entities to retrieve snippets from the Web that conform to the dependency patterns extracted from snippets of Wikipedia entities, which results in poor performance.

In short, it is effective to use a dependency tree-based similarity, homepage information, and fine-grained named entity recognition in the REF system. Figure 4 shows the nDCG@R scores of Our$_{comb}$ and Baseline for each of the 40 queries.

4.3 Evaluation on Entity Names

The experiments above are based on homepages only in which correct entities with wrong homepages are not rewarded. This section discusses the performance based on named entities in which failures of finding homepage are ignored. In calculating nDCG@R, each answer entity gains 1 and a

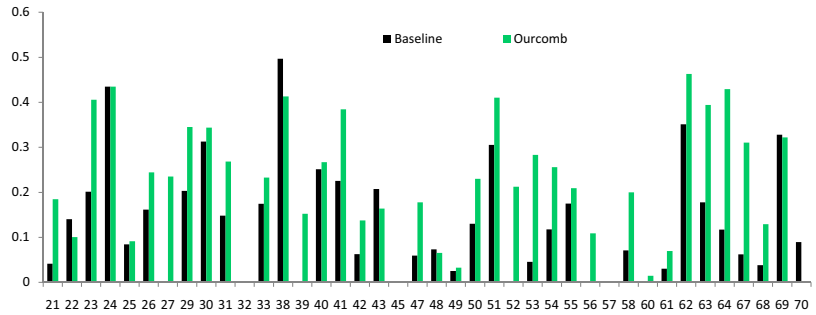

Figure 4: nDCG@R score for each test query.

non-relevant entity gains 0. Figure 5 shows the performance. This figure indicates that the improvements from each proposed component are more significant when errors from homepage finding are ignored. For example, the absolute enhancements of the FG-NER in terms of P@1 and nDCG@R scores are 22.5%, and 3.1%, respectively. This experiment indicates that the Homepage Finder component needs to be improved.

	P@1	P@5	P@10	nDCG@R
Baseline	22.5	18.0	15.0	18.9
+ DTBS	32.5	19.5	18.0	22.0
+ p(Q|hei)	27.5	26.0	22.3	24.3
Ourcomb	50.0	31.0	23.5	27.4

Figure 5: Metrics based on named entities.

5 Conclusion

This paper focused on developing a model for retrieving homepages of entities relevant to a query from a huge collection, and proposed three algorithms for improvements: a dependency tree-based similarity method, incorporating homepages of entities to supplement text snippets that the entities are from, and fine-grained classification of named entities. The comparison experiments on the TREC 2010 test data set showed that the proposed algorithms can significantly improve the system; e.g., the cumulative improvements of the nDCG@R, P@1, and P@5 scores over the Baseline reach 8.4%, 27.5%, and 12.0%, respectively. Moreover, our approaches can also be used in other tasks such as factoid QA. For example, in the TREC 2007 QA test set, about 50% questions (except for questions which answers are numeric and time expresses) contain fine-grained types of answers. Thus, our fine-grained entity recognition module can be expected to lead to improvements in QA systems.

In the future, we will work toward entity extraction and fine-grained named entity recognition. Table and list-based entity extraction may be essential due to the considerable number of answer entities scattered in tables, lists, and other structured forms. For example, answer entities to TREC 2010 query 29 (Find companies that are included in the Dow Jones industrial average.) are contained in a table at `http://www.1728.com/dowjone2.htm`. Li (2010) summarized the statistics of the TREC 2010 test queries in which answer entities are expressed in tables and lists. This means the NER tool trained by the newspaper corpus might fail at identifying the entities from tables and lists, and we have a great deal of work to do in order to correctly identify them. For fine-grained named entity recognition, more studies are needed on identifying fine-grained types of non-famous entities. For example, it is hard to determine whether "Rosenberg Gallery" is a gallery from the snippets relevant to the query "Rosenberg Gallery, gallery".

Abstract

This paper explores new approaches to active learning (AL) for semantic role labeling (SRL), focusing in particular on combining typical informativity-based sampling strategies with a novel measure of representativeness based on compressed dependency trees (CDTs). In essence, the compressed representation encodes the target predicate and the key dependents of the verb complex in the sentence. We first present our method for producing CDTs from the output of an existing dependency parser. The compressed trees are used as features for training a supervised SRL system. Second, we present a study of AL for SRL. We investigate a number of different sample selection strategies, and the best results are achieved by incorporating CDTs for example selection based on both informativity and representativeness. We show that our approach can reduce by up to 50% the amount of training data needed to attain a given level of performance.

1 Introduction

The focus of this paper is active learning for semantic role labeling, a little-studied intersection of two rather substantial bodies of work.

One aim of active learning (AL) is to reduce the number of labeled training instances required to reach a given performance level using supervised machine learning techniques. This is accomplished by allowing the learner to guide the selection of examples to be annotated and added to the training set; at each iteration the learner queries for the example (or set of examples) that will be most informative to its present state. AL is an attractive idea for natural language processing (NLP) because of its potential to dramatically reduce the need for expensive expert annotation, and it has been successfully applied in various areas of natural language processing (Tang et al., 2002; Settles and Craven, 2008), including named entity recognition (Shen et al., 2004),text classification (Yang et al., 2009), image retrieval (Zhou, 2006), part-of-speech tagging (Ringger et al., 2007), morpheme glossing (Baldridge and Palmer, 2009), and syntactic parsing (Hwa, 2004; Osborne and Baldridge, 2004).

The problems of scarce annotated data and the expense of annotating new data are at least as relevant for semantic role labeling (SRL) as for the above-mentioned areas of NLP. Existing work on automatic SRL usually explores supervised machine learning approaches to mark the semantic roles of predicates automatically by training classifiers using large annotated corpora.[1] Although such approaches can achieve reasonably good performance, annotating a large corpus is still expensive and time consuming. Moreover, the performance of trained classifiers may degrade remarkably when they are applied to out-of-domain data (Johansson and Nugues, 2008a). There is very little work on AL for SRL (e.g. Roth and Small (2006)), although much interesting work has been done with semi-supervised and unsupervised approaches to the problem (Grenager and Manning, 2006; Fürstenau and Lapata, 2009; Lang and Lapata, 2010; Titov and Klementiev, 2011, among others).

In this paper we explore the use of compressed dependency trees (CDTs) as features for supervised semantic role labeling and, most importantly, as a way of measuring how representative an individual instance is of the input data. We then incorporate representativeness as part of the metric used for sample selection in active learning. The

[1] For recent work on SRL, see, among others: (Das et al., 2010; Hajič et al., 2009; Surdeanu et al., 2008; Carreras and Màrquez, 2005; Baker et al., 2007).

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 183–191,
Chiang Mai, Thailand, November 8 – 13, 2011.

compressed dependency trees encode the target predicate and the key dependents of the verb complex in a sentence. As illustrated in Section 3, the structural relationships defined by the compressed dependency trees well encapsulate key features used in automatic SRL.

For a more complete picture of the potential for AL with respect to SRL, we investigate a set of strategies designed to select the most **informative** training examples. We further develop a more effective approach to select training examples concerning both their informativity and **representativeness**. We use the compressed dependency trees to measure the similarity of two sentences, and select the training examples with a higher priority which are more informative and representative among the unlabeled sentences in the pool. The experimental results show that our approaches can reduce up to 50% of training examples compared to traditional supervised learning solutions.

We begin with a brief description of the semantic role labeling task and our supervised learning model. Section 3 presents our method for compressing dependency tree representations, followed by the active learning model, including definitions of all sampling strategies investigated in this work (Section 4). Experiments and results are presented and discussed in Section 5 and Section 6. We end with related work (Section 7) and brief conclusions.

2 Semantic Role Labeling

Parsing the semantic argument structure of a sentence involves identification and disambiguation of target predicates as well as identification and labeling of their arguments. Because our focus is on the active learning more so than on the semantic role labeling itself, we address only the argument labeling stage of the process, assuming that predicates and argument spans alike have already been identified and correctly labeled.

Broadly speaking, there are two different styles of semantic parsing and semantic role labeling (SRL): those based on FrameNet-style analysis (Ruppenhofer et al., 2006) and those using PropBank-style analysis (Palmer et al., 2005). This work takes the PropBank approach, which considers only verbal predicates and is strongly tied to syntactic structure. In (1), for example, the two arguments of the predicate *idolize* are labeled as *Arg0* and *Arg1*.

(1) [John]$_{Arg0}$ idolizes [his sister]$_{Arg1}$.

In this text, we refer to each argument to be labeled, together with its target predicate, as an **instance**; the sentence in (1) contains two instances.

2.1 Supervised Learning Model

The aim of the current work is not to surpass state-of-the-art performance on semantic role labeling. Therefore, although state-of-the-art semantic role labelers are freely available, we chose to implement our own labeler in order to have more control over the underlying machinery. This allows straightforward access to the predicted probability of outputs, which is crucial for the informativity-based selection strategies in Section 4. In addition, compressed dependency trees (Section 3) serve as features for our labeler as well as guiding sample selection in the active learning experiments.

In our study, we applied an L1-regularized[2] logistic regression model (Lee et al., 2006) for labeling instances, using the liblinear package (Lin et al., 2007) to build one classifier per label. There are 6 core and 13 non-core argument labels in PropBank annotations. Thus our SRL system is a suite of binary classifiers, and we then use the one-versus-all method (Duda et al., 2001) to assign labels to each instance.

2.2 Data and Features

We used the version of PropBank provided for the CoNLL-2008 SRL shared task (Surdeanu et al., 2008). A test set of 500 randomly selected sentences was constructed at the outset of the project; this was used only for evaluation of both supervised and active learning models. In all AL experiments, we simulate the oracle by hiding and then uncovering gold-standard labels.

The CoNLL-2008 data set includes both gold-standard dependency parses and automatic dependency parses from the Malt parser (Nivre and Hall, 2005). We use a combination of features taken directly from the gold-standard parses,[3] features derived from the Malt parses, and features from the output of the Stanford dependency parser (de

[2]Note that logistic regression is used together with a regularized term to avoid the overfitting problem by penalizing the complexity of the trained model. Generally, the regularized term is defined as a function of the learned parameters over the weights. The L1 regularization, also called lasso penalty, is used to penalize both large and small weights.

[3]In ongoing work, we replace gold-standard parses with more realistic automatic parses.

Table 1: Three feature groups: CoNLL basic, CoNLL derived, and from additional parser

FEATURE TYPE	EXPLANATION/EXAMPLE
Part of Speech	JJR, JJS, LS, CD, etc.
Head word	Head words of predicate and argument
isNEG	Instance includes NOT or NEVER
Argument position	Before or after predicate
Argument chunk position	Beginning or end of corresponding chunk
Lemma of argument	Lemma of argument whose dependency role is PRD or DIR
Lemma context	Two words before and after argument
Cue words	DIR ('up', 'toward', 'forward', 'along') REC ('self' as suffix) PRD ('as', 'as if') CAU ('because', 'why', 'as a result of')
Voice of predicate	Active or passive
Dependency relation of predicate and argument	LOC, TMP, etc. 1) Sbj*, obj* are defined as: Sbj* ← Obj_Passive Sbj* ← LGS_passive Sbj* ← Active_vt_sbj Obj* ← Sbj_Passive Obj* ← Sbj_VI (intransitive verb) Obj* ← Obj_Active
Predicate Properties	VT = 1; transitive VI = 2; intransitive TO_IM=3; begins with 'to' V_ Adj = 4; verb followed by adjective words (e.g. 'sounds good', 'looks pretty') PV = 5; phrasal verb (e.g. 'pick up')
Verb Complex	e.g. "has not been set" in figure 1
Acomp	adjectival complement
Advmod	adverbial modifier
Infmod	infinitival modifier
Rcmod	relative clause modifier
Rel	relative (word introducing an rcmod)
Xsbj	controlling subject
Iobj	indirect object
Advcl	adverbial clause modifier
Prep_to,Prep_in, Prep_for, Prep_with	Prepositional phrases with 'to', 'in', 'for', 'with'

Marneffe et al., 2006). To apply the logistic regression model, the features are represented in a binary fashion. The features are described in Table 1, in three groups separated by double lines. The derived features, including a heuristically-identified verb complex and altered dependency labels, are described in more detail in Section 3.

We use cross-validation on the training data to select for each individual classifier the subset of features most relevant for that label. In feature selection, features are ranked based on their Fisher score calculated using the training data set (as in Duda et al. (2001)).

3 Dependency Tree Compression

Given a sentence, the task of dependency parsing is to identify the head word and its corresponding dependents and to classify their functional relationships according to a set of dependency relations (e.g., subject, modifier). Thus, a dependency tree of a sentence encodes the dependency relation between the head words and their dependents. It has been reported that SRL can benefit from phrase-structure and dependency-based syntactic parsing (Hacioglu, 2004; Johansson and Nugues, 2008b; Pradhan et al., 2005). At the same time, much of the structural and relational information represented in a dependency tree is not relevant for the SRL task.

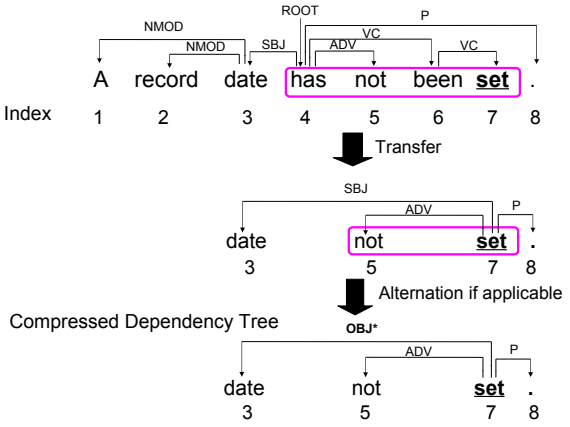

Figure 1: Producing compressed dependency tree

We use a **compressed dependency tree** (CDT) to encode just the relationships between a target predicate and the key dependents of the verb complex. The new tree is always rooted in the target predicate, which often means resetting the root from an auxiliary or other finite main verb. We generate the CDT from the output of an existing dependency parser through the process described in a simplified form below, using the example sentence in Fig. 1.

1. Fix target predicate (e.g. *set*) as root of CDT.
2. Identify the verb chain to which the target predicate belongs; this group of tokens will now be treated as the **verb complex**. The verb chain is produced by collecting elements connected by relevant dependency relations (VC, IM, CONJ), stopping when a ROOT node, a subordinate clause (SUB), or a verbal OBJ node is encountered.
3. Collect direct dependents of each word in the new verb complex; set these as dependents of the target predicate in the CDT, transferring the dependency relation to the target predicate. (e.g. *date* is a dependent of *have*).
4. Negation, modal verbs, and other main verbs in the verb complex also become dependents of the root predicate in the CDT. In some cases of 'new' dependency relations introduced by the tree compression process, we use output from the Stanford parser to complement the dependency relations found in the gold-standard data.

5. Heuristically determine voice of clause and alter some CDT dependency labels(e.g. SBJ_PASSIVE becomes OBJ*); these are the asterisk-marked relations in Table. 1.

For example, in (2):

(2) At the same time, the government did not want to appear to favor GM by allowing a minority stake that might preclude a full bid by Ford.

the verb complex is {*did, n't, want, appear, favor*}. The subject phrase *the government*, originally a dependent of *did*, becomes a dependent of the new three-verb predicate {*want, appear, favor*}; the negation word *n't* is a dependent of the target predicate *want*.

4 Active Learning

This section provides some background on the active learning process, as well as detailing the various sampling strategies we investigate.

4.1 The basic model

In this study we apply a standard active learning model (Settles, 2010; Lewis and Gale, 1994) to the task of semantic role labeling. Algorithm 1 illustrates this model as we use it.[4]

Algorithm 1 Active learning for SRL.

```
1: Randomly select initial seed of labeled instances;
2: Add initial seed to the training data;
3: Apply logistic regression model to train system of classifiers, one for each label;
4: while number of instances in training data is less than X do
5:     Randomly select pool of Y unlabeled sentences;
6:     Select a sentence or sentences from the unlabeled pool according to a given selection strategy;
7:     Ask oracle to label the selected unlabeled sentence;
8:     Add instances from selected sentence to training data;
9:     Re-train system using the updated training data;
10:    Use system to label test data, record accuracy;
11: end while
```

Much recent work in AL has to do with Step 6 of Algorithm 1, designing and refining selection strategies. The main selection criterion used to date has been **informativity**, measuring how much a training example can help to reduce the uncertainty of a statistical model. A less-frequently considered criterion, especially in AL for NLP, is **representativeness**, or how well a training example represents the overall input patterns of the unlabeled data.

While some results from AL are robust across different datasets and even different tasks, it is clear that there is no single approach to AL that is suitable for all situations (Tomanek and Olsson, 2009). Because there is very little previous work on AL for the task of semantic role labeling, we do not assume previous solutions but rather investigate a number of different strategies.

4.2 Informativity

Informativity is exploited in our approaches in terms of uncertainty, which is measured based on how confidently the system labels instances and, by extension, sentences. The lower the confidence on labeling a particular sentence, the more uncertainty is assigned to the sentence. At each iteration, then, we select from the unlabeled pool the single sentence with the greatest uncertainty. We compare 4 different scoring functions for measuring the system's certainty (CER) regarding an unlabeled sentence. These are presented below as INF1-INF4.

Let s represent an unlabeled sentence with instances $i = 1$ to n. Given a set of binary classifiers, one each for labels $y = 1$ to m, let $p_{i,y}$ be the probability of i being labeled as y. Finally, P is a pool of unlabeled sentences. At each iteration, we select the single $s \in P$ with the lowest value for CER.

RAND: Random selection. Random selection (randomly select an unlabeled sentence $s \in P$) serves as a strong baseline in active learning.

INF1: Average uncertainty. After labeling each instance in a sentence with the most-likely predicted label, we calculate uncertainty for the sentence as the average of the classifiers' confidence in assigning the predicted labels. Let $Top(i) = p_{i,y_k}$, where $\forall h \neq k, p_{i,y_k} > p_{i,y_h}$; $CER(s) = (\sum_{j=1}^{n} Top(i_j))/n$.

INF2: Average uncertainty variance. Our second informativity-based strategy evaluates the uncertainty of the labeling for an instance using the variance of the confidence for each instance. A smaller variance implies that it is more difficult for the system to differentiate between possible label assignments for the instance. We then calculate sentence uncertainty as the average variance for

[4] Recall that each sentence contains one or more instances.

all instances. Let $AVG(i) = (\sum_{k=1}^{m} p_{i,y_k})/m$, $VAR(i) = \sum_{k=1}^{m}(p_{i,y_k} - AVG(i))^2/(m-1)$; $CER(s) = \sum_{j=1}^{n} VAR(i_j)/n$.

INF3: Average top-2 Margin. The intuition behind this approach is that the top 2 most confident labels are likely to be more informative than other labels. Therefore, we only select the two most likely labels to calculate uncertainty.[5] Let $Margin(i) = p_{i,y_{k_1}} - p_{i,y_{k_2}}$, where $p_{i,y_{k_1}} > p_{i,y_{k_2}} \wedge \forall h \neq k_1, k_2, p_{i,y_{k_2}} > p_{i,k_h}$; $CER(s) = (\sum_{j=1}^{n} Margin(i_j))/n$.

INF4: Most top-2 Margin Instances. Finally, we further extend the approach of INF3 by selecting the sentence which has the greatest number of instances with a small margin between the top 2 labels (which means that the sentence is more uncertain than other sentences). Let Q be a set of instances with the top-2 margin less than a small threshold (i.e., $Margin(i) \leq 0.1$). $CER(s)$ is defined as the inverse of the number of instances of s that are in Q (i.e. $1/$*# qualifying instances*). Ties are resolved by random selection.

4.3 Representativeness

A disadvantage of selecting examples based only on informativity is the tendency of the learner to query outliers (Settles, 2010). It has therefore been proposed (Dredze and Crammer, 2008; Settles and Craven, 2008) to temper such selection strategies with a notion of relevance or representativeness. Ours is the first work to use such a combined strategy for SRL. We measure the representativeness of unlabeled sentences based on sentence similarity, taking two different approaches: cosine similarity, and a measure based on CDTs.

COS: Cosine Similarity. Given two sentences s and s', let $i_1, i_2, \ldots, i_m$, and $i'_1, i'_2, \ldots, i'_n$ be their instances, respectively. The similarity of the two sentences, denoted as $similarity(s, s')$, is defined as $\sum_{j=1}^{m}\sum_{k=1}^{n} sim(i_j, i'_k)$, where $sim(i_j, i'_k)$ is the similarity between the instances i_j and i'_k, defined as the cosine of the two feature vectors.[6] For purposes of comparison, we use the same formulation of COS as Settles and Craven (2008).

[5] Note that in the binary classification case, INF3 is equivalent to INF1.

[6] Features are extracted from CDTs rather than full sentences, reducing to some extent the appearance of noisy information (e.g. stop words). Whether this can be further reduced by a modified implementation of COS is a question for future work.

Given a pool P of unlabeled sentences, for every unlabeled sentence $s \in P$, the representativeness of the sentence, denoted as $rep(s)$, is measured as the sum of the similarity between the sentence and all the other sentences in the pool, that is, $rep(s) = \sum sim(s, s')$, where $s' \in P \wedge s' \neq s$.

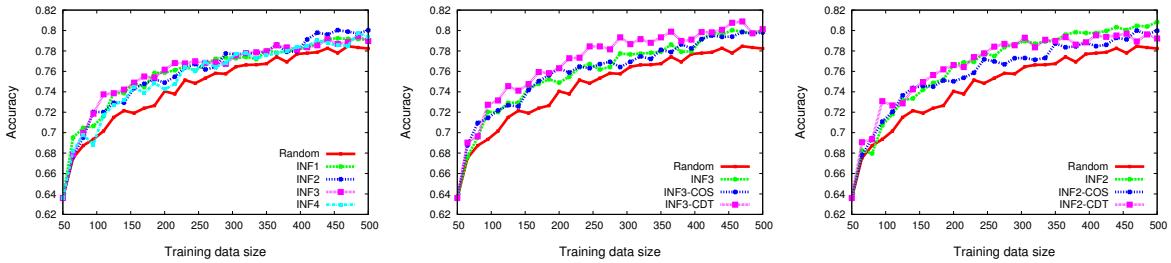
COS evaluates the similarity of two sentences based on the cosine of their instances. This may not be accurate enough because the instances include more information than the relationships between the target predicate and the key dependents of the verb complex in the sentence. Therefore, we exploit the compressed dependency trees as a metric to evaluate the similarity between two sentences, as illustrated below:

CDT: Compressed Dependency Trees. For target predicate p, let (p, r_i, a_i) be the edges of the CDT rooted in p, where a_i is an argument and r_i is the dependency relationship between p and a_i. We call two edges similar if **all** of p, r, and a meet their respective similarity criteria. Two predicates are considered to be similar if they have the same value for the PREDICATE PROPERTIES feature as defined in Table 1 (e.g. both are transitive verbs). Two relations are considered to be similar if they have the same dependency relation label (e.g. SBJ, TMP, MOD, etc.). Finally, two arguments are considered to be similar if they share the same coarse-grained part-of-speech tag.

Given a pool P of unlabeled sentences, for every unlabeled sentence $s \in P$, the representativeness of the sentence, denoted as $rep(s)$, is defined as $n_{similar}$, representing the number of edges in the pool that are similar to the edges of the CDT for s. Intuitively, the larger the number of similar CDT edges in the unlabeled pool, the more representative the sentence is overall of the input data.

4.4 Combining Informativity and Representativeness

The final step in our model is to define a selection strategy that incorporates *both* selection criteria. We define the priority of selecting a sentence as $priority(s) = \alpha \times rep(s) - (1-\alpha) \times CER(s)$. Given a pool P, we select the single $s \in P$ with the highest value for $priority(s)$. This approach is very similar to the information density (ID) approach of Settles and Craven (2008); the key difference is in the balance between the two criteria. Ours is a linear combination; ID instead multiplies informativity by a weighted measure of rep-



(a) Informativity-only strategies (b) INF3 with COS & CDT (c) INF2 with COS &CDT

Figure 2: Combining informativity and representativeness.

resentativeness.

5 Experimental Setup

To evaluate our approach to AL for SRL, we investigate three different questions. First, which informativity strategy is most appropriate for the task? Second, which representativeness measure works best? And third, how shall we weight the trade-off between the two selection criteria?

All of our active learning experiments share some characteristics. First, we randomly select a seed of 50 instances from the labeled training data. The seed set, as well as the test data, are kept consistent across all experimental conditions. In each iteration of the training-selection cycle (see Algorithm 1), a new unlabeled pool (n=500) is selected, and from that pool a single example is labeled by the oracle and added to the training set. We stop once 500 examples have been labeled.

To evaluate the effectiveness of each strategy, we tested the classifier in each interaction, and measured the accuracy of the predicted labels. The accuracy measure is defined as the number of correct labelings divided by the total number of labelings in the test data. Results are presented as the average over 20 runs.

To investigate the influence of representativeness, we run the same experiment with all cross-combinations of {INF1,INF2,INF3,INF4} and {COS,CDT}. For weighting the two criteria, we use both information density (ID) as defined in Settles and Craven (2008) and our *priority* metric (Section 4.4) with α set at 0.3, 0.5, and 0.7.

6 Results and Discussion

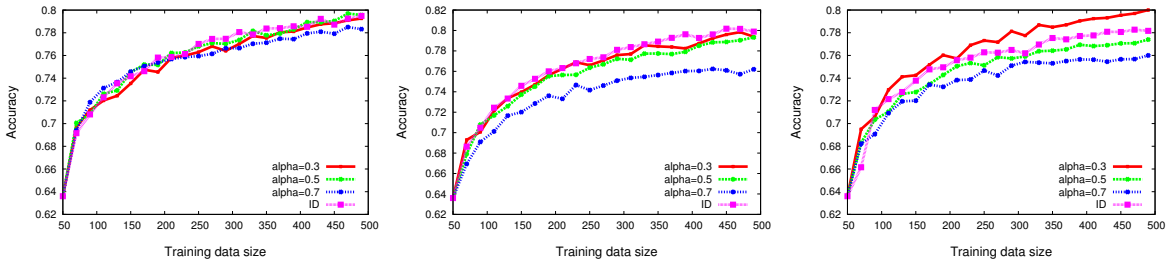
In this section, we analyze and discuss the experimental results. The gains achieved by AL can be measured in a number of different ways; first, we plot number of labeled training examples against system accuracy (Figure 2 and Figure 3). The figures presented here stop at 500 training examples, with averaged accuracies in the range of 80%. For comparison, the fully-supervised system when trained on *20000* instances performed at 89.71%. Second, we calculate the percent reduction in error of each strategy compared to the random selection baseline (Table 2), following Melville and Mooney (2004). Because most gains from AL happen early in the learning curve, we consider performance at two different points.

6.1 Informativity-based Strategies

Fig. 2a shows the expected result that the four informativity-based strategies outperform the random selection baseline. INF3 performs best early in the learning curve, but is overtaken by INF2 at the end of our curve. To reach the accuracy achieved by the four informativity strategies at the halfway point (250 training instances), RAND needs 100-150 additional instances.

6.2 Informativity plus Representativeness

Fig. 2b shows the result of combining the informativity (INF3) and representativeness (both COS and CDT). As illustrated in Section 6.1, INF3 outperforms the other informativity-based strategies. However, we see that Fig. 2b shows combining CDT with INF3 achieves a better performance than using INF3 only (α = 0.3); representativeness improves performance, outperforming RAND by approximately 250 training instances. For INF3, COS is a less effective measure of representativeness. This may be because the feature vectors for the training instances share too much information, including stop words and a large number of 0-valued features, to make them easily differentiated. As a result, the most representative sentence selected using COS may not reflect the real simi-



(a) INF3 with COS (b) INF3 with CDT (c) INF2 with CDT

Figure 3: Trade-off between informativity and representativeness.

larity of the sentences. In CDT, we choose only the structural relation between the predicate and its arguments to measure the similarity between sentences. As a result, the sentences selected using CDT are more representative than that of using COS, as confirmed by the result in Fig. 2b.

We also applied the solution of combining informativity and representativeness (4.3) to other informativity-based strategies. However, the advantage the combined solution for other strategies is less obvious than for INF3. For example, Fig. 2c shows the result of combining INF2 ($\alpha = 0.3$) with both COS and CDT. The result shows that the combined solution with CDT performs slightly better than using INF2 only when the number of training instances is less than 200. However, when the number of instances is larger than 350, the solution of using INF2 only achieves a higher accuracy than the combined solution. This may be due to a conflict between the two selection criteria. In any event, there is clearly a trade-off between informativity and representativeness, and results are influenced by the details of the manner of combining the two.

The results of other INF/REP combinations are presented in Table 2, in terms of their reduction in error compared to random selection.

6.3 Weighting the two criteria

Finally, we set α with different values (i.e., 0.3, 0.5 and 0.7) to investigate how the trade-off between informativity and representativeness may affect the SRL performance. We also compare our solution to the information density solution proposed by *et al.* (Settles and Craven, 2008) (denoted as ID) multiplies the informativity and representativeness instead of summing them. Here we display only the results of INF2 and INF4 combining with CDT in Fig. 3. Other combinations share a similar pattern with these results and their error reduction percentage can be found in Table. 2. Fig. 3a and Fig. 3b compare the two representativity measures for INF3, as the best overall result was achieved by INF3 in combination with CDT. We see that parameter tuning seems to be more influential for the CDT measure than for the COS measure.

Fig. 3c shows how parameter tuning affects INF2; $\alpha = 0.3$ has a higher accuracy than that of 0.5 and 0.7. We can observe that when $\alpha = 0.3$, our solution (INF2) has a better performance than that of ID. However, regarding the combination of INF4 and CDT, ID performs better (no graph; see 2. Note that the INF4 selects the sentences which has greatest number of instances with a small margin. Then representativeness of the sentences within the margin was calculated. In other word, the combination was done step by step not in parallel as the other combination. Therefore, the combination of INF4 and CDT accounts for informativity prior to representativeness; this may be why ID is more successful.

In general, the balance and trade-offs between the two criteria deserve further investigation.

7 Related Work

Much research efforts have been devoted to statistical machine learning methodologies for SRL (Bjkelund et al., 2009; Gildea and Jurafsky, 2002; Shi et al., 2009; Johansson and Nugues, 2008a; Lang and Lapata, 2010; Pradhan et al., 2008; Fürstenau and Lapata, 2009; Titov and Klementiev, 2011, among others). For example, Johansson *et al.* (Johansson and Nugues, 2008a) applied logistic regression with L2 norm to dependency-based SRL. Similarly, we also use logistic regression to train the classifier with a probabilistic explanation. However, we use L1 normed

Table 2: Percentage error reduction over RAND(200 / 500 examples)

	NOREP	COS	CDT	COS-ID	CDT-ID
INF1	6.56 / 5.18	3.68 / -0.86	2.60 / -0.74	7.43 / 6.45	6.44 / 6.60
INF2	5.12 / 8.31	5.51 / 5.37	7.74 / 8.19	7.21 / 5.67	3.49 / 2.24
INF3	5.07 / 5.54	6.13 / 5.52	8.15 / 9.54	5.94 / 5.72	5.65 / 7.18

logistic regression due to its desirable property that can result in few nonzero feature weights. This allows us to select the most important features from an otherwise very large feature set.

Roth *et al.* (Roth and Small, 2006) proposed a margin based active learning framework for structured output and experiment on SRL task. They defined structured output by constraining the relations among class labels, e.g., one predicate only has one of the labels. The classification problem is defined via constraints among output labels. The most uncertain instances are selected to satisfy predefined constraints. Rather than a structured relation between output labels, our work exploits the structure of the sentences themselves via compressed dependency trees.

In the area of sentence similarity measurement, most current work focuses on semantic similarity (Haghighi et al., 2005; Tang et al., 2002; Shen and Lapata, 2007). We define similarity between sentences in terms of the nodes and edges in the dependency tree instead of semantic/lexical similarity of the sentences. We are interested in the structure of a sentence and how it is constructed due to the need of SRL tasks. Wang and Neumann (2007) use a similar sort of compressed dependency tree comprised of keywords and collapsed dependency relations to calculate the semantic similarity of sentences for the textual entailment task. Under their approach, dependency relations themselves are collapsed; we keep the specific dependency relations and collapse the trees, aiming for structural rather than semantic similarity.

In addition, Filippova *et al.* (Filippova and Strube, 2008) proposed to compress a sentence using dependency trees and take the importance of words as weight. They found compressed dependency tree can better ensure the grammaticality of the sentences to preserve the same lexical meaning as much as possible. In our work, we are more interested in the explicit dependency relation of predicate-argument pairs. Our goal is to apply compressed dependency tree to extract explicit relation between predicate and argument as precise as possible for SRL purpose. Therefore, we construct the compressed tree by identifying predicate-argument units and then re-linking them if there exist dependency relation among them. Consequently, most of the nodes in our compressed tree are predicates and arguments.

8 Conclusions

This paper investigates the use of active learning for semantic role labeling. To improve the learning accuracy and reduce the size of training set, compressed dependency trees are exploited as features. Strategies to select informative unlabeled sentences are proposed. Moreover, the compressed dependency trees are also utilized as a criterion to measure the representativeness of unlabeled sentences. A solution to select unlabeled sentences combining both informativeness and representativeness is developed. The experimental results show that our solution can save up to 50% on a small training data set compared to the supervised learning solution.

Possibilities for future work include exploring the use of constraints on label outputs, implementation of entropy-based informativity metrics, and perhaps combining COS andCDT for measuring representativeness. Another potentially promising direction is to employ multi-kernel based methods as a structure-oriented similarity measurement.

Abstract

We describe a method for training a semantic role labeler for CCG in the absence of gold-standard syntax derivations. Traditionally, semantic role labeling is performed by placing human-annotated semantic roles on gold-standard syntactic parses, identifying patterns in the syntax-semantics relationship, and then predicting roles on novel syntactic analyses. The gold standard syntactic training data can be eliminated from the process by extracting training instances from semantic roles projected onto a packed parse chart. This process can be used to rapidly develop NLP tools for resource-poor languages of interest.

1 Introduction

Semantic role labeling is the process of generating sets of semantic roles from syntactic analyses. The process of training a semantic role labeler, however, is costly in resources. First, it requires gold-standard semantic role data, like Propbank (Palmer et al., 2005). Secondly, it requires a detailed syntactic annotation of the same resource. We are fortunate to have the reasonably-sized Penn Treebank (Marcus et al., 1993) and adaptations for formalisms like Tree Adjoining Grammar (Chen and Shanker, 2004) and Combinatory Categorial Grammar (Hockenmaier and Steedman, 2007) alongside the Propbank data, but for other languages, such resources are unlikely to be available. There has been work in generating semantic role labelers using gold-standard trees in the absence of semantic training data (Fürstenau and Lapata, 2009; Lang and Lapata, 2010). But what if we had semantic training data, but no syntactic training data? If we could develop and train a semantic role labeler without syntactic training data, we could greatly reduce the cost and development time of NLP tools for languages of interest.

One option is to use some automatic means to generate a treebank – instead of creating a corpus of syntax trees by hand, we could use an automatic parser. This, however, leads to a chicken-and-egg problem – we would need a high-quality parse model to choose a single-best analysis for each training sentence, and a parse model needs syntactic training data. No automatic parser can currently generate high quality single-best parses in the absence of a parse model. But a parser can, given word tags and combinatory rules, generate a parse forest – a very large collection of possible analyses – and say little or nothing about their relative merit.

In this paper, we extract SRL features from the entire parse forest, effectively training on every possible parse in the training set simultaneously. This can be done efficiently by representing the parse chart as a hypergraph, enabling us to iterate over every constituent in the parse forest without enumerating every individual parse (which would be computationally infeasible). This, combined with the parsing advantages afforded by Combinatory Categorial Grammar (CCG), enables us to train a semantic role labeler without gold-standard trees.

2 Combinatory Categorial Grammar

Combinatory Categorial Grammar (Steedman, 2000) is a grammar formalism that describes words in terms of their combinatory potential. For example, determiners belong to the category NP/N, or "the category of words that become noun

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 192–200,
Chiang Mai, Thailand, November 8 – 13, 2011.

phrases when combined with a noun to the right". The rightmost category indicates the argument that the category is seeking, the leftmost category indicates the result of combining this category with its argument, and the slash indicates the direction of combination. Categories can be nested within each other: a transitive verb like *devoured* belongs to the category (S\NP)/NP, or "the category that would become a sentence if it could combine with a noun phrase to the right and another noun phrase to the left". The process of automatically assigning CCG categories to words is called "supertagging", and CCG categories are sometimes informally referred to as "supertags". An example of how categories combine to make sentences is shown in Figure 1.

CCG has many capabilities that go beyond that of a typical context-free grammar. First, it has a sophisticated internal system of managing syntactic heads and dependencies[1]. These dependencies are used to great effect in CCG-based semantic role labeling systems (Gildea and Hockenmaier, 2003; Boxwell et al., 2009), as they do not suffer the same data-sparsity effects encountered with treepath features in CFG-based SRL systems. Secondly, CCG permits these dependencies to be passed through intermediary categories in grammatical structures like relative clauses. In Figure 2, *the steak* is still in the object relation to *devoured*, even though the verb is inside a relative clause. Finally and most importantly, *these dependencies are represented directly on the CCG categories themselves*. This is crucial for the prediction of semantic roles inside a packed parse chart – because the dependency is formed when the two heads combine, it is available to be used as a local feature by the semantic role labeler. This property of CCG and its impact on packed-chart SRL is described extensively in Boxwell et al. (2010). This ability to predict dependencies (and semantic roles) at parse time figures heavily into the process described here.

3 Brutus: A CCG Based Semantic Role Labeler

The Brutus Semantic Role Labeler (Boxwell et al., 2009)[2] is a semantic role labeling system for CCG.

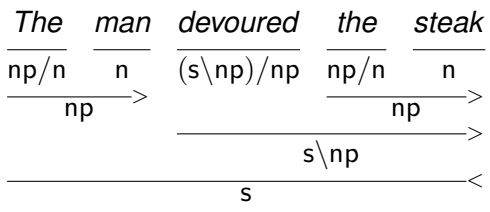

Figure 1: A simple CCG derivation.

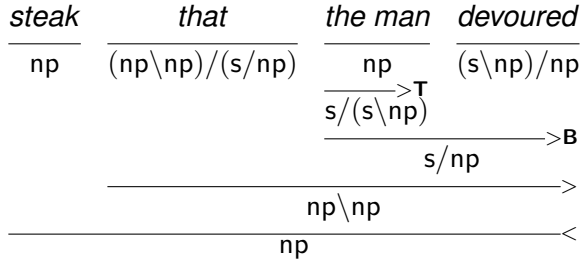

Figure 2: An example of CCG's treatment of relative clauses. The syntactic dependency between *devoured* and *steak* is the same as it was in figure 1.

It is trained using CCGbank and a version of Propbank that has been aligned to the CCGbank in order to account for discrepancies in terminal indexation (Honnibal and Curran, 2007; Boxwell and White, 2008). The system is organized in a two-stage pipeline of maximum entropy models[3], following the organization of a previous CFG-style approach (Punyakanok et al., 2008). The first stage is the identification stage, where, for each predicate in the sentence, each word is tagged as either a role or a nonrole (figure 3). The second stage is the classification stage, where the roles are sorted into ARG0, ARG1, and so on (figure 4). The identification model and the classification model share the same features, but they are trained and run separately.

For the results presented here, we use a version of Brutus that has been stripped down to only use local features so as to enable us to perform SRL at parse time. Recall from section 1 that we wish to extract training features not from a complete parse tree, but from a packed parse chart. For this reason, global features (those that are inaccessible to a single edge in the parse chart) cannot be used. After removing all global features from the seman-

[1] A complete explanation of CCG predicate-argument dependencies can be found in the CCGbank user manual (Hockenmaier and Steedman, 2005)

[2] Found at `http://www.ling.ohio-state.edu/~boxwell/software/brutus.html`

[3] We use the Zhang Le maxent toolkit, available at `http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html`, using the BFGS training method, trained to 500 iterations with gaussian priors of 1 and 5, for the identification and classification steps, respectively.

tic role labeler, the local features that remain are as follows:

- **Words.** A three-word window surrounding the candidate word.
- **Predicate.** The predicate whose semantic roles the system is looking for.
- **Predicate Category.** The CCG category of the predicate.
- **Result Category Detail.** This indicates the feature on the result category of the predicate. Possible values include DCL (for declarative sentences), PSS (for passive sentences), NG (for present-progressive phrases like "running the race"), etc. These are read trivially off of the verbal category.
- **Syntactic Dependency.** As with a previous approach in CCG semantic role labeling (Gildea and Hockenmaier, 2003), this feature shows the exact nature of the syntactic dependency between the predicate and the word we are considering, if any such dependency exists. This feature is represented by the category of the predicate, the argument slot that this word fits into, and whether or not the predicate is the head of the resultant category, represented with a left or right arrow.
- **Before / After.** A binary indicator feature indicating whether the candidate word is before or after the predicate.

4 Parsing Without Syntactic Training Data

In order to test the performance of our semantic role labeler, we will need automatically generated parses to run the SRL models over. Even though we are able to train SRL models in the absence of syntactic training data, we still need test parses on which to predict roles. So why not use the fast, accurate CCG parser (Clark and Curran, 2004b) used with previous CCG-based SRL systems? It makes sense to use the highest quality parses available. But recall that the reason for this roundabout way of training the semantic role labeler is to enable us to generate SRL models *without syntactic training data*. If we use an off-the-shelf syntactic parser that was trained on gold-standard training data, we introduce a source of additional training data that we wish to exclude. But how will we generate reasonably accurate parses without a trained parse model? Even a simple MLE-style approach requires training data.

Combinator	Penalty
Function Application	0
Function Composition	1
Crossing Composition	1
Type Raising	1
Null Coordination	2
Full Coordination	0
Substitution	∞

Table 1: The complete sub-baseline model, which requires no syntactic training data. The substitution combinator is used to model parasitic gaps in English, which are so rare that we make the pragmatic decision to disallow substitution entirely.

To satisfy this need, we develop a very simple parse model that penalizes any non-normal-form rule applications, effectively relying on the CCG supertags to identify likely grammatical relations. Specifically, combinators like function composition and type raising are penalized by a fixed amount, while function application is allowed to pass without penalty. The candidate analysis with the lowest penalty is chosen as the single-best – in case of a tie, the most right-branching analysis is chosen. The complete parse model is shown in table 1.

5 Experiment 1: Generating Traditional Identification and Classification Models from the Chart

In the first experiment, we use a parser to create a set of parse forests from the training set. The individual parses are not enumerated – we extract features from every possible syntactic derivation simultaneously by iterating over every edge in the packed chart. Local syntactic features are accessible, as are the gold-standard semantic roles from Propbank. The identifier and classifier models are then trained from these features, instead of from features obtained from gold-standard syntactic derivations. We will call this two-part SRL model the CHART model. We compare this model to the more traditional GOLD model, which uses the same features but is generated from gold standard trees. We test the system using both gold-standard parse trees and single-best auto-

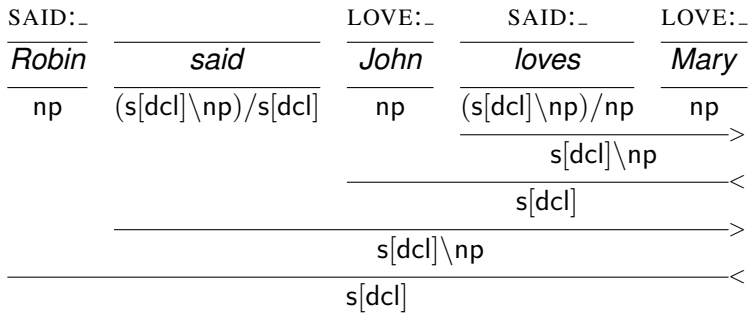

Figure 3: In the first stage of the semantic role labeling process, candidate semantic roles are chosen by the identifier model. We have not yet decided which role (ARG0, ARG1, etc) each word plays, only that there is a role there.

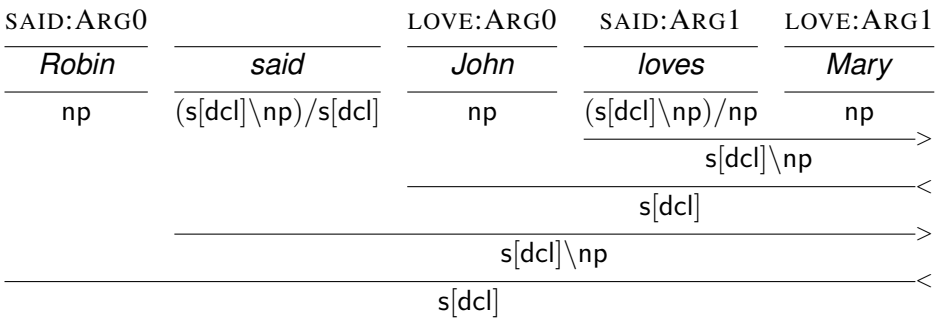

Figure 4: In the second stage of the semantic role labeling process, the classifier model sorts the roles into ARG0, ARG1, etc.

matically generated parse trees (generated from gold-standard supertags by the parser from section 4). Interestingly, SRL performance drops only slightly between gold standard test parses and automatically generated parses when using the chart-based SRL model. Table 2 shows the results for the development set, and table 3 shows the results for the test set.

	Gold Parse			Auto Parse		
Train	P	R	F	P	R	F
GOLD	88.4	85.7	87.0	84.8	80.4	82.5
CHART	83.5	70.8	76.6	83.0	69.4	75.6

Table 2: SRL performance on gold-standard parses and automatic parses from the development set (section 00). The models are defined in section 5.

Manual inspection of the results reveals that the CHART model frequently fails to identify modifier roles, contributing to the very low recall score. This was traced to a consistent weakening of the adjunct dependency feature, resulting largely from the ambiguous attachment of auxiliary verbs. Consider a simple sentence *Jon will visit tomorrow*. Syntactically, there are two possible attachments for *tomorrow*. It can be attached low, to *visit* (figure 5), or it can be attached high, to *will visit* (figure 6). The former will result in a dependency between *visit* and *tomorrow*, while the latter will result in a dependency between *will* and *tomorrow*. Now, imagine training over this sentence's chart. For both analyses, we notice that a role should be placed on *tomorrow*. In one case, there is a dependency between *visit* and *tomorrow*, and in one case there is not. Our simple parsing model does not necessarily do a good job of discriminating in favor of the analysis that we want, so the SRL components may see both options with nearly equal weight. Empirically, the identification model learns that the dependency feature is not a good predictor of modifier roles. This is in-

	Gold Parse			Auto Parse

Table 3: SRL performance on the test set (section 23) using the same models as table 2.

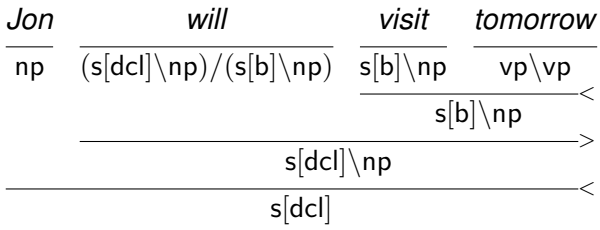

Figure 5: The correct analysis for *Jon will visit tomorrow*. In this case, there is a syntactic dependency between *tomorrow* and *visit*. Note that vp is an abbreviation for s\np.

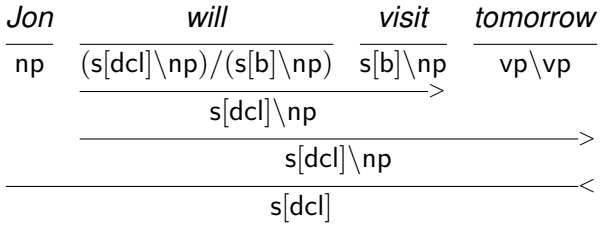

Figure 6: An erroneous analysis for *Jon will visit tomorrow*. There is no syntactic dependency between *tomorrow* and *visit*.

correct – in fact, the presence of a syntactic dependency between a predicate and a target word is almost always a dead giveaway to the presence of a semantic role. In our effort to downplay the role of syntax we may have set up a situation in which a sophisticated machine-learning based argument identifier does exactly the wrong thing. It could be that a less sophisticated argument identifier will be better suited to the task that our system requires.

6 Experiment 2: Improving Argument Identification with a Simpler Model

The CHART identification model performs poorly because it does not recognize syntactic dependencies as good predictors of semantic roles. Suppose that instead of using that identification model, we used a simple heuristic: if there is a syntactic dependency between a word and the predicate, then label that word with a semantic role – otherwise, do not. This simple identification "model" requires no training – it simply relies on the pattern that semantic role bearing units tend to be joined to their predicates by syntactic dependencies. We will refer to this as the chart-dependency model, or C-DEP. In addition to this model, we propose another model that similarly identifies roles with dependencies, but enumerates certain exceptional dependencies that do not predict semantic roles (like those originating from auxiliary verbs like *to* and *has*) according to the Propbank guidelines. We will refer to this as the improved chart-dependency model, or C-DEP+[4]. In both cases, the classification model is identical to that of the CHART model.

Tables 4 and 5 show the effect of using the two chart-dependency identification models compared to the GOLD and CHART models from section 5. Performance using the C-DEP and C-DEP+ models greatly improves on the disappointing recall of the CHART model, while retaining the favorable property of eschewing gold-standard syntactic training data. Instead of systematically weakening the most predictive identification feature available, the simple identification models use *only* that feature. This results in a major improvement in recall at the cost of an acceptable drop in precision.

	Gold Parse			Auto Parse

[4]The C-DEP+ model ignores all dependencies originating from the following categories: (s[to]\np)/(s[b]\np), (s[dcl]\np)/(s[pt]\np), (s[dcl]\np)/(s[pss]\np), (s[b]\np)/(s[pss]\np), and (s[dcl]\np)/(s[ng]\np).

7 Experiment 3: Generating an SRL Model Without Gold-Standard Supertags

In the experiments described in sections 5 and 6, we used four different training methods to generate semantic role labeling models, which are then tested on gold standard syntactic parses and parses that were automatically generated from gold-standard supertags. But much of the challenge of parsing in CCG comes down to the choice of supertags – choosing the correct supertag for a preposition, for example, makes the difference between attaching the prepositional phrase high or low. But surely using gold-standard supertags gives us an unfair advantage; in real-world applications, these supertags would have to be predicted. We could use an off-the-shelf CCG supertagger (Clark and Curran, 2004a), but this would open us to the same chicken-and-egg problem already encountered with automatic parsers – the C&C supertagger is trained on gold-standard syntactic data. Doing without a supertagger and using every possible supertag in a tag dictionary is computationally infeasible; most words have at least two or three possible tags; the most ambiguous word has 133 supertags (*as*). Therefore, we have no choice but to investigate ways to get supertags that do not rely on gold-standard syntactic annotation.

We use a weakly supervised approach to supertagging that augments an HMM with an oracle CCG tag dictionary and a set of broad grammar-informed constraints (Baldridge, 2008; Ravi et al., 2010). The tag dictionary provides only a simple mapping from word to supertag – it does not use any kind of cutoff, nor does it give a prior probability on individual supertags. Using an HMM that has been initialized with grammar-based transition probabilities, combined with a two-stage integer programming strategy, this approach can achieve single-best accuracy of 64.3% on ambiguous supertags. These supertags are then used to generate parse forests, which are used to train the CHART, C-DEP, and C-DEP+ models. Notice that, although most of the tag sequences do not produce spanning analyses, we can still produce a packed chart and generate SRL training features.

We also train a secondary discriminative supertagger using the induced tags that are the output of the tag-dictionary-based HMM supertagger for the training set, and use this supertagger with the parser from section 4 to generate single-best parses to test the SRL models on. It is necessary to train a secondary supertagger over the induced tags because the induced tags by themseleves are unlikely to produce a spanning analysis. The induced supertags from the HMM are only given for the most probable sequence from the HMM; using the beta-best tag predictions of the secondary supertagger produces acceptable coverage. This supertagger is a simple Maxent tagger conditioned on a 5-word window surrounding the target word and trained using a gaussian prior of 5. SRL performance over automatic parses generated with these predicted supertags is not as strong as with gold standard supertags, but is reasonable considering the absence of syntactic training data. Results for the development set are shown in table 6, and results for the test set are shown in table 7.

Table 7: SRL performance on the test set (section 23), using the same models as table 7.

Manual inspection of the induced supertag data reveals some unusual predictions of supertags. For example, it is difficult to think of a valid category for the determiner *the* besides NP/N. The word *the* almost always has the category NP/N in CCGbank. CCGbank does assign other categories for *the*, though most, if not all, of them are errors. Table 8 shows the token frequencies of select cate-

gories for *the* from the training set of CCGbank. Even though there are 46 possible categories in all, only one of them is really worth considering (18 of the categories appear only once). The automatic method for inducing supertags from the tag dictionary, however, frequently predicts categories for *the* that are extremely rare in the English CCGbank. This is because the tag dictionary is generated with no cutoff and provides no prior probability across tags – each tag in the dictionary is given equal consideration by the Markov Model, which ranks them according to how well they interact with their neighbors.

For this reason, we revisit our earlier decision to generate a tag dictionary with no cutoff. Instead, we generate a tag dictionary of categories that make up at least 10% of the word tokens. For example, suppose the word *direct* appears in the corpus 100 times. For a category to be listed for the word *direct* in the tag dictionary, it must appear as the category for *direct* no fewer than 10 times. This can effectively eliminate a large number of very rare categories that overwhelm the HMM. It also more closely simulates a hand-written tag dictionary for closed-class words, or a tag dictionary that was generated automatically from a traditional part-of-speech dictionary. Using a tag dictionary with a 10% cutoff greatly improves performance on semantc role labeling, coming to within 7% accuracy of using gold-standard supertags. The results for the development set are shown in table 9, and the results for the test set are shown in table 10.

Category	Frequency
NP/N	47255
N/N	99
((S\NP)\(S\NP))/NP	78
⋮	⋮
(S/S)/(S/S)	1
(S[adj]\NP)/N	1
(N\N)/N	1

Table 8: The frequencies of select categories for *the* from sections 02-21 of the CCGbank (there are 46 in all). Some categories, like NP/N, are extremely common, whereas others, like (N\N)/N, appear only once.

We have shown that simple and easy syntactic processing is still beneficial for SRL.

Table 10: SRL performance on the test set (section 23) using cutoff of 10% on tag dictionary and the same models as table 9.

For completeness, we briefly explore another option, even simpler than this: we trained SRL models that relied on no syntactic features at all. Specifically, we included the word, predicate, and before/after features (described in detail in section 3). Unsurprisingly, the performance was unacceptably low (P=.73, R-.31, F=.44), most of that coming from successful identification of the predicate itself. This method makes the identifier exceptionally timid, and on the rare occasion that a word *is* identified as a role-bearing unit, it is often assigned roles corresponding to every predicate in the sentence. We conclude that it is necessary to include syntactic features, but that these can be rough and ready.

8 Conclusions and Future Work

In the three experiments presented, we demonstrated that an effective SRL model can be trained without a corpus of parse trees. This can be achieved by using a simple baseline parser to generate a parse forest for a large amount of unannotated newspaper text, then extracting training instances from all possible syntactic analyses simultaneously. This approach is most effective when we have some syntactic knowledge of the sentence in the form of supertags, but is still effective when only a tagging dictionary is available.

In the future, we hope to expand this work into

other languages. Armed only with a Propbank-like corpus of semantic roles and a tag dictionary, we can train a surprisingly effective semantic role labeler. To this end, we hope to further investigate issues surrounding the generation of supertags – particularly, minimally supervised approaches to generating CCG tag dictionaries. Recall that performance actually improved when very rare categories were excluded from the tag dictionary; one option to achieve similar results is to annotate by hand, say, the 200 most common words (almost certainly syntactically interesting closed class words), then using these to guide the generation of a comprehensive tag dictionary, or perhaps by bootstrapping from traditional part-of-speech tags. It would also be beneficial to investigate alternate methods of inducing tags from the tag dictionary that produce n-best tag predictions, as this would improve coverage over the training set.

Another avenue of future research could be the generation of semantic predictions without committing single-best test sentences. Recall that in order to test the semantic role labeler, we needed to generate parse trees for the target sentences. Because we assume that gold-standard syntactic training data is not available, we use a sub-baseline model that requires no training data. But is it really necessary to choose a single best parse at all? Because the version of Brutus used here can extract features from inside the chart, it can also predict semantic roles at parse time (Boxwell et al., 2010). We could therefore predict all possible roles in the chart and explore ways of identifying likely rolesets, using a mechanism for the enforcement of global constraints, such as the integer linear programming solution of Punyakanok et al (2008).

Abstract

We propose an approach to Japanese predicate argument structure analysis exploiting *argument position* and *type*. In particular, we propose the following two methods. First, in order to use information in the sentences in preceding context of the predicate more effectively, we propose an improved similarity measure between argument positions which is more robust than a previous co-reference-based measure. Second, we propose a flexible selection-and-classification approach which accounts for the minor types of arguments. Experimental results show that our proposed method achieves state-of-the-art accuracy for Japanese predicate argument structure analysis.

1 Introduction

The goal of predicate-argument structure analysis is to extract semantic relations such as "who did what to whom" that hold between a predicate and its arguments constituting a semantic unit of a sentence. It is an important step in many Natural Language Processing applications such as machine translation, summarization and information extraction.

Arguments are classified into three categories according to their positions relative to the predicates: intra-sentential arguments (those that have direct syntactic dependency with the predicates), zero intra-sentential arguments (those appearing as zero-pronouns but have their antecedents in the same sentence), and inter-sentential arguments (those appearing as zero-pronouns and their antecedents are not in the same sentence). We call them *INTRA_D, INTRA_Z*, and *INTER* respectively. Furthermore, we call these categories the *argument types*. While the analysis of INTRA_D is comparatively easy, INTRA_Z and INTER are more difficult. We consider that there are two reasons for this.

The first reason is the poverty of features for argument identification compared to INTRA_D. While for INTRA_D we have important clues such as the function word or directly dependency relation, we don't for INTRA_Z and INTER.

The second reason is the limited amount of training examples. For example, in a Japanese newswire corpus, INTRA_Z and INTER account for 30.5% and 12.4% of all the nominative (ga) cases, and 13.1% and 0.2% of all of the accusative (wo) cases (Iida et al., 2007).

In this paper, in order to solve these problems we propose the following two methods exploiting *argument position* and type.

First, we propose an improved similarity measure between argument positions of two predicates that take semantically similar arguments. For example, someone possibly arrested can also surrender him/herself, that is, objects of "arrest" and subjects of "surrender (oneself)" are occupied by semantically similar nouns. Gerber and Chai (2010) proposed analysis of English nominal predicates with this similarity to take discourse context into account. However, the similarity measure they used has drawbacks: it requires a co-reference resolver and a large number of documents. We improve their similarity measure alleviating these drawbacks by using argument position. We detail previous work on capturing discourse context in Section 2, and our proposal in Section 3.1.

Second, we propose a selection-and-classification approach. In this approach, in order to compensate for the relative infrequency of examples of INTRA_Z and INTER, we select a candidate argument for each argument type independently. After selecting candidates, we use classifiers to choose the correct argument type. This allows us to flexibly design features for each

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 201–209,
Chiang Mai, Thailand, November 8 – 13, 2011.

step and we can use pairwise features between the candidate arguments. We detail this in Section 3.2.

The experimental results demonstrated that our proposed method achieved the state-of-the-art of Japanese predicate argument structure analysis.

2 Related Work Capturing Discourse Context

2.1 Salient Reference List

Iida et al. (2003) used Salient Reference List (Nariyama, 2002) based on Centering Theory (Grosz et al., 1995), which explains the structure of discourse and the transition of topics in order to capture discourse context. The list has the following four ordered slots.

TOPIC (marked by *wa*-particle)
> SUBJECT (*ga*)
> INDIRECT OBJECT (*ni*)
> DIRECT OBJECT (*wo*),

We check whether each candidate corresponds to any slots from the beginning of a document. If the candidate corresponds to a slot, we (over)write the slot with the candidate. We repeat this until we reach the predicate to analyze. We use the ranks of candidates in the list as a feature.

2.2 Argument Frequency

Iida et al. (2003) used a feature (*CHAIN LENGTH*) that stands for how often each candidate is used as an argument of predicates in preceding context. Imamura et al. (2009) used a similar binary feature (*USED*) that shows if each candidate is ever used as an argument of predicates or not. However, they did not investigate the effect of these features explicitly in their systems. Therefore we also investigate these in this paper.

2.3 Similarity between an Argument Position and a co-Reference Chain

In the study of implicit arguments[1] for English nominal predicates, Gerber and Chai (2010) used similarity features between an argument position and a co-reference chain, inspired by Chambers and Jurafsky (2008), who proposed unsupervised learning of narrative event chains using pointwise mutual information (PMI) between syntactic positions. This method stands on the assumption that similar argument positions tend to have the arguments which belong to a common co-reference chain. For instance, co-referring arguments at such argument positions like $\langle plead, ARG_0 \rangle$, $\langle admit, ARG_0 \rangle$, $\langle convict, ARG_1 \rangle$, tend to take semantically similar nouns as the argument positions like $\langle sentence, ARG_1 \rangle$, $\langle parole, ARG_1 \rangle$.

They first automatically label a subset of the Gigaword corpus (Graff, 2003) with verbal and nominal semantic role labeling. They then identify co-references between arguments using a co-reference resolver. They compute PMI as follows.

Suppose the resulting data has N co-referential pairs of argument positions and M of these pairs comprising $E_a = \langle P_a, A_a \rangle$, $E_b = \langle P_b, A_b \rangle$, and $E_c = \langle P_c, A_c \rangle$. P_a, P_b, and P_c are predicates, and A_a, A_b, and A_c are labels such as ARG_0 or ARG_1.

$$pmi(E_a, E_b) = \log \frac{G(E_a, E_b)}{G(E_a, *)G(E_b, *)}$$

$$G(E_a, E_b) = \frac{M}{N}$$

With this similarity between argument positions, they defined scores between an argument position and a co-reference chain.

3 Predicate Argument Structure Analysis Exploiting Argument Position and Type

3.1 Similarity between Argument Positions using Distribution Similarity

Suppose we want to identify the argument of **自首した** (surrendered) in Example (1). The argument is an antecedent of zero-pronoun ϕ of the predicate.

(1) 警察(police) は(*wa*-particle) 花子(hanako) を(*wo*-particle) 逮捕した(arrested).
Police arrested Hanako.

私は(I) (ϕ が) **自首した**(had surrendered) と(that) 聞いた(heard).
I heard that ϕ *had surrendered*.

With Salient Reference List for "自首する (surrendered)", the rank of "警察 (police)" is higher than that of "花子 (Hanako)" and it is noisy information for analysis. We also cannot distinguish them with argument frequency information, because frequencies of both "花子 (Hanako)" and "警察 (police)" are 1.

Though it is reasonable to use the similarity between an argument position and a co-reference

[1] In short, this is equivalent to INTER.

1599	が[ga] 自首する (surrender)	5651	が[ga] 逮捕する (arrest)	82112	を[wo] 逮捕する (arrest)
136	-者 person	702	署員 PS staff	15285	人 person
117	犯人 criminal	698	警察 police	8484	-者 person
96	彼 he	376	警察官 police officer	5563	男 man
68	人 person	368	-署 police station	2804	-名 name
63	男 man	230	県警 prefectural police	1188	犯人 criminal
36	-犯 crime	177	-員 -staff	1185	男性 male
30	少年 boy	153	府警 prefectural police	763	-ら -s
26	高校生 high-scool student	137	当局 authorities	671	おまえ you

Table 1: Argument distributions of each argument position (Sorted by frequency)

chain, the similarity measure described in Section 2.3 has two problems.

One is the strong dependency on the accuracy of co-reference resolver system. In fact, the accuracy of Japanese co-reference resolvers is not accurate enough to create co-reference chains in good quality.[2] The other problem is the problem that it needs a lot of documents, because the method does not use any non co-referring nouns.

To avoid using an unreliable co-reference resolver, we can suppose the same noun lemmas without pronouns in the same document are co-references. Pekar (2006) called the noun lemmas *anchors* and they supposed the similarity measure between syntactic positions. For example, there are two anchors: "Mary" and "house" in the sentences "Mary bought a house. The house belongs to Mary." They extract two groups: { buy(obj:X), belong(subj:X) } and {buy(subj:X), belong(to:X). } Nevertheless, this method also requires many documents because noun lemmas without anchors are not used for the calculation.

In this paper, we propose a more robust similarity measure between argument positions which does not depend on unreliable co-reference annotations by the resolver.

Table 1 shows the list of nouns that have direct dependency arcs in syntactic dependency structures along with case markers が[ga] (nominative case), を[wo] (accusative case) and に[ni] (dative case) extracted from the *WEB* corpus described in Section 4. According to Table 1, the distributions of nouns of "自首する (surrender)" following が[ga] and "逮捕する (arrest)" following を[wo] look alike. We can expect that an arrested person is more likely to be a person who has surrendered than an arrestee. We define a novel similarity of two argument positions

[2]We implemented the method proposed by Iida et al. (2005a), and the F-measure was 66%.

		E_1	E_2	E_3
E_1	が[ga] 自首する (nominative case of *surrender*)	0	0.5409	0.2431
E_2	が[ga] 逮捕する (nominative case of *arrest*)	0.5409	0	0.5139
E_3	を[wo] 逮捕する (accusative case of *arrest*)	0.2431	0.5139	0

Table 2: An example of similarities between argument positions calculated with *WEB* corpus.

encoding such information as Jensen-Shannon divergence between argument distributions of argument positions. A sample of the calculated similarities is shown in Table 2. This table illustrates the most similar argument positions are the nominative (が[ga]) case of "自首する (surrender)" (E_1) and the accusative (を[wo]) case of "逮捕する (arrest)" (E_3). We will use these values as features of predicate-argument analysis in the experiments.

3.2 Selection-and-Classification Approach Considering Argument Type

In previous work, argument analysis was performed with common features regardless its argument type. However, these methods have difficulty in distinguishing the marginal cases where two candidates have different argument types because of the difference of quantity by argument types. Thus we propose the *selection-and-classification approach* for Japanese predicate argument structure analysis. This approach consists of two steps: the *selection* step and the *classification* step.

This approach is inspired by two models. The first is the selection-and-classification model (Iida et al., 2005b) for noun phrase anaphora resolution. The model first selects a likely antecedent of the target (possibly) anaphoric expression. Second, the model classifies the target anaphoric ex-

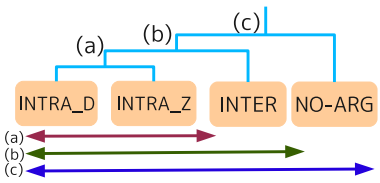

Figure 1: Argument selection in the 'Classification' step from three most likely argument candidates

	Label	Arguments to make features
a	INTRA_D	⟨*INTRA_D*, INTRA_Z⟩
	INTRA_Z	⟨INTRA_D, *INTRA_Z*⟩
b	INTRA	⟨*INTRA_D*, INTER⟩, ⟨*INTRA_Z*, INTER⟩
	INTER	⟨{INTRA_D or INTRA_Z }, *INTER*⟩
c	HAVE-ARG	⟨{INTRA_D or INTRA_Z or INTER}⟩
	NO-ARG	⟨*INTRA_D*⟩, ⟨*INTRA_Z*⟩, ⟨*INTER*⟩

Table 3: Examples made for training. *Italic texts* in (b) and (c) refer most likely argument which (a) and (b) selected respectively. Non-italic texts refer to the correct argument.

pression either true anaphoric or not with the most likely antecedent. They took this approach since there are almost no clues for a Japanese noun phrase to determine anaphoric or not by looking only at the noun phrase.

Similarly, in our approach, after selecting the most likely candidate of the argument, we classify it into either of INTRA_D, INTRA_Z, INTER or no argument.

The second is the *tournament model* (Iida et al., 2003) for zero-anaphora resolution. For all the candidate antecedents (virtually all noun phrases appearing in preceding context), the model repeats two-class classification: which candidate in the pair of candidates is likely to be the antecedent for the zero-anaphora. The advantage of the tournament model is that the model can use pairwise features of candidates. Similarly, in the classification step of our approach we select an argument comparing most likely candidates of arguments of each argument type.

A Method of Argument Analysis

Selection: At the first step, we select three most likely arguments of INTRA_D, INTRA_Z, and INTER for each predicate using any argument identification model. We may use different features for models of different argument types.

Classification: At the second step, we determine which INTRA_D, INTRA_Z, and INTER is the correct argument or if there is no explicit argument appearing in the context. This step is composed

Gold Scope	Example made for training
NO-ARG	(c)NO-ARG
INTER	(b)INTER, (c)HAVE-ARG
INTRA_Z	(a)INTRA_Z, (b)INTRA, (c)HAVE-ARG
INTRA_D	(a)INTRA_D, (b)INTRA, (c)HAVE-ARG

Table 4: Examples made for training with human-annotated data. Generated examples depend on the argument type.

of three binary classification models illustrated in Figure 1.

(a) Judge which of INTRA_D or INTRA_Z is more likely to be an argument of the predicate.
(b) Judge which of INTER or the candidate selected at (a) is more likely to be an argument of the predicate.
(c) Judge whether the candidate selected at (b) qualifies as an argument of the predicate or not.

We show the example of analysis of ϕ in Example (1). We first select argument candidates of INTRA_D, INTRA_Z, and INTER. Suppose the most likely argument of INTRA_D is not selected and "私 (I)" and "花子 (Hanako)" are selected as ones of INTRA_Z and INTER respectively in the 'selection' step. Because INTRA_D is not selected, the classifier selects INTRA_Z at (a). Suppose INTER is selected at (b) comparing "私" selected at (a) and "花子". Finally, "花子" is selected as the argument by the classifier of (c).

Furthermore, though we tried different orders for 'Classification' step in the preliminary experiment, this order was the best.

Training Method of Classifiers for the 'Classification' Step

We train each binary classifier in the order of (a), (b), and (c). We create training examples of classifiers with two argument candidates and a predicate as shown in Tables 3 and 4. The following arguments are used for training:

(a) the correct argument and the most likely argument selected at the 'Selection' step
(b) the correct argument and the most likely argument selected by (a) at the 'Classification' step
(c) the correct argument and the most likely argument selected by (b) in the 'Classification' step

For instance, ϕ in Example (1) is "花子 (Hanako)" whose argument type is INTER. Hence

CHAIN_LENGTH	A frequency of being arguments in previous sentences (Iida et al., 2003)
USED	Whether being arguments in former sentences or not (Imamura et al., 2009)
SIM_COREF	Scores between an argument position and co-reference chain calculated with the similarity which Gerber and Chai (2010) used (described in Section 2.3)
SIM_CS	Scores between an argument position and co-reference chain calculated with our proposed similarity

Table 5: Discourse context features used in the experiment

we generate two training examples: One is an example of (b) with the label INTER, "花子", and the most likely argument selected by (a) at 'Classification' step. The other one is an example of (c) with the label HAVE-ARG and "花子".

4 Evaluation Setting of Predicate Argument Structure Analysis Exploiting Argument Position and Type

We evaluate our proposed selection-and-classification approach by comparing it with other models and the discourse context features shown in Table 5 by adding them to the baseline features at Japanese predicate argument structure analysis of nominative case.

In the experiment, systems refer only nouns in co-reference chains which are intra-sentential arguments. In addition, we used human annotated data of co-reference and predicate-argument structure to make discourse context features. For SIM_COREF and SIM_CS, we used maximum, minimum and average scores of similarities.

4.1 Dataset for Similarity Calculation

We used two datasets for the calculation of similarities: the Newspapers (NEWS) and the Web texts (WEB).

NEWS: We used about 21,000,000 sentences in Mainichi newspapers published from 1991 to 2003 (excluded 1995). We part-of-speech tagged the data with MeCab 0.98[3] and dependency structure parsed with CaboCha 0.60pre4[4]. Both taggers used the NAIST Japanese Dictionary 0.6.3[5]. We extracted 27,282,277 pairs of a predicate and an argument.[6]

We also extracted 111,173,873,092 co-reference chains to calculate SIM_COREF with the anaphora resolver which is our re-implementation of (Iida et al., 2005a). These chains include 2,280,417,516,455 nouns. We used 173,778,624 pairs of a predicate and an argument with the case maker が[ga], を[wo] and に[ni].

WEB: We used about 500,000,000 sentences which Kawahara and Kurohashi (2006) collected from the web. They are part-of-speech tagged with JUMAN[7] and dependency structure parsed with KNP[8]. We extracted 1,101,472,855 pairs of a predicate and an argument.[9]

4.2 Training and Evaluation Dataset

We used NAIST Text Corpus 1.4β (Iida et al., 2007) for training and evaluation. It is based on Kyoto Text Corpus 3.0[10] and annotated with predicate-argument structure, event noun structure, and co-reference of nouns about 40,000 sentences of Japanese newspaper text. We excluded 11 articles due to annotation error.

We conducted five-fold cross-validation. In the experiments, base phrases and dependency relations are acquired from the Kyoto Text Corpus 3.0 in the same way of related work.

4.3 A Model in the 'Selection' Step

In order to identify the most likely argument candidate of each INTRA_D, INTRA_Z, and INTER, we used the tournament model. We emphasize that our proposed approach can use any argument identification model to identify the most likely candidate of an argument.

4.4 Baseline Features and Classifier

As baseline features, we employed features proposed by Iida et al. (2005a, 2007a) and Imamura et al. (2009) in addition to a novel one 'PRED DEP POS' shown in Table 6.

We used Support Vector Machine (Cortes and Vapnik, 1995) for each classification model with

[9]Unique total are; Verb:about 801 million, Noun: about 288 million, Pair: 15,994 million

[10]http://nlp.kuee.kyoto-u.ac.jp/nl-resource/corpus.html

Type	Name	Description (NP and PRED refer a noun phrase and a predicate.)
Lexical	HEAD BF	Head word of NP and PRED.
Grammatical	PRED IN MATRIX	1 if PRED exists in the matrix clause; otherwise 0.
	PRED IN EMBEDDED	1 if PRED exists in the relative clause; otherwise 0.
	PRED VOICE	1 if PRED contains auxiliaries such as '(ra)reru'; otherwise 0.
	PRED AUX	1 if PRED contains auxiliaries such as '(sa)seru', 'hosii', 'morau'
	PRED ALT	0 if PRED VOICE and PRED AUX are 1; otherwise 1.
	POS	Part-of-speech of NP.
	DEFINITE	1 if NP contains the article corresponding to DEFINITE 'the', such as 'sore' or 'sono'; otherwise 0.
	DEMONSTRATIVE	1 if NP contains the article corresponding to DEMONSTRATIVE 'that' or 'this', such as 'kono', 'ano'; otherwise 0.
	PARTICLE	Particle followed by NP.
	PARTICLE IF PRED VOICE	PARTICLE followed by NP if PRED VOICE is 1.
Semantic	NE	Named entity of NP: PERSON, ORGANIZATION, LOCATION, ARTIFACT, DATE, TIME, MONEY, PERCENT or N/A.
	PRONOUN TYPE	Pronoun type of NP. (e.g. 'kare (he)': PERSON, 'koko (here)': LOCATION, 'sore (this)': OTHERS)
	SELECT REST	1 if NP satisfies selectional restrictions in Nihongo Goi Taikei (Japanese Lexicon) (Ikehara et al., 1997); otherwise 0.
	NCV NPS PMI	PMI score of [⟨Noun, Case⟩,⟨Predicate⟩] calculated from the WEB corpus.
Positional	DIST NP PRED	Distance between NP and PRED.
	DIST NPS	Distance between NP and NP.
	BEGINNING	1 if NP is located in the beginning of sentence; otherwise 0.
	END	1 if NP is located in the end of sentence; otherwise 0.
	PRED NP	1 if PRED proceeds NP; otherwise 0.
	NP PRED	1 if NP precedes PRED; otherwise 0.
	DEP PRED	1 if NP depends on PRED; otherwise 0.
	DEP NP	1 if PRED depends on NP; otherwise 0.
	PRED DEP POS	Part-of-speech of head word depended by PRED.
	IN QUOTE	1 if NP exists in the quoted text; otherwise 0.
	PATH	Dependency relation between PRED and NP.
Context	SRL RANK	A rank of NP in Salient Reference List.
	GA REF	1 if the phrase which contains noun and 'ga' depend on NP with 'nagara', 'te', 'shi', 'tsutsu', 'tameni', 'tari', ϕ; otherwise 0.

a linear kernel. We used the implementation of LIBLINEAR 1.7[11] with its default parameters.

4.5 Targets for Comparison of Predicate Argument Analysis Model

We evaluate our selection-and-classification approach by comparing our baseline model with two previous approaches TA and IM.

TA: Taira et al. (2008) used decision lists where features were sorted by their weights learned from Support Vector Machine. They simultaneously solved the argument of event nouns in the same lists.

IM: Imamura et al. (2009) used discriminative models based on maximum entropy. They added the special noun phrase NULL, which expresses that the predicate does not have any argument.

Because previous work use different features and machine learning methods and experiment on different setting from ours, we also compare with a baseline model BL in order to analyze the effect of dividing a model considering argument type.

BL: This model has a single step in 'classification' step. In other words, 'selection' step in this model selects the most likely argument from all noun phrases preceding the predicate.

5 Discussion

Table 7 presents the result of the experiments. According to the bottom row in Table 7, we achieved the state-of-the-art of Japanese predicate argument structure analysis by combining all discourse context features (+A+B+C+D+E).

We investigate our result from five different standpoints.

5.1 Effect of the Selection-and-Classification Approach

We analyze the effect of our proposed selection-and-classification approach by comparing the first row of Table 7. SC is superior to BL in all types. This shows that dividing a model considering argument type improves the performance.

Table 7: Comparison of predicate argument structure analysis of nominative case: P, R, and F_1 indicate Precision, Recall, and F-measure($\beta = 1$), respectively.

5.2 Comparison between previous work

By comparing SC and TA, and SC+USED and IM[12], the result of our proposed method is competitive or superior to others. Additionally, recall is higher in any type; therefore we consider there is still much room for improvement by replacing the argument identification model in the selectional step with other models.

5.3 Effect of Similarity Metrics

On comparing +A (CHAIN_LENGTH), +B (USED), and +C (SIM_COREF_NEWS) or +D (SIM_CS_NEWS) in Table 7, similarity-based features are superior or competitive to frequency-based feature.

(2) 婚姻は毎年一万—四万組も増え、 ...
The number of marriages increases 10,000 to 40,000 couples annually ...

...**流行し**て ...の引き金となったインフルエンザが、
The flu that *has been going around* and triggered ...,

For instance, the argument of "流行し (be going around)" in Example (2) is "インフルエンザ (flu)" of INTER and is not an argument of previous arguments. Though the topic changes between two sentences, A and B cannot take it into account this and output "婚姻 (Marriages)" which is an argument of "増え (increase)" because the frequency-based feature is active. In contrast, C and D handle this because the similarity between the nominative case of "増え" and "流行し" is low.

On comparing +C (SIM_COREF_NEWS) and +D (SIM_CS_NEWS) in Table 7, our proposed similarity metrics work better than the co-reference-based metrics in INTRA_D or INTRA_Z by a large margin. This result shows the robustness of our metrics compared to the co-reference based similarity between argument positions.

5.4 Effect of In and Out-of-domain Data

On comparing +D (SIM_CS_NEWS) and +E (SIM_CS_WEB) in Table 7 respectively, the similarity measure using the newswire texts works better for INTRA_D and one using the web texts works better for INTRA_Z and INTER.

Additionally, the result of +D+E shows that combining proposed similarities calculated from different sources work complementary.

5.5 Ablation Features

Removing features one by one from ALL (Adding all of A to E), we inquire about features which have strong effect on ALL. Table 7 shows that the F-measures of INTRA_D and INTRA_Z fall by a large margin, by removing D and E respectively. Though the F-measure of INTER degrades by removing C, it makes little difference to other argument types. This shows it is our proposed similarity that mainly contributes to the improvement of the F-measure of the overall system.

6 Error Analysis

We analyze errors where our proposed similarity does not work well.

[12]We compare SC+USED and IM, because IM used the USED feature.

6.1 Copula

In NAIST Text Corpus, the copula "だ"(In English, "be") is annotated as a predicate.

(3) マンション価格が . . . 下がってきた . . . 。
The price of apartments is going down.

. . . （ϕ が） 前年は五・八倍**で**あった
ϕ of last year *was* 5.8 times higher than that of this year.

However, the behavior of copula is different from other predicates, thus it is difficult to resolve them with the same model. To solve this problem, the model of copula should be separated.

6.2 Light Verb Construction

In this experiment, we regarded the predicate of "する (do) + noun" such as "逮捕する (do arrest)" as a single predicate. On the other hand, we regarded the predicate of "する (do) + particle + noun" such as "まかせにする" in Example (4) as "する (do)."

(4) （ϕ が） 分権を国 まかせ (relegation) に[ni] **する** *(do)* のではなく、. . .
ϕ should not relegate promotion of decentralization . . .

However, verbs like "do" in such examples do not play central roles, whereas the noun such as "まかせ (relegation)" carries the main meaning of the event. This phenomenon is called "light verb construction" (Miyamoto, 1999).

"まかせ" is the nominalized form of the verb "まかせる (relegate)." Thus we need to calculate similarity with "まかせる" instead of "する". When the predicate is a light verb, we have to use the original verb to calculate the similarity.

6.3 Predicate Sense Ambiguity

A predicate may have several senses and hence have several argument distributions. For example, "詰める" has two senses at least: to pack and to bring to a conclusion. "詰める" in Example (5) means the latter.

(5) （ϕ が） 数字を早急に**詰める**必要性を強調した。
They emphasized that ϕ should be brought to an conclusion as soon as possible.

The distributions of arguments of such ambiguous verbs tend to have a mixture of several distributions of arguments. Therefore this makes it hard to calculate the similarity of an argument position and a co-reference chain. Additionally, it is even more difficult when the predicate is more essential verb such as "持つ (have)" and "取る (take)." This suggests the close relationship between the word sense disambiguation and the predicate argument structure analysis. In fact, Meza-Ruiz and Riedel (2009) showed that the joint model for semantic role labeling and word sense disambiguation performs better than a pipeline system.

Since NAIST Text Corpus is not annotated with verb senses, we are annotating the sense of verbs to allow similar analysis.

7 Conclusion

We improved Japanese predicate argument structure analysis exploiting *argument position* and *type*. In particular, we proposed two methods: the improved similarity measure between argument positions and the selection-and-classification approach considering argument type.

Experimental results show that our proposed method achieved state-of-the art accuracy for the Japanese predicate argument structure analysis. Proposed similarity between argument positions exploiting case maker is more robust than previous co-reference-based method that makes use of an unreliable automatic co-reference resolver. Furthermore, we proposed flexible approach which accounts for the minor types of arguments.

Future work includes four topics: (1) to distinguish copula from other predicates; (2) to combine internal argument to take semantic argument into consideration if the verb is in light verb construction; (3) to perform word sense disambiguation before calculating similarity; (4) to conduct experiments not only on nominative case but also on other cases .

Abstract

A multiword is compositional if its meaning can be expressed in terms of the meaning of its constituents. In this paper, we collect and analyse the compositionality judgments for a range of compound nouns using Mechanical Turk. Unlike existing compositionality datasets, our dataset has judgments on the contribution of constituent words as well as judgments for the phrase as a whole. We use this dataset to study the relation between the judgments at constituent level to that for the whole phrase. We then evaluate two different types of distributional models for compositionality detection – constituent based models and composition function based models. Both the models show competitive performance though the composition function based models perform slightly better. In both types, additive models perform better than their multiplicative counterparts.

1 Introduction

Compositionality is a language phenomenon where the meaning of an expression can be expressed in terms of the meaning of its constituents. Multiword expressions (Sag et al., 2002, MWEs) are known to display a continuum of compositionality (McCarthy et al., 2003) where some of them are compositional e.g. "swimming pool", some are non-compositional e.g. "cloud nine", and some in between e.g. "zebra crossing".

The past decade has seen interest in developing computational methods for compositionality in MWEs (Lin, 1999; Schone and Jurafsky, 2001; Baldwin et al., 2003; Bannard et al., 2003; McCarthy et al., 2003; Venkatapathy and Joshi, 2005; Katz and Giesbrecht, 2006; Sporleder and Li, 2009). Recent developments in vector-based semantic composition functions (Mitchell and Lapata, 2008; Widdows, 2008) have also been applied to compositionality detection (Giesbrecht, 2009).

While the existing methods of compositionality detection use constituent word level semantics to compose the semantics of the phrase, the evaluation datasets are not particularly suitable to study the contribution of each constituent word to the semantics of the phrase. Existing datasets (McCarthy et al., 2003; Venkatapathy and Joshi, 2005; Katz and Giesbrecht, 2006; Biemann and Giesbrecht, 2011) only have the compositionality judgment of the whole expression without constituent word level judgment, or they have judgments on the constituents without judgments on the whole (Bannard et al., 2003). Our dataset allows us to examine the relationship between the two rather than assume the nature of it.

In this paper we collect judgments of the contribution of constituent nouns within noun-noun compounds (section 2) alongside judgments of compositionality of the compound. We study the relation between the contribution of the parts with the compositionality of the whole (section 3). We propose various constituent based models (section 4.3) which are intuitive and related to existing models of compositionality detection (section 4.1) and we evaluate these models in comparison to composition function based models. All the models discussed in this paper are built using a distributional word-space model approach (Sahlgren, 2006).

2 Compositionality in Compound Nouns

In this section, we describe the experimental setup for the collecting compositionality judgments of English compound nouns. All the existing datasets focused either on verb-particle, verb-noun or adjective-noun phrases. Instead, we focus on *compound nouns* for which resources are rel-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 210–218,
Chiang Mai, Thailand, November 8 – 13, 2011.

atively scarce. In this paper, we only deal with compound nouns made up of two words separated by space.

2.1 Annotation setup

In the literature (Nunberg et al., 1994; Baldwin et al., 2003; Fazly et al., 2009), compositionality is discussed in many terms including simple decomposable, semantically analyzable, idiosyncratically decomposable and non-decomposable. For practical NLP purposes, Bannard et al. (2003) adopt a straightforward definition of a compound being compositional if *"the overall semantics of the multi-word expression (here compound) can be composed from the simplex semantics of its parts, as described (explicitly or implicitly) in a finite lexicon"*. We adopt this definition and pose compositionality as a literality issue. *A compound is compositional if its meaning can be understood from the literal (simplex) meaning of its parts*. Similar views of compositionality as literality are found in (Lin, 1999; Katz and Giesbrecht, 2006). In the past there have been arguments in favor/disfavor of compositionality as literality approach (e.g. see (Gibbs, 1989; Titone and Connine, 1999)). The idea of viewing compositionality as literality is also motivated from the shared task organized by Biemann and Giesbrecht (2011). From here on, we use the terms compositionality and literality interchangeably.

We ask humans to score the compositionality of a phrase by asking them *how literal the phrase is*. Since we wish to see in our data the extent that the phrase is compositional, and to what extent that depends on the contribution in meaning of its parts, we also ask them *how literal the use of a component word is within the given phrase*.

For each compound noun, we create three separate tasks – one for each constituent's literality and one for the phrase compositionality. The motivation behind using three separate tasks is to make the scoring mechanism for each task independent of the other tasks. This enables us to study the actual relation between the constituents and the compound scores without any bias to any particular annotator's way of arriving at the scores of the compound w.r.t. the constituents.

There are many factors to consider in eliciting compositionality judgments, such as ambiguity of the expression and individual variation of annotator in background knowledge. To control for this, we ask subjects if they can interpret the meaning of a compound noun from *only* the meaning of the component nouns where we also provide contextual information. All the possible definitions of a compound noun are chosen from WordNet (Fellbaum, 1998), Wiktionary or defined by ourselves if some of the definitions are absent. Five examples of each compound noun are randomly chosen from the ukWaC (Ferraresi et al., 2008) corpus and the same set of examples are displayed to all the annotators. The annotators select the definition of the compound noun which occurs most frequently in the examples and then score the compound for literality based on the most frequent definition.

We have two reasons for making the annotators read the examples, choose the most frequent definition and base literality judgments on the most frequent definition. The first reason is to provide a context to the decisions and reduce the impact of ambiguity. The second is that distributional models are greatly influenced by frequency and since we aim to work with distributional models for compositionality detection we base our findings on the most frequent sense of the compound noun. In this work we consider the compositionality of the noun-noun compound type without token based disambiguation which we leave for future work.

2.2 Compound noun dataset

We could not find any compound noun datasets publicly available which are marked for compositionality judgments. Korkontzelos and Manandhar (2009) prepared a related dataset for compound nouns but compositionality scores were absent and their set contains only 38 compounds. There are datasets for verb-particle (McCarthy et al., 2003), verb-noun judgments (Biemann and Giesbrecht, 2011; Venkatapathy and Joshi, 2005) and adjective-noun (Biemann and Giesbrecht, 2011). Not only are these not the focus of our work, but also we wanted datasets with each constituent word's literality score. Bannard et al. (2003) obtained judgments on whether a verb-particle construction implies the verb or the particle or both. The judgments were binary and not on a scale and there was no judgment of compositionality of the whole construction. Ours is the first attempt to provide a dataset which have both scalar compositionality judgments of the phrase as well as the literality score for each component word.

We aimed for a dataset which would include compound nouns where: 1) both the component words are used literally, 2) the first word is used literally but not the second, 3) the second word is used literally but not the first and 4) both the words are used non-literally. Such a dataset would provide stronger evidence to study the relation between the constituents of the compound noun and its compositionality behaviour.

We used the following heuristics based on WordNet to classify compound nouns into 4 above classes.

1. Each of the component word exists either in the hypernymy hierarchy of the compound noun or in the definition(s) of the compound noun. e.g. *swimming pool* because *swimming* exists in the WordNet definition of *swimming pool* and *pool* exists in the hypernymy hierarchy of *swimming pool*
2. Only the first word exists either in the hypernymy hierarchy or in the definition(s) of the compound and not the second word. e.g. *night owl*
3. Only the second word exists either in the hypernymy hierarchy or in the definition(s) of the compound and not the first word. e.g. *zebra crossing*
4. Neither of the words exist either in hypernymy hierarchy or in the definition(s) of the compound noun. e.g. *smoking gun*

The intuition behind the heuristics is that if a component word is used literally in a compound, it would probably be used in the definition of the compound or may appear in the synset hierarchy of the compound. We changed the constraints, for example decreasing/increasing the depth of the hypernymy hierarchy, and for each class we randomly picked 30 potential candidates by rough manual verification. There were fewer instances in the classes 2 and 4. In order to populate these classes, we selected additional compound nouns from Wiktionary by manually inspecting if they can fall in either class.

These heuristics were only used for obtaining our sample, they were *not* used for categorizing the compound nouns in our study. The compound nouns in all these temporary classes are merged and 90 compound words are selected which have at least 50 instances in the ukWaC corpus. These 90 compound words are chosen for the dataset.

2.3 Annotators

Snow et al. (2008) used Amazon mechanical turk (AMT) for annotating language processing tasks. They found that although an individual turker (annotator) performance was lower compared to an expert, as the number of turkers increases, the quality of the annotated data surpassed expert level quality. We used 30 turkers for annotating each single task and then retained the judgments with sufficient consensus as described in section 2.4.

For each compound noun, 3 types of tasks are created as described above: a judgment on how literal the phrase is and a judgment on how literal each noun is within the compound. For 90 compound nouns, 270 independent tasks are therefore created. Each of these tasks is assigned to 30 annotators. A task is assigned randomly to an annotator by AMT so each annotator may work on only some of the tasks for a given compound.

2.4 Quality of the annotations

Recent studies[1] shows that AMT data is prone to spammers and outliers. We dealt with them in three ways. **a).** We designed a qualification test[2] which provides an annotator with basic training about literality, and they can participate in the annotation task only if they pass the test. **b).** Once all the annotations (90 phrases * 3 tasks/phrase * 30 annotations/task = 8100 annotations) are completed, we calculated the average Spearman correlation score (ρ) of every annotator by correlating their annotation values with every other annotator and taking the average. We discarded the work of annotators whose ρ is negative and accepted all the work of annotators whose ρ is greater than 0.6. **c).** For the other annotators, we accepted their annotation for a task only if their annotation judgment is within the range of ± 1.5 from the task's mean. Table 1 displays AMT statistics. Overall, each annotator on average worked on 53 tasks randomly selected from the set of 270 tasks. This lowers the chance of bias in the data because of any particular annotator.

Spearman correlation scores ρ provide an estimate of annotator agreement. To know the difficulty level of the three types of tasks described in section 2, ρ for each task type is also displayed in

[1] A study on AMT spammers `http://bit.ly/e1IPil`

[2] The qualification test details are provided with the dataset. Please refer to footnote 3.

No. of turkers participated	260	
No. of them qualified	151	
Turkers with $\rho <= 0$	21	
Turkers with $\rho >= 0.6$	81	
No. of annotations rejected	383	
Avg. submit time (sec) per task	30.4	
	highest ρ	avg. ρ
ρ for phrase compositionality	0.741	0.522
ρ for first word's literality	0.758	0.570
ρ for second word's literality	0.812	0.616
ρ for over all three task types	0.788	0.589

Table 1: Amazon Mechanical Turk statistics

Function f	ρ	$\mathbf{R^2}$
ADD	0.966	0.937
MULT	0.965	0.904
COMB	0.971	0.955
WORD1	0.767	0.609
WORD2	0.720	0.508

Table 3: Correlations between functions and phrase compositionality scores

table 1. It is evident that annotators agree more at word level than phrase level annotations.

For each compound, we also studied the distribution of scores around the mean by observing the standard deviation σ. All the compound nouns along with their mean and standard deviations are shown in table 2.

Ideally, if all the annotators agree on a judgment for a given compound or a component word, the deviation should be low. Among the 90 compounds, 15 of them are found to have a deviation $> \pm 1.5$. We used this threshold to signify annotator disagreement. The reason for disagreement could be due to the ambiguity of the compound e.g. *silver screen, brass ring* or due to the subjective differences of opinion between the annotators.

Overall, the inter annotator agreement (ρ) is high and the standard deviation of most tasks is low (except for a few exceptions). So we are confident that the dataset can be used as a reliable gold-standard with which we conduct experiments. The dataset is publicly available for download[3].

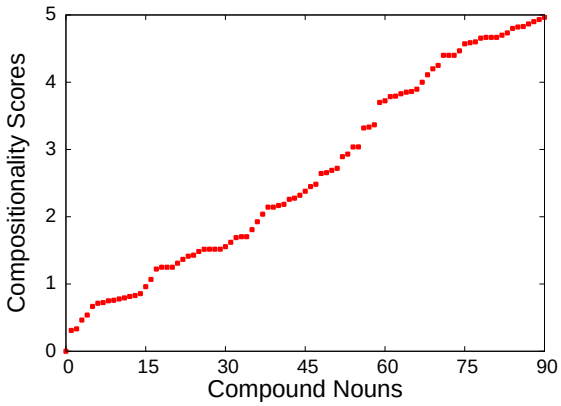

Figure 1: Mean values of phrase-level compositionality scores

3 Analyzing the Human Judgments

By analyzing the mean values of the phrase level annotations, we found that compounds displayed a varied level of compositionality. For some compounds annotators confirm that they can interpret the meaning of a compound from its component words and for some they do not. For others they grade in-between. Figure 1 displays the mean values of compositionality scores of all compounds. Compounds are arranged along the X-axis in increasing order of their score. The graph displays a *continuum of compositionality* (McCarthy et al., 2003). We note that our sample of compounds was selected to exhibit a range of compositionality.

3.1 Relation between the constituents and the phrase compositionality judgments

The dataset allows us to study the relation between constituent word level contributions to the phrase level compositionality scores.

Let $w1$ and $w2$ be the constituent words of the compound $w3$. Let $s1$, $s2$ and $s3$ be the mean literality scores of $w1$, $w2$ and $w3$ respectively. Using a 3-fold cross validation on the annotated data, we tried various function fittings f over the judgments $s1$, $s2$ and $s3$.

- ADD: $a.s1 + b.s2 = s3$
- MULT: $a.s1.s2 = s3$
- COMB: $a.s1 + b.s2 + c.s1.s2 = s3$
- WORD1: $a.s1 = s3$
- WORD2: $a.s2 = s3$

where a, b and c are coefficients.

We performed 3-fold cross validation to evaluate the above functions (two training samples and

Table 2: Compounds with their constituent and phrase level mean±deviation scores

one testing sample at each iteration). The coefficients of the functions are estimated using least-square linear regression technique over the training samples. The average Spearman correlation scores (ρ) over testing samples are displayed in table 3. The goodness of fit R^2 values when trained over the whole data are also displayed in table 3.

Results (both ρ and R^2) clearly show that a relation exists between the constituent literality scores and the phrase compositionality. Existing compositionality approaches on noun-noun compounds such as (Baldwin et al., 2003; Korkontzelos and Manandhar, 2009) use the semantics of only *one* of the constituent words (generally the head word) to determine the compositionality of the phrase. But the goodness of fit R^2 values show that the functions ADD, COMB and MULT which intuitively make use of *both* the constituent scores fit the data better than functions using only one of the constituents. Furthermore, COMB and ADD suggest that additive models are preferable to multiplicative. In this data, the first constituent word plays a slightly more important role than the second in determining compositionality.

Overall, this study suggests that *it is possible to estimate the phrase level compositionality scores given the constituent word level literality scores*. This motivates us to present constituent

based models (section 4.3) for compositionality score estimation of a compound. We begin the next section on computational models with a discussion of related work.

4 Computational Models

4.1 Related work

Most methods in compositionality detection can be classified into two types - those which make use of lexical fixedness and syntactic properties of the MWEs, and those which make use of the semantic similarities between the constituents and the MWE.

Non compositional MWEs are known to have lexical fixedness in which the component words have high statistical association. Some of the methods which exploit this feature are (Lin, 1999; Pedersen, 2011). This property does not hold always because institutionalized MWEs (Sag et al., 2002) are known to have high association even though they are compositional, especially in the case of compound nouns. Another property of non-compositional MWEs is that they show syntactic rigidness which do not allow internal modifiers or morphological variations of the components, or variations that break typical selectional preferences. Methods like (Cook et al., 2007; McCarthy et al., 2007; Fazly et al., 2009) exploit this property. This holds mostly for verbal idioms but not for compound nouns since the variations of any compound noun are highly limited.

Other methods like (Baldwin et al., 2003; Sporleder and Li, 2009) are based on semantic similarities between the constituents and the MWE. Baldwin et al. (2003) use only the information of the semantic similarity between one of the constituents and the compound to determine the compositionality. Sporleder and Li (2009) determine the compositionality of verbal phrases in a given context (token-based disambiguation) based on the lexical chain similarities of the constituents and the context of the MWE. Bannard et al. (2003) and McCarthy et al. (2003) study the compositionality in verb particles and they found that methods based on the similarity between simplex parts (constituents) and the phrases are useful to study semantics of the phrases. These findings motivated our constituent based models along with the findings in section 3.1.

In addition to the constituent based models (section 4.3), there are composition function based vector models (Mitchell and Lapata, 2008; Widdows, 2008) which make use of the semantics of the constituents in a different manner. These models are described in section 4.4 and are evaluated in comparison with the constituent-based models.

The vector space model used in all our experiments is described as follows.

4.2 Vector space model of meaning

Our vector space model is also called a word space model (Sahlgren, 2006, WSM) since we represent a word's meaning in a dimensional space. In the WSM, a word meaning is represented in terms of its Co-occurrences observed in a large corpora where the co-occurrences are stored in a vector format. The lemmatised context words around the target word in a window of size 100 are treated as the co-occurrences. The top 10000 frequent content words in the ukWaC (along with their part-of-speech category) are used for the feature co-occurrences i.e. the dimensionality of the WSM. To measure similarity between two vectors, cosine similarity (sim) is used. Following Mitchell and Lapata (2008), the context words in the vector are set to the ratio of probability of the context word given the target word to the overall probability of the context word[4].

4.3 Constituent based models

Given a compound word $w3$ with the constituents $w1$ and $w2$, constituent based models determine the compositionality score $s3$ of the compound by first determining the literality scores $s1$ and $s2$ of $w1$ and $w2$ respectively (section 4.3.1) and then using one of the functions f (described in section 3.1), the compositionality score $s3$ is estimated using $s3 = f(s1, s2)$ (section 4.3.2).

4.3.1 Literality scores of the constituents

If a constituent word is used literally in a given compound it is highly likely that the compound and the constituent share common co-occurrences. For example, the compound *swimming pool* has the co-occurrences *water*, *fun* and *indoor* which are also commonly found with the constituents *swimming* and *pool*.

We define the literality of a word in a given compound as the similarity between the compound and the constituent co-occurrence vectors i.e. if the number of common co-occurrences are

[4]This is similar to pointwise mutual information without logarithm

numerous then the constituent is more likely to be meant literally in the compound.

Let $v1$, $v2$ and $v3$ be the co-occurrence vectors of $w1$, $w2$ and $w3$. The literality scores $s1$ and $s2$ of $w1$ and $w2$ in the compound $w3$ are defined as

$$s1 = sim(v1, v3)$$
$$s2 = sim(v2, v3)$$

where sim is the cosine similarity between the vectors.

4.3.2 Compositionality of the compound

Given the literality scores $s1$ and $s2$ of the constituents, we can now compute the compositionality score $s3$ of the compound $w3$ using any of the functions f defined in section 3.1.

$$s3 = f(s1, s2)$$

4.4 Composition function based models

In these models (Schone and Jurafsky, 2001; Katz and Giesbrecht, 2006; Giesbrecht, 2009) of compositionality detection, firstly a vector for the compound is composed from its constituents using a compositionality function $\oplus$. Then the similarity between the composed vector and true co-occurrence vector of the compound is measured to determine the compositionality: the higher the similarity, the higher the compositionality of the compound. Guevara (2011) observed that additive models performed well for building composition vectors of phrases from their parts whereas Mitchell and Lapata (2008) found in favor of multiplicative models. We experiment using both the compositionality functions simple addition[5] and simple multiplication, which are the most widely used composition functions, known for their simplicity and good performance.

Vector $\mathbf{v1} \oplus \mathbf{v2}$ for a compound w_3 is composed from its constituent word vectors **v1** and **v2** using the vector addition $a\mathbf{v1} + b\mathbf{v2}$ and simple multiplication **v1v2** where the i^{th} element of $\mathbf{v1} \oplus \mathbf{v2}$ is defined as

$$(a\mathbf{v1} + b\mathbf{v2})_i = a.\mathrm{v1}_i + b.\mathrm{v2}_i$$
$$(\mathbf{v1v2})_i = \mathrm{v1}_i.\mathrm{v2}_i$$

[5]Please note that simple additive model (Mitchell and Lapata, 2008) is different from the additive model described in (Guevara, 2011). In (Mitchell and Lapata, 2008) the coefficients are real numbers whereas in (Guevara, 2011) they are matrices.

	first constituent	second constituent
s1	0.616	–
s2	–	0.707

Table 4: Constituent level correlations

The compositionality score of the compound is then measured using $s3 = sim(\mathbf{v1} \oplus \mathbf{v2}, \mathbf{v3})$ where **v3** is the co-occurrence vector of the compound built from the corpus. For more details of these models please refer to (Mitchell and Lapata, 2008; Giesbrecht, 2009).

4.5 Evaluation

We evaluated all the models on the dataset developed in section 2. Since our dataset has constituent level contributions along with phrase compositionality judgments, we evaluated the constituent based models against both the literality scores of the constituents (section 4.3.1) and the phrase level judgments (section 4.3.2). The composition function models are evaluated only on phrase level scores following (McCarthy et al., 2003; Venkatapathy and Joshi, 2005; Biemann and Giesbrecht, 2011): higher correlation scores indicate better compositionality predictions.

Constituent based models evaluation

Spearman's ρ correlations of s1 and s2 with the human constituent level judgments are shown in table 4. We observed that the predictions for the second constituent are more accurate than those for the first constituent. Perhaps these constitute an easier set of nouns for modelling but we need to investigate this further.

For the phrase compositionality evaluation we did a 3-fold cross validation. The parameters of the functions f (section 4.3.2) are predicted by least square linear regression over the training samples and optimum values are selected. The average Spearman correlation scores of phrase compositionality scores with human judgements on the testing samples are displayed in table 5. The goodness of fit R^2 values when trained over the whole dataset are also displayed.

It is clear that models ADD and COMB which use both the constituents are better predictors of phrase compositionality compared to the single word based predictors WORD1 and WORD2. Both ADD and COMB are competitive in terms of both the correlations (accuracy) and goodness of

Model	ρ	R^2
Constituent Based Models		
ADD	0.686	0.613
MULT	0.670	0.428
COMB	0.682	0.615
WORD1	0.669	0.548
WORD2	0.515	0.410
Compositionality Function Based Models		
$a\mathbf{v1} + b\mathbf{v2}$	0.714	0.620
v1v2	0.650	0.501
RAND	0.002	0.000

Table 5: Phrase level correlations of compositionality scores

fit values. The model MULT shows good correlation but the goodness of fit is lower. First constituent (model WORD1 i.e. $sim(\mathbf{v1}, \mathbf{v3})$) was found to be a better predictor of phrase compositionality than the second (WORD2) following the behaviour of the mechanical turkers as in table 3.

Composition function based models evaluation

These models are evaluated for phrase compositionality scores. As with the constituent based models, for estimating the model parameters a and b of the composition function based models, we did a 3-fold cross validation. The best results of additive model on the training samples are found at a=0.60 and b=0.40. Average Spearman correlation scores of both addition and multiplication models over the testing samples are displayed in table 5. The goodness of fit R^2 values when trained over the whole dataset are also displayed.

Vector addition has a clear upper hand over multiplication in terms of both accuracy and goodness of fit for phrase compositionality prediction.

Winner

For phrase compositionality prediction (table 5), both constituent based and compositionality function based models are found to be competitive, though compositionality function based models perform slightly better. The reason could be because while constituent based models use contextual information of each constituent *independently*, composition function models make use of collective evidence from the contexts of both the constituents *simultaneously*. In the public evaluations of compositionality detection (Biemann and Giesbrecht, 2011), our system (Reddy et al., 2011) which uses the notion of contexts salient to both the constituents achieved better performance than the system which uses only one of the constituent's contexts.

All the results when compared with random baseline (RAND in table 5), which assigns a random compositionality score to a compound, are highly significant.

5 Conclusions

In this paper we examined the compositionality judgments of noun compounds and also the literality judgments of their constituent words. Our study reveals that both the constituent words play a major role in deciding the compositionality of the phrase. We showed that the functions which predict the compositionality using both the constituent literality scores have high correlations with compositionality judgments. Based on this evidence we proposed constituent based models for compositionality detection. We compared constituent based models with compositionality function based models. The additive compositionality functions were slightly superior to the best performing constituent models (again additive) but performance is comparable and we plan to examine more sophisticated constituent models in the future.

All the 8100 annotations collected in this work are released publicly. We hope the dataset can reveal more insights into the compositionality in terms of the contribution from the constituents. Future directions of this work include token based disambiguation of phrases and designing more sophisticated constituent based models. Extending this study on other kinds of phrases such as adjective-noun, verb particle, verb-noun phrases may throw more light into our understanding of compositionality.

Feature-Rich Log-Linear Lexical Model for Latent Variable PCFG Grammars

Zhongqiang Huang and **Mary Harper**
Department of Computer Science
University of Maryland, College Park
{zqhuang,mharper}@umd.edu

Abstract

Context-free grammars with latent annotations (PCFG-LA) have been found to be effective for parsing many languages; however, currently their lexical model may be subject to over-fitting and requires language engineering to handle out-of-vocabulary (OOV) words. Inspired by previous studies that have incorporated rich features into generative models, we propose to use a feature-rich log-linear lexical model to train PCFG-LA grammars that are more robust to rare and OOV words. The proposed lexical model has three advantages: over-fitting is alleviated via regularization, OOV words are modeled using rich features, and lexical features are exploited for grammar induction. Our approach results in significantly more accurate PCFG-LA grammars that are flexible to train for different languages (with test F scores of 90.5, 85.0, and 81.9 on WSJ, CTB6, and ATB, respectively).

1 Introduction

The latent variable approach of (Matsuzaki et al., 2005; Petrov et al., 2006) is capable of learning high accuracy context-free grammars directly from a raw treebank, and has achieved state-of-the-art parsing accuracies on multiple languages, outperforming many other parsers that are engineered for performance in a particular language (Petrov, 2009; Green and Manning, 2010). However, the lexical model of PCFG-LA grammars (responsible for emitting words from latent POS tags) is not designed to effectively handle OOV words universally. In fact, hand-crafted rules designed for English OOV words were used in the multi-language study of (Petrov, 2009) for non-English languages, leaving room for further improvement for each of the languages studied.

Huang and Harper (2009) and Attia et al. (2010) studied the impact of rare and OOV word handling for parsing with PCFG-LA grammars, especially for non-English languages. They both found that language-specific handling of OOV words significantly improves parsing performance. However, hand tailoring of the language-specific module with expert knowledge may produce suboptimal results, and would not be applicable to new languages. Petrov and Klein (2008) presented a discriminatively trained PCFG-LA model that makes use of rich morphological features for handling OOV words and obtained improved performance on some languages; however, this method was considerably less accurate than its strong generative counterpart on English WSJ.

Berg-Kirkpatrick et al. (2010) demonstrated that each generation step of a generative process can be modeled as a locally normalized log-linear model so that rich features can be incorporated for learning unsupervised models, e.g., POS induction. Inspired by their work, we propose a log-linear lexical model for generative PCFG-LA grammars. It maintains the advantages of generative models, while providing a principled way to: 1) alleviate over-fitting via regularization, 2) handle OOV words using rich features, and 3) exploit lexical features for grammar induction. The proposed approach produces significant improvements for all of the three studied languages.

The rest of the paper is structured as follows. We first review PCFG-LA grammars and issues related to the lexical model in Section 2, and then describe the proposed log-linear lexical model and the training methods in Sections 3 and 4, respectively. Experiments are presented in Section 5. Section 6 concludes this paper.

2 PCFG-LA Grammar

PCFG grammars with latent annotations (Matsuzaki et al., 2005; Petrov et al., 2006) augment

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 219–227,
Chiang Mai, Thailand, November 8 – 13, 2011.

the observed parse trees in the treebank with a latent variable at each tree node. Each latent variable effectively refines an observed category t into a set of latent subcategories $\{t_x|x = 1, \cdots, |t|\}$, where $|t|$ denotes the number of latent tags split from t. Each syntactic category in the original tree in Figure 1(a) is split into multiple latent subcategories, and that parse tree is decomposed into many derivation trees whose non-terminals are latent categories; Figure 1(b) depicts one such derivation tree, where each grammar rule expands a latent non-terminal category into a sequence of latent non-terminals and/or terminal words, e.g., VP-4→VBD-5 NP-6.

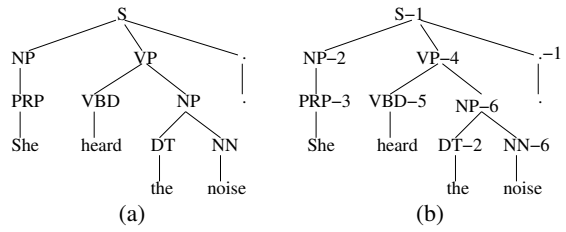

Figure 1: (a) treebank tree (b) derivation tree

The objective of PCFG-LA training is to induce a grammar with latent variables that maximizes the probability of the training trees. Given a PCFG-LA grammar with model parameter θ, $\mathcal{R}$ denotes the set of grammar rules, $\mathcal{D}(T)$ the set of derivation trees for parse tree T, and $\mathcal{R}(T)$ and $\mathcal{R}(D)$ the sets of rules comprising T and D, respectively. The probability of T under the grammar is computed as:

$$\mathrm{P}_\theta(T) = \sum_{D \in \mathcal{D}(T)} \mathrm{P}_\theta(D) = \sum_{D \in \mathcal{D}(T)} \prod_{r \in \mathcal{R}(D)} \mathrm{P}_\theta(r)$$

An EM-algorithm is used to optimize θ based on the training likelihood. The E-step computes the expected count e_r of rule r over the training set $\mathcal{T}$ under the current model parameter θ':

$$e_r \leftarrow \sum_{T \in \mathcal{T}} \sum_{r' \in \mathcal{R}(T)} \delta(r', r) \mathrm{P}_{\theta'}(r'|T) \qquad (1)$$

where $\delta(\cdot, \cdot)$ is an indicator function that returns 1 if the two operands are identical and 0 otherwise, and $\mathrm{P}_{\theta'}(r'|T)$ is the posterior probability of having (latent) rule r' in parse tree T. The M-step aims to maximize the intermediate objective:

$$l(\theta) = \sum_{r \in \mathcal{R}} e_r \log \mathrm{P}_\theta(r) \qquad (2)$$

which results in the following update formula for lexical rule probability $\theta_{t_x \to w} = \mathrm{P}_\theta(w|t_x)$:

$$\mathrm{P}_\theta(w|t_x) = \frac{e_{t_x,w}}{\sum_{w'} e_{t_x,w'}} \qquad (3)$$

where $e_{t_x,w}$ denotes the expected count of lexical rule $r{=}t_x{\to}w$. The phrasal rule probabilities are updated similarly.

In order to allocate the grammar complexity to where it is most needed, Petrov et al. (2006) developed a simple split-and-merge procedure. In every split-merge (SM) round, each latent category is first split into two, and the model is re-estimated using several rounds of EM iterations. A likelihood criterion is then used to merge back the least useful splits. The result is that categories, such as NP and VB, that occur frequently in different syntactic environments, are split more heavily than categories such as UH (interjection). This approach also creates a hierarchy of latent categories that enables efficient coarse-to-fine parsing (Petrov and Klein, 2007).

We next discuss two important issues related to the lexical model of PCFG-LA grammars: over-fitting and OOV word handling.

2.1 Over-fitting

As the number of latent annotations increases, a PCFG-LA grammar has an increasing power to fit the training data through EM training, leading to over-fitting. In order to counteract this behavior, Petrov et al. (2006) introduced a linear smoothing method to smooth lexical emission probabilities:

$$\begin{aligned} \bar{\mathrm{P}} &= \frac{1}{|t|} \sum_x \mathrm{P}_\theta(w|t_x) \\ \mathrm{P}_\theta(w|t_x) &\leftarrow \epsilon \bar{\mathrm{P}} + (1-\epsilon) \mathrm{P}_\theta(w|t_x) \end{aligned}$$

A similar smoothing method was used for phrasal rules.

While the above method has been found to be effective, Huang and Harper (2009) observed that rare words suffer more from over-fitting than frequent words and suggested tying rare words together when estimating their emission probabilities. Using their approach, all words with a frequency less than a threshold τ are mapped to symbol *rare*[1], and their emission probability $\mathrm{P}_\theta(w|t_x)$ is set in proportion to their co-occurrences with the surface POS tag:

$$\mathrm{P}_\theta(w|t_x) = \frac{c_{t,w}}{\sum_{w': c_{\cdot,w'} < \tau} c_{t,w'}} \mathrm{P}_\theta(\mathit{rare}|t_x)$$

[1] τ is tuned on the development set.

where $c_{\cdot,w}$ and $c_{t,w}$ are the observed counts of words and word/tag pairs, respectively, and $\mathrm{P}_\theta(\textit{rare}|t_x)$ is a free parameter estimated by the EM algorithm. This constraint greatly reduces the number of free parameters and was found to significantly improve parsing accuracies.

2.2 OOV Handling

Since the lexical model can only generate words observed in the training data, a separate module is needed to handle OOV words that can appear in novel test sentences. A simple approach might be to estimate the emission probability of an OOV word w based on how likely it is that t_x generates a rare word in the training data:

$$\mathrm{P}_\theta(w|t_x) = \mathrm{P}_\theta(\textit{rare}|t_x)$$

We call this type of approach the *simple* method[2].

A better approach would exploit the word formation process for the language being modeled. As with other generative English parsers, the PCFG-LA parser implementation of (Petrov et al., 2006) classifies OOV words into a set of OOV signatures based on the presence of features such as capital letters, digits, dashes, as well as a list of indicative suffixes (e.g., *-ing*, *-ion*, *-er*), and estimates the emission probability of an OOV word w given a latent tag t_x as:

$$\mathrm{P}_\theta(w|t_x) \propto \mathrm{P}_\theta(s|t_x)$$

where s is the OOV signature for w and $\mathrm{P}_\theta(s|t_x)$ is computed by $e_{t_x,s}/e_{t_x,\cdot}$.

While this approach performs well for English, the same OOV word handling module would not be adequate for other languages since they have different word formation processes, which should be exploited for better disambiguation of OOV words. For example, Huang and Harper (2009) improved Chinese parsing performance by estimating the emission probability of an OOV word using the geometric average of the emission probabilities of all of the characters ch_k in the word:

$$\mathrm{P}_\theta(w|t_x) = \sqrt[n]{\prod_{ch_k \in w, \mathrm{P}_\theta(ch_k|t_x) \neq 0} \mathrm{P}_\theta(ch_k|t_x)}$$

where $n = |\{ch_k \in w | \mathrm{P}_\theta(ch_k|t_x) \neq 0\}|$. As will be shown later in Section 5, handling Arabic OOV words in a similar way to Chinese produces improved parsing performance on Arabic[3]; however, the aforementioned language dependent OOV handling approaches are most likely suboptimal and designing a method for a new language could be nontrivial. We call this type of approach the *heuristic* method.

Researchers have exploited discriminative parsing models (Finkel et al., 2008; Petrov and Klein, 2008) to utilize naturally occurring overlapping features, including features for OOV handling. The discriminative version of the PCFG-LA grammar (Petrov and Klein, 2008) was found to be more accurate than its generative counterpart on some languages, partially due to its use of regularization and multi-scale grammars to alleviate data sparsity and rich features to improve OOV word handling. However, such a model is much slower to train and considerably less accurate on English WSJ than its strong generative counterpart. Hence, we will investigate a locally normalized log-linear lexical model to take advantage of rich features within the generative learning framework.

3 Log-Linear Lexical Model for PCFG-LA grammars

Instead of treating each $\mathrm{P}_\theta(w|t_x)$ as a free parameter of a multinomial distribution as in a standard PCFG-LA grammar, we first model the conditional probability of latent tag t_x given the surface POS tag t and word w using a log-linear model:

$$\mathrm{P}_\phi(t_x|t,w) = \frac{\exp\langle\phi, \mathbf{f}(t_x,w)\rangle}{\sum_{x'} \exp\langle\phi, \mathbf{f}(t_{x'},w)\rangle} \quad (4)$$

where $\mathbf{f}(t_x,w)$ represents the feature vector extracted from the pair (t_x,w), ϕ is the feature weight vector, and the denominator sums over all latent tags for POS tag t. This model is applicable to both known and OOV words as long as there are active features; otherwise, a uniform latent tag distribution would be assumed. We call this the *latent lexical model* as it deals with the distribution of latent tags.

The conditional probability of t_x given word w can then be expressed as:

$$\mathrm{P}_\theta(t_x|w) = \mathrm{P}_\theta(t_x,t|w) = \mathrm{P}_\phi(t_x|t,w)\mathrm{P}(t|w)$$

and finally the word emission probability given a latent tag can be computed via Bayes' rule:

$$\mathrm{P}_\theta(w|t_x) = \frac{\mathrm{P}_\phi(t_x|t,w)\mathrm{P}(t|w)\mathrm{P}(w)}{\sum_{w'} \mathrm{P}_\phi(t_x|t,w')\mathrm{P}(t|w')\mathrm{P}(w')} \quad (5)$$

[2]This method is used in the simple lexicon of the Berkeley parser.

[3]We use prefixes and suffixes up to three characters for handling Arabic OOV words.

This new lexical model is composed of the latent lexical model $\mathrm{P}_\phi(t_x|t,w)$ and two other parts: $\mathrm{P}(t|w)$ and $\mathrm{P}(w)$, which are computed differently for known and OOV words.

For words observed in the training data, both $\mathrm{P}(t|w)$ are $\mathrm{P}(w)$ are computed using the maximum-likelihood estimation (based on the observed training trees) so that $\mathrm{P}_\theta(w|t_x)$ forms a proper distribution of observed words during grammar induction.

For OOV words, we use a log-linear *OOV model* to estimate the POS tag distribution:

$$\mathrm{P}_\gamma(t|w) = \frac{\exp\langle\gamma, \mathbf{g}(t,w)\rangle}{\sum_{t'}\exp\langle\gamma, \mathbf{g}(t',w)\rangle} \quad (6)$$

where $\mathbf{g}(t,w)$ represents the feature vector extracted from the pair (t,w), γ is the feature weight vector, and the denominator sums over all POS tags with active features. The *simple* approach in Subsection 2.2 is used when no feature is active. $\mathrm{P}(w)$ is approximated by one over the number of training tokens. It should be noted that $\mathrm{P}_\gamma(t|w)$ may use different features than $\mathrm{P}_\phi(t_x|t,w)$.

Compared with modeling $\mathrm{P}_\theta(w|t_x)$ directly as a multinomial distribution, the new lexical model separates $\mathrm{P}(t|w)$ from $\mathrm{P}_\phi(t_x|t,w)$, offering three important advantages:

- The parameter ϕ of the latent lexical model $\mathrm{P}_\phi(t_x|t,w)$ can be smoothed through regularization to address data sparsity.
- Rich features can be utilized in the OOV model $\mathrm{P}_\gamma(t|w)$ to estimate POS tag distributions of OOV words for a variety of languages. This is important when working on new languages.
- Rich features can be utilized in the latent lexical model $\mathrm{P}_\phi(t_x|t,w)$ to guide the induction of latent POS tags.

The reader should note that Berg-Kirkpatrick et al. (2010) modeled $\mathrm{P}_\theta(w|t_x)$ directly using a log-linear model:

$$\mathrm{P}_\phi(w|t_x) = \frac{\exp\langle\phi, \mathbf{f}(t_x,w)\rangle}{\sum_{w'}\exp\langle\phi, \mathbf{f}(t_x,w')\rangle}$$

This would be problematic for our parsing model because it would not be trained to estimate the probability of OOV words given a latent tag. For parsing, we must model OOV words that can appear in previously unseen sentences. One might compute the numerator for an OOV word based on its features and divide it by a denominator approximated using the words in the training data, but such an estimate is inaccurate and results in poor performance in our preliminary experiments.

We also choose not to model $\mathrm{P}_\theta(t_x|w)$ directly using a log-linear model:

$$\mathrm{P}_\phi(t_x|w) = \frac{\exp\langle\phi, \mathbf{f}(t_x,w)\rangle}{\sum_{t'}\sum_{x'}\exp\langle\phi, \mathbf{f}(t'_{x'},w)\rangle}$$

and compute $\mathrm{P}_\theta(w|t_x)$ via Bayes' rule. Such a model cannot guarantee that the probability $\mathrm{P}_\theta(t|w)$ computed by $\sum_x \mathrm{P}_\theta(t_x|w)$ is equal to the maximum likelihood estimate, which is a reasonable constraint.

4 Model Training

The parameter θ for our parser model consists of ϕ for the log-linear latent lexical model, γ for the log-linear OOV model, and ψ for the phrasal rule expansion probabilities. The other parameters (e.g., $\mathrm{P}(t|w)$ and $\mathrm{P}(w)$ for known words and $\mathrm{P}(\textit{rare}|t_x)$) can be computed based on observable or fractional counts once θ is determined.

γ of the OOV model is independent of the latent categories, and we simply use a gradient-based optimization approach to maximize the following objective:

$$l'(\gamma) = \sum_{t,w} c_{t,w}\log\mathrm{P}_\gamma(t|w) - \kappa'||\gamma||^2$$

where $c_{t,w}$ is the count of the pair (t,w) in the training data, and κ' is the regularization weight.

For parameters ψ and ϕ, we follow the split-merge training procedure in (Petrov et al., 2006) to induce latent categories. Given a set of latent categories, the goal is to find θ that maximizes the regularized training likelihood:

$$L(\theta) = \sum_{T\in\mathcal{T}}\log\mathrm{P}_\theta(T) - \kappa||\phi||^2 \quad (7)$$

where $\kappa||\phi||^2$ is the regularization term[4] for the feature weights of the latent lexical model.

The two optimization approaches described in (Berg-Kirkpatrick et al., 2010) can be extended naturally to our problem. One approach is EM-based with an E-step identical to Equation 1 in

[4]Both κ' and κ are tuned on the development set. We could also use L1 regularization and leave it to future work.

Section 2. The objective of the M-step becomes:

$$l(\theta) = \sum_{w \to t_x \in \mathcal{R}_l} e_{t_x,w} \log \mathrm{P}_\phi(w|t_x) - \kappa||\phi||^2 + \sum_{r \in \mathcal{R}_p} e_r \log \mathrm{P}_\psi(r)$$

where we separate the set of rules $\mathcal{R}$ into lexical rules $\mathcal{R}_l$ and phrasal rules $\mathcal{R}_p$. The phrasal rule parameter ψ is updated as before by normalizing the expected rule counts and is smoothed in the same way as in (Petrov et al., 2006). The intermediate objective function $l(\phi)$ related to ϕ, i.e.,

$$l(\phi) = \sum_{w \to t_x \in \mathcal{R}_l} e_{t_x,w} \log \mathrm{P}_\phi(w|t_x) - \kappa||\phi||^2$$

can be optimized by a gradient descent optimization algorithm (we use LBFGS (Liu and Nocedal, 1989)). Its gradient has the following form:

$$\nabla l(\phi) = \sum_{w \to t_x \in \mathcal{R}_l} e^*_{t_x,w} \Delta_{t_x,w}(\phi) - 2\kappa \cdot \phi$$

$$\Delta_{t_x,w}(\phi) = \mathbf{f}(t_x, w) - \sum_{x'} \mathrm{P}_\phi(t_{x'}|w,t)\mathbf{f}(t_{x'}, w)$$

where $e^*_{t_x,w} = e_{t_x,w} - e_{t_x,\cdot}\mathrm{P}_\phi(w|t_x)$.

It can be shown that $l(\phi)$ is not a concave function with respect to ϕ, but this created no problems in our experiments. It should be noted that if we set the regularization weight κ to 0, the maximum of $l(\phi)$ is achieved when $\mathrm{P}_\phi(w|t_x)$ is set to $e_{t_x,w}/e_{t_x,\cdot}$, which is identical to the update formula in Equation 3, and would thus be unable to use rich features. This is less of an issue when regularization takes effect as it favors common discriminative features to reduce the penalty term.

The second approach, which was found to outperform the EM-based approach in (Berg-Kirkpatrick et al., 2010), optimizes on the regularized log-likelihood (Equation 7) directly by updating both ψ and ϕ using a gradient descent approach. In order to convert this to an unconstrained optimization problem[5], we set each phrasal rule expansion probability ψ_i as the output of a log-linear model, i.e., $\psi_i = \exp(\psi'_i)/Z$ with Z being the normalization factor, and treat ψ' as the parameter for the phrasal rules to be optimized. The gradient of $L(\theta)$ with respect to ϕ turns out to be the same as in the first approach (Salakhutdinov et al., 2003). The gradient of $L(\theta)$ with respect to ψ' can be derived similarly. We omit the details here due to space limitations.

In the original EM-based training approach (Petrov et al., 2006), many of the rule expansion probabilities become very small and are pruned to dramatically reduce the grammar size. The phrasal rule probabilities computed from the log-linear model with parameter ψ' are not usually low enough to be pruned, due to the fact that a large decrease in ψ'_i results in a much smaller change in ψ_i when ψ_i is already relatively small. In order to address this problem, we combine the two optimization approaches together: first run rounds of EM-based optimization to initialize the grammar parameters and prune many of the useless phrasal rules, and then switch to the direct gradient descent optimization approach. This combined approach outperforms the standalone EM-based approach in our study and is used in the experiments reported in this paper.

5 Experiments

In this section, we will show the effect of rare word smoothing and OOV handling on the accuracy of the standard PCFG-LA grammars, and investigate how the proposed feature-rich lexical model addresses these problems. In what follows, we first describe the experimental data and then the results of the standard PCFG-LA grammars. We then describe the features and results of the PCFG-LA grammars with log-linear lexical models, and present some analyses. Finally, additional features are discussed and the final test results are compared with the literature.

5.1 Data & Setup

We experiment with three languages: English, Chinese, and Arabic. For English, we used the WSJ Penn Treebank (Marcus et al., 1999) and the commonly used data splits (Charniak, 2000). For Chinese, we used the Penn Chinese Treebank 6.0 (CTB6) (Xue et al., 2005) and the preparation steps and data splits in (Huang and Harper, 2009). For Arabic, we used the Penn Arabic Treebank (ATB) (Maamouri et al., 2009) and the preparation steps[6] and data splits in (Green and Manning, 2010; Chiang et al., 2006). Table 1 provides gross statistics for each treebank. As we can see, CTB6 and ATB both have a higher OOV rate than WSJ,

[5]The elements of ψ are constrained to form proper probability distributions.

[6]Except that clitic marks were removed, which results in about 0.3 degradation in F score (p.c.).

and hence have greater need for effective OOV handling.

	Statistics	Train	Dev	Test
English (WSJ)	#sents	39832	1700	2416
	#tokens	950.0k	40.1k	56.7k
	%oov_types	-	12.8%	13.2%
	%oov_tokens	-	2.8%	2.5%
Chinese (CTB6)	#sents	24416	1904	1975
	#tokens	678.8k	51.2k	52.9k
	%oov_types	-	20.6%	20.9%
	%oov_tokens	-	5.0%	5.3%
Arabic (ATB)	#sents	18818	2318	2313
	#tokens	597.9k	70.7k	70.1k
	%oov_types	-	15.6%	16.7%
	%oov_tokens	-	3.2%	3.4%

Table 1: Gross Statistics of the treebanks.

Due to the variability (caused by random initialization) among the grammars (Petrov, 2010), we train 10 grammars with different seeds in each experiment and report their average F score on the development set. The best grammar selected using the development set is used for evaluation on the test set.

5.2 Standard PCFG-LA Grammars

We first study the effect of rare word smoothing and OOV handling on the standard PCFG-LA grammars using our reimplementation of the Berkeley parser. The *no+simple* row in Table 2 represents the baseline, for which the grammars are trained without rare word smoothing described in Subsection 2.1 and OOV words are handled by the simple method described in Subsection 2.2. Each language-dependent heuristic-based OOV word handling method improves parsing accuracies, and the rare word smoothing method provides even greater improvement across the languages. Their combination results in further improvement. This confirms that both over-fitting and OOV words are issues to consider for training accurate PCFG-LA grammars.

Rare Word Smoothing	OOV	WSJ	CTB6	ATB
no	simple	89.86	82.52	79.12
no	heuristic	90.07	82.98	79.44
yes	simple	90.53	83.25	80.30
yes	heuristic	90.69	83.73	80.64

Table 2: The effect of rare word smoothing and OOV handling on parsing F scores evaluated on the respective development set.

5.3 Log-Linear Lexical Model

Here we investigate a core set of features that have proven effective for POS tagging to demonstrate the effectiveness of our model and its robustness across languages, and leave it to future work to include additional features as discussed in Subsection 5.5. Table 3 lists the templates we used to extract predicates on words. For the log-linear OOV model, we use the *full* feature set, i.e., (t, pred) pairs extracted using all of the predicates. For the log-linear latent lexical model, we experiment with two feature sets: 1) the *wid* feature set containing only (t_x, wid) pairs, which are the same as those used in the standard PCFG-LA grammars, 2) the *full* feature set using all of the predicates.

Predicate	Explanation
$\delta(w = \cdot)$	word identity (wid)
$\delta(\text{hasDigit}(w) = \cdot)$	contains a digit?
$\delta(\text{hasHyphen}(w) = \cdot)$	contains a hyphen?
$\delta(\text{initCap}(w) = \cdot)$	first letter capitalized?
$\delta(\text{prefix}_k(w) = \cdot)$	prefix of length $k \leq 3$
$\delta(\text{suffix}_k(w) = \cdot)$	suffix of length $k \leq 3$

Table 3: Predicate templates on word w.

We first evaluate the effectiveness of regularization and the log-linear OOV model by training the latent lexical model using the *wid* feature set with regularization and examining different OOV handling methods. As shown in Table 4, the *wid+simple* and *wid+heuristic* approaches[7] produce results comparable to the corresponding PCFG-LA grammars trained with rare word smoothing and respective OOV handling. This shows that regularizing the latent lexical model alleviates data sparsity, however, we will illustrate in Subsection 5.4 that this is achieved in a different way than rare word smoothing.

The log-linear OOV model using the *full* feature set results in improved parsing performance over all languages, with the most improvement seen on Arabic (0.71 F), followed by Chinese (0.28 F), confirming that the log-linear OOV model is more accurate than the heuristic approach, and can be flexibly used for different languages. The improvement on English is marginal possibly because the signature-based OOV features are sufficiently accurate for handling English unknown

[7]Training the latent lexical model using the *wid* feature set and handling OOV words using the *simple* or *heuristic* approach.

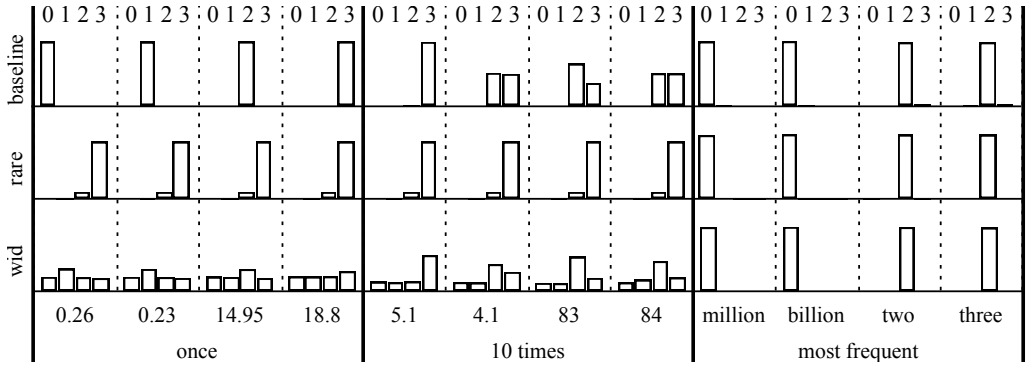

Figure 2: The conditional distribution $\mathrm{P}(t_x|t, w)$ of latent tags for selected cardinal numbers (e.g., 0.26, million) that appear only once, 10 times, or frequently for standard PCFG-LA grammars trained with (labeled rare) or without (labeled baseline) rare word smoothing and for PCFG-LA grammars with regularized feature-rich lexical model using the *wid* feature set (labeled wid). The distribution is represented by the four bars separated by dotted vertical lines, and each bar represents the conditional probability of a latent tag.

words after years of expert crafting.

We next investigate the effect of training the latent lexical model using the *full* feature set. Compared with the *wid*+*full* model, the *full*+*full* model improves 0.38 F on Arabic and 0.27 F on Chinese, despite the fact that the additional features are very simple, mostly prefixes and suffixes of words. The improvement on English is again marginal possibly because the features do not provide such insights on fine-grained syntactic subcategories (e.g., suffix *-ed* is indicative of past tense verbs, but not their sub-categories). Admittedly, many of the features are noisy, but as we will show in Subsection 5.4, some of the features can guide the learning of the latent categories to reflect the similarity between syntactically similar words of the same POS type.

Compared with the baseline (*no*+*simple* in Table 2), the feature-rich *full*+*full* model significantly improves parsing F scores by 1.03, 1.66, and 2.67 absolute on English, Chinese, and Arabic, respectively.

Latent Lexical	OOV	WSJ	CTB6	ATB
wid	simple	90.54	83.18	80.32
wid	heuristic	90.71	83.63	80.70
wid	full	90.81	83.91	81.41
full	full	90.89	84.18	81.79

Table 4: The effect of features (wid vs. full) for training the latent lexical model and the OOV handling methods (simple, heuristic, or the log-linear model using the full feature set) on parsing performance (F score) on the development set.

5.4 Analysis

We examine in Figure 2 the effect of regularization and rare word smoothing on the learned rules by looking at the distribution $\mathrm{P}(t_x|t, w)$ for PCFG-LA grammars trained in different ways[8]. For standard PCFG-LA grammars trained without rare word smoothing (labeled baseline), rare words have sparse distributions of latent tags, which are determined solely based on limited contexts and are thus not reliable. The rare word smoothing approach (labeled rare) collapses all rare words into a single token so that $\mathrm{P}(t_x|t, w) = \mathrm{P}(t_x|t, \textit{rare})$ is identical for any rare word w. This constraint greatly reduces data sparsity; however, treating all rare words as one token could eliminate too much lexical information (e.g., the distribution of latent tags is the same for all rare cardinal numbers no matter whether they appear only once or 10 times). Regularization of the log-linear latent lexical model (labeled wid) favors a uniform distribution (zero penalty when all feature weights are zero). There is not much evidence to skew the distribution from uniform for rare words. However, when more evidence is available, the distribution becomes smoothly skewed to reflect the different syntactic preferences of the individual words, and it can eventually become as spiky as in the other approaches given sufficient evidence.

In order to provide some insights into why parsing accuracies are improved for Arabic and Chinese by using the *full* feature set when training the latent lexical model, we look at the country names

[8]For standard PCFG-LA grammars, $\mathrm{P}(t_x|t, w)$ is simply computed by $e_{t_x,w}/e_{t,w}$; whereas, for the feature-rich lexical model, $\mathrm{P}(t_x|t, w)$ is computed from the latent lexical model.

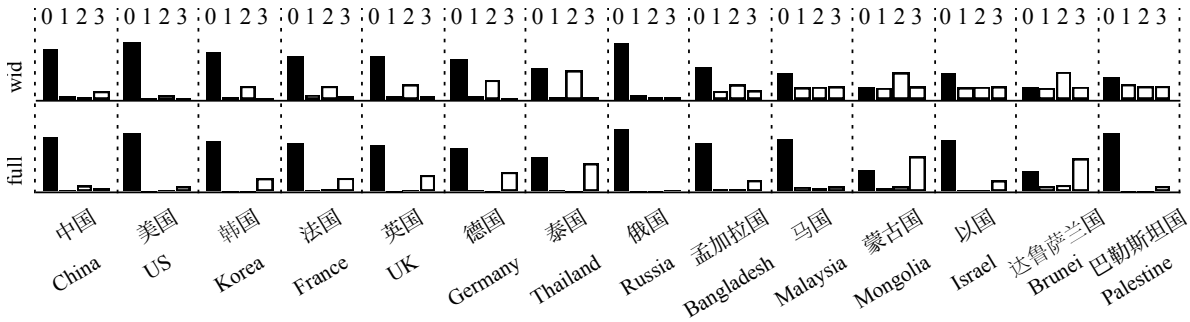

Figure 3: The conditional distribution $P(t_x|t, w)$ of latent tags for selected country names (proper nouns) listed in order of decreasing frequency from the Chinese treebank (English translations are provided under Chinese names), after training using the *wid* and the *full* feature set, respectively. The distribution is represented by the four bars separated by dotted vertical lines, and each bar represents the conditional probability of a latent tag. The preferred latent tag for country names is highlighted in black.

that end with the character 国 (country) in the Chinese treebank. These names appear in similar contexts and would be expected to favor certain latent tag or tags; however, when training using the *wid* feature set, this is only true for the frequent names as shown in Figure 3. For the rare names, there is not much evidence to divert the distribution away from uniform. When training with the *full* feature set, the suffix1=国 predicate is active for all of those country names and has a large feature weight associated with the preferred latent tag. As a result, the distribution of latent tags for the rare names is skewed more toward the preferred latent tag due to strong evidence from that suffix feature.

5.5 Other Features

Our model supports any local features that can be extracted from the pair (t_x, w), including the language-dependent features studied in (Attia et al., 2010). In addition, features related to word semantics (e.g., using WordNet (Fellbaum, 1998)) or word clusters (e.g., using unsupervised clustering (Brown et al., 1992; Koo et al., 2008; Goyal and Daume, 2011)) might also be beneficial for modeling $P_\phi(t_x|t, w)$ and/or $P_\gamma(t|w)$. Features extracted from (t, w) could also be helpful for providing some smoothing effect across the latent tags. Moreover, it might be beneficial to perform feature selection prior to training. We leave this to future work.

5.6 Final Results

Table 5 compares the final test results of our best grammars (the *full+full* approach) with the literature[9]. Our PCFG-LA grammars with a feature-rich lexical model significantly outperform the standard PCFG-LA grammars of (Petrov and Klein, 2007) for all of the three languages, especially on Chinese (+1.6 F) and Arabic (+2.2 F).

[9] All of the parsers from the referenced papers are trained and evaluated using the data splits in our experiments.

TB	Parser	LP	LR	F
WSJ	Charniak (2000)	89.9	89.5	89.7

6 Conclusions

We have presented a feature-rich lexical model for PCFG-LA grammars to: 1) alleviate over-fitting via regularization, 2) handle OOV words using rich features, and 3) exploit lexical features for grammar induction. Experiments show that the proposed approach allows us to train more effective PCFG-LA grammars for more accurate and robust parsing of three different languages. It is expected that even more accurate parsers can be produced by using this approach together with self-training (Huang and Harper, 2009) and/or product models (Petrov, 2010; Huang et al., 2010).

Acknowledgments

This research was supported in part by NSF IIS-0703859. We would like to thank Spence Green for providing the processed Arabic Treebank data and lots of insightful suggestions.

Abstract

In this paper, we present a simple and effective fine-grained feature generation scheme for dependency parsing. We focus on the problem of grammar representation, introducing fine-grained features by splitting various POS tags to different degrees using HowNet hierarchical semantic knowledge. To prevent the oversplitting, we adopt a threshold-constrained bottom-up strategy to merge the derived subcategories. We conduct the experiments on the Penn Chinese Treebank. The results show that, with the fine-grained features, we can improve the dependency parsing accuracies by 0.52% (absolute) for the unlabeled first-order parser, and in the case of second-order parser, we can improve the dependency parsing accuracies by 0.61% (absolute).

1 Introduction

In natural language parsing, part-of-speech (POS) information is seen as crucial to resolving ambiguous relationships, yet POS tags are usually too general to encapsulate a word's syntactic behavior. It is therefore attractive to consider intermediate entities which exist at a finer level than the POS tags, and the relationship between specific words and their syntactic contexts may be best modeled.

In this paper, we introduce the fine-grained features by splitting various POS tags to different degrees. First, we split the POS tags of each word in the Treebank using HowNet hypernym-hyponymy hierarchical semantic knowledge (Dong and Dong, 2000). Then we adopt a threshold-constrained bottom-up strategy to merge the semantic-related subcategories which are plagued by the oversplitting problems. Finally, we use the generated sub-categories to construct a new fine-grained feature mapping for a discriminative learner. We are thus relying on the ability of discriminative learning methods to identify and exploit informative features.

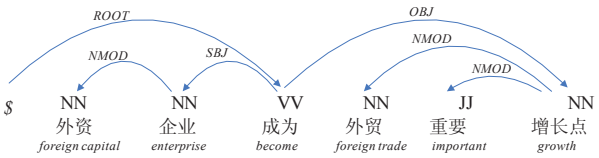

Figure 1: An example of a labeled dependency tree. The tree contains a special token "$" which is always the root of the tree. Each arc is directed from head to modifier and has a label describing the function of the attachment.

To demonstrate the effectiveness of our approach, we conduct the dependency parsing experiments on the Penn Chinese Treebank (CTB) (Xue et al., 2005). The results show that, with the fine-grained features, we can obtain mildly significant improvements both for first-order and second-order parsing (e.g., the absolute improvements are 0.52% and 0.61%, respectively) (see Section 6).

The remainder of this paper is organized as follows. Section 2 introduces the Motivation. Section 3 gives background on dependency parsing and HowNet hierarchical semantic knowledge. Section 4 describes the fine-grained feature generation scheme. Section 5 presents fine-grained features. Experimental evaluation and results are reported in Section 6. Section 7 discusses related work. Finally, in Section 8 we draw conclusion.

2 Motivation

In dependency parsing, we attempt to build head-modifier (or head-dependent) relations between words in a sentence. A simple example is shown in Figure 1, where NN, VV, and JJ are POS tags.

Currently, a variety of statistical methods have

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 228–236,
Chiang Mai, Thailand, November 8 – 13, 2011.

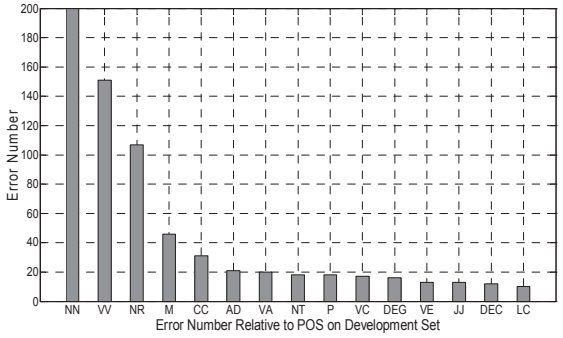

Figure 2: The number of the most frequent errors relative to POS types on development set for first-order parsing.

been developed for dependency parsing, such as **graph-based** (McDonald et al., 2005; McDonald and Pereira, 2006), **transition-based** (Yamada and Matsumoto, 2003; Hall et al., 2006), or **hybrid methods** (Nivre and McDonald, 2008; Martins et al., 2008; Zhang and Clark, 2008). These methods mainly rely on the POS information as important features, but the POS tags are usually too general to encapsulate a word's syntactic behavior, especially for Chinese dependency parsing on CTB (e.g., it assumes that all the words with the POS tag NN share the same syntactic behavior). In the limit, each word may well have its own unique syntactic behavior (Petrov and Klein, 2006). However, in practice, given limited data, the relationships between the specific words and their context dependencies may be best modeled at a level finer than the POS tags but coarser than the words themselves. Take the sentence in Figure 1 for example, although the words 外资(foreign capital) and 增长点(growth) have the same POS tag NN, they should have different context dependencies in dependency parsing tree. In HowNet, the two words are defined with different hypernyms. The word 外资(foreign capital) is defined as a kind of objective things, while the word 增长点(growth) is defined as an event role feature. Intuitively, the different senses can represent their different syntactic behavior, and we attempt to split the POS tags to different degrees based on hierarchical semantic knowledge.

Figure 2 shows the number of the most frequent errors relative to POS types on the development set for the first-order parsing. From the figure, it is seen that the main errors are nominal and verbal categories. Therefore, we may suspect that whether the complex and frequent categories like NN and VV should be split heavily while barely split rare or simple ones. Our experiments demonstrate that this strategy can be quite effective in Chinese dependency parsing task (see Table 2 in Section 4 for empirical results).

3 Background

3.1 Dependency Parsing

In dependency parsing, we attempt to build head-modifier (or head-dependent) relations between words in a sentence. The discriminative parser we used in this paper is based on the *part-factored* model and features of the MSTParser (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007). The parsing model can be defined as a conditional distribution $p(y|\mathbf{x};\mathbf{w})$ over each projective parse tree y for a particular sentence $\mathbf{x}$, parameterized by a vector $\mathbf{w}$. The probability of a parse tree is

$$p(y|\mathbf{x};\mathbf{w}) = \frac{1}{Z(\mathbf{x};\mathbf{w})}\exp\Big\{\sum_{\rho\in y}\mathbf{w}\cdot\mathbf{\Phi}(\mathbf{x},\rho)\Big\} \quad (1)$$

where $Z(\mathbf{x};\mathbf{w})$ is the partition function and $\mathbf{\Phi}$ are *part-factored* feature functions that include *head-modifier* parts, *sibling* parts and *grandchild* parts. Given the training set $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$, parameter estimation for log-linear models generally resolve around optimization of a regularized conditional log-likelihood objective $\mathbf{w}^* = \arg\min_{\mathbf{w}} L(\mathbf{w})$ where

$$L(\mathbf{w}) = -C\sum_{i=1}^{N}\log p(y_i|\mathbf{x}_i;\mathbf{w}) + \frac{1}{2}||\mathbf{w}||^2 \quad (2)$$

The parameter $C > 0$ is a constant dictating the level of regularization in the model. Since objective function $L(\mathbf{w})$ is smooth and convex, which is convenient for standard gradient-based optimization techniques. In this paper we use the dual exponentiated gradient (EG)[1] descent, which is a particularly effective optimization algorithm for log-linear models (Collins et al., 2008).

3.2 HowNet Semantic Knowledge

HowNet is a bilingual general knowledge-base describing relations between concepts and relations between the attributes of concepts in Chinese and their English equivalents (Gan and Wong, 2000).

HowNet constructs a hierarchical structure of its knowledge base from hypernym-hyponymy

[1] http://groups.csail.mit.edu/nlp/egstra/

relations. The unit of meaning is called sememe that can not be further decomposed, which can be represented in Chinese and their English equivalents, such as the sememe **fund**|资 金. The explicated relations of HowNet include hypernym-hyponymy, synonymy, metonymy, antonymy, part-whole, attribute-host, material-product, dynamic role and concept co-occurrence, and so on. In this paper, we only consider the hypernym-hyponymy relations at different levels of granularities. Since a word may have different senses, and therefore different definitions in HowNet, we just use the first definition as the semantic-related tag of the word. Take the concept 外资(foreign capital) for example, its definition and the hypernym-hyponymy relations are listed below from speciality to generality, which we call the hierarchical semantic information in this paper.

Definition:

DEF = {fund|资金:modifier= {foreign|外国}}

Hierarchy:

fund|资 金→wealth|钱 财→artifact|人工 物→inanimate|无 生 物→physical|物质→thing|万物→entity|实体

In the definition, HowNet decomposes the concept into sememes 'fund|资 金', 'wealth|钱 财', 'artifact|人 工 物', 'inanimate|无 生 物', 'physical|物质', 'thing|万物', 'entity|实体'. The sememe appearing in the first position of Definition ('fund|资 金') is the categorical attribute, which names the hypernym of the concept 外资(foreign capital). Those sememes appearing in other positions (e.g., 'foreign|外国') are additional attributes, which give more specific information to the concept.

It is clear that the word 外资(foreign capital) has hypernyms from the most special hypernym fund|资金 to the most general hypernym entity|实体 in a hierarchical way.

HowNet contains very limited words, so there are many words which cannot be found in HowNet. In this paper, we extend HowNet with Chinese Knowledge base "TongYiCiLin" (abbreviation: CiLin) (Mei et al., 1983), which represents 77,343 words in a dendrogram (or tree).

CiLin is organized as a hierarchical tree structure, each node represents a semantic category. To balance the words coverage, we extract semantic categories at level 3, which covers 1,400 subcategories.

HowNet and CiLin have different ontologies and representations of semantic categories (Xiong et al., 2005), we combine the two dictionaries: given a word w, if we cannot find in HowNet, but found in CiLin, we try to replace w with a synonym s in the synset defined by CiLin. If the synonym s can be found in HowNet, the corresponding semantic-related tag in HowNet will be assigned to w.

4 Fine-Grained Feature Generation

4.1 Splitting the POS Tags

In this subsection, we split the original POS tags to different degrees based on HowNet hierarchical semantic knowledge. The challenge is how to deal with the problem of polysemous words. Since each word may have multiple senses, and therefore different definitions in HowNet. Following Xiong et al. (2005) and Lin et al. (2009), we just use the first sense to determine the sense of each token instance of a target word (e.g., all token instances of a given word are tagged with the sense that occurs most frequently in HowNet).

As mentioned in Section 3.2, the semantic information of each word can be represented as hierarchical hypernym-hyponymy relations. In this paper, we attempt to establish the mapping from top to down and split the words into different subcategories based on hypernym-hyponymy relations defined in HowNet. For easy explanation of the splitting process, we take the words with POS tag NN for example; the fine-grained feature generation is shown in Figure 3. The left part of the figure is the word subcategories, which is split based on HowNet hierarchy. As shown by the dashed line from left to right, we generate each subcategory with the hierarchical semantic-related tag, such as NN-event, NN-entity, NN-thing, NN-time and so on. If the hypernym node has no hyponym, the corresponding subcategory will stop splitting (e.g., at the level 3 in figure 3, "fruit" is the most speciality hypernym of the corresponding words "banana" and "apple" in HowNet hierarchy, which cannot be further decomposed). The details of HowNet hierarchy were presented in Dong and Dong (2000).

As shown in Figure 3, the original relationships between the words and their syntactic contexts are modeled by the POS tag NN, after hierarchically split, the relationships can be best modeled at the

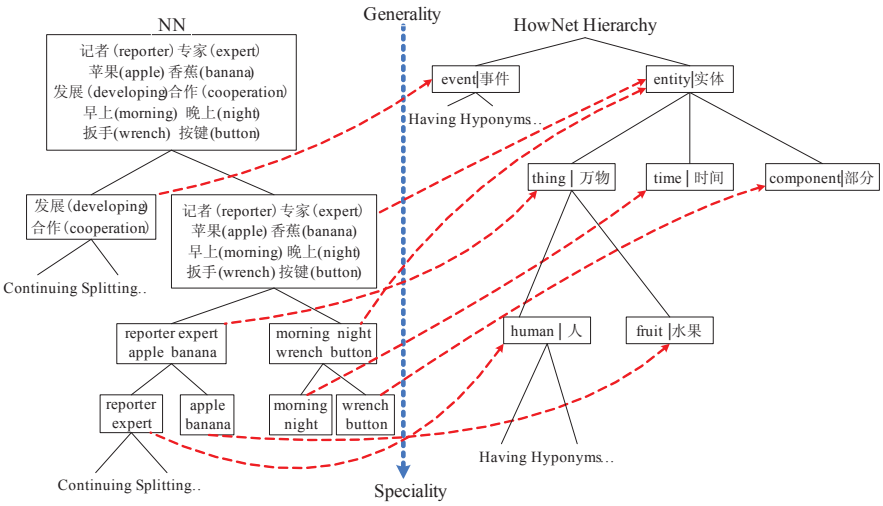

Figure 3: Fine-grained feature generation for words with POS tag NN. The left part is word subcategory and the right part is HowNet hierarchy from generality to speciality.

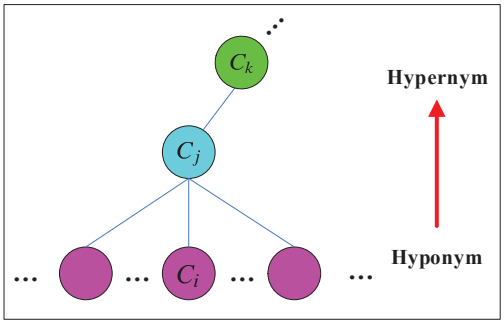

Figure 4: The merging procedure based on hypernym-hyponymy relations from bottom-up.

different levels of the fine-grained subcategories. By this observation, the fine-grained feature generation is just a hierarchical clustering of words themselves with the fine-grained semantic-related tags. Unlike the previous work, such as word cluster technique (Koo et al., 2008), data-driven split manner (Matsuzaki et al., 2005; Petrov and Klein, 2006), our approach does not exploit unlabeled data, and the splitting is based on hierarchical semantic knowledge instead of maximizing posterior probability, which is much simpler than their methods.

4.2 Merging Based on Threshold Constraint

Intuitively, creating more subcategories can increase parsing accuracy. On the other hand, oversplitting can be a serious problem, the details were presented in Klein and Manning (2003). To prevent oversplitting, we merge the subcategories based on the threshold constraint. After the splitting, each subcategory contains a group of words which share the same semantic-related tag. Then we measure the size of each subcategory to determine whether the subcategory should be further merged. For easy explanation, we show an example in Figure 4, where each node C_i denotes a subcategory, C_j is the nearest hypernym subcategory of C_i , C_k is the nearest hypernym subcategory of C_j , and so on. Assuming that $f(C_i)$, $f(C_j)$ and $f(C_j)$ denote the number of the words contained in the subcategory C_i , C_j and C_k respectively, f is the threshold. We judge C_i should be further merged into C_j if $f(C_i) < f$, and update the number of the words contained in C_j using the following formula:

$$f^{update}(C_j) = \begin{cases} f(C_i) + f(C_j) & \text{if } f(C_i) < f \\ f(C_j) & \text{other} \end{cases} \quad (3)$$

where $f^{update}(C_j)$ is the number of the words contained in the updated subcategory C_j . In this way, we repeatedly merge each subcategory from bottom-up through the hypernym ladders according to the formula (3). Finally, we generate appropriate granularity of the fine-grained subcategories by splitting and merging approach.

In our approach, each POS tag is divided into several subcategories. The subcategories of some POS tags with the words are shown in Table 1. The categories compose of the original POS tags and the subcategories derived from HowNet. For example, NN is split into NN-InstitutePlace, NN-aValue, and so on. The subcategories' number of each POS tag is shown in Table 2. Nominal categories are the most heavily split. For ex-

NN		VV	
NN-InstitutePlace	企业(enterprise) 公司(company)	VV-event	猜到(guess) 预见(foresee)
NN-aValue	经济(economy)国际(international)	VV-aValue	小心(care) 可以(can)
NN-organization	国家(country) 政府(government)	VV-SelfMoveInDirection	进行(conduct) 扩散(spread)
NN-event	发展(developing)合作(cooperation)	VV-change	增长(increase) 涨价(deform)
NN-human	记者(reporter) 专家(expert)	VV-attribute	简称(abbreviation) 库容(storage capacity)
NN-affairs	贸易(trading) 金融(financial)	VV-entity	经历(experience) 考虑(consider)
NN-mental	情绪(mood) 感受(feelings)	VV-AlterRelation	围困(siege) 脱离(separate)
NN-entity	后者(latter) 机会(opportunity)	VV-AlterPossession	借用(borrow) 购进(buy)
NN-artifact	棉花(cotton) 维生素(vitamin)	VV-AlterPhysical	建造(build) 制成(make)
...	...	...	...
AD		**JJ**	
AD-aValue	以后(after) 唯有(only)	JJ-aValue	共同(together) 特别(special)
AD-event	还(also) 不管(no matter)	JJ-event	继续(continue) 相对(relatively)
...	...	...	...

Table 1: The two words with their English translations in the subcategories of some POS tags.

NN	24	VC	2	MSP	1

LC	1	CD	1	IJ	1
PN	1	DEC	1	ETC	1
DT	1	AS	1	PU	1

Table 2: The number of subcategories generated by our hierarchical semantic knowledge based split-merge procedure.

ample, common noun (NN) category is divided into the maximum number of subcategories (24). One subcategory consists primarily of objective things, whose typical semantic knowledge is an entity. Another subcategory is defined as an attribute, and so on. These kinds of semantic-related subcategories are typical, and give a division similar to the distributional clustering results like those of Schuetze (1998). The proper noun (NR) category is split into the 5 subcategories, including entity, institute-Places, attribute, aValue, and so on, which are defined in HowNet. The temporal noun (NT) category is also split into 3 subcategories.

Verbal categories are also heavily split. Verbal subcategories sometimes reflect syntactic selectional preferences, and sometimes reflect other aspects of verbal syntax (Petrov and Klein, 2006). For example, the common verb (VV) category is divided into the number of 17 subcategories based on hierarchical split-merge procedure. The predictive adjective (VA) category is also split into 4 subcategories.

Functional categories generally have fewer splits shown in Table 2. Intuitively, those categories are known to be strongly correlated with syntactic behavior. For example, determiner (DT), interjection (IJ), onomatopoeia (ON), and so on.

5 Feature Design

Key to the success of our approach is the use of HowNet hierarchical semantic knowledge to generate the fine-grained features to assist the dependency parsers. The feature sets we used in this paper are similar to other feature sets in the literature (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007), so we will not attempt to give an exhaustive description of the features in this Section. Rather, we describe our fine-grained features at a high level and concentrate on our motivations. In the experiments, our employed two different feature sets: a baseline feature set which draws upon "normal" information sources such as word forms and POS, and a fine-grained feature set that also information derived from the HowNet hierarchical semantic knowledge.

Our first-order baseline feature set is similar to the feature set of McDonald et al. (2005) and McDonald and Pereira (2006). The second-order baseline features are the same as those of Carreras (2007) and include indicators for triples of POS tags for sibling interactions and grandparent interactions, as well as additional bigram features based on pairs of words involved these higher order interactions.

The first- and second-order fine-grained features are complementary with the baseline features. We generate the fine-grained features by mimicking the word-to-tag and tag-to-tag interactions between the head and modifier of a dependency. Also, We include indicators for triples of fine-grained subcategory tags for sibling and grandparent interactions. Examples of these features are provided in Table 3.

Till now, we have demonstrated our fine-grained generation scheme using HowNet hierarchical semantic knowledge. With the derived subcategories, we can construct a new fine-grained

Baseline	Fine-grained
ht, mt	hf, mf
hw, mw	hw, mf
hw, ht, mt	hf, mw
hw, ht, mw, mt	hw, hf, mf
ht, mt, gt	hw, hf, mw, mf
ht, mt, st	hf, mf, gf
ht, mt, gt, st	hf, mf, sf
...	hf, mf, gf
gt, ht, mt, st	...
	gf, hf, mf, sf

Table 3: Baseline (left) and fine-grained (right) feature templates. Abbreviation: ht=head POS, hw= head word, hf=fine-grained POS of head, mf=fineg-grained POS of modifier. st, gt, sf, gf= likewise for sibling and grandchild.

feature mapping for a discriminative learner, similar to (Koo et al., 2008). We are relying on the ability of discriminative learning methods to identify and exploit informative features.

6 Experiments

In order to evaluate the effectiveness of the proposed approach, we conducted dependency parsing experiments in Chinese. The experiments were performed on the Penn Chinese Treebank (CTB) version 5.0 (Xue et al., 2005), using a set of head-selection rules (Zhang and Clark, 2008) to convert the phrase structure syntax of the Treebank to a dependency tree representation, dependency labels were obtained via the "Malt" hard-coded setting.[2] We split the data into training set (files 1-270 and files 400-931), development set (files 301-325) and test set (files 271-300). The development and test set were used gold-standard segmentation and POS tags in CTB.

We measured the parser quality by the unlabeled attachment score (UAS), e.g., the percentage of tokens (excluding all punctuation tokens) with the correct HEAD. And we also evaluated on complete dependency analysis (CM).

6.1 Splitting Experiments

In this subsection, we conduct the experiments only using the splitting operator. The results are shown in Table 4, where Ord1/Ord2 refers to a first-/second-order parsers (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007) with baseline features. Ord1f/Ord2f refers to a first-/second-order parsers with baseline+fine-grained features, and the improvements by the fine-grained features over the baseline features are shown in parentheses. There are some clear trends in the results.

[2]http://w3.msi.vxu.se/ nivre/research/MaltXML.html

Models	UAS	CM
Ord1	86.57	42.24
Ord1f	86.72 (+0.15)	42.81
Ord2	88.27	46.84
Ord2f	88.51 (+0.24)	47.99

Table 4: Dependency parsing results on the test set only using the splitting operator.

First, the performance increases with the order of the parser: the first-order model (Ord1) has the lowest performance, adding sibling and grandparent interactions (Ord2) yield better performance. Similar observations regarding the effect of model order have also been made by Carreras (2007) and Koo et al. (2008).

Second, note that the parsers using the fine-grained features outperform the baseline, regardless of model order. Moreover, the benefits of the fine-grained features can improve the performance with the increasing of the model order. For example, increasing the model order from Ord1 to Ord1f results in a relative reduction in error of roughly 1.12%, while introducing fine-grained features from Ord2 to Ord2f yields an additional relative error reduction of roughly 2.05%.

6.2 Merging Experiments

To prevent oversplitting, we merge the subcategories based on the threshold constraint. For parameter f in equation (3), different POS tags (e.g., NN, VV, JJ, ON, $\cdots$) need different values. We do the experiments on the development set to determine the best value among 10, 20, 50, 100, 200, 300, $\cdots$, 1,000 in terms of UAS for each POS tag. The number of the subcategories are shown in Table 2 (in Section 4). Our experiments corresponding to the best parameter values are evaluated on the test set of CTB 5.0.

Table 5 shows the results. The performances can be further increased after using the merging operator. Such a fact validates the effectiveness of merging operator. Overall, for the first-order parser, we find that there is an absolute improvement of 0.52 points (UAS) by adding fine-grained features. For the second-order parser, we get an absolute improvement of 0.61 points (UAS) by including fine-grained features. The improvements of parsing with fine-grained features are mildly significant using the Z-test of Collins et al. (2005).

Models	UAS	CM
Ord1	86.57	42.24
Ord1f	**87.09**	43.39
improvement	+0.52	-
significant level	$p < 0.08$	-
Ord2	88.27	46.84
Ord2f	**88.88**	48.85
improvement	+0.61	-
significant level	$p < 0.05$	-

Systems	UAS
Duan et al. (2007)	84.38
Zhang and Clark (2008)	**86.21**
Huang and Sagae (2010)	85.20
Ours	85.45

Table 7: Comparison of our final results with other best-performing systems on this data set.

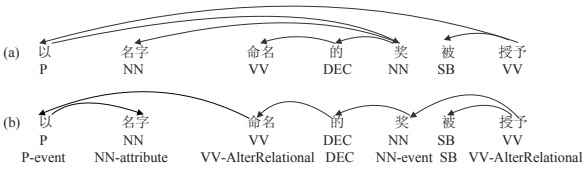

Figure 5: Dependency trees of an example sentence "以(with) 名字(name) 命名(named) 的(of) 奖(prize) 被(by) 授予(award)" as its English translation "$\cdots$ prize named by $\cdots$ name is awarded $\cdots$". (a) Dependency tree produced by the baseline model; (b) Dependency tree produced by the proposed approach.

6.3 Comparison with Previous Work

To put our results in perspective, we also compare our second-order system with other best systems: Wang et al. (2007), Yu at al. (2008), Zhao et al. (2009) and Chen et al. (2009), respectively. The results are shown in Table 6, our approach outperforms the first three systems. Chen et al. (2009) reports a very high performance using subtree features from auto-parsed data. In our systems, our do not use such knowledge.

Some researchers conducted experiments on CTB with a different data split: files 1-815 and files 1001-1136 for training, files 816-885 and files 1137-1147 for test, files 886-931 and 1148-1151 for development. The development and test sets were also performed using the gold-standard assigned POS tags. We report the experimental results as well as the performance of previous work on this data set shown in Table 7. Our results are better than most previous work, although Zhang and Clark (2008) achieved an even higher accuracy (86.21) by combining both graph-based and transition-based parsing into a single system for training and decoding. Moreover, their technique is orthogonal to ours, and we suspect that integrating the fine-grained features into the combined parsers might get an even better performance.

6.4 Discussion

Our purpose in this paper is to incorporate the fine-grained features to assist the dependency parsing. Figure 5 shows an example of dependency trees produced by the baseline parser and our proposed approach.

In Figure 5(a), the baseline parser incorrectly assigned 奖/NN (prize) as the modifier of 以/P (with) and the head of 以/P was also incorrectly recognized as 授予/VV (award). The reason may be that the POS features (**P**→**NN** and **VV**→**P**) are too general to model the syntactic dependencies. However, after introducing the fine-grained features **P-event**→**NN-attribute** and **VV-AlterRelational**→**P-event**, 名字/NN (name) was selected as modifier of 以/P (with) and the head of 以/P (with) was correctly recognized (Figure 5(b)).

Besides, there exist a large number of neighborhood ambiguities in Chinese dependency parsing, such as "NN NN NN", "JJ NN NN", "AD VV VV", "JJ NN CC NN" and so on they have possible parsing trees as shown in Figure 6. For those ambiguities, our approach can provide the fine-grained features as additional information for the parser. For example, we have the following case in the data set: "外商NN(foreign tradesman)/投资NN(investment) /企业NN(enterprise)/". We can provide additional information about the relations of "外商**NN-human**(foreign tradesman)/ 企业**NN-InstitutePlace**(enterprise)" and "外商**NN-human**(foreign tradesman)/投资**NN-event**(investment)", which can be used to help the parser make the correct decision. Our approach

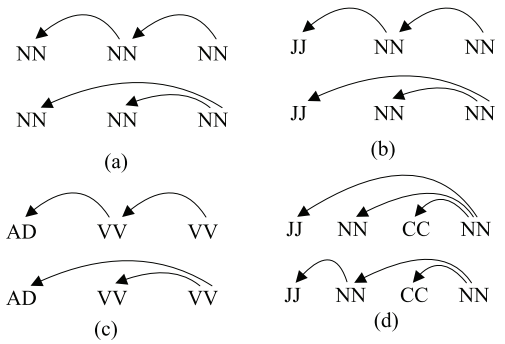

Figure 6: Neighborhood ambiguities in Chinese dependency parsing.

can also help the longer dependencies, such as "JJ NN NN NN" and "NN NN NN NN". For "JJ NN1 CC NN2" ambiguity, we can provide the additional information about the relations of JJ/NN1 and JJ/NN2. In this case, the dependency parser can correctly differentiate the ambiguity.

Our proposed approach is only a preliminary work. Despite the success, there are still some problems which should be extensively discussed in the future work.

(1) In this paper we split the POS tags by using the gold-standard POS tags of CTB. However, in many real application problems, the sentences to be parsed are often from the plain text and the POS tagging is an inevitable phase before dependency parsing. But the split of POS tags will bring great difficulty to the POS tagging phase. Whether the increase the parsing performance will cover the decrease of the POS tagging, this is a very appealing and challenging task in practice. We will leave it for future research.

(2) To deal with the problem of polysemous words, we just use the first definitions in HowNet. A natural avenue for further research would be the development of word sense disambiguation (WSD) technology to solve this problem.

7 Related Work

In this paper, we have focused on developing new representations for POS information. The idea of exploiting different granularities of information for dependency parsing has previously been investigated.

Liu et al. (2007) subdivided verbs according to their grammatical functions and integrated the information of verb subclasses into the dependency parsing model. They regarded the verb subdividing process as a classification task. In contrast, we split the POS tags based on HowNet hierarchical semantic knowledge and relax the subdivision to be all types of POS tags, which is much simpler than the classification-based method.

Koo et al. (2008) introduced lexical intermediaries at a coarser level than words themselves via a cluster method. Our approach is similar to theirs in that we used the fine-grained feature generation scheme based on HowNet hierarchical semantic knowledge, and the fine-grained features can be viewed as being a kind of "back-off" version of the baseline features. However, we focus on the problem of POS representation instead of lexical representation.

Recently, there are some studies focusing on parsing task using semantic knowledge. Agirre et al. (2008) used word sense information to improve English parsing and PP attachment. Xiong et al. (2005) and Lin et al. (2009) extracted hypernym features from HowNet semantic knowledge and integrated the features into a generative model for Chinese constituent parsing. As with their work, we also use semantic knowledge for parsing. However, our gold is to employ HowNet hierarchical semantic knowledge to generate fine-grained features to dependency parsing, rather than to PCFGs, requiring a substantially different model formulation. Besides, Bansal and Klein (2011) and Zhou et al. (2011) exploited web-scale semantic information for parsing.

8 Conclusion

In this paper, we focus on the problem of grammar representation, introducing fine-grained features by splitting various POS tags to different degrees using HowNet hierarchical semantic knowledge. To prevent the oversplitting, we adopt a threshold-constrained bottom-up strategy to merge the derived subcategories. The results show that, with the fine-grained features, we can improve the dependency parsing accuracies by 0.52% (absolute) for the unlabeled first-order parser, and in the case of second-order parser, we can improve the dependency parsing accuracies by 0.61% (absolute).

Natural Language Programming Using Class Sequential Rules

Cohan Sujay Carlos

cohan@aiaioo.com

Abstract

This paper presents a system for Natural Language Programming using Class Sequential Rules (CSR). The system recognizes a number of procedural primitives and operators. The domain of the system is presently limited to the world of numbers and operations on numbers. We evaluate the effectiveness of CSRs at the task of Natural Language Programming using an annotated corpus of programming instructions in natural language, achieving a precision and recall of 85% and 64% respectively. We also compare the performance of a system trained on annotated data with that of a system using handcrafted rules.

1 Introduction

Since the early days of computing, there have been those who have longed for a programming system wherein the use of a formal symbolism for programming was not strictly necessary. Though high level languages greatly improve the ease of programming, it might be easier for a user to be allowed to communicate with an application in a natural language rather than a formal language with a specialized syntax. Moreover, a significant fraction of the population of the world is not conversant in the English language or remains unfamiliar with the Roman alphabet, and for them, a system for programming in their native tongues would be of great benefit. It is also easy to foresee a future where speech recognition systems are so accurate and robust that users might seek to provide instructions by means of speech to their computers. Thus there seems to be a need for algorithms capable of accepting commands and programming instructions in unconstrained human languages.

Type	Arity	Example
if	2 or 3	If x is 2, say "Hi"
unless	2	Exit unless x is 2
while	2	While $x \leq 2 \ldots$
until	2	Till x is 2 add 1 to x
continuation	1	Also, increment y
assignment	2	Let x be 1
imperatives	0 to ∞	Display x
questions	1	What is y?
y/n questions	1	Is x equal to 2?

Table 1: Types of Procedural Primitives.

We present a Natural Language Programming system capable of accepting programming commands in a natural language, executing them and returning any requested results to the user. It is limited to the domain of real numbers and can be used to write programs to compute the values of various functions of real numbers, or to generate different number series. The system can recognize nine broad categories of procedural primitives, some of which are conditionals, loops, assignments and function calls (imperatives). The complete list of types of procedural primitives with their arity and examples of usage can be found in Table 1.

We also present and evaluate a novel approach for processing user instructions. Instead of the traditional programming language approach of using a parser to produce a parse tree starting from modules or blocks of programming instructions, we first break up the programming instructions into sentences. We then use a short text classifier to first classify each resulting sentence into one of the categories of primitives listed above. Then we perform entity extraction to obtain as many contiguous and non-overlapping word subsequences as the arity of the primitive recognized, and then repeat the process with each of the word subse-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 237–245,
Chiang Mai, Thailand, November 8 – 13, 2011.

quences. Our system is capable of learning to recognize programming instructions belonging to the categories described above from an annotated corpus. It can also use manually crafted rules for the recognition of commands from sentences in a natural language.

The output of the above process is a semantic parse of the program. The semantic parses of consecutive sentences are joined into blocks if continuations are indicated. For example, if the first line is "If x is 3, display x." and the second line is "Also, increment x.", the first line is semantically parsed into "x = 3 =>print(x)." and the second line is parsed to "also(++x)." Then the two lines are combined to get "x = 3 =>print(x) && ++x." The semantic parse is also an interlingua representation that can be stored, used to perform an automatic translation of the program from one language to another, or executed to obtain the output.

Mihalcea et al (2006) distinguish the two complementary programming tasks of *description* and *proceduralization*. The present paper deals with proceduralization, the process of constructing procedures out of steps, blocks, conditionals and loops. Of the procedural primitives listed in Table 1, the first two are *conditional* statement primitives; the next two are *loop* primitives; the fifth is used to construct *blocks* of statements by agglutination; the remainder are primitives for *steps*.

Imperatives tend to be function calls or commands that result in an action or change. Examples of imperatives include calls to "display the value of x" and "Go to the step marked 'Subroutine 1'."

Wh-questions and yes/no questions have the effect of displaying the value of a variable, literal or expression. Yes/no questions are distinguished from wh-questions because their argument is constrained to be a boolean expression whereas wh-questions can refer to non-boolean variables, literals and expressions.

The set of expressions supported by the system is listed in Table 2. It will be observed that many commonly used mathematical operations like exponentiation and logarithms are not included in the list. The list does however include the arithmetic and relational operators that have their own keywords in the C, C++ and Java programming languages. At present, only two of the logical operators, namely *or* and *and*, are supported.

The rest of this paper is organized as follows:

Expression	Arity
addition	2
subtraction	2
multiplication	2
division	2
modulus	2
divisible	2
equality	2
inequality	2
less than	2
less than or equal to	2
greater than	2
greater than or equal to	2
conjunction	2
disjunction	2
negation	1

Table 2: Expressions.

Section 2 presents related work on the topic of natural language programming. The annotated corpus used to evaluate the system and the annotation guidelines for the same are presented in Section 3. Section 4 describes the entity recognition algorithms in some detail. The entity recognition systems are evaluated in Section 5 on the annotated corpus, and the novel approach of training a natural language programming system from annotated text is compared with the approach of using manually crafted rules. The conclusions and future directions are presented in Section 6.

2 Related Work

Attempts to develop natural language programming systems have been made in the past, and a working prototype called "NLC" was described by Ballard and Biermann (1979). NLC was capable of accepting English commands in the imperative mood. It did not accept declaratives and interrogatives. Each input was required to begin with an imperative verb. However, NLC was capable of dealing with pronominal references, like the ones in the command "Put the average of the first four entries in that row into its last entry" and with procedure definitions and loops, though not with conditionals. A sample NLC program from Ballard and Biermann (1979) is provided in Table 3. An example of a looping instruction in NLC is the last line of the sample program that instructs the computer to repeat the preceding steps over other rows of the matrix under consideration. Biermann et

“Choose a row in the matrix” “Divide its last entry by 3” “Repeat for the other rows”

Table 3: Sample NLC Program.

Take the array [3, 5, 7, 4, 6, 2, 1]. Count from one up to the size of the array: Go over the array from the beginning to the end minus the counter: If the current element is bigger than the following element then exchange the current element with the following element. Print ”After: ” and print the array.

Table 4: Sample Pegasus Program.

al (1983) also described attempts to provide commands to the NLC system using the Nippon Electric DP-200 Connected Speech Recognizer.

Knoell and Mezini (2006) described a programming language called Pegasus that lets users program using plain German or English statements. Pegasus uses a handcrafted phrase structure grammar to parse English or German language commands and convert them into an intermediate representation. The intermediate representation is turned into a Java program using a dictionary of code snippets or translated into a different language. Knoell and Mezini (2006) did not perform an evaluation of the system on a corpus of natural language programming commands. A sample program written in the Pegasus language (see Table 4) was provided in the paper to show what a Pegasus program to sort an array of numbers would look like.

Objections to Natural Language Programming have been recorded, most notably by Dijkstra (1978) in an article titled ‘On the Foolishness of “Natural Language Programming”’. Knoell and Mezini (2006) on the other hand opine that a system capable of dealing with both, formal symbolism and natural text, might be better than one that only understands either.

A system for generating program skeletons from the text of programming assignments like the one shown in Table 5 was described by Mihalcea et al (2006). The system did not attempt to generate an executable program.

Pane and Myers (2000) studied how non-programmers would describe solutions to problems arising within a Pacman game, and from their study, Pane and Myers (2001) proposed several principles of usability for developing a programming system for children. Lieberman and Liu (2006) examine mixed-initiative dialog as a way of more precisely ascertaining user intention with respect to programming commands, again in the context of the Pacman game.

Write a program to generate 1000 numbers between 0 and 99 inclusive. You should count how many times each number is generated and write these counts out to the screen.

Table 5: Programming Assignment.

The present work is also related to the area of natural language understanding. Shapiro (2001) describes a system that understands user statements about their beliefs about the world. This is in essense a form of descriptive programming, similar to that described in Lieberman and Liu (2005) who explore the possibility of using natural language descriptions as a representation for programs, and describe a system called “Metafor” capable of generating Python scaffolding (referred to as the visualization code) from them, though not fully specified programs.

There has been, to our knowledge, no prior attempt to measure the performance of a natural language programming system using a corpus of annotated programming statements in a natural language. There has also not been, to our knowledge, any prior attempt to use entity recognition on natural language commands to generate fully specified programs. We also believe that this is the first attempt to learn patterns of language for programming from an annotated corpus.

3 Data Set

At the time of writing, there was no corpus available for evaluating the performance of a system for procedural programming in a natural language. Therefore, a corpus was developed[1] consisting of sentences in the English language, which the contributors of the sentences perceived to be commands that ought to invoke the programming primitives listed in Table 1 or specify the expressions listed in Table 2.

[1]The annotated corpus can be downloaded from the URL http://www.aiaioo.com/corpora/vaklipi2011.

Order	Survey Question
1	How would you say "x = 2" in English?
2	How would you say "x != 2" in English?
4	How would you say "$x \leq 2$" ?
6	How would you say "$x \geq 2$" ?
9	How would you say "x multiplied by 2" ?
10	How would you say "x / 2" ?

Table 6: Survey Questions.

The sentences were collected by setting up an online survey on a website, sending out requests over social networks and using email. All the questions were presented to the user at the same time, and the instructions at the top said:

> Please type into the box under each of the following, one way of saying the same thing in English and click on the Submit link below it. You can repeatedly enter different phrases if you can think of many ways of saying the same thing. For example, to communicate the idea of $x = y$, you might say x and y are equal or assign the value y to x.

The survey consisted of a total of thirty questions, and took approximately thirty minutes to complete. All users were presented with the same set of questions and in the same order. The answers provided by previous users were not made available to subsequent survey takers.

A total of 3,517 sentences[2] was collected over a period of one month.

The annotation procedure involved recategorizing the submissions according to the procedural primitive or expression they most closely matched and marking the entity spans according to the following annotation rules:

- **Conditional primitives:** A complex sentence specifying a condition for performing an action is a conditional statement. It is classified as an *if conditional statement* if it is conditional upon a **positive** outcome of the conditioning expression and the action to be taken does not undeniably suggest repeatedly checking the conditioning expression as a precondition for performing the action. It is classified as an *unless conditional statement* if it is conditional upon a **negative** outcome of the conditioning expression.

- **Loop primitives:** A complex sentence specifying a condition that is repeatedly evaluated for performing an action until it is satisfied or denied is a loop statement. It is classified as a *while loop statement* if it is conditional upon a **positive** outcome of the conditioning expression. It is classified as an *until loop statement* if it is conditional upon a **negative** outcome of the conditioning expression.

- **Operations with side effects:** Requests to add a value to a variable or to subtract a value from a variable are considered increment and decrement operations if the value of the variable would normally be considered to have changed at the end of the operation. For example, "Add 2 to x" would be considered an increment operation, whereas "Add x to 2" would not. The latter would be considered an addition operation and not an increment operation since it does not suggest a change in the value of x whereas the former does.

- **Operations without side effects:** Sentences in the indicative mood, informative clauses and phrases are classified as operations that do not have side effects, if they are not expected to alter the value of a variable. For example, "x added to 5" and "x by 5" have no side effects.

- **Relational Operations:** The classification of relational operations like *less than* depends on the order in which the parameters are supplied. So, "x is less than 2" and "x is not greater than or equal to 2" are both valid ways of representing "$x < 2$", but not "2 is greater than x". The last example is classified as a *greater than* operator.

From the counts for the categories *if conditional statement* (95 before annotation and 118 after cleaup) and the *unless conditional statement* (64 before and 15 after) it appears to be the case that people strongly prefer using an *if conditional statement* to an *unless conditional statement*. Thus the number of test sentences in each of the categories is not balanced.

[2]The number 3,517 included blank sentences and names as well. When these were removed, we were left with about 3,100 sentences of which we annotated 3,000.

4 System Description

As the system is intended for use as a multilingual teaching tool for students of computer programming, especially for those who do not possess a knowledge of English or the Roman alphabet, it was thought desirable to use a method of processing natural language programming instructions that would permit the rules for processing instructions to be learnt from annotated text in a number of possibly very different human languages.

One approach that seemed very promising was Class Sequential Rules (CSR) as described by Hu and Liu (2006). CSRs have been shown to outperform existing methods at the task of associating opinions with product features (Liu et al, 2006). Moreover, CSRs can also be easily created by hand since they are a subset of cascading grammar rules such as those described by the Common Pattern Specification Language (CPSL) (Appelt, 1996), which incidentally was developed as a language for specifying finite-state grammars for the purpose of information extraction. It was intuitively felt that a less powerful formalism might not only suffice for the task of processing programming commands, but also prove learnable from an annotated corpus.

4.1 Class Sequential Rules

A Class Sequential Rule consists of a sequence of ordered tokens, that we indicate by the symbols $i_1 \dots i_n$, for example, $I = < i_1 i_2 i_3 >$. A CSR matches a sentence only when each token in the CSR's token sequence matches a word token in the text under evaluation, in the right order. The CSR I will match a sentence s if and only if, in the sentence, there is a token s_3 that matches i_3, and this token follows a token s_2 that matches i_2. This second token must in turn follow a token s_1 that matches i_1. For example, I will match the sequence $< i_1 x_3 i_2 x_4 i_3 x_5 >$ but not $< i_2 i_3 >$ or $< i_3 i_2 i_1 >$. CSRs like I can be used for classification as follows: a number of mutually exclusive CSRs are assigned to each class and used in conjunction with a priority or ordering scheme to resolve conflicts when CSRs from different classes match the input.

CSRs can also have class labels $c_1 \dots c_n$ in their sequences. A class label can match zero or more tokens in the sentence. The tokens that class labels match represent entites in the sentences when CSRs are used for entity extraction. For example, the CSR $J =< i_1 c_4 i_2 c_5 i_3 >$ will match the sentence $< i_1 x_3 x_4 i_2 i_3 >$. The two class labels in J, namely c_4 and c_5 will at the same time match the sub-sequence $< x_3 x_4 >$ and the empty sequence $<>$ respectively. As you can see, the actual matching is performed by the sequence tokens $i_1 \dots i_n$. The class labels pick up the tokens in between.

Sequences
$< c_2 keab >$
$< dc_2 kb >$

Table 7: Sequence database.

Length	Sequences
1	$< c_2 >$
2	$< c_2 k >$
3	$< c_2 kb >$

Table 8: Extracted sequences with support 2.

If two class labels follow one another in quick succession (are not separated by a token in the sequence), for example $< i_1 c_2 c_3 i_4 >$, the extents of their spans are not well defined. The tokens that class labels match can be thought of as entities. Thus, in addition to classification, CSRs can be said to be capable of performing entity extraction.

The task of understanding a programming command given in natural language can be broken down into the two sub-tasks that CSRs perform: a) classifying the command into one of several categories of commands; and b) extracting the arguments for further processing. Both tasks can be performed by CSRs in a single step.

The algorithm for mining CSRs used in the present work is described in more detail in Hu and Liu (2006). Using the algorithm, it is possible to mine sequences with a given minimum *support*. For instance, given two sequences such as those shown in Table 7, and a minimum required support of 2, it is possible to extract all the patterns of length 1, 2 and 3 indicated in Table 8. CSRs are only a special case of sequential patterns. With CSRs, the sequential patterns mined are text tokens. Some algorithms for sequential pattern mining have been studied in Agrawal and Srikant (1995).

Other pattern exraction concepts closely related to CSRs include the surface patterns described by

Sequences
Also { x = 2 }.
Also, { x = 2 }.
Also { if x = 3 , ++x }.

Table 9: Three annotated sentences that demonstrate the inadequacy of CSRs for natural language programming.

Order	CSRs
1	Also , EXPRESSION .
2	Also EXPRESSION .

Table 10: Class Sequential Rules for the entity spans in Table 9.

Ravichandran and Hovy (2002), Hearst (1992), Snow et al (2005) and Lin and Pantel (2001).

In the course of developing a hand-crafted set of rules for natural language programming using CSRs, it was observed that the discriminative power of CSRs did not always suffice. For example, it was observed that CSRs could not accurately identify the entity spans in the three sentences listed in Table 9.

The reason is that the two rules in Table 10 are needed to match the spans in the first two sentences and these are ordered to fire one behind the other as shown in the table. Now, however, the first rule "Also , EXPRESSION ." incorrectly picks out the single entity span in the third sentence owing to the comma in the middle of the sentence, and there is no way to rectify the problem using a different number of CSRs or changing the ordering.

Thus, a family of rules with more discriminative power was needed. We attempted to extend the concept of CSRs to give them more discriminative power, as described in the next subsection.

4.2 Extended Class Sequential Rules

The extension that solved the problem described in the preceding section was that of allowing each token in the CSR to be an n-gram. The rules presented in Table 11 contain a special term "NONE" which indicates an n-gram constraint as follows:

Order	Extended CSRs
1	Also NONE , EXPRESSION .
2	Also EXPRESSION .

Table 11: Two CSRs of the extended variety.

- When the term "NONE" appears between two tokens, the tokens they match in a sentence must be consecutive tokens. This is equivalent to making tokens on either side of "NONE" part of an n-gram. In the example in Table 11, the first rule can only match sentences where a comma immediately follows the word "Also."
- The term "NONE" can also appear at the beginning of an extended CSR to indicate that the following token must appear at the beginning of the matched sentence.
- Similarly, it can appear at the end of an extended CSR to indicate that the preceding token can only appear as the last token of a matched sentence.

The set of rules in Table 11 will be seen to be able to match all three sentences' spans correctly.

4.3 Rule Selection and Ordering

The two parameters used to evaluate the suitability of a rule are *support* (the percentage the sentences belonging to a category that it correctly identifies as belonging to that category) and *confidence* (the percentage of matches of the rule that were right), which are analogous to precision and recall. Only those rules were selected whose support and confidence values on the training data both exceeded minimum thresholds. The selected rules were ordered as follows:

- Rules whose accuracy of span matching exceeded the threshold were placed first.
- Rules whose accuracy of span matching fell below the threshold followed.
- Within the two categories described above, longer rules went ahead of shorter rules.

4.4 Intermediate Representation

The intermediate representation is a programming language that mimics the ambiguities of the language used in mathematics. The intermediate representation differs from a conventional programming language like Python in the following ways:

- Terms which tend to be ambiguous in natural language remain so in the intermediate representation. For example, the 'assignment operator' doubles as the 'equal to operator'

Let x be 3. y is 9.
What is x times y?
While x is less than y, print x and then increment x.

Table 12: Sample commands in our system.

in many natural languages. This overloading poses no problem since the right form can be resolved from context.

- The intermediate representation also attempts to capture the logical operator priority of Indian languages. In many Indian languages, it is not possible to set *or*-phrases as subphrases of *and*-phrases. So, we have chosen a priority order for operations in the intermediate representation that naturally maintains the restriction.

A program written in the present system would look like that in Table 12.

5 Evaluation and Results

The natural language programming system was evaluated against the annotated corpus described in Section 3. The manual rules used in the evaluation were developed and fixed prior to the start of corpus collection to avoid the introduction of biases through any knowledge of the corpus to be tested on.

5.1 Categories

The categories that were used in testing were equality, inequality, less than, greater than, less than or equal to, greater than or equal to, addition, subtraction, multiplication, division, increment, decrement, if, while, unless, until, print, conjunctive, disjunctive, divisible and continuation.

The categories in the corpus that were left out of the evaluation were as follows:

- Three categories were left out because of the lack of manually crafted rules for those categories.
- Of the three categories recognized as the print command by the manual rules, only one was retained for the experiment.
- Two of the omitted categories were merely synomyms for boolean constants 'true' and 'false.'

Category	Cnt	Precision	Recall	F1
equality	298	79.0 ± 06	66.5 ± 19	71.9 ± 10
inequality	165	90.6 ± 14	78.6 ± 06	84.3 ± 09
less than	151	66.8 ± 10	88.4 ± 07	76.8 ± 08
$\leq$	137	99.1 ± 02	75 ± 13	86.0 ± 07
more than	158	76.6 ± 08	83.1 ± 06	79.6 ± 02
$\geq$	132	92.9 ± 05	80.8 ± 13	86.5 ± 09
addition	140	97.9 ± 04	61.2 ± 10	77.2 ± 06
subtract	113	92.5 ± 15	71.0 ± 06	80.8 ± 06
multiply	144	98.8 ± 02	64.1 ± 12	79.4 ± 08
division	143	89.8 ± 10	69.8 ± 08	79.2 ± 09
increment	136	92.5 ± 08	57.3 ± 08	72.8 ± 08
decrement	131	96.9 ± 06	23.5 ± 15	46.7 ± 15
if	118	84.2 ± 05	96.0 ± 08	89.8 ± 04
while	61	92.1 ± 02	88.0 ± 12	89.8 ± 11
unless	15	100 ± 00	60.7 ± 15	77.6 ± 09
until	86	98.8 ± 02	85.8 ± 15	91.9 ± 08
print	82	92.3 ± 06	33.9 ± 14	55.1 ± 09
and	68	52.8 ± 11	82.8 ± 14	66.1 ± 12
or	67	92.1 ± 08	37.8 ± 04	58.8 ± 03
divisible	66	92.7 ± 08	71.1 ± 18	80.7 ± 10
continue	48	78.3 ± 23	22.1 ± 11	40.0 ± 05

Table 13: Evaluation of CSR-EX.

- The modulus operator was left out of the evaluation because the manual rules treated the operator as 'modulus' whereas the question used in the survey used to develop the corpus had suggested that the operator was the 'absolute value' operator.

5.2 Experiments

The 3,000 sentences in the annotated corpus belong to 29 distinct categories of which 21 are used for evaluating the system. Support and confidence values of 0.0001 and 0.70[3] respectively were used during training (for rule discovery).

Since we performed 3-fold cross validation, three sets of experiments were conducted for each of the following settings, for a total of 9 experiments in all:

- Conventional CSRs (CSR-BL)
- Extended CSRs (CSR-EX)
- Manually crafted rules (CSR-Man)

[3]These values were manually chosen keeping in mind the small size of the corpus. The support threshold was chosen to be low enough to not affect rule selection. The confidence threshold was kept low enough to permit single failures (incorrect matches) from time to time.

Setting	Prec.	Recall	F1
CSR-Man	89.2 ± 3.7	64.8 ± 6.2	73.0 ± 4
CSR-BL	85.7 ± 4.5	65.3 ± 5.9	73.1 ± 4
CSR-EX	88.4 ± 3.4	66.5 ± 5.6	74.8 ± 3

Table 14: Categorization Evaluation.

Metric	CSR-Man	CSR-BL	CSR-EX
PSCS	52.4 ± 9.1	50.2 ± 8.4	49.7 ± 8.6

Table 15: Entity Span Matching Evaluation.

In all experiments, the Precision, Recall and F1 Score (the harmonic mean of Precision and Recall) were measured for each of the categories, as well as the overall accuracy of categorization. The Precision, Recall and F1 scores for the CSR-EX algorithm are presented in Table 13. In the second column of the table is listed the number of sentences used in the test. This value in some cases drops to as low as fifteen sentences. The confidence intervals are rather high, making it difficult to draw comparisons between algorithms based on this data. The average of these scores for all categories is reported in Table 14.

The accuracy of entity span boundary detection is measured as follows: A recall-based score for correct span detection is computed by dividing the number of sentences with perfectly identified spans by the number of sentences in the category. This score is reported as the PSCS (percentage of sentences with correct spans). This score is similar to but not quite the same as the PCS (percentage of correct scopes) metric used in Councill et al (2010).

The PSCS scores for the three algorithms are reported in Table 15. We observe from the results that for the corpus the evaluation was performed on, there is no significant difference between the algorithms evaluated.

The overall accuracy scores presented in Table 16 again reveal no significant differences between CSR-Man, CSR-BL and CSR-EX in their behaviour with respect to the data-set.

Metric	CSR-Man	CSR-BL	CSR-EX
Acc.	64.3 ± 7	64.4 ± 6	66.0 ± 4

Table 16: Accuracies.

6 Conclusions and Future Work

This paper presents a system for Natural Language Programming capable of recognizing a number of categories of procedural programming instructions in a natural language. The system uses Class Sequential Rules to convert a natural language representation of a program into an intermediate representation that can be executed. The system is capable of using manually crafted rules or rules learnt from an annotated corpus.

Since no corpus was available for evaluation of a system for Natural Language Programming, a corpus consisting of 3,000 sentences in twenty-nine categories (of which only twenty-one were used), was collected over the internet, cleaned, re-categorized, annotated with entity spans and made publicly available.

Since the existing formalism of Class Sequential Rules (CSR-BL) was not powerful enough to tease certain sets of sentences apart into the right categories, an extension to Class Sequential Rules was proposed (CSR-EX) and implemented.

Finally, the system was evaluated by three-fold cross validation using the corpus. Three settings of the system were tested: a) a setting where it used extended CSR-EX rules manually crafted before the collection of the corpus; b) a setting where it used CSR-BL rules learnt from the annotated corpus; and c) a setting where it used CSR-EX rules learnt from the annotated corpus. Precisions of around 85% and recalls of approximately 64% were measured with confidence intervals as large as 7%. The large confidence intervals make it impossible to establish if one of the approaches works better than the others with the present corpus and the present set of categories.

Future research could include an evaluation on a larger corpus, on more languages and on the system's ability to adapt to new domains. It would also be interesting to examine system accuracies with an increased number of categories covering more operations and functions. It might also be of interest to build a corpus of complete programs rather than individual sentences, to capture more variations in language.

Acknowledgments

We are very grateful to all the volunteers who contributed to the corpus and to Govind Sharma, Kartik Asooja, Dr. Pushpak Bhattacharyya and the reviewers for helpful suggestions and references.

Abstract

We describe "treeblazing", a method of using annotations from the GENIA treebank to constrain a parse forest from an HPSG parser. Combining this with self-training, we show significant dependency score improvements in a task of adaptation to the biomedical domain, reducing error rate by 9% compared to out-of-domain gold data and 6% compared to self-training. We also demonstrate improvements in treebanking efficiency, requiring 25% fewer decisions, and 17% less annotation time.

1 Introduction

Computational linguistic research is driven by the development of reference resources for specific tasks and languages. The advent of services such as Amazon's Mechanical Turk has driven down the cost of annotation considerably, assuming a given task can be broken down into piecemeal units which are intuitive and manageable for non-experts. This is not an option, however, for fine-grained tasks which require an expert understanding of a theory or domain, such as syntactic treebanking or discourse annotation.

Two main approaches have been adopted to efficiently create new resources: (1) domain adaptation, where a trained model from one domain is stochastically adapted to a new domain, using unlabelled data from the new domain (Daumé III and Marcu, 2006); and (2) annotation projection, where the labels in a pre-existing resource are semi-automatically translated into an independent formalism, e.g. in translating the PTB into the CCG formalism (Hockenmaier and Steedman, 2002). This paper looks at both of these approaches: domain adaptation from unannotated data in the form of self-training combined with resource translation over the GENIA treebank (Yuka et al., 2005), in the context of training an HPSG parse selection model for biomedical text, and using the GENIA treebank annotations and retrained parse selection model to accelerate treebanking.

Our contributions are: (1) we propose a series of methods for transferring annotation from a traditional phrase structure treebank to constrain the parse forest of a precision grammar; (2) we show that this constrained forest can be used to domain-adapt a parse selection model; (3) we demonstrate improvements in treebanking performance using the constrained forest; and (4) we develop a small-scale HPSG treebank for the biomedical domain.

2 Related Work

Domain adaptation is an active research area, triggered by the observation that parsers trained on one domain show decreased performance when used in other domains (Gildea, 2001). Much domain-adaptation work involves some small amount of in-domain data to tune a model, but McClosky et al. (2006) showed "self-training" using unannotated in-domain data could achieve significant improvements in parser accuracy.

In parsing-related research that has used annotated data, but in an incompatible format, we see two main use cases. The first uses an existing treebank to create a treebank for some completely different linguistic framework, generally to induce a grammar in that framework. Xia (1999) presents work on transforming Penn Treebank (PTB) trees into Lexicalized Tree Adjoining Grammar (LTAG) structures. The work of Hockenmaier and Steedman (2002) is roughly parallel, but targets Combinatory Categorial Grammar (CCG). The techniques include binarisation, adding an extra level

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 246–254,
Chiang Mai, Thailand, November 8 – 13, 2011.

of NP structure, and remapping node labels to CCG categories. An analog in the framework of Head-driven Phrase Structure Grammar (HPSG) is described by Miyao et al. (2004).

The second use case is to use the incompatible annotations to select the correct tree from the output of a compatible parser. Sometimes, a function over the original annotations produces a score of the new analysis candidates, and a single best analysis is selected (Wang et al., 1994; Niu et al., 2009). In other work, the original annotations do not uniquely disambiguate the parse forest, but the partial annotations can still be used. Riezler et al. (2002) used PTB annotations to partially disambiguate a parse forest built using a grammar in the Lexical-Functional Grammar (LFG) framework (Butt et al., 2002), and then built a model using the partially-disambiguated forest. Another use of partially disambiguated forests is described by Tanaka et al. (2005), who manually created a Japanese treebank (Bond et al., 2004) by selecting the best parses from the candidate parses offered as candidates from JaCy, an HPSG grammar of Japanese. The annotators reject or affirm *discriminants* to select the best tree, as is described in more detail in §3.1. Their data was already human-annotated with POS tags, which they used to constrain the parse forest, requiring on average 19.5% fewer decisions and 15% less time per tree.

Tanaka et al. (2005) used only POS tags. Our work can be viewed as a syntactic extension of this. We investigate strategies for adapting the English Resource Grammar (ERG: Flickinger (2000)) to the biomedical domain using information contained in the GENIA treebank (GTB), a corpus of 1,999 abstracts from PubMed in the domain of human blood cells and transcription factors, annotated according to a slightly simplified version of the PTB II annotation guidelines.

3 Setup

We explore two branches of experimentation using a common core of tools, resources and methods. This section describes the necessary details of our treebanking process, the test data we use, and some peculiarities of parsing biomedical data that affected our experiments.

3.1 Treebanking

All our experiments are based on the Redwoods treebanking methodology (Oepen et al., 2004), where the treebank is constructed by selecting from a parse forest of candidate trees licensed by the grammar. All experiments reported in this paper make use of the ERG. We first parse an input, and then select the (up to) 500 top-ranked parse trees according to a parse selection model. This set of parse trees is then presented to the human treebanker in the form of *discriminants* (Carter, 1997; Oepen et al., 2004). The discriminants used here correspond to instantiations of the 200 lexical and syntactic rules of the ERG, as well as the lexical entries themselves, but only those that correspond to ambiguity in the parse forest and can thus discriminate between candidate parse trees.

During treebanking, the annotator confirms or rejects some subset of discriminants, and at each stage, the Redwoods machinery performs inference to automatically reject those discriminants that are incompatible with the current set of manually-selected and inferred discriminants. This means that each manual decision can directly or indirectly rule out a large number of trees, and the number of decisions required is on average proportional to the logarithm of the number of parses (Tanaka et al., 2005).

Treebanking gives us a large number of rejected trees, along with the single correct gold tree, which can be used to build a discriminative parse selection model, in our case using TADM (Malouf, 2002). This is applied to parsing unseen data, and also for the next iteration of treebanking.

3.2 Data: a new biomedical HPSG treebank

In order to evaluate the impact of the proposed method on parser accuracy over biomedical text, we require a gold-standard treebank in the target domain. We use a subset of the data used in the GTB, created by first removing those abstracts (approximately half) that overlap with the GENIA event corpus (GEC: Kim et al. (2008)), to hold out for future work. From this filtered set, our test corpus comes from the 993 sentences of the first 118 abstracts (PubMed IDs 1279685 to 2077396).

Our treebankers both have detailed knowledge of the ERG, but no domain-specific biomedical expertise. As a proxy for this, they used the original GTB syntactic annotations when a tie-breaker was needed for ambiguities such as PP-attachment or co-ordination. The annotators were instructed to only refer to GTB trees when the ambiguity was not resolvable on linguistic grounds. The first 200

sentences of the corpus were double-annotated in each round of treebanking (agreement figures for unseen data are shown in §6.3)

The first round of annotation of a 500-sentence subset of the corpus served to determine a suitable parser configuration and calibrate between annotators using the 200-sentence overlap. From this, we developed a set of annotation guidelines, which will be made available with the corpus. One key domain-specific guideline related to the treatment of noun compounds, which are never disambiguated in the flat GTB structure. In the biomedical domain, noun compounds are generally left-bracketed – 83% of three-word compounds according to Nakov and Hearst (2005) – so we stipulated that noun compounds should be left-bracketed and adjectives attached high in cases of doubt, as a tie-breaking strategy.

We also used this first-iteration treebank to build a domain-tuned parse-selection model (duplicating the data 10 times and combining it with a larger out-of-domain corpus, using the DUPLIC method of MacKinlay et al. (2011) to provide improvements for sparse in-domain data). The external corpus was the WeScience corpus (Ytrestøl et al., 2009), a selection of Wikipedia articles on NLP. We improved the parser's handling of named entities, as described in §3.3, and then reparsed the treebank with the new parsing configuration and parse selection model, giving 866 parseable sentences. After updating the treebank according to the new guidelines using this new parse forest, and checking inter-annotator agreement on the overlap, we annotated the remaining sentences. All accuracy figures we report are over the data set of 669 trees complete at the time of experimentation.

3.3 Biomedical parsing setup

We parsed sentences using the ERG with the PET parser (Callmeier, 2000), which uses POS tags to constrain unknown words. Following Velldal et al. (2010), we primarily use the biomedically trained GENIA tagger (Tsuruoka et al., 2005), but defer to TnT (Brants, 2000) for tagging nominal elements, because it makes a useful distinction between common and proper nouns.

Biomedical text poses a unique set of challenges, mostly relating to named entities, such as proteins, DNA and cell lines. To address this, we used the GENIA tagger as a named-entity (NE) recogniser, treating named entities as atomic lexical items. However, the NE tagging is often overzealous and discards internal structure, misleading the parser. To overcome this, we supply multi-token NEs as both a single atomic NE token and the individual words, thus giving PET a lattice as input. The increased parse coverage and better parse quality made this a worthwhile strategy, with the downside of increased ambiguity, making parse selection more difficult.

4 Blazing

In §2, we reviewed work that uses linguistic information from superficially incompatible formalisms for treebanking or parse selection. Our experiments here use syntactic information from the GTB to partially disambiguate the parse forest produced by the ERG. We do this by disallowing certain candidate ERG trees on the basis of GTB-derived information, and we follow Tanaka et al. (2005) in denoting this process "blazing".[1]

As detailed below, we can use this partially disambiguated forest: (1) to train parse selection models; and (2) to reduce treebanking effort, abstractly similarly to Tanaka et al. (2005). The goal is not to apply all constraints from the GTB to the ERG parse trees; rather, we want to apply the *minimal* amount of constraints possible, while still sufficiently restricting the parse forest for our target application. We call the set of trees remaining after blazing *silver* trees, to represent the fact that they are not gold standard, but are generally of better quality than the discarded analyses.

For an iteration of blazing, we parse each GTB sentence, obtaining the top-500 trees according to the parse selection model. Each discriminant (as discussed in §3.1) which corresponds to a meaningful difference between the candidate trees (derivations) is supplied to the blazing module.

A given discriminant can be ruled out, ignored or asserted to be true, but we never make use of the latter, since we can just rule out incompatible discriminants, which are easier to identify. This process happens with all discriminants for a sentence simultaneously, so it is possible to rule out all parse trees. This may indicate that none of the candidate parses are desirable, or that the imperfect blazing process is not completely successful.

The blazing module is given the GTB XML source for the tree, and a set of discriminants, each of which includes the name of the rule or lexical

[1] Which is a term in forestry: marking trees for removal.

entry, as well as the corresponding character span in the source tree. It applies some pre-configured transformations to the GTB tree, and examines each discriminant for whether it should be ruled out, by comparing to the corresponding GTB constituents overlapping with the supplied character span. Primarily, these decisions depend on whether a discriminant is a *crossing-bracket discriminant*, i.e. corresponds to phrase structures in the ERG derivation trees which would have crossing brackets with any overlapping constituents (ignoring punctuation). As discussed below, in some configurations we can also use the rule name or lexical type to rule out particular discriminants.

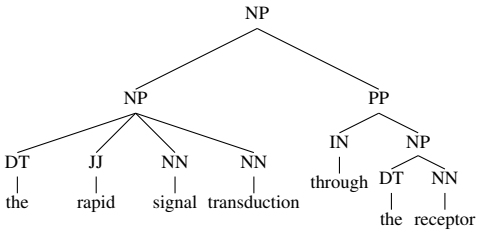
5 Parse Selection

Our first set of experiments was designed to evaluate the impact of blazing on parse selection, specifically in a domain-adaptation scenario. As mentioned in §3.1, parse selection is the process of selecting the top *n* parses, using a discriminative statistical model trained using the correct and incorrect trees from the treebanking process. However, as discussed in §2, statistical models are highly sensitive to differences in domain, and ideally, one would domain-tune off in-domain treebank data. Self-training (e.g. McClosky et al. (2006)) bypasses this need for in-domain annotations, by parsing the new domain with an out-of-domain model, treating the top-ranked parse as gold, and training a new model accordingly. In this work, we extend that idea by using blazing to transfer annotations from the GTB, hopefully filtering out incorrect trees in the process, and arrive at better-quality top-ranked parses.

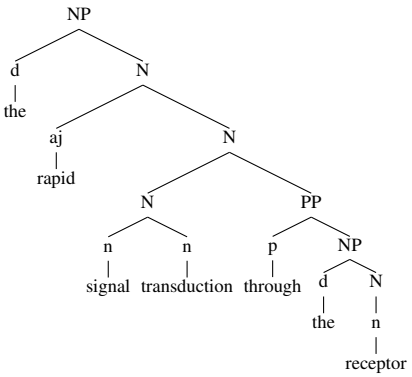
5.1 Blazing configurations

Blazing depends on the fact that the ERG and the GTB both have a theoretical linguistic underpinning, and so we expect they would share many assumptions about phrase structure, particularly for phenomena such as PP-attachment and co-ordination. However there are also disparities, even between the unlabelled bracketing of the GTB and ERG trees.

One pervasive difference is the attachment of specifiers and pre- and post-modifiers to NPs. The GTB attaches pre-modifiers and specifiers as low as possible, before attaching post-modifying PPs at a higher level, while the ERG makes the opposite decision and disallows this order of attachment. The other important difference is phrase branching – the GTB allows arbitrarily many children per node, while the ERG allows at most two. We show a sample NP exemplifying the differences in Figure 1.



(a) A sample native GTB subtree



(b) A simplified ERG subtree

Figure 1: Sample trees

One strategy for handling this is to make as few assumptions as possible while avoiding spurious conflicts. Denoted **IEP** (*ignore equal parent*), it involves ignoring GTB nodes with the same label as the parent when looking for crossing-bracket constituents. From the GTB tree in Figure 1, the blazing module would ignore the boundaries of the second-level NP when looking for crossing-bracket discriminants. This ensures that we never rule out the corresponding good subtree shown in the figure in favour of some invalid bracketing from the ERG that by chance has no conflicts with the GTB tree; meanwhile the PP would still be considered. Note that for a flat NP with no post-modifiers, no changes are necessary as the external boundaries still correspond with the edges of the top-level NP in the ERG, and the extra internal boundaries in the ERG have no effect since they cannot cause any crossing brackets.

Alternatively, to avoid discarding possibly valid syntactic information, we can attempt to account for the systematic differences by mapping the GTB as closely as possible to the structures we would expect in the ERG before looking

for crossing-bracket discriminants. Firstly, the phrases are binarised in a similar way to much previous work (Miyao et al., 2004; Hockenmaier and Steedman, 2002). We heuristically determine the head of each phrase using a simple category match between the phrase category and the POS, then recursively split multiple-branched nodes. This binarisation applies to all phrasal categories, not just NPs. We then systematically alter the attachment positions of determiners and pre-nominal modifiers, forcing them to attach as high as possible, but preserving the binary branching. As a lightweight but imperfect attempt to avoid creating invalid structures for appositions and conjunctions, this NP rearrangement is abandoned if any tokens are parentheses, commas or conjunctions. The transformation is labelled **RP** (*raise premods*).

5.2 Experimental Configuration

We create a parse forest by parsing 10747 sentences from a GTB subset not overlapping with the test corpus, using the WeScience model to determine the top 500 parses. The best-performing method we found to create parse selection models from this parse forest was to apply the blazing configurations to determine the *silver* trees, and then select the top-ranked parse from that set, according to the WeScience model. We call this top parse our *pseudo-gold* analysis. Remaining silver trees are ignored, while incorrect trees are used as negative data as usual. To show how much effect blazing has, we also used two other methods to select the pseudo-gold parse: random selection from that same top 500, to give us a baseline, and 'plain' self-training using the top-ranked parse without the blazing-based filtering, in each case using other trees from the forest as negative data. We then trained parse selection models using the gold standard out-of-domain (WeScience) data plus the in-domain pseudo-gold analyses from each configuration, and evaluated by parsing our test corpus.

5.3 Evaluation

We use two different styles of evaluation metric. In keeping with previous work using the ERG, we report exact match figures, denoted Acc_N, representing the percentage of sentences for which the exact gold tree was in the top *N* parses. Here, as in Zhang et al. (2007), we use Acc_1 and Acc_{10}. However, exact match can be very blunt for the fine-grained ERG analyses, giving no indication of how 'right' or 'wrong' the top analysis is. To supplement Acc_N, we use Elementary Dependency Match (EDM: Dridan and Oepen (2011)). This is based on triples extracted from the semantic output of the parser, providing a more granular measure of the quality of the analyses. We use the EDM_{NA} configuration that is arguably the most compatible with other dependency-based parser evaluation, although we make no claims of direct comparability.

Config	Gold Added	Acc A_1 / A_{10}	EDM_{NA} P / R / F
(WeSc only)	WeSc	12.3 / 39.2	82.4 / 79.2 / 80.7
Random	WeSc	6.1 / 20.0	70.7 / 70.2 / 70.5
Self-train	WeSc	12.9 / 39.2	82.4 / 80.3 / 81.3 *
IEP + S-T	WeSc	12.9 / 39.2	83.5 / 80.9 / 82.2 *** ††
RP + S-T	WeSc	13.3 / 40.1	83.8 / 81.2 / 82.5 *** †††

Table 1: Results over the test corpus. "WeSc only" shows parsing using a pure WeScience model. Other configurations used models trained from the same training sentence parse forest, setting a pseudo-gold tree either randomly, self-trained (best from a WeScience model), or blazing (highest-ranked of the silver trees, other silver trees discarded). The gold WeScience data is also used for training. Significance figures are against "WeSc only", (*: $p < 0.05$; ***:$p < 0.001$), and "Self-train", (††: $p < 0.01$; †††: $p < 0.001$)

5.4 Results

We present our results in Table 1, including the best-performing blazing configurations, the self-training results and the weak baseline trained on a random tree from the same GTB parse forest as used in blazing.

We also show the parsing accuracy results obtained using only out-of-domain data, designated "WeSc only", as a strong baseline. We see some evidence that self-training can be a useful domain-adaptation strategy, giving a weakly significant F-score improvement over using WeScience only. This echoes previously mentioned work, although has not been evaluated for this parser or grammar before. More importantly, our blazing strategy yields strongly significant F-score improvements over both the strong baseline out-of-domain model and the standard self-training.

5.5 Discussion

There is strong evidence that these blazing methods can help create a parse selection model to give

	IEP	RP
Discrims/Sent	144.2	144.2
Rejected/Sent	40.8	42.8
Unblazed Sents	3.9%	3.4%
Overblazed Sents	14.2%	15.3%
Usably Blazed Sents	81.9%	81.3%
Trees/Sent (overall)	423.3	423.3
Silver Trees/Sent (blazed)	98.4	88.5
Silver Trees/Sent (usable)	120.1	108.8

Table 2: Blazing Statistics, over all 10747 parseable training sentences. The first block shows discriminants available per sentence, and how many were rejected by the blazing (removing ≥ 1 tree). The second block shows percentage of unblazed sentences (no discriminants rejected), overblazed sentences (all trees removed) and usably-blazed sentences (≥ 1 removed and ≥ 1 silver tree remaining). The third block shows how many parses were produced initially, the average number of trees remaining over blazed sentences (inc. overblazed with 0 trees) and the average number remaining over usably blazed.

a significant boost in dependency score without needing additional human annotation. The exact match results are inconclusive – the best improvement is not significant, although the granular EDM metric may provide a better reflection of performance for downstream applications in any case.

In our initial investigations, a range of configurations failed to provide improvements over the baseline. If we don't augment the training data with human-annotated WeScience data, the performance drops. Also, if we don't use the self-training/blazing combination as described but instead treated all silver trees as pseudo-gold (i.e treat all remaining post-blazing parse trees as if they were manually marked as good), the model performs poorly. Table 2 provides some explanation for this. Over sentences which provide usable discriminative training data (at least one incorrect and one silver tree), on average more than 100 silver trees remain, so it is failing to disambiguate sufficiently between the ERG analyses. This is probably due to an imperfect transfer process and shallower, less precise GTB analyses.

6 Reducing treebanking labour

Blazing is designed to reduce the size of the parse forest, so it seems natural to evaluate its impact on the treebanking process, and whether we can reduce the amount of time and number of decisions required to enable more efficient treebanking.

6.1 Mapping between treebanks

In addition to the transformation strategies mentioned in §5.1, we used a number of additional strategies (most of which we had already tried initially, for parse selection, but rejected). One rule concerns the internals of noun compounds, which are flat in the GTB; we may wish to add some structure to them. As discussed in §3.2, biomedical noun compounds are predominantly left-bracketed, and left-bracketing was also our tie-breaking policy for annotating the test set. In the **BNC** strategy (*bracket noun compounds*), we added bracketing to noun compounds to have noun sequences maximally left bracketed, and adjectives attaching as high as possible. This makes assumptions which are not explicitly licensed by the data (and arguably overfits to our data set), so this transformation is only applied where no useful distinctions are made by less restrictive approaches.

We also use a mapping strategy which does not make changes to the tree structure but which use the POS labels to rule out trees, denoted **MP** for *map POS*. It uses the prefixes of the lexical types – e.g. a simple transitive verb would have the lexical type *v_np_le*, where the prefix 'v' indicates 'verb'. We used a mapping constructed by manual inspection of a correspondence matrix between the POS tags produced by TnT (Brants, 2000) and the lexical type prefixes from the gold-standard ERG parse of the same sentences over a WeScience subset. This gave us the matching ERG type prefixes for 20 PTB/GTB POS tags, which are mostly what we would expect for the open classes – e.g. *VB** verb tags map to the 'v' prefix.

During mapping, given a pairing of a GENIA tree and a set of ERG discriminants, for each POS tag or inner node in the GENIA tree, we find all lexical discriminants with the same character span. If there are multiple discriminants with different matching labels, and there is at least one allowed and one disallowed by the mapping, then we reject all disallowed discriminants. This is less sophisticated than the mapping technique of Tanaka et al. (2005) for various reasons.

6.2 Selecting a blazing strategy

There are a range of blazing strategies and combinations thereof, with varying levels of validity and restrictiveness. Ideally, during treebanking we would start with a more restrictive blazing strat-

		Standard		Blazed	
Ann 1	Decisions	6.25	7	3.51	4
	Time (sec)	150	144	113	107
Ann 2	Decisions	6.42	7	4.68	4
	Time (sec)	105	101	96	80

Table 3: Number of decisions and treebanking time (mean then median) using the fallback blazing configuration (80 sentences for each column)

	Ann. 1			
	Std	Blz		
Agreed Sentences	42.5	45.0	Std	Ann. 2
Agreed, excl rej	32.4	33.3		
Rejection F-score	80.0	82.4		
Constituent F-score	88.7	87.6		
Agreed Sentences	42.5	57.5	Blz	
Agreed, excl rej	39.5	45.2		
Rejection F-score	44.4	78.3		
Constituent F-score	86.2	84.8		

Table 4: Agreement figures for different combinations of blazed and unblazed overlap between annotators 1 and 2, with 40 sentences per cell. 'Agreed' is the percentage of those with an identical tree selected, or all trees rejected; 'excl rej' ignores sentences rejected by either annotator. 'Constituent F-score' (also excludes rejections) is the harmonic mean of the labelled per-constituent precision. 'Rejection F-score' is the harmonic mean of the precision of rejection decisions.

egy, and dynamically fall back to a less restrictive strategy, but this capability is not yet present in the Redwoods machinery. Our approach is based on the number of decisions being logarithmic in the number of trees. If we can get roughly 40 silver trees, the remaining treebanking is very tractable and fast, only requiring a few decisions chosen from a handful of remaining discriminants. However further restriction below this saves relatively little time, and increases the chance of the blazing removing the correct tree, which we wish to avoid (the machinery does not allow the treebanker to 'undo' either manual or blazed decisions, except by clearing and restarting).

The parse forest for treebanking was created by having a list of candidate blazing strategies using various combinations of **IEP** (least restrictive), **RP**, **BNC** and **MP** – with the combination **RP +BNC +MP** as the most restrictive. For each sentence, we select the least restrictive strategy which still gives us fewer remaining trees than a threshold of 40. If no strategies do so, we use the strategy which gives us the fewest trees for the given sentence. Using another subset of the GENIA treebank containing 864 parseable sentences, 48% of sentences came below the threshold of 40, while 36% were above and 16% were not disambiguated at all. Most sentences (41%) used the least restrictive configuration using **IEP** alone.

6.3 Blazed Treebanking Results

For this strategy to be useful for treebanking, it should be both more efficient, in terms of fewer decisions and less annotation time, and valid, in terms of not introducing a bias when compared to conventional unblazed treebanking. To evaluate these questions, we selected 160 sentences at random from the previously described parse forest of 864 sentences. These sentences were divided randomly into four equal-sized groups: blazed for both annotators, standard for both annotators, and two groups blazed for one annotator only, so we could compare data about timing and decisions between the standard and blazed sentences for each annotator, and inter-annotator agreement for each possible combination of blazed and standard treebanking. The divisions took no account of whether we were able to usably blaze the sentences, reflecting the real-world scenario, so some sentences in the blazed configuration had no restrictions applied. The items were presented to the annotators so they could not tell whether the other annotator was treebanking in standard or blazed configuration, to prevent subconscious biases affecting inter-annotator agreement. The experiments were conducted after both annotators had already familiarised themselves with the treebanking environment as well as the characteristics of the domain and the annotation guidelines.

Annotators worked in a distraction-free environment so we could get accurate timing figures. The treebanking machinery records how many decisions were made as well as annotation time, both important factors in annotation efficiency. The results for efficiency are shown in Table 3 where we see a 43% reduction in the mean decisions required for annotator 1, and 27% reduction for annotator 2. Annotator 1 also shows substantial 25% reduction in mean annotation time, but the time decrease for annotator 2 is only 8%. In 30% of successfully-blazed sentences, the annotators cleared all blazed decisions, suggesting it is sometimes too zealous.

For agreement, we show results for the strictest

possible criterion of exact tree match. For a less blunt metric that still roughly reflects agreement, we also follow Tanaka et al. (2005) in reporting the (micro-averaged) harmonic mean of precision across labelled constituents indexed by character span, where constituents selected by both annotators are treated as gold (inaccurately denoted 'F-score' for brevity). Annotators should also agree on rejected trees, where no parses are valid. In Table 4, we show exact match agreement accuracy (identical trees and matching rejections both count as correct), as well as the same figure ignoring sentences rejected by either, and the harmonic mean of precision of both labelled constituents and tree rejections. The figures are similar between cells, with notable exceptions being higher exact match when both annotators had blazed forests, and a surprising dip in the rejection "F-score" in the bottom left cell. The latter is partially because the rejection scores are based on small numbers of trees (5–10, the union of the sets of rejected trees), so are sensitive to small numbers of disagreements. In this particular case, of 7 trees rejected by either annotator, 2 were rejected by both.

6.4 Blazed Treebanking Discussion

The reductions in mean numbers of decisions strongly support the efficacy of this technique, although the discrepancies between the annotators suggest that the different treebanking techniques may be more or less amenable to speed-up using these tools. The timing figures are somewhat more equivocal, although still a substantial 25% for annotator 1. This is partially to be expected, since some of the treebanking will be taken up with unavoidable tasks such as evaluating whether the final tree is acceptable that blazing cannot avoid. However, the 8% reduction in mean annotation time for annotator 2 is still fairly modest. This could be affected by annotator 2's more extensive treebanking experience leading to a lower baseline time, with less room for improvement, but as we still see a 21% reduction in median parsing time this could be due to a few outlier sentences inflating the mean for the blazed configuration.

For agreement, we are primarily concerned here with whether blazing here introduces a bias that is distinguishable from what we see when annotators are working under standard non-blazed conditions – which may be manifested in decreased agreement between configurations where only one annotator has blazed data, and when both have non-blazed data. Thus the fact that we see quite similar agreement figures between the half-blazed and standard configurations is very encouraging (apart from the low F-score for rejections in one cell). This small amount of data suggests that any changes in the resultant trees introduced by blazing are hard to distinguish from the inevitable "background noise". Given this, the fact that we see a noticeably higher exact match score when both annotators have blazed sentences suggests we may be justified in using blazing to improve inter-annotator agreement, although the lower constituent score may indicate we have insufficient data to reach that conclusion.

7 Conclusion and Future Work

We have presented a procedure for blazing – using annotations from an external phrase structure treebank to constrain the parse forest produced by a precision HPSG grammar. Our work used the GENIA treebank and the ERG as the target grammar, although it would in principle be applicable to any similar phrase structure treebank and other grammars or even frameworks. The GENIA trees were mapped onto corresponding ERG parse forests and used to exclude incompatible trees. In conjunction with self-training, we used this to create a parse selection model for the ERG adapted to the biomedical domain. We also used it as a prefilter to the treebanking process to improve treebanking efficiency, and created an HPSG treebank of biomedical text.

For future work, we would investigate whether this training data can be useful to augment a small in-domain human-annotated treebank, and whether the methods do indeed generalise to other corpora and grammars.

Abstract

There has been substantial recent interest in aligning mentions of named entities in unstructured texts to knowledge base descriptors, a task commonly called *entity linking*. This technology is crucial for applications in knowledge discovery and text data mining. This paper presents experiments in the new problem of *cross-language entity linking*, where documents and named entities are in a different language than that used for the content of the reference knowledge base. We have created a new test collection to evaluate cross-language entity linking performance in twenty-one languages. We present experiments that examine issues such as: the importance of transliteration; the utility of cross-language information retrieval; and, the potential benefit of multilingual named entity recognition. Our best model achieves performance which is 94% of a strong monolingual baseline.

1 Introduction

Entity Linking involves aligning a textual mention of a named entity to the entry in a knowledge base (KB) that represents the mentioned entity, if it is present. The problem has two main complicating features: entities can be referred to using multiple name variants (*e.g.,* aliases or misspellings); and several entities can share the same name (*e.g.,* many people are named María Sánchez). Applications of entity linking include linking patient health records from separate hospitalizations, maintaining personal credit files, preventing identity crimes, and supporting law enforcement.

Starting in 2009 the NIST Text Analysis Conference (TAC) began conducting evaluations of technologies for knowledge base population (KBP). Systems addressing the entity linking subtask take as input a name string from a document and produce as output the knowledge base node, if any, corresponding to the mentioned entity. This capability is vital for knowledge discovery; without it, extracted information cannot be properly inserted in the correct KB node. We follow the TAC-KBP problem formulation and use its reference knowledge base, which was derived from a 2008 snapshot of English Wikipedia. In the present work our focus is on person entities. We seek to develop and evaluate technologies for matching foreign language names to the appropriate knowledge base descriptor (or *kbid*) in the English KB.

To support this research we created what we believe to be the first cross-language entity linking test collection. Our dataset includes twenty-one languages in addition to English, and covers five writing systems. Compared to the problem of monolingual (English) entity linking, a solution to the cross-language variant requires both a method to match foreign names to their English equivalents, and a way to compare contextual features from the non-English source document with contextual information about known entities stored in the KB. Figure 1 illustrates the process.

The rest of this paper is structured as follows. In Section 2 we discuss related work in entity linking and cross-language name matching. In Section 3 we present our approach to monolingual entity linking and describe the adaptations that are required to address the cross-language problem. Section 4 discusses the TAC-KBP evaluation and the construction of our test collection. Sections 5 and 6 present experiments exploring the effects of transliteration and cross-language content matching on the problem. Section 7 summarizes the main contributions of this work.

2 Related Work

Three types of named entity resolution are found in the literature: *identity resolution,* which matches structured or semi-structured entity descriptions, such as database records; *coreference resolution,* which clusters textual entity descriptions; and *entity linking,* which matches a textual description to a structured or semi-structured description. All three types of resolution have significant literature on monolingual processing; cross-language matching is less well studied.

Identity resolution and its closely related cousin *record linkage* grew out of the database community, which needs to determine when two database records represent the same entity. When matching records are found, identity resolution merges the two records, while record linkage simply notes the correspondence. Brizan and Tansel (2006) present a short overview of work in these fields. Typical approaches combine algorithmic matching of individual column values with hand-coded heuristics to combine the column scores and threshold the result.

Coreference resolution operates over text, determining when two entity mentions refer to the same entity. Approaches to within-document coreference resolution typically exploit syntactic, grammatical and discourse-level features, information that is not available when trying to resolve references across documents. Ng (2010) presents a comprehensive review of recent approaches to within-document coreference resolution. In contrast, cross-document coreference resolution typically assumes that within-document references have been resolved, and tries to place all such mention chains that refer to the same entity into a single cluster that represents that entity. Because the kinds of document-specific features that guide within-document coreference resolution are missing, research in cross-document coreference resolution tends to be more directly applicable to entity linking (which also lacks those features). The Web People Search Evaluation Workshop (Artiles et al., 2010) has been one of the recent drivers of research in cross-document coreference resolution, defining a clustering task that groups Web pages for multiple people bearing the same name.

Entity linking is a hybrid of the preceding two types of named entity resolution, matching a textual entity mention to a set of structured entity representations (usually called the *knowledge base*). Ji and Grishman (2011) present a good overview of the state of the art in monolingual entity linking, as practiced in the TAC evaluation. TAC data sets use a subset of Wikipedia entities for the knowledge base, manually curated query names, and ground truth identified by human assessors without pooling. Wikipedia has been another significant source of training and test data. Adafre and de Rijke (2005) explore automatically adding links between Wikipedia pages (albeit without focusing specifically on named entities). Bunescu and Pasca (2006) trained an SVM to predict whether a query entity matches a Wikipedia page by using hyperlinks within Wikipedia itself as the source of training and test data. Cucerzan (2007) studied identifying entity mentions in text and mapping them to Wikipedia articles. Mihalcea and Csomai (2007) and Milne and Witten (2008) each attempt to identify and properly induce hyperlinks for informative terms in Wikipedia articles (again without specific focus on named entities). Cross-language entity linking has not yet been

widely explored. TAC[1] and NTCIR.[2] have both for the first time announced plans for shared tasks for cross-language entity linking. Steinberger and Pouliquen (2007) describe a system that uses multilingual named entity recognition and cross-language name matching to automatically analyze tens of thousands of news stories daily; however, they do not conduct a formal evaluation of their name merging algorithm.

Contributing to each of these three kinds of named entity resolution are two essential underlying technologies: name matching and context matching. In name matching we ask the question, "Do two different strings represent the same name?" For example, we might like to know whether "Gadhafi" and "Khadafy" are two spellings of the same name. When used as a feature for machine learning, we ask the related question, "How similar are two name strings?"

Cross-language name matching is closely related to name transliteration. Indeed, transliterating a name to the language of the knowledge base, then performing monolingual name matching in that language, is a reasonable approach to cross-language name matching. Name transliteration has an extensive literature; Karimi *et al.* (2011) present a comprehensive survey of the topic.

Name matching does not demand transliteration though; transliteration is a generative process, and name matching requires only that a known name pair be given a score representing the degree of match. Snae (2007) presents a survey of popular name matching algorithms from the record linkage perspective. Monolingually, Levenshtein distance (1966) and its variants are used for basic string matching in many contexts. Cross-language approaches typically combine cross-language mappings of some sort with edit distance metrics. For example, Mani *et al.* (2008) demonstrate a machine learning approach to the problem.

The second crucial underlying technology is context matching. Monolingually, context matching can match on many contextual attributes, including words, entities, topics, or graph structures. Context matching in the translingual setting is closely related to cross-language information retrieval (CLIR); both tasks attempt to estimate the degree of similarity between texts written in different languages. Kishida (2005) presents an overview of the key methods in CLIR.

3 Cross-Language Entity Linking

Our approach to entity linking breaks the problem down into two main parts: *candidate identification* and *candidate ranking*. Candidate identification quickly identifies a small set of KB nodes that with high probability contain the correct answer, if it is present. Candidate ranking then considers each candidate in greater detail, producing a ranked list. We give a description of each of these steps in this section; complete details of our English entity linking approach, including descriptions of all of the features used and performance on the TAC-KBP datasets can be found in (McNamee, 2010).

3.1 Candidate Identification

As a KB may contain a large number of entries, we prefer to avoid brute force comparisons between the query and all KB entities. To identify the entries that might reasonably correspond to the input named entity, we rely on a set of fast name matching techniques. We have found that it is possible to achieve high recall without resorting to contextual features. We create indexes for the names in the KB to support fast lookup of potential matches. The specific techniques that we use include:

- Exact match of query and candidate names
- Known alias or nickname lookup
- Number of character 4-grams in common between query and candidate
- Sum of IDF-weighted words in common between query and candidate[3]

In tests on the TAC-KBP 2009 test collection, this approach achieved 97.1% recall. For only 2.9% of the queries, the proper KB referent for the query was not one of the candidates. These cases were particularly challenging because they involved ambiguous organization names or obscure personal nicknames. Our methods are similar to methods used in the database community, sometimes known as *blocking* (Whang et al., 2009) or *canopies* (McCallum et al., 2000).

[3] Inverse document frequency weights enable us to effectively match, for example, Q: Mary Elizabeth Surratt and KB: Mary Surratt, since *Surratt* is a highly discriminating term even though *Mary* is not.

Greek	9590	Albanian	257
Portuguese	6335		

Table 1: Number of training pairs for transliterating to English from each language.

To perform cross-language candidate identification, we transliterate[4] the query name to English, then apply our monolingual English heuristics. We used the multilingual transliteration system and training data developed by Irvine *et al.* (2010) in their experiments in orthographic transliteration. The number of training name/transliteration pairs varied by language and is given in Table 1. The source for most of this training data is Wikipedia, which contains links between article pages in multiple languages.

3.2 Candidate Ranking

The second phase in our approach is to score each viable candidate using supervised machine learning, and to select the highest scoring one as output. Each entity linking query is represented by a feature vector $\mathbf{x}$, where $\mathbf{x} \in \mathbb{R}^{\mathbf{k}}$, and each candidate y is a member of $\mathbb{Y}$, the set of entities in the knowledge base. Individual feature functions, $f_i(\mathbf{x}, y)$, are based on intrinsic properties of the query $\mathbf{x}$, intrinsic properties of a specific KB candidate y, and most commonly, on comparisons between the query and candidate. For each query our goal is to select a single KB entity y or choose NIL if the mentioned entity is not represented in the KB.

Thus, we desire that the correct knowledge base entity y' for a query $\mathbf{x}$ receives a higher score than any other knowledge base entities $y \in \mathbb{Y}, y \neq y'$. We chose a soft maximum margin approach to learning and used the ranking Support Vector Machine approach described by Joachims (2002) and implemented in the SVM$^{\text{rank}}$ tool. We selected a linear kernel for training speed, and set the slack parameter C to be 0.01 times the number of training examples.

In our system absence from the knowledge base is treated as a distinct ranked candidate, the so-called NIL candidate. NIL prediction is integrated into the process by including features that are indicative of no other candidate being correct. Considering absence as a ranked candidate eliminates the need to select a threshold below which NIL will be returned.

The classes of feature functions we use include:

- Name matching features between the query name (Q_{name}) and KB candidate (KB_{name})
- Text comparisons between the query document (Q_{doc}) and the text associated with the KB candidate
- Relation features, chiefly evidence from relations in the KB being evidenced in the Q_{doc}
- Co-occurring entities, detected by running named entity recognition (NER) on the Q_{doc} and finding matching names in the candidate's KB entry
- Features pertaining to the entity type of the KB candidate
- Indications that no candidate is correct and that NIL is therefore the appropriate response

3.2.1 Name matching

A variety of string similarity features are incorporated to account for misspellings, name variants, or partially specified names when trying to match the query name and KB entry. Christen (2006) discusses a variety of name matching features, several of which we adopt. One of the most useful is the Dice score over sets of character bigrams.

3.2.2 Cross-language name equivalence

In all of our cross-language experiments we added name matching features designed to directly calculate the likelihood that a given non-English name is equivalent to a given English name. The model is based on projections of character n-grams across languages (McNamee, 2008).

3.2.3 Contextual Similarity

We measure monolingual document similarity between Q_{doc} and the KB text (KB_{doc}) in two ways: using cosine similarity with TF/IDF weighting; and using the Dice coefficient over bags of words. IDF values are approximated using counts from the Google 5-gram dataset following the method of Klein and Nelson (2008). We also used features such as whether the query string occurs in the KB_{doc} and the KB_{name} occurs in the Q_{doc}.

[4]We use *transliteration* in a broad sense, to include situations where word translation rather than character transliteration is warranted.

To match contexts when the query document and KB are in different languages we treat cross-language context linking as a CLIR problem in which the query is created from the words in the vicinity of mentions of the query name. We adopt Probabilistic Structured Queries (PSQ) (Darwish and Oard, 2003), the key idea of which is to treat alternate translations of a query term as synonyms and to weight the contributions of each "synonym" using a statistical translation model. We index the Wikipedia articles in our test collection using a publicly available IR tool (Indri), learn isolated word translation probabilities from a parallel text using the Berkeley aligner[5] and Joshua,[6] and implement PSQ using Indri's *#wsyn* operator. Based on initial tests on training data, we use a contextual window size of $\pm$ 40 terms to the left and right of the query name mention as the source language query. In Roman alphabet languages, untranslated terms are retained in a character-normalized form.

3.2.4 Relation Features

As can be seen in Figure 2, the KB contains a set of attributes and relations associated with each entity (*e.g.,* age, employer, spouses, etc.). While one could run a relation extractor over the query document and look for relational equivalences, or contradictions, we chose a more straightforward approach: we simply treat the words from all facts as a surrogate "document" and calculate document similarity with the query document.

3.2.5 Named Entity Features

We applied the named entity tagger by Ratinov and Roth (2009) to query documents and created features from the tagger output, including: the percentage of NEs present in KB_{doc}; the percentage of words from all NEs that are present in KB_{doc}; and, the number of co-occurring NEs from Q_{doc} that are present in KB_{doc}. Except for an experiment described in Section 6.1, these features are only used in our monolingual English runs.

3.2.6 Entity Type Features

In English experiments the type of the query entity is determined from the NER output for the query document. Since the reference knowledge base provides a class (*e.g.,* scientist) and a type (*e.g.,* PER) for most entities, we can check whether the type of the KB entity is consistent with the query. This helps discourage selection of eponymous entries named after famous people (*e.g.,* the *USS Abraham Lincoln (CVN-72)*, a nuclear-powered aircraft carrier named after the 16th US president).

3.2.7 NIL Features

Some features can indicate whether it is likely or unlikely that there is a matching KB entry for a query. For example, if many candidates have strong name matches, it is reasonable to believe that one of them is correct. Conversely, if no candidate has high textual similarity with the query, or overlap between KB facts and the query document text, it becomes more plausible to believe that the entity is missing from the KB.

4 Building a Test Collection for Entity Linking in Twenty-One Languages

The TAC-KBP entity linking test collections from 2009 and 2010 include the following resources: (a) a large collection of English documents; (b) approximately 7,000 queries comprising English name mentions from those documents; (c) a reference knowledge base with over 818K entries; and (d) a set of annotations that identify the appropriate KB entry for each query, or absence (McNamee and Dang, 2009; Ji et al., 2010). The KB was created by processing a 2008 dump of English Wikipedia; each entry includes structured attributes obtained from Wikipedia's infoboxes in addition to the unstructured article text. A sample KB entry is shown in Figure 2. We use the TAC KB in all of our experiments.

Since the TAC-KBP queries and documents are only available in English, these data are not directly usable for cross-language entity linking. One approach would be to manually translate the TAC documents and queries into each desired language. This would be prohibitively expensive. Instead, we use parallel document collections and crowdsourcing to generate ground truth in other languages. A fundamental insight on which our work is based is that if we build an entity linking test collection using the English half of a parallel text collection, we can make use of readily available annotators and tools developed specifically for English, then project the English results onto the other language. Thus, we apply English NER to find person names in text (Ratinov and Roth, 2009), our English entity linking system to identify candidate entity IDs, and English annotators on Amazon's Mechanical Turk to select the correct

kbid for each name. Finally, we use standard statistical word alignment techniques implemented in the Berkeley Word Aligner (Haghighi et al., 2009) to map from English name mentions to the corresponding names in the non-English documents.

The six parallel collections we used came from the LDC and online sources. Together, these collections contain 196,717 non-English documents in five different scripts and twenty-one different languages. The final size of the query sets by language is shown in Table 2. We partitioned these queries and their associated documents into three sets per language: 60% for training, 20% for development, and 20% for test. In other work we give additional details about the creation of our test collection (Mayfield et al., 2011).

5 Experimental Results

5.1 English Baselines

Since all of our documents are from parallel corpora, every query is available in English and at least one other language. To serve as a point of comparison, we ran our monolingual entity linking system using the English version of the queries. We also determined performance of a baseline that predicts a *kbid* if its entity's name is a unique, exact match for the English query string, and NIL otherwise.

To compare approaches we calculate the percentage of time that the top-ranked prediction from a system is correct, which we call Precision-at-rank-one (P@1).[7] For the exact match baseline (*Exact*), the mean P@1 accuracy across all query sets is 0.897; on the TAC-KBP 2010 person queries, this baseline achieves a score of 0.832, which is lower most likely because of the intentional efforts at TAC to artificially increase query name ambiguity. Results for both English baselines are included in Table 3.

5.2 Cross-Language Name Matching

Table 3 also reports cross-language experiments in twenty languages where cross-language name matching is used to project the non-English query name into English (*NameMatch*), but the document remains untranslated. If the correct transliteration is known from our transliteration training data, we perform table lookup; otherwise the 1-best transliteration produced by our model is used.

Name matching alone produces serviceable performance. Averaged over all languages, performance on all queries is 93% of the monolingual English baseline. Losses tend to be small in the languages that use a Latin alphabet.

To investigate how errors in automated transliteration affect the system, we also conducted an experiment where the human-produced translations of the entity name were obtained from the English side of the parallel data. In Table 4 we report how this condition (*PerfectTrans*) performs relative to the monolingual baseline. Perfect name translation reduces the error rate dramatically, and performance of 99.2% of monolingual is obtained.

5.3 Name Matching and Context Matching

Table 3 also reports the use of both name matching and context matching using CLIR (+Context). Over all queries, performance rises from 92.9% to 93.9% of the English baseline. Bigger gains are evident on non-NIL queries. In fact, the pan-language average hides the fact that much larger gains are observed for non-NILs in Arabic, Czech, Macedonian, Serbian, and Turkish. We checked whether these gains are significant compared to NameMatch using the sign test; values indicating significant gains ($p < 0.05$) are emboldened.

5.4 Learning Rate

Our approach depends on having a quantity of labelled data on which to train a classifier. To investigate the effect that the number of training ex-

[7] At TAC this metric is called micro-averaged accuracy.

Table 4: Cross-language effectiveness (P@1) over all queries with optimal (a) transliteration and (b) named entity recognition. Simply having access to perfect transliterations achieves 99% of monolingual performance, on average. Providing lists of named entities mentioned in the document, in English, also improves performance. Bold values indicate statistically significant gains compared to the NameMatch (NM) run.

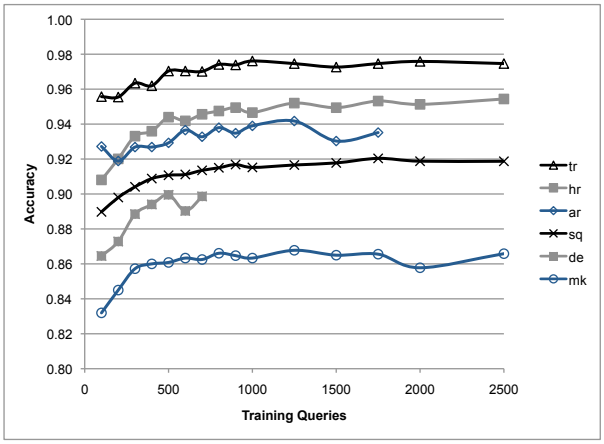

Figure 3: Classifier accuracy and training set size.

emplars has on classifier accuracy we built classifiers using fixed numbers of training queries. Figure 3 shows these results for selected languages. Each curve was produced by generating a random permutation of the training data, selecting the first k queries, and averaging the results over five trials. Note that the total amount of available training data differs by language. In all cases, accuracy rises quickly for the first 500 queries, and little improvement is observed after 1000 examples.

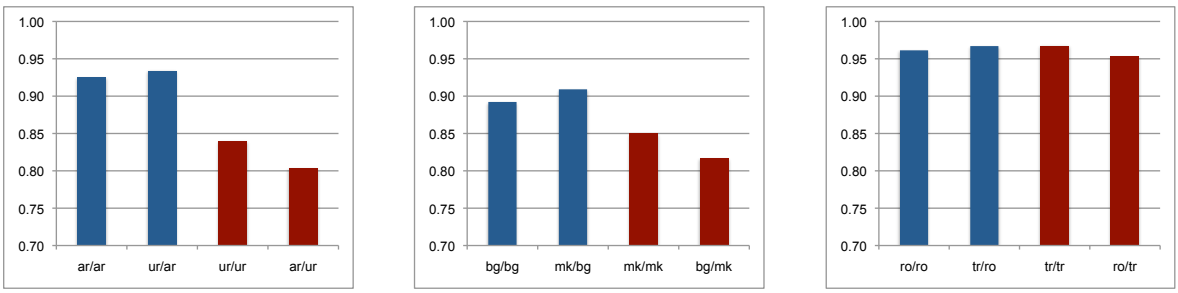

Figure 4: Training with annotations from another language using the same writing system. A label of xx/yy indicates that feature weights were trained using labelled data from language xx and then applied to queries on language yy.

6 Additional Experiments

6.1 Multilingual NER and Transliteration

We believe that the entities in a document that co-occur with a target entity are important clues for disambiguating entities. However, while we had ready access to named entity recognizers in English, we did not have NER capability in all of the languages of our collection. We would like to know how useful multilingual NER could be. To simulate this using our test collection, where all documents are from parallel texts with an English translation, we conducted an experiment that used the English documents only to recognize English named entities that co-occur with the query string; in every other respect, the untranslated foreign document was used by the system. The English NER may make errors, but we use it to simulate the performance of excellent non-English NER coupled with perfect entity translation.

Table 4 shows that co-occurring entities are a very helpful feature. Compared to name matching alone, average P@1 rises from 89.9% to 92.7%.

6.2 Cross-Language Training

Although we have demonstrated an efficient method for building a test collection for cross-language entity linking, it may still be difficult to obtain training data and tools for some less-resourced languages. Our process and feature set is largely language-independent, and we would like to know how feasible it is to make predictions without any language-specific training data by exploiting entity linking annotations from a related language. We examined pairs of languages using the same script – Arabic/Urdu, Bulgarian/Macedonian, and Romanian/Turkish – and trained classifiers using labeled data for the other language. Figure 4 shows that performance is not dramatically different when using annotations from a language sharing a common alphabet. This suggests that it is plausible to build a cross-language entity linking system without manually-produced annotations for a particular language.

7 Conclusions

In this paper we introduced a new problem, cross-language entity linking, and we described an approach to this problem that uses statistical transliteration and cross-language information retrieval. Using a newly-developed test collection for this task,[9] we demonstrated the success of the approach in twenty languages. Our best model using both name and context matching achieves average performance across twenty languages which is 94% of a strong monolingual English baseline, with individual languages ranging from 86% to 99%. Additionally, we characterized the number of training exemplars needed, demonstrated the feasibility of off-language training, and illustrated performance gains that are possible if combined multilingual NER/transliteration is available.

Acknowledgments

We are grateful to Chris Callison-Burch and Ann Irvine for their support with machine translation and orthographic transliteration, and to Tan Xu and Mohammad S. Raunak for their help in data curation. Support for one of authors was provided in part by NSF grant CCF 0916081.

[8] The English NEs run was significantly *worse* vs. NameMatch in Bulgarian (bg).

[9] The test collection is available at `http://web.jhu.edu/HLTCOE/datasets.html`.

Abstract

Annotating Named Entity Recognition (NER) training corpora is a costly process but necessary for supervised NER systems. This paper presents an approach to generate large-scale Chinese NER training data from an English-Chinese discourse level aligned parallel corpus. Difficulty of NER is different among languages due to their unique features. For example, the performance of English NER systems is usually higher than the Chinese ones on average. In our method, we first employ a high performance NER system on one side of a bilingual corpus. And then, we project the NE labels to the other side according to the word level alignment. At last, we select high-quality labeled sentences using different strategies and generate an NER training corpus. In our experiments, we generate a Chinese NER corpus with 167,100 sentences through an English-Chinese parallel corpus. The system trained on the automatically generated corpus attains a comparable result with the one trained on the manually-annotated corpus. Further experiments show that the NER performance is significantly improved on two different evaluation sets by using the generated training data as an additional corpus to the manually-labeled data.

1 Introduction

Named Entity Recognition (NER) is the task of identifying and classifying the names of persons, locations, organizations and other named entities in text, which plays an important role in many Natural Language Processing (NLP) applications such as information extraction, information retrieval, machine translation, and so on.

Supervised machine learning systems have proved successful for NER (Zhou and Su, 2002; Chieu and Ng, 2002; Takeuchi and Collier, 2002; Settles, 2004). They usually need manually-annotated high performance textual corpora. These corpora are considered as gold standards for training statistical models. However, corpora manually-annotating is so costly and time-consuming that the existing corpora are limited in both scale and scope for Chinese NER.

More seriously, the domain overfitting problem even worsens the corpora-shortage problem. Supervised NER approaches can often achieve high accuracy when a large annotated training set similar to the test data is available (Zhou and Su, 2002; Florian et al., 2003; Klein et al., 2003; Finkel et al., 2005). Unfortunately, if the test data has some difference from the training data, these approaches tend to not perform well. For instance, Ciaramita and Altun (2005) reported that the F1-score of a named entity recognizer trained on CoNLL 2003 Reuters corpus dropped from 90.8% (when tested on a similar Reuters set) to 64.3% (when tested on a Wall Street Journal set). A similar phenomenon of performance degradation in Chinese NER will be presented later in this paper (see Table 3).

Therefore, we try to solve the problems for Chinese mentioned above by automatically constructing large scale and scope training corpora.

Chinese NER is more difficult than English NER because of the lack of capitalization and the uncertainty in word segmentation. Our motivation is to collect large-scale training data and improve Chinese NER with the help of an exist-

Chiang Mai, Thailand, November 8 – 13, 2011.

ing high performance English NER system and a bilingual corpus.

In this paper, we employ a high performance NER system on the English side of a bilingual corpus. And then, the NE labels are projected to the Chinese side according to the word level alignment. At last, we select high-quality labeled sentences using different strategies and generate an NER training corpus.

In our experiments, statistical models are trained on the generated corpora, and compared with the model trained on a manually annotated corpus. The results show that our corpus is comparable to the manually-labeled corpus. Furthermore, the model trained on the combined corpus (generated and manually-labeled corpora) obtains an F1-score of 67.89% on 863-Evaluation corpus and 73.20% on OntoNotes corpus, which significantly outperforms the one trained on the manually-labeled corpus.

The contributions of this paper are as follows.

First, we present a method to generate large-scale Chinese NER training data from a bilingual corpus automatically. Our method trades off manual effort to annotate named entities in documents for effort to identify pairs of parallel documents, which is easier than NE manual annotation. For example, large scale of parallel documents can be extracted from the web automatically (Resnik and Smith, 2003; Zhang et al., 2006).

Second, we propose some strategies to select high-quality training data, which are very effective and important as the experiments show.

And third, we prove that our generated training data can be used as an additional corpus to improve the NER performance.

This paper is organized as follows. Section 2 discusses the related work. Section 3 describes our approach in detail. Section 4 presents and discusses the results of our experiments. Finally, we present our conclusions and future work in section 5.

2 Related Work

In this section, we introduce some previous work about NER training data generation.

The most closed related work to our approach is Yarowsky et al. (2001). They used word alignment on parallel corpora to induce several text analysis tools from English to other languages for which such resources are scarce. An NE tagger was transferred from English to French and achieved good classification accuracy. However, Chinese NER is more difficult than French and word alignment between Chinese and English is also more complex because of the tremendous difference between the two languages.

Huang and Vogel (2002) presented an integrated approach to extract an NE translation dictionary from an English-Chinese parallel corpus while improving the monolingual NE annotation quality for both languages. They started with low-quality NE tagging for both languages and improved the annotation result using alignment information. But they did not filter the annotated data and evaluate its impact for NER as training data.

Besides, some other resources have been used to generate NE tagged corpus.

An et al. (2003) and Whitelaw et al. (2008) used seed sets of entities and search engines to collect NER training data from the web. However, constructing of a high-quality seed list is also a time-consuming work.

Richman and Schone (2008) and Nothman et al. (2008) used similar methods to create NE training data. They transformed Wikipedia's links into named entity annotations by classifying the target articles into common entity types. But the article classification seeds also had to be hand-labeled in advance.

In the biomedical domain, Vlachos and Gasperin (2006) automatically created training material for the task of gene name recognition from the broader raw corpus using existing domain resources.

In our work, we generate a large scale Chinese NER training data from a bilingual corpus without any NE seed lists and filter it by using effective strategies. And we prove that it can improve the performance of Chinese NER as additional training data.

3 Our Approach

In this section we describe our approach of generating NER training data from a parallel corpus. The framework of our system consists of four components as shown in Figure 1.

- **Alignment:** Sentence alignment and word alignment is performed on a discourse-level aligned bilingual corpus.
- **English NER:** We identify NEs on the English side of the parallel corpus, making use of an existing high performance English NER system.
- **NE Candidates Generation:** Based on the result of the word alignment, we

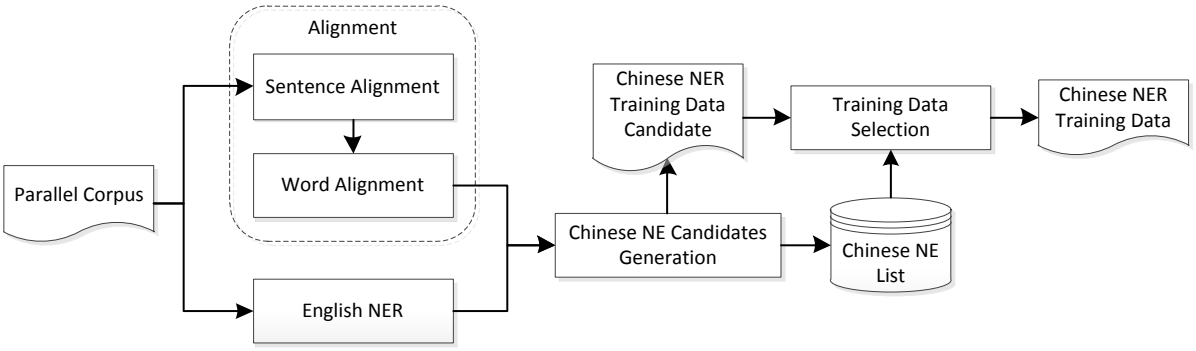

Figure 1. System Framework

project the English NE labels to the Chinese side and generate training data candidates. At the same time, we extract a Chinese NE list, which can be used as a dictionary resource.

- **Training Data Selection:** According to the different filtering strategies, we select high-quality labeled sentences from the candidates to form Chinese NER training data.

3.1 Alignment and Automatic English NER

First, we perform sentence level alignment by using Champollion toolkit[1].

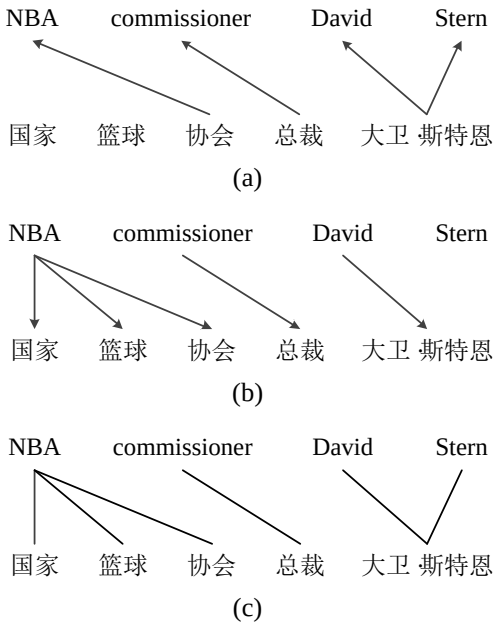

Figure 2. (a) Word Alignment from Chinese to English. (b) Word Alignment from English to Chinese. (c) The Merged Result of Both Directions. In (a), *国家* and *篮球* are aligned to NULL, the same to *Stern* in (b).

[1] http://champollion.sourceforge.net/

And then, GIZA++ toolkit[2] is used for word alignment. This toolkit can generate one-to-many word alignments in a certain direction (Chinese to English or English to Chinese). However, we need many-to-many alignments. Hence, we need GIZA++ to run on the bilingual corpus in both directions and merge the results, as shown in Figure 2.

English NER is easier than Chinese because of the capitalization information and the needlessness of word segmentation. So the performance of English NER systems is usually higher than the Chinese ones on average. Hence a widely used open-source NER system, Stanford Named Entity Recognizer[3] is employed to label NEs on the English side of the parallel corpus. The system is based on linear chain Conditional Random Field (CRF) (J.Lafferty et al., 2001) sequence models and can recognize three kinds of named entities (PERSON, LOCATION and ORGANIZATION).

To evaluate the robustness of Stanford NER system, we manually labeled 1000 English sentences from our bilingual corpus as a test set where the system achieves an F1-score of 89.32%. It is close to the result of 87.94%[4] on CoNLL 2003 NER test set.

3.2 Chinese NE Candidates Generation

After the English NER, we map the English NE labels to the Chinese side to discover Chinese NEs candidates, according to the result of word alignment.

We consider all related alignment pairs of every word within an English NE. For example, in Figure 3, the index of the organization name *NBA* is 1 and the related word alignment pairs

[2] http://www-i6.informatik.rwth-aachen.de/Colleagues/och/software/GIZA++.html
[3] http://nlp.stanford.edu/software/CRF-NER.shtml
[4] http://nlp.stanford.edu/projects/project-ner.shtml

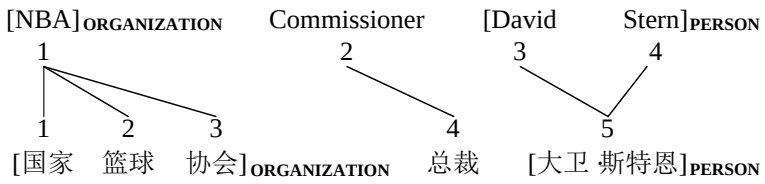

Figure 3. An Example of Chinese NE Candidates Generation

include 1-1, 1-2 and 1-3. Therefore, we can find the boundaries (from 1 to 3) of the corresponding Chinese translation *国家 篮球 协会*. There are also some English words connecting with NULL at Chinese side. We ignore these word alignment pairs.

According to the alignment, we project the NE labels from English to Chinese and generate the named entity candidates on the Chinese side.

3.3 Training Data Selection

However, the generated NER training data candidates are noisy because of the errors in English NER or word alignment. In this section, we present the strategies of selecting training data.

3.3.1 Filtering Based on Rules

As the common definition, a named entity is a continuous string, whether it is in English or in Chinese. So we assume that every named entity alignment pair is a closed alignment pair of two continuous strings, as shown in Figure 4 (a).

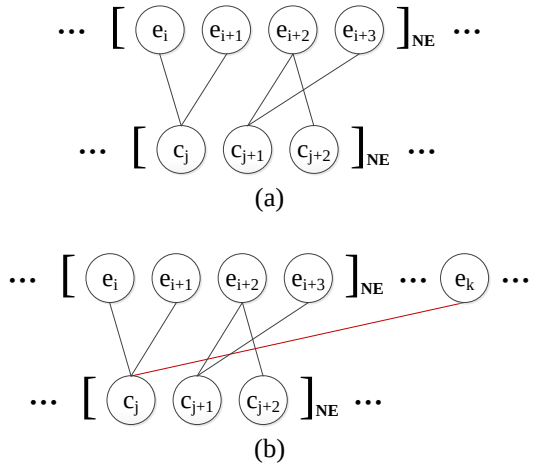

Figure 4. (a) An eligible case; (b) An ineligible case. In (b), the word alignment pair e_k - c_j is against the rule, while k > i+3 or k < i.

Based on this assumption, we make two alternative rules to filter the training data candidates. One is a soft filtering rule to retain training instances as many as possible. Another is a hard filtering rule to guarantee the quality of the generated corpus. These two rules are shown as follows:

- **Rule 1 (the soft rule):** Label a Chinese NE candidate as a non-NE, if a word within it has an alignment pair with an English word out of the corresponding English NE, such as Figure 4 (b).
- **Rule 2 (the hard rule):** Discard the whole sentence where there is a case satisfying Rule 1.

Rule 1 prefers to keep training instances as many as possible. But it may make some NEs be labeled as non-NE mistakingly on the Chinese side for incorrect word alignments, which are the noises in the generated training data. Rule 2 prefers to guarantee the quality of the generated data but may make useful training instances be discarded and the data scale shrinking.

Based on the rules, we can filter lots of ill conditioned named entity candidates, such as overlapped entities, nested entities and so on.

3.3.2 Filtering Based on Scores

Although many ill conditioned candidates are filtered out by the rules, the remaining data is still noisy because of the incorrect labeling of the English NER and the incorrect NE alignment. In fact, the accuracy of NE alignment is only affected by the boundary alignment of English and Chinese NEs. In other words, we do not care about how to align within or without the NEs. Hence, we score Chinese named entity candidates by formula 1.

$$score(N_c) = \varphi(N_e) \prod_{w \in B(N_c)} \left(\frac{1}{|A(w)|} \sum_{\langle e,w \rangle \in A(w)} p(\langle e,w \rangle) \right) \quad (1)$$

Here, $\varphi(N_e)$ denotes the confidence of the English named entity N_e, which is derived from Stanford NER system. $B(N_c)$ denotes the boundaries of the Chinese named entity N_c, which are actually the left-most and the right-most word within N_c. e denotes an English word, and w denotes a Chinese word. $A(w)$ denotes all related alignment pairs of word w in current Chinese

named entity N_c. $p(\langle e,w\rangle)$ denotes the probability of alignment $\langle e,w\rangle$, which is obtained from GIZA++.

As mentioned in section 3.1, Stanford NER is based on CRF. The inference of CRF is that given an observable sequence $\vec{x}$, we want to find the most likely set of labels $\vec{y}$ for $\vec{x}$. The probability of $\vec{y}$ given $\vec{x}$ is calculated as follows (J.Lafferty et al., 2001):

$$p(\vec{y}|\vec{x}) = \frac{1}{Z(\vec{x})}\prod_{j=1}^{n}\psi_j(\vec{x},\vec{y}) \quad (2)$$

$$Z(\vec{x}) = \sum_{\vec{y}'}\prod_{j=1}^{n}\psi_j(\vec{x},\vec{y}') \quad (3)$$

$$\psi_j(\vec{x},\vec{y}) = exp\left(\sum_{i=1}^{m}\lambda_i f_i(\mathrm{y}_{j-1},y_j,\vec{x},j)\right) \quad (4)$$

In formulae 2, 3 and 4, j denotes the index of the jth word in sequence $\vec{x}$. n denotes the length of $\vec{x}$. m denotes the number of the features.

Now the substring $x_k x_{k+1}\cdots x_{k+l}$ in $\vec{x}$ is labeled as an NE N_e. The label sequence of N_e is $y_k^* y_{k+1}^*\cdots y_{k+l}^*$ which is denoted as $\vec{y}_{N_e}^*$. We compute the marginal probability $\varphi(N_e)$ as follows:

$$\varphi(N_e) = \frac{Z(N_e,\vec{x})}{Z(\vec{x})} \quad (5)$$

$$Z(N_e,\vec{x}) = \sum_{\vec{y}':\, y'_{k\ldots k+l}=\vec{y}_{N_e}^*}\prod_{j=1}^{n}\psi_j(\vec{x},\vec{y}') \quad (6)$$

The factor $\varphi(N_e)$ of every English NE is used to measure the confidence of NER. We apply the forward-backward algorithm to compute them.

For $p(\langle e,w\rangle)$, we use the probabilities of alignment pairs which are computed by GIZA++. GIZA++ outputs the probability $p(t|s)$ of translating source word *s* as target word *t*. There are two kinds of probabilities of alignment in two directions. Since our alignment is bidirectional, we merge the probabilities in two directions to come up with formula 7.

$$p(\langle e,w\rangle) = max\{p(e|w),p(w|e)\} \quad (7)$$

Particularly we set $p(t|s)$ zero while the translation pair "s → t" does not exist in the translation table given by GIZA++.

We set experiential thresholds for every category to filter the Chinese NE candidates.

3.3.3 Recalling by a Chinese NE List

During the time of filtering the NE candidates, we can also extract the high-quality candidates as an NE list. We calculate the frequencies and the average scores of the candidates. We set thresholds of frequency and average score for every kind of NE candidate, and select the candidates with the highest frequency and score to compose a list. Table 1 shows some samples of the list.

An NE may be found correctly in some sentences where word alignment is easy, while the same one may be missed in others. Hence we use the extracted NE list to recall the missed NEs in the result of the former two steps.

NEs	Label	Average Score	Freq.
北京 (Beijing)	LOC	0.637	4615
克林顿 (Clinton)	PER	0.853	969
联合国 (UN)	ORG	0.471	436
台湾 海峡 (Taiwan Strait)	LOC	0.244	82

Table 1. Samples of the Chinese NE List

4 Experiments

We carried out experiments to investigate the quality and practical applicability of our NER training corpora generated from the bilingual corpus.

4.1 Data Set

We selected the LDC2003E14 multilanguage corpus and several bilingual parallel corpora[5] as the source corpus to generate NER training data. LDC2003E14 was derived from news of Foreign Broadcast Information Service (FBIS). We used the English-Chinese parallel news composed of 11,645 document pairs. The other bilingual parallel corpora contain 11,750 sentence pairs in all.

A manually annotated Chinese NER gold-standard data from People's Daily corpus was prepared as the contrasting data. The corpus was annotated with 7 tags: person, location, organization, date, time, number and miscellany. For the evaluation, the last 4 tags were removed. The corpus, composed of 47,426 sentences, was di-

[5] Six Chinese-English sentence-aligned corpora were used as extra data, including LDC2002T01, LDC2003E04, E07, E08, T17 and LDC2004T07.

vided into two parts: 37,426 for training and 10,000 for evaluation.

We also use other two corpora for the evaluation. One is the Chinese NER evaluation corpus from the National High Technology Development 863 Program of China in 2004. The other is OntoNotes Release 2.0 corpus. The tags except person, location and organization were removed in the 863-Evaluation corpus. The OntoNotes corpus was annotated with 18 fine-grained tags: 11 for named entities and 7 for numerical and time terms. We reduced the tags *NORP* and *LOCATION* into location, *FACILITY*, *GPE* and *ORGANIZATION* into organization, and *PERSON* into person. After this preprocessing, 14,547 NEs remained in the 863-Evaluation corpus and 13,658 NEs remained in the OntoNotes corpus. See Table 2 for a summary of the corpora used.

Corpus	# of sentences	
	TRAIN	TEST
People's Daily	37,426	10,000
863-Evaluation	---	3,923
OntoNotes	---	6,904

Table 2. Corpora Used for Evaluation

In addition, we manually labeled 1,000 sentences randomly extracted from FBIS corpus for the direct evaluation about the quality of our generated corpus.

4.2 The Baseline System

We trained a Maximum Entropy Markov Model (MEMM) on People's Daily training set as our baseline. State-of-the-art features (Wu et al., 2005) are used, which contain word features, POS features, position features, and labeled NE tag features. The model was evaluated on the People's Daily test set, 863-Evaluation corpus and OntoNotes corpus. The result is shown in Table 3.

	P	R	F1
People's Daily	90.77%	88.90%	89.82%
863-Evaluation	74.55%	59.13%	65.87%
OntoNotes	78.32%	64.28%	70.56%

Table 3. Evaluation Result of the Baseline System

From the evaluation result, we can see that the F1-score drops from 89.82% on People's Daily corpus to 65.87% on 863-Evaluation corpus and to 70.56% on OntoNotes corpus. It's similar to the report of Ciaramita and Altun (2005). The reason for this problem is that the model is overfitted to the training data and fails to fit the test data with different distribution. To ease the problem, we attempt to improve the coverage of the model by generating large scale and scope training corpora.

4.3 The Quality of the Generated Data

We evaluated the training data generated by using different strategies on the 1000 manually annotated sentences.

	Size	P	R	F1
Rule1 only	1,000	76.16%	48.56%	59.30%
Rule1+Score	1,000	76.36%	48.49%	59.32%
Rule1+List	1,000	73.99%	67.71%	70.71%
Rule1+Score + List	1,000	74.28%	67.65%	70.81%
Rule2 only	661	78.61%	74.76%	76.64%
Rule2+Score	661	**78.77%**	74.76%	76.72%
Rule2+List	661	78.06%	86.44%	82.04%
Rule2+Score +List	661	78.19%	**86.44%**	**82.11%**

Table 4. The Quality of Generated Corpora

Comparing the upper and lower parts of Table 4, we get a larger corpus based on Rule 1, but the recall rate is low. Rule 2 requires removing whole sentences with ineligible cases, so that we can get a higher quality but smaller corpus. The result is reasonable. If an ineligible case as shown in Figure 4 (b) occurs in a pair of English and Chinese sentences, it is possible that a named entity is labeled in the English sentence, but is not mapped to the correct Chinese string due to the errors of word alignment. For example, if *National Basketball Association* is recognized as an organization name in an English sentence, it is very possible that the translated organization name *国家篮球协会* exists in the Chinese sentence. But if *National Basketball Association* is not aligned to *国家篮球协会*, the Chinese NE will be missed. We should remove the whole sentences from the corpus, or they will be noises in the training data. The results show that Rule 2 outperforms Rule 1. In the remainder of our experiment, we use Rule 2 instead of Rule 1.

The strategy filtering candidates by scores can help to improve the precision. But the improvement of F1-score is marginal, because some correct training instances may be filtered out, which makes the recall rate decrease.

Training data	863-Evaluation corpus			OntoNotes corpus		
	P	R	F1	P	R	F1
People's Daily (PD)	74.55%	59.13%	65.87%	78.32%	64.28%	70.56%
Rule2 only	72.94%	41.73%	53.09%	77.79%	46.90%	58.52%
Rule2+Score	73.66%	41.53%	53.11%	78.42%	46.72%	58.56%
Rule2+List	72.64%	58.08%	64.55%	76.84%	61.80%	68.50%
Rule2+Score+List	73.04%	58.12%	64.73%	76.90%	61.82%	68.54%
Rule2+Score+List+PD	**75.95%**	**61.38%**	**67.89%**	**80.35%**	**67.22%**	**73.20%**

Table 5. Test Results for the Generated Training Data

We extract a Chinese NE list containing 824 NEs with the highest frequency and scores from the corpus. Based on the NE list, we can recall many NEs missed by other strategies with only a little expense of precision. The recall rates are substantially improved from 48.56% to 67.71% based on Rule 1 and from 74.76% to 86.44% based on Rule 2.

Here, we chose the best-performing thresholds of the strategies in our experiments. The results show that our strategies are effective for improve the quality of the training data.

As mentioned in section 3.1, the F1-score of Stanford NER on our parallel corpus is 89.32%. The best F1-score of the generated training data in Table 4 is 82.11%. Thus, we roughly infer that about 8.07% (= 1 - 82.11% / 89.32%) correct NE information is lost in the process of the Chinese NER training data generation.

4.4 Comparison between the Manually-labeled Data and the Generated Data

We trained MEMMs on the generated corpora using the same features as the baseline. As shown in Table 5, we get a basic result by using Rule 2. On 863-Evaluation corpus for example, we get a marginal raise (0.72%) of precision but a drop (0.20%) of recall by using Rule 2 and Score strategy, and get a substantial raise (16.35%) of recall with a drop (0.30%) of the precision by using Rule 2 and List strategy. The situation is similar on OntoNotes corpus. The results are consistent with the quality of the training data shown in Table 4. And it is reasonable that better training data leads to higher NER performance. The model trained on our corpus generated by using all of the strategies gets a comparable result with the baseline system.

We also use the generated corpus as additional training data to the gold-standard data. The last row in Table 5 shows that this approach leads to an improvement of the NER performance. We also perform a paired significance test[6], which shows that the improvement is significant.

Our generated corpus contains 167,100 sentences, which are much more than sentences in the baseline corpus. Furthermore, it is generated without any manual annotation. The size could be limitless as long as there are plenty of parallel corpora available.

4.5 The Effect of the Generated Data Size

Figure 5 illustrates the effect of varying the size of the generated training data set. Increased training data tends to improve performance until the size reaches about 67k sentences for 863-Evaluation corpus and 33k for OntoNotes corpus. But after that, improvements are marginal.

We believe that there are two reasons causing this result. On the one hand, the noises increase when more training data is used. And the training data gets a balance between the noises and the correct training instances when the size reaches a certain point. On the other hand, a subset of the training data can represent the whole data, especially for the data from a simplex source. So we should collect data from a wider range of sources.

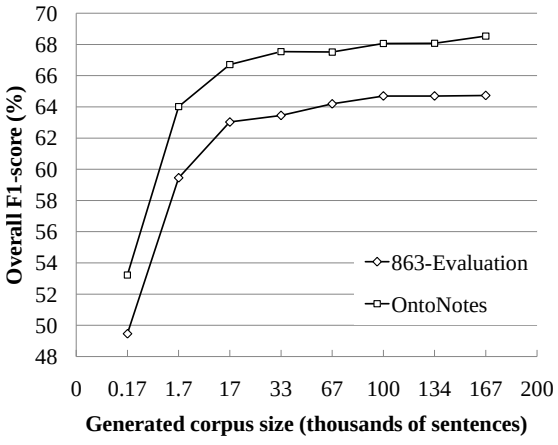

Figure 5. The Effect of Varying the Generated Corpus Size

[6] We used Zhang's significance tester (Zhang et al., 2004).

Training data	863-Evaluation corpus			OntoNotes corpus		
	PER	LOC	ORG	PER	LOC	ORG
People's Daily (PD)	59.91%	74.97%	35.61%	72.96%	76.89%	47.72%
Rule2+Score+List	62.68%	72.36%	28.81%	66.36%	76.43%	44.78%
Rule2+Score+List+PD	**66.15%**	**75.00%**	**36.22%**	**75.24%**	**78.31%**	**55.10%**

Table 6. Test Results for Each NE Category

4.6 The Performance of Each NE Category

To analyze overall error, our per-class F1-score is shown in Table 6. Training on the combined corpus could improve the performance of each NE category. The improvements are substantial in all categories except LOC on 863-Evaluation.

In general, the results of ORG entities are lower than the results of PER and LOC. The possible reason may be that ORG names are more complex than PER and LOC names. They usually consist of more words, which may result in more word alignment errors and then lead to more training instances filtered out. Fewer training instances might lead to a poorer performance. In addition, English ORG entity recognition is also more difficulty, which also results in more noises among the ORG name training instances.

5 Conclusion and Future Work

To solve the data-shortage and domain overfitting problems, we attempt to enlarge the Chinese NE training data automatically.

In this paper, we present a method of generating NER training data automatically from a bilingual parallel corpus. We employ an existing high-performance English NER system to recognized NEs at the English side, and then project the labels to the Chinese side according to the word alignment. To guarantee the quality of the training data, we propose effective filtering strategies. The results show that our training data is comparable with the manually-labeled data and can improve the performance of NER as an additional corpus.

Besides, the training data could be expanded easily as long as there are plenty of parallel corpora available. And identifying pairs of parallel documents is much easier than NE training data annotation. Generating training data from parallel corpora thus provides an alternative way of collecting data required for Chinese NER. Our method can be easily adapted to other languages.

In the future, we will try to improve the entity alignment and propose other better filtering strategies. Moreover, we will try to make use of more parallel corpora from a wider range of sources, because more parallel corpora may improve the accuracy of word alignment and widen the coverage of the generated NE corpus.

Learning the Latent Topics for Question Retrieval in Community QA

Abstract

Community-based Question Answering (cQA) is a popular online service where users can ask and answer questions on any topics. This paper is concerned with the problem of question retrieval. Question retrieval in cQA aims to find historical questions that are semantically equivalent or relevant to the queried questions. Although the translation-based language model (Xue et al., 2008) has gained the state-of-the-art performance for question retrieval, they ignore the latent topic information in calculating the semantic similarity between questions. In this paper, we propose a topic model incorporated with the category information into the process of discovering the latent topics in the content of questions. Then we combine the semantic similarity based latent topics with the translation-based language model into a unified framework for question retrieval. Experiments are carried out on a real world cQA data set from Yahoo! Answers. The results show that our proposed method can significantly improve the question retrieval performance of translation-based language model.

1 Introduction

Over the past few years, large scale question and answer archives have become an important information resource on the Web. These include the traditional FAQ archives constructed by the experts or companies for their products and the emerging community-based online services, such as Yahoo! Answers[1] and Live QnA[2].

The major challenge for cQA retrieval is the lexical gap (or *lexical chasm*) between the queried questions and the question-answer pairs in the archives (Jeon et al., 2005; Xue et al., 2008). To solve the *lexical gap* problem, most researchers regarded the question retrieval task as a statistical machine translation problem by using IBM model 1 (Brown et al., 1993) to learn the word-to-word translation probabilities (Berger and Lafferty, 1999; Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009; Cao et al., 2010). Although the translation-based language model(TRLM) has yielded the state-of-the-art performance for question retrieval, they model the word translation probabilities without taking into account the distribution of words in the whole content.

In this paper, we argue that it is beneficial to exploit the latent topic information for question retrieval. The basic idea is as follows: first we employ the topic model (e.g., LDA) to discover the latent topics in the content of questions, and calculate the semantic similarity between questions based on the latent topic information. Moreover, a distinctive feature of question-answer archives in cQA is that cQA services always organize questions into a hierarchy of categories. We propose an improved latent topic model by introducing the category information of questions. To solve the *lexical gap* problem, the translation-based language model extracts knowledge from question-answer pairs which are collected from cQA service. Latent topic model extracts knowledge from the distribution of words and categories in whole cQA archives. We assume that the two knowledge are complementary to each other, as we will show in the experiment.

In order to illustrate the above ideas clearly, we give an example of retrieving semantically equivalent or relevant to the queried questions in Figure 1. Given question $Q1$, we get a ranked list of semantically similar questions (Q_2, Q_3, Q_4, Q_5) using state-of-the-art translation-based lan-

Chiang Mai, Thailand, November 8 – 13, 2011.

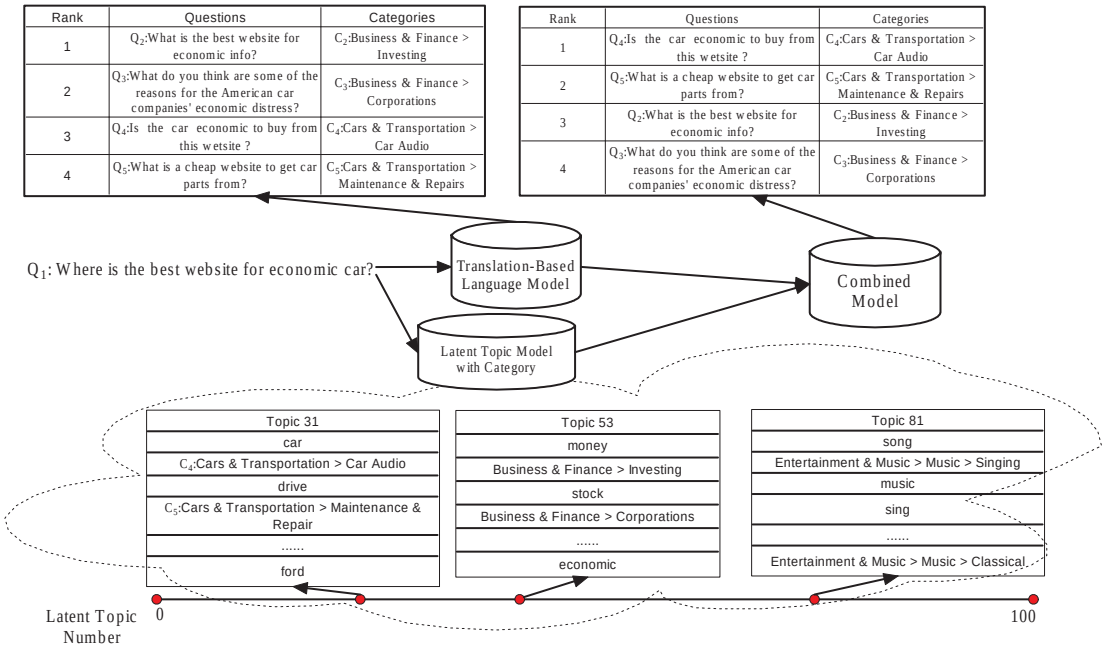

Figure 1: Illustration of our proposed approach.

guage model. All the semantically similar questions are with their corresponding categories. Our proposed latent topic model models the distribution of words, categories of the whole content. We illustrate in Figure 1 a matching of the top words and categories from a few topics. We can see that the word *car* is more related to categories "Cars & Transportation>Car Audio" and "Cars & Transportation>Maintenance & Repairs" than the word "economic" to categories "Business & Finance>Investing" and "Business & Finance>Corporations" in latent topics. Using this information from the latent topic model, we can rerank the retrieved question. Therefore, combining the translation-based language model with the latent topic model with categories, we can get the ranked list of semantically similar questions (Q_4, Q_5, Q_2, Q_3) which are better than the previous retrieval result.

Specifically, our contributions are as follows:

1. We employ the topic model to discover the latent topic information in the content of questions for cQA retrieval (in Section 4.1.)

2. We introduce the category information into the process of discovering the latent topics. (in Section and 4.2).

3. We propose to combine the semantic similarity based latent topics with the translation-based language model into a unified framework to further improve the retrieval performance (in Section 4.4).

4. Finally, we conduct the experiments on cQA data set from Yahoo! Answers for question retrieval. The results show that our proposed approach significantly outperform the state-of-the-art translation-based language model (in Section 5).

The remainder of this paper is organized as follows. Section 2 reviews the related work on community-based question retrieval. Section 3 presents the existing question retrieval models. Section 4 presents the topic model incorporated with category information for question retrieval. Section 5 presents the experimental results. Finally, we conclude and offer the further work in Section 6.

2 Related Work

Recently, the research of question retrieval has been further extended to the cQA data. Jeon et al. (2005) proposed a word-based translation model for automatically fixing the lexical gap problem. Experimental results demonstrated that translation model significantly outperformed the traditional methods (i.e., VSM, BM25, LM). Xue et al. (2008) proposed a translation-based language model for question retrieval. The results indicated that translation-based language model further improved the retrieval results and obtained the

state-of-the-art performance.

Subsequent work on translation models focused on providing suitable parallel data to learn the translation probabilities. Lee et al. (2008) tried to further improve the translation probabilities based on question-answer pairs by selecting the most important terms to build compact translation models. Bernhard and Gurevych (2009) proposed to use as a parallel training data set the definitions and glosses provided for the same term by different lexical semantic resources. Cao et al. (2010) explored adding the category information into the translation model for question retrieval. Zhou et al. (2011) proposed a phrase-based translation model for question retrieval and obtained the state-of-the-art performance.

However, all the existing methods ignore the latent topics information in calculating the semantic similarity between questions. In this paper, we present a new approach to discover the latent topic of questions for improving the performance of translation-based language models for question retrieval. Moreover, we introduce the category information into the process of discovering the latent topics. To the best of our knowledge, none of the existing studies addressed question retrieval in cQA by learning the latent topics.

3 Preliminaries

3.1 Language Model

The unigram language model has been widely used for question retrieval on community-based Q&A data (Jeon et al., 2005; Xue et al., 2008; Cao et al., 2010). To avoid zero probability, we use Jelinek-Mercer smoothing (Zhai and Lafferty, 2001) due to its good performance and cheap computational cost. So the ranking function for the query likelihood language model with Jelinek-Mercer smoothing can be written as:

$$P_{LM}(q|Q) = \prod_{w \in \mathbf{q}} (1-\lambda) P_{ml}(w|Q) + \lambda P_{ml}(w|C) \quad (1)$$

$$P_{ml}(w|Q) = \frac{\#(w,Q)}{|Q|}, \;\; P_{ml}(w|C) = \frac{\#(w,C)}{|C|} \quad (2)$$

where $\mathbf{q}$ is the queried question, Q is a historical question, C is background collection, λ is smoothing parameter. $\#(t,Q)$ is the frequency of term t in Q, $|Q|$ and $|C|$ denote the length of Q and C, respectively.

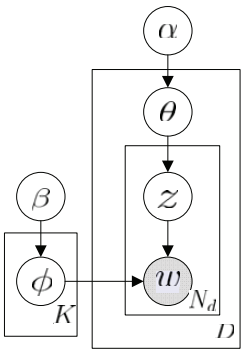

Figure 2: Latent Dirichlet Allocation.

3.2 Translation Model

Previous work (Berger et al., 2000; Jeon et al., 2005; Xue et al., 2008) consistently reported that the word-based translation models (TR) yielded better performance than the traditional methods (VSM, Okapi and LM) for question retrieval. These models exploited the word translation probabilities in a language modeling framework. According to Jeon et al. (2005) and Xue et al. (2008), the ranking function can be written as:

$$P_{TR}(q|Q) = \prod_{w \in \mathbf{q}} (1-\lambda) P_{tr}(w|Q) + \lambda P_{ml}(w|C) \quad (3)$$

$$P_{tr}(w|Q) = \sum_{t \in Q} P(w|t) P_{ml}(t|Q), \;\; P_{ml}(t|Q) = \frac{\#(t,Q)}{|Q|} \quad (4)$$

where $P(w|t)$ denotes the translation probability from word t to word w.

3.3 Translation-Based Language Model

Xue et al. (2008) proposed to linearly mix two different estimations by combining language model and translation model into a unified framework, called TRLM. The experiments show that this model gains better performance than both the language model and the translation model. Following Xue et al. (2008), this model can be written as:

$$P_{TRLM}(q|Q) = \prod_{w \in \mathbf{q}} (1-\lambda) P_{mx}(w|Q) + \lambda P_{ml}(w|C) \quad (5)$$

$$P_{mx}(w|Q) = \delta \sum_{t \in Q} P(w|t) P_{ml}(t|Q) + (1-\delta) P_{ml}(w|Q) \quad (6)$$

4 Topic Model Incorporated with Category Information for Question Retrieval

Previous work on question retrieval in cQA, employs different retrieval models, such as

Symbol	Description
K	the number of topics
N	the number of questions
$\|V\|$	the number of unique words
$\|C\|$	the number of unique leaf categories
N_q	the number of distinct words in question q
θ_q	multinomial distribution over topics specific to question q
ϕ_z	multinomial distribution over words specific to topic z
ψ_z	multinomial distribution over categories specific to topic z
z_{qi}	the topic of the ith word in question q
c_{qi}	the category of the ith word in question q
w_{qi}	the ith word in question q

Table 1: Meanings of the notations used in this paper

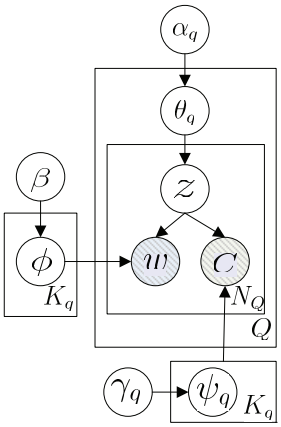

Figure 3: Topic model incorporated with category information.

VSM (Salton et al., 1975), LM (Zhai and Lafferty, 2001), TR (Jeon et al., 2005) and TRLM (Xue et al., 2008). However, all these existing models ignore the latent topics in calculating the semantic similarity between questions. In this Section, we explore the latent topic information for question retrieval.

4.1 Topic Model for Question Retrieval

Before introducing our proposed method, we first briefly describe the basic Latent Dirichlet Allocation (LDA) model (Blei et al., 2003). The notations we used in this paper are presented in Table 1, and the graphic model representations of LDA model is shown in Figure 2. LDA models the generation of document content as two independent stochastic processes by introducing latent topic space. For an arbitrary word w in document d, (1) a topic z is first sampled from the multinomial distribution θ_d, which is generated from the Dirichlet prior parameterized by α; (2) and then the word w is generated from multinomial distribution ψ_z, which is generated from the Dirichlet prior parameterized by β. The two Dirichlet priors for documents-topic distribution θ_d and topic-word distribution ψ_z reduce the probability of overfitting training documents and enhance the ability of inferring topic distribution for new documents.

In cQA, the historical questions in the archives can be considered as documents. In this paper, we employ the state-of-the-art topic model −− LDA (Blei et al., 2003) to discover the latent topics in the content of questions. We assume that a queried question q and the historical questions Q in cQA archives are represented by a distribution over topics. We obtain the topic distribution of a question by merging the topic distributions of words in question. Formally, we have

$$P_{TM}(z|q) = \frac{1}{|q|}(\lambda_1 \sum_{w \in q} P(z|w) \tag{7}$$

Then, we assume that a question Q in the archives and a queried question q have the same prior probability, so the score function between the two questions can be written as:

$$\begin{aligned} P_{TM}(q|Q) &= \sum_z P(q|z) P_{TM}(z|Q) \\ &= \sum_{z \in K} \frac{P(z|q)P(q)}{p(z)} P_{TM}(z|Q) \\ &= \frac{K}{|q|} \sum_{z \in K} P_{TM}(z|q) P_{TM}(z|Q) \end{aligned} \tag{8}$$

4.2 Topic Model Incorporated with Category Information

In cQA, the questions are organized into a hierarchy of categories. For example, the subcategory "Computer Networking" is a child category of "Computers & Internet" in Yahoo! Answers. When a user asks a question, the user chooses a category for the question and at then post the question in that category. For example, the questions in the subcategory "Computer Networking" mainly related to computer software or networking equipments.

To utilize the category information provided by cQA, we propose a topic model incorporated with category information (TMC) to discover the latent topics in the content of questions. The graphic

representation of our proposed TMC model is presented in Figure 3. Inspired by the related work on topic analysis (Blei et al., 2003; Griffiths and Steyvers, 2004; Zhou et al., 2008; Wang and McCallum, 2006; Guo et al., 2008; Celikyilmaz et al., 2010; Jo and Oh, 2011), we make the following assumptions about the probabilistic structure of TMC model. First, each question is modeled as a multinomial distribution over latent topics, and each topic is modeled as a multinomial distribution over words and a multinomial distribution over categories. Second, the prior distributions for topics, words and categories follow different parameterized Dirichlet distribution, which is conjugate prior for multinomial distribution. In Figure 3, for each word w in question q, a topic z is first drawn from the multinomial distribution θ_q, and then a word is sampled from the multinomial distribution ϕ_z and a category c is also sampled from the multinomial distribution ψ_z for the word. Repeating this process N_q times, we get the words and category for a question. We obtain the whole question set by repeating the above process N times. After that, we obtain the topic distribution of a question by merging the topic distributions of words category. So equation (7) can be rewritten as:

$$P_{TMC}(z|q) = \frac{1}{1+|q|}(\lambda_2 P(z|c) + \lambda_3 \sum_{w \in q} P(z|w)) \quad (9)$$

In equation (9), the topic distribution of question category is modeled by $\lambda_2 P(z|c)$, the topic distribution of words in question is modeled by $\lambda_3 \sum_{w \in q} P(z|w)$. The relative importance of these two parts is adjusted through λ_2 and λ_3.

Introducing the category information into the process of discovering the latent topics, equation (8) can be rewritten as:

$$\begin{aligned} P_{TMC}(Q|q) &= \sum_z P(Q|z) P_{TMC}(z|q) \\ &= \sum_{z \in K} \frac{P(z|q)P(q)}{p(z)} P_{TMC}(z|Q) \\ &= \frac{K}{|q|} \sum_{z \in K} P_{TMC}(z|q) P_{TMC}(z|Q) \quad (10) \end{aligned}$$

4.3 Parameter Estimation for TMC

After introducing our proposed TMC method, we will describe how to estimate the parameter used in the model. In TMC, we introduce the new parameters, which lead to the inference not be done exactly. Expectation-Maximum (EM) algorithm is a possible choice for estimating the parameters of models with latent variables. However, EM suffers from the possibility of running into local maxima and the high computational burden. Therefore, we employ an alternative approach − Gibbs sampling (Griffiths, 2002), which is gaining popularity in recent work on latent topic analysis (Griffiths and Steyvers, 2004; Zhou et al., 2008; Wang and McCallum, 2006; Guo et al., 2008; Jo and Oh, 2011).

After training the model, we can get the following parameter estimations as:

$$\hat{\theta}_{qz} = \frac{n_{qz} + \alpha_z - 1}{\sum_{z'=1}^{K}(n_{qz'} + \alpha_{z'}) - 1}$$

$$\hat{\phi}_{zw} = \frac{n_{zw} + \beta_w - 1}{\sum_{v=1}^{|V|}(n_{zv} + \beta_v) - 1}$$

$$\hat{\psi}_{zc} = \frac{n_{zc} + \gamma_c - 1}{\sum_{c'=1}^{|C|}(n_{zc'} + \gamma_{c'}) - 1}$$

4.4 Combining the TMC with the TRLM for Question Retrieval

Since the TMC model and the translation-based language model use different strategies for question retrieval, it is interesting to explore how to combine their strength. In this section, we propose an approach to linearly combine the TMC model with the TRLM model for question retrieval. In this paper, we choose translation-based language model (TRLM) (Xue et al., 2008) as the foundation of our solution since TRLM has gained the state-of-the-art performance for question retrieval (Xue et al., 2008; Cao et al., 2010). Formally, we have

$$\begin{aligned} P_{TMC-TRLM}(q|Q) = \mu P_{TRLM}(q|Q) \\ + (1-\mu) P_{TMC}(q|Q) \quad (11) \end{aligned}$$

In equation (11), the relative importance of TMC and the TRLM is adjusted through μ. When $\mu = 1$, the retrieval model is based on TMC. When $\mu = 0$, the retrieval model is based on TRLM.

5 Experiments

5.1 Data Set and Evaluation Metrics

We collect the questions from Yahoo! Answers and use the *getByCategory* function provided in Yahoo! Answers API[3] to obtain Q&A threads

Table 2: Number of questions in each first-level category

from the Yahoo! site. More specifically, we utilize the *resolved* questions and the resulting question repository that we use for question retrieval contains 2,288,607 questions. Each resolved question consists of four parts: "question title", "question description", "question answers" and "question category". For question retrieval, we only use the "question title" part and "question category" part. It is assumed that the titles and categories of the questions already provide enough semantic information. There are 26 categories at the first level and 1,262 categories at the leaf level. Each question belongs to a unique leaf category. Table 2 shows the distribution across first-level categories of the questions in the training data set. To learn the translation probabilities, we use about one million question-answer pairs from another data set.[4]

We randomly select 252 questions for test set and another 252 questions for development set. We select the test set and development set in proportion to the number of questions and categories against the whole distribution to have a better control over a possible imbalance. To obtain the ground-truth of question retrieval, we employ the Vector Space Model (VSM) (Salton et al., 1975) to retrieve the top 20 results and obtain manual judgements. The top 20 results don't include the queried question itself. Given a returned result by VSM, an annotator is asked to label it with "relevant" or "irrelevant". If a returned result is considered semantically equivalent to the queried question, the annotator will label it as "relevant"; otherwise, the annotator will label it as "irrelevant". Two annotators are involved in the annotation process. If a conflict happens, a third person will make judgement for the final result. In the process of manually judging questions, the annotators are presented only the questions. **Metrics**: We evaluate the performance of our approach using the following metrics: **Mean Average Precision** (MAP) and **Precision@n** (P@n). MAP rewards methods that return relevant questions early and also rewards correct ranking of the results. P@n reports the fraction of the top-n questions retrieved that are relevant. We perform a significant test, i.e., a t-test with a default significant level of 0.05.

Parameter Selection: The experiments use many parameters. Following the literature, we set the smoothing parameter λ in equations (1), (3) and (5) to 0.2 (Cao et al., 2010), and the parameter δ in equation (6) to 0.8 (Xue et al., 2008; Cao et al., 2010), which controls the translation component's impact. Other parameters are tuned on the development set, as we will show in the experiments.

5.2 Topic Number Selection

In this section, we concentrate on how to select proper topic numbers to obtain our model with best performance on our test set and enough iterations in Algorithm 1 to prevent overfitting problem. Here, following (Guo et al., 2008), we use perplexity to estimate the performance of our model. We calculate the perplexity on development set, which is a sequence of tuples $(q, w, c) \in D_{dev}$:

$$\text{Perplexity}(D_{dev}) = exp\{-\frac{\sum_{(q,w,c)\in D_{dev}} \ln P(w,c|q)}{|D_{dev}|}\}$$

Here, the probability $P(w, c|q)$ is calculated according to the parameters trained from the historical question-answer pairs:

$$P(w,c|q) = \sum_{z=1}^{K} P(w|z)P(c|z)P(z|q)$$

Figure 4(a) shows the influence of iteration number of Gibbs sampling on the model generalization ability. Empirically, we set the topic number as 100 and change the iteration number in the experiments. Note that the lower perplexity value indicates better generalization ability on the hold-out testing set. From Figure 4(a), it is seen that the perplexity values decreases dramatically when the iteration times are below 200.

Figure 4(b) shows the perplexity values for different settings of topic number. From the Figure, we see that the perplexity decreases when the

[4]The Yahoo! Webscope dataset Yahoo answers comprehensive questions and answers version 1.0.2, available at http://reseach.yahoo.com/Academic_Relations.

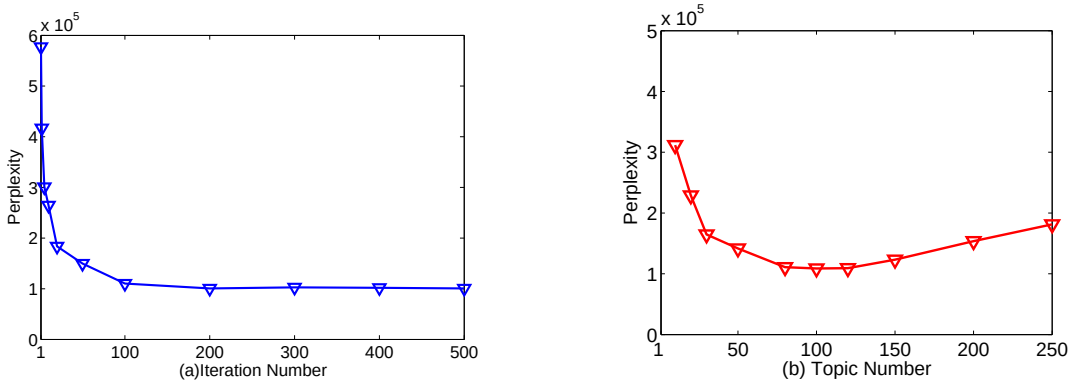

Figure 4: Perplexity on different iteration numbers(a) and topic number selection(b).

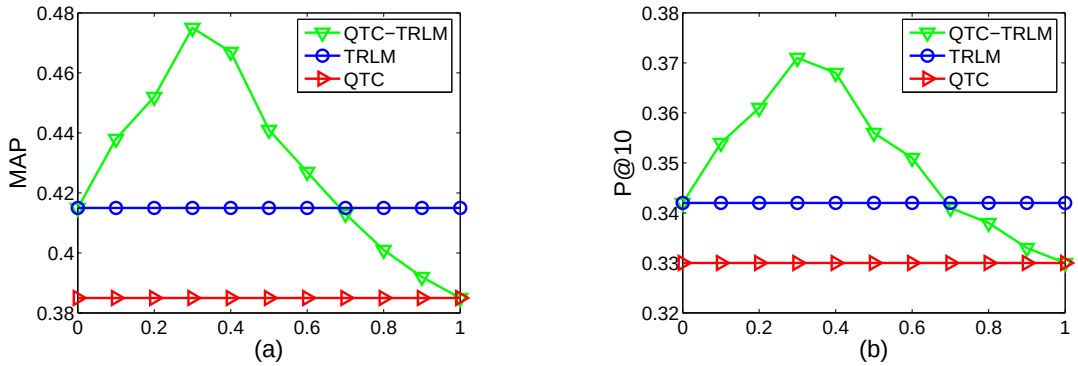

Figure 5: The relative importance of μ on the performance of TMC-TRLM.

number of topics starts to increase. However, after a certain point, the perplexity values start to increase. Based on the above experiments, we train our model using 100 topics and 200 iteration times.

5.3 The Relative Importance of Parameter μ

In equation (11), we use the parameter μ to adjust the relative importance of the TMC and the TRLM. Figure 5 illustrates the relative importance the value of μ is on the performance of question retrieval in terms of MAP and P@10, respectively. The TMC and TRLM are used for reference. The results are obtained with the 252 questions on the development set. From Figure 5, we see that for MAP and P@10, the combined model TMC-TRLM performs better than the TMC and TRLM when μ is between 0 and 0.7. In both cases, a relatively broad set for good parameter values is observed.

5.4 The Effectiveness of Our Proposed TMC Model

Table 3 shows the main results of question retrieval using the baseline methods and our proposed TMC-TRLM. In Table 3, VSM refers to the vector space model of (Salton et al., 1975); BM25 refers to the model of (Robertson et al., 1994); LM refers to the language model of (Zhai and Lafferty, 2001); TR refers to the translation model of (Jeon et al., 2005; Xue et al., 2008), TRLM refers to the translation-based language model of (Xue et al., 2008) and TRLM+CE refers to the method of (Cao et al., 2010).[5] In row 7, we show our approach and choose the best parameter $K = 100$. There are some clear trends in the results of Table 3:

#	Models	MAP	P@10
1	VSM	0.242	0.226
2	BM25	0.301	0.294
3	LM	0.352	0.327
4	TR	0.383	0.330
5	TRLM	0.415	0.342
6	TRLM+CE	0.437	0.358
7	TMC	0.385	0.331
8	**TMC-TRLM** ($K = 100$)	**0.475**	**0.371**

Table 3: Comparison with different methods for question retrieval.

[5]Here, we implement the method of (Cao et al., 2010) and use the TRLM to compute the global relevance and local relevance.

(1) The simple unigram language model (LM) performs slightly better than the classical retrieval models: VSM and BM25 (row 1 vs. row 3; row 2 vs. row 3).

(2) Translation model (TR) outperforms the LM by significant margins (row 3 vs. row 4).

(3) Translation-based language model (TRLM) significantly outperforms the translation model (TR) (row 4 vs. row 5), similar observations have been done by Xue et al. (2008).

(4) Exploiting category information of questions into the translation-based language model (TRLM) can significantly improve the question retrieval performance (row 5 vs. row 6), similar observations have been done by Cao et al. (2010).

(5) Our proposed approach TMC does not outperform the baseline methods TRLM and TRLM+CE (row 5 vs. row 7; row 6 vs. row 7). This demonstrates that the knowledge extracted from TMC is not as effective as that extracted from TRLM for question retrieval. TRLM learns the word-to-word translation probabilities from parallel corpus collected from question answer archives. However, TMC models word-category-topic distribution from the whole question answer content. The knowledge extracted from TMC is much noisier than that of TRLM. We suspect the above reason leads to the poor performance of TMC.

(6) Our proposed approach TMC-TRLM significantly outperforms the baseline methods TRLM and TRLM+CE (row 5 vs. row 8; row 6 vs. row 8). We conduct a significant test (t-test) on the improvements of our approach over TRLM and TRLM+CE. The result indicates that the improvements are statistically significant in terms of all the evaluation measures.[6] This demonstrates that the knowledge extracted from TMC is complementary to the knowledge extracted from TRLM+CE for question retrieval.

5.5 The Effectiveness of Category Information

Like the previous approaches, we treat the questions as a multinomial distribution over latent topics, and each topic is a multinomial distribution over words too. Different from previous work on topic analysis (Blei et al., 2003; Griffiths and Steyvers, 2004; Zhou et al., 2008; Wang and McCallum, 2006; Guo et al., 2008; Celikyilmaz et al., 2010; Jo and Oh, 2011), we introduce the category information of questions, which is predefined by cQA services, into the process of discovering latent topics. To see how much the category information benefit the question retrieval, we introduce a baseline method for comparison. The baseline method (denoted as TM-TRLM) is used to denote the proposed method without using the category information. Table 5 provides the comparison. From the Table, we see that the exploring category information can significantly improve the performance for question retrieval (row 1 vs. row 2).

[6]The comparisons are significant at $p < 0.05$.

#	Models	MAP	P@10
1	TM-TRLM	0.454	0.366
2	**TMC-TRLM**	**0.475**	**0.371**

Table 4: The effectiveness of category information for question retrieval.

6 Conclusions and Future Work

In this paper, we present a new approach to discover the latent topic of questions for improving the performance of translation-based language model for question retrieval. Experiments conducted on real cQA data demonstrate that our proposed approach significantly outperforms the state-of-the-art methods (TRLM and TRLM+CE).

There are some ways in which this research could be continued. First, question structure should be considered, so it is necessary to combine the proposed approach with other question retrieval methods (e.g., (Duan et al., 2008; Wang et al., 2009; Bunescu and Huang, 2010)) to further improve the performance. Second, we will try to investigate the use of the proposed approach for other kinds of data set, such as categorized questions from forum sites and FAQ sites.

Identifying Event Descriptions using Co-training with Online News Summaries

Abstract

Systems that distill information about events from large corpora generally extract sentences that are relevant to a short event query. We present a novel co-training strategy for this task that employs a multi-document news summary corpus featuring 2.5 million unlabeled sentences, thus obviating the need for extensive manual annotation. Our experiments indicate that this technique significantly outperforms standard classification approaches with linear feature combination on this task. An analysis of our approach under various settings reveals how classifier and parameter choice can be used to control runtime overhead while contributing to an absolute increase of 22% in recall.

1 Introduction

Automatic identification of event descriptions is a crucial, yet difficult, problem with impact on applications such as question answering (QA), query-focused summarization (QS), and text mining (TM) systems. In such applications, a system is given a description of an event in the form of a query and the task is to identify sentences within relevant documents (retrieved by an information retrieval system) that describe the event. We define *event-relevant* sentences as those describing a unique event as specified in the query, typically occurring at a specific location, on a specific date, or with specific participants. The task is made difficult by the fact that words in the query rarely provide enough identifying information (Xu and Croft, 2000; Chirita et al., 2007) to reliably find descriptive sentences; the query may not specify all named entities and may provide other descriptive terms that are not easily matched. For example, given the query requesting a description of *"the Israeli-Palestinian peace talks"*, the sentence *"The discussions between Israelis and Palestinians follow last month's Annapolis meeting where Israeli Prime Minister and Palestinian President Mahmoud Abbas met and agreed to try to negotiate a deal before the end of 2008."* is event-relevant, whereas the sentence *"Turkey has close ties to both Israel and the Palestinians."* is not. Yet both sentences feature the named entities from the query. The term "peace talks" does not appear in the event-relevant sentence, but is implied by "negotiate".

Previous approaches have addressed this problem using supervised learning (Mani et al., 2003; Bethard and Martin, 2006; Manshadi et al., 2008), where the relation between the query and event-relevant sentences is learned. Still, gathering a large amount of training data is difficult and people often do not agree on what counts as relevant to an event description (Filatova and Hatzivassiloglou, 2003), making the process of manually labeling sentences as events both time consuming and expensive. This is supported by our own experiments with Amazon Mechanical Turk (AMT); we were only able to obtain 685 labeled event-relevant sentences on which 3 or more AMT users agreed after 16 days of posting. This is a striking contrast with use of AMT for other labeling tasks where thousands of labeled examples can be obtained in a matter of hours (Snow et al., 2008; Marge et al., 2010; Rosenthal et al., 2010).

In this paper, we present a novel semi-supervised learning method using co-training to classify sentences as salient event descriptions for a given event query. We use a small amount of manually annotated seed data, in the form of (query, sentence) pairs. Critically, we then augment this with a large amount of unlabeled news summaries, spanning nine years, from the Web. We hypothesize that the headline of each summary can be viewed as a single event query, and

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 282–291,
Chiang Mai, Thailand, November 8 – 13, 2011.

the corresponding summary sentences include a good number of salient event sentences that directly describe the event, as well as a small number of non-event sentences. We note that such data is abundantly available on the Web given naturally-occurring news stories as well as mature multi-document summarization systems. We use two relatively simple sets of features, one based on keywords and the other based on named entities, to train two Bayesian network classifiers on seed training data and employ co-training over the collected news summaries to incrementally augment the training set with increasingly robust labeled examples. Experimental results show a significant, absolute gain of 8% over training of the classifiers on the seed data alone.

Our primary contributions in this paper include:

- Collection of an online news summary corpus for detecting event relevance[1] that includes 166,435 summaries (2.5M sentences) generated by an online news summarizer in the period 2003-2011.
- An efficient co-training strategy for identifying event descriptions using online news summaries and compact, simple feature sets.
- An evaluation of the impact of classification techniques, experimental parameters and amount of novel Web data on the accuracy and efficiency of co-training.

In the following sections, we first present related work on event identification and then present our approach, outlining our hypothesis, the data we used, the co-training strategy and feature sets for this task. Following this, we present experimental results and conclude with a discussion of the implications and limitations of this work.

2 Related Work

The problem of identifying and understanding events in natural language text has been explored in many ways that have produced a variety of perspectives on the challenges involved. Tasks explored have included the mapping of verb-level events into aspectual classes (Siegel and McKeown, 2000), detection of specific *atomic* events (Filatova and Hatzivassiloglou, 2003), supervised event classification (Bethard and Martin, 2006) and unsupervised learning of event schemas (Chambers and Jurafsky, 2009). The notion of what constitutes an event has similarly ranged across perspectives, from general verb-level events (Siegel and McKeown, 2000; Chambers and Jurafsky, 2009) and predicate-argument pairs (Manshadi et al., 2008) to more specific news events (Spitters and Kraaij, 2002; Filatova and Hatzivassiloglou, 2003) and public health events (Fisichella et al., 2010).

Our task also adheres to a more specific definition of events: we assume that event queries refer to unique and newsworthy events such "the Beijing Olympics", rather than more general lexical-level events such as "the game". Our sentence-retrieval task aligns with the perspective of Filatova and Hatzivassiloglou (2003) who defined the notion of *atomic* events at the sentence level. They also show how event identification at this level can benefit indexing, summarization, and QA using low-level lexical features (Filatova and Hatzivassiloglou, 2004).

Many event identification tasks rely on supervised learning methods (Siegel and McKeown, 2000; Mani et al., 2003; Bethard and Martin, 2006; Manshadi et al., 2008) that can incur high annotation costs. While fully unsupervised methods (Bejan, 2008; Spitters and Kraaij, 2002) for event discovery are not encumbered by the availability of training data, they can produce event clusters or topics which are difficult to interpret. In contrast, our semi-supervised learning approach balances the pros and cons of both supervised and unsupervised approaches.

3 Our Approach

We frame the task of selecting event-relevant sentences as a binary classification problem over all sentences in the corpus. The following sections detail the data, features and techniques used.

3.1 Corpora

Seed Training Data and Test Data Annotation

Our primary corpus of news documents and queries is derived from the DARPA Global Autonomous Language Exploitation (GALE) distillation training and evaluation sets. Fifty event queries provided for the GALE task were used for our experiments (randomly divided into 30 training queries and 20 test queries), and the set of documents was restricted to those containing at least one keyword bigram from any query in the set[2]. For each query, we consider all sentences from the

[2] As determined by the information-retrieval pipeline built using Lucene: `http://lucene.apache.org`

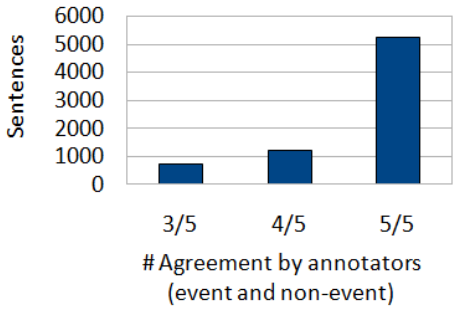

Figure 1: Number of sentences where a proportion of AMT users agreed on the classification (*event-related/unrelated*). With a binary task, 1/5 implies 4/5 agreement and 2/5 implies 3/5 agreement.

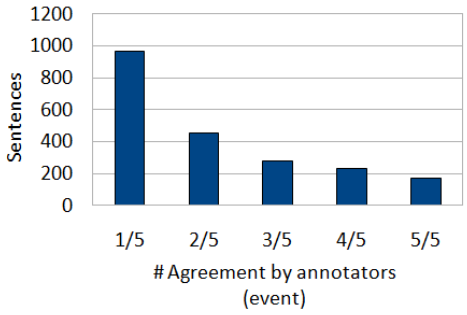

Figure 2: Number of sentences where a majority of AMT users agreed on the classification *event-related*.

top 10 retrieved documents and resort to AMT[3] to obtain sentence-level labels.

Each AMT annotation task presented AMT users with four contiguous sentences in conjunction with the query and asked them to indicate whether each of the individual sentences was relevant to the query[4]. The users could also view the entire document for context. Each task was assigned to 5 AMT users and a total of 252 unique users from the United States participated in the tasks. The full study lasted 16 days and had an overall cost of $350.

Fig. 1 shows the number of sentences (out of a total of 7161 candidates for all 50 queries) whose classification was agreed upon by a certain proportion of annotators. This result appears to suggest that annotators often agree when labeling event-relevant sentences[5]. However, these numbers are dominated by the majority class (irrelevant sentences), indicating that it is relatively easy for AMT users to agree when a sentence is not relevant. This is confirmed by Fig. 2, which displays the number of sentences that were specifically tagged as event-relevant for their respective queries. The breakdown for event-relevant sentences shows that about 30% of the sentences were identified as event-relevant by at least one AMT user and only a third of these received a majority vote for the label. This skewed distribution poses a significant challenge to the construction of a balanced training corpus for this task at low cost. Our observations are commensurate with Filatova and Hatzivassiloglou (2003) who note that event annotation is difficult for human annotators.

[3] `http://mturk.com`

[4] We also added an obviously fake sentence to detect sloppy annotators and robots.

[5] Fleiss' $\kappa = 0.417$, generally assumed to indicate moderate agreement between annotators

Unlabeled News Summary Data

Since manual creation of a large set of event-relevant sentences is difficult, we make use of a semi-supervised technique that employs a large quantity of unlabeled data to iteratively augment the small corpus described above. Unlabeled training data for our task also must comprise event queries and groups of sentences that are both related and unrelated to these events.

We experiment with automatically-generated news summaries as unlabeled training data for identifying event-related sentences. We postulate that the title of each news summary forms a single query and assume that at least some of the sentences in the summary will relate to the event mentioned in the title, while some may not. The choice of *summaries* of online news documents rather than the documents is prompted by the assumption that the distribution of query-related sentences and query-unrelated sentences is more balanced in short, informative summaries; this allows us to use the data more efficiently and avoid the sparse occurrence of event-specific sentences in online news articles.

The unlabeled dataset used in this work was retrieved from the output of an online news summarization system, Newsblaster http://newsblaster.cs.columbia.edu/, that crawls the Web for news articles, clusters them on specific topics and produces multidocument summaries for each cluster. We collected a total of 166,435 summaries containing 2.5 million sentences and covering 2,129 days in the 2003-2011 period.

As an initial experiment in augmenting the training corpus, we assumed that *all* summary sentences were relevant to the title query and trained

classifiers over a balanced corpus created by directly adding some summary data to the seed corpus. We observed the performance of these classifiers was poorer than that of classifiers trained only on the unaugmented seed corpus, suggesting that the assumption was too strong and that the summaries consist of both query-related and query-unrelated sentences. This supports the use of such a corpus in a semi-supervised setting.

3.2 Semi-Supervised Approach

The original co-training framework (Blum and Mitchell, 1998) was introduced in the context of Web page classification where one typically has access to a limited number of labeled pages but to a potentially unlimited number of unlabeled pages. Co-training involves building two independent views (classifiers), letting them automatically label the unlabeled data and incorporating this self-labeled data into the seed training set to improve system performance. Mihalcea (2004) shows that co-training is useful in word sense disamgibuation, Wan (2009) uses SVM for co-training and shows improvement for cross-lingual sentiment analysis, and recent research has established the effectiveness of co-training for a variety of NLP tasks (Yu and Kübler, 2011; Li et al., 2011; Bergsma et al., 2011). In this section, we present our co-training classifiers, as well as an algorithm that is specifically tailored to automatic event identification.

Features

Implementation of the co-training algorithm involves the design of two independent views (classifiers) for the same instance. In the original co-training algorithm for Web page classification, Blum and Mitchell (1998) use hyperlinks and bag-of-words as the approximation[6] of two distinct views of a Web page. In our approach, we choose two simple views to represent each candidate sentence for a given event query: (1) keyword features that include unigram and bigram overlaps between a candidate sentence and the event query. (2) named entity features including the number of exact entity (*Person*, *Location*, and *Organization*) matches between a candidate sentence and the query, as well as the total number of co-occurring named entity tags (regardless of the actual entity being tagged) between a candidate sentence and the query. We used the Stanford Named Entity tagger (Finkel et al., 2005) to obtain named entities features from the unlabeled data.

Note that the second view of our approach is clearly not independent of the first view, as the named entity matching is based on lexical matching. However, named entities are known as an informative source for selecting relevant sentences for a query since they serve as unique identifiers (Parton et al., 2008). Previous studies (Krogel and Scheffer, 2004) show that if the independence assumption of co-training approach is violated, the co-training approach can yield negative results. However, our results show that co-training yields improvement even though are classifiers are not independent.

The Co-training Algorithm

The motivation behind our co-training algorithm is to make use of the online summarization data for event identification, and improve recall as well as precision.The pseudo code of this algorithm is provided in Algorithm 1.

Algorithm 1 The co-training algorithm

Given:
(1) a set S of labeled seed training examples;
(2) a set U of unlabeled news summary examples;

Initialize the iteration parameter k, pool size u, and leap size v;
for $i = 1 \rightarrow k$ **do**
  Create a temporary pool by randomly choosing u examples from U;
  Use L to train a classifier C_1 using only keyword features;
  Use L to train a classifier C_2 using only named entity features;
  Run C_1 to label $u/2$ examples and select $v/2$ balanced examples;
  Run C_2 to label $u/2$ examples and select $v/2$ balanced examples;
  Add all selected examples to L;
  Return the remaining examples back to U;
end for

Earlier work (Mihalcea, 2004) indicates that by choosing only high confidence examples from the self-labeled data set, we can improve the co-training results. However, we disagree with this assumption; if low-confidence examples are re-

[6]Note that it is very difficult to prove that two views are completely independent of each other. (Du et al., 2010)

moved from training, the final co-trained classifier will have problems evaluating difficult examples in the held-out data set [7].

Our algorithm is a variation of the original co-training algorithm (Blum and Mitchell, 1998). In the original algorithm, p represents the number of self-labeled positive cases and n represents the number of self-labeled negative cases in each iteration. We now eliminate the p and n parameters, and use v to measure the *leap size*, the amount of self-labeled data added to the training set in each iteration. This is to ensure that, in each iteration, balanced selection of unlabeled examples from the two views can be added to the labeled data. We keep the unselected examples and return them to the pool U at the end of each iteration to make sure we use the unlabeled data exhaustively.

Bayesian Network Classifier

We employ a Bayesian network classification scheme for the co-training experiments described in section 4. Previous approaches to co-training have successfully used the well-known naive Bayes classification scheme (Blum and Mitchell, 1998; Mihalcea, 2004), which assumes conditional independence between features.

A Bayesian network approach is a variation on this probabilistic classification scheme that avoids making strong independence assumptions between features. Building the classifier entails an additional step for estimating the conditional dependencies between the features; this is accomplished by using search algorithms and scoring metrics[8] to learn a DAG structure representing a Bayesian network over the features. Once such structure is estimated, conditional probabilities $p(x_i|\pi_i)$ are estimated[9] where π_i represents the set of features that feature x_i is assumed to conditionally depend on. Classification of an unseen example $\mathbf{x}'$ is performed similarly to the naive Bayes approach with the estimation of $\arg\max_y p(y|\mathbf{x}')$.

[7] Under the same parameter settings, accuracy was reduced by 1% when training only with high-confidence instances (posteriors > 0.9) or low-confidence instances (posteriors < 0.75).

[8] In our experiments, we use the K2 hill-climbing search strategy to estimate network structure with the standard Bayesian scoring metric (Cooper and Herskovits, 1992).

[9] Conditional probabilities are obtained using the simple estimation strategy ($\alpha = 0.5$) as implemented in the Weka machine learning toolkit (Witten and Frank, 2000).

4 Experiments

We present four experiments to test system performance. First, we present the comparisons between our approach and other supervised/semi-supervised baselines, arbitrarily choosing settings for the number of co-training iterations k and the number of sentences added in each iteration[10]. We then test the trade-off between k and v by fixing the total amount of unlabeled data available, i.e., $k * v$ sentences[11]. In the third experiment, we test the impact of leap size v on both accuracy and efficiency by fixing k, as well as the impact of the iteration parameter k by fixing v. In the final experiment, we empirically choose the best possible v to test the influence of unlabeled data size on the recall and precision of our system. Due to the randomness in our co-training algorithm, we repeat every experiment 5 times and report the average results.

4.1 Comparing with Baseline Approaches

Table 1 shows the overall Bayesian network co-training results in comparison to various baseline systems. Previous work (Blum and Mitchell, 1998; Mihalcea, 2004; Wan, 2009) points out that naive Bayes and SVM classifiers can achieve promising results for co-training, so we use the same co-training settings ($k = 50$, $v = 500$) to compare these two classifiers with the Bayesian network classifier. Classifier 1 corresponds to the keyword matching view and Classifier 2 corresponds to the named entity view. When comparing single classifiers using either keyword matching or named entity features, SVM outperforms all other classifiers with an accuracy of 75.3%. When linearly combining all features using the seed data set, the Bayesian network yields a better result of 77.6%. The Bayesian network co-training outperforms the linear kernel SVM[12] co-training algorithm by 12.4% in accuracy, and it is also 55 times faster than SVM co-training algorithm in terms of average runtime. The co-trained result also has an absolute improvement of 8% over a Bayesian network linear combination classifier (Table 1: Combination).

Note that in all of our co-training experiments, the performance of the Bayesian network co-

[10] We use $k = 50$ iterations and $v = 500$ sentences per iteration

[11] Here we restrict $k * v = 200,000$ sentences

[12] We have also experimented with polynomial and RBF kernels, but performance was worse than the linear kernel.

Table 1: Comparing with baseline systems (NB: naive Bayes. SVM: linear kernel support vector machines. Bnet: Bayesian network. N-: the class of sentences unrelated to the event query P-: the class of event-related sentences). The best result in each column is indicated in boldface.

trained classifier 1 (Table 1: Co-training with $k = 50 and v = 500$ improves performance substantially over the Bayesian network classifier using all features (Table 1: Combination). The performance of co-trained Classifier 2, not shown in the table[13], does not improve over the linear feature combination. The results suggest that when the keyword view is augmented with Bayesian network co-trained unlabeled data from both views, the co-training approach boosts the results, but the reverse does not hold true. These results are consistent with our previous claim (Section 3.2) that named entity features help the keyword view to identify key information in events. The above results also indicate that although the keyword view and named entity view are not independent, the Bayesian network co-training approach still produces promising results.

The strong performance of the Bayesian network classifier in these experiments is partly attributable to the fact that both classification views consist of features that are interdependent and therefore correlated to some degree, as the model assumes. The dramatic performance gains of the Bayesian network co-trained classifier when compared to Naive Bayes are therefore somewhat unsurprising; however, the poor performance of the SVM classifier was unexpected.

Although all the basic variants of classifiers using n-gram count features exhibit similar accuracy on the test corpus, we note that the Bayesian classifiers tend to select fewer high-precision event-related sentences resulting in skewed precision/recall numbers. Co-training has the effect of relaxing these models to gradually expand the set of high-precision event sentences (resulting in large gains in P-Recall and N-Precision) using the implicit information gained through new training examples classified by event features. No improvement is observed when co-training for classifiers that start out with balanced precision and recall, i.e., the SVM and all event feature classifiers. We therefore conjecture that this phenomenon of high-precision event sentence extraction is especially helpful in co-training for this task.

We aim to further analyze the effect of classifier choice in future work. For all of the following experiments in this section, we only evaluate the performance of the Bayesian network classifier.

4.2 Trade-off between Co-training Parameters

In this experiment, we evaluate the trade-off between the number of iterations and leap size in our co-training setting given a fixed amount of unlabeled data. A total number of 200,000 unlabeled summary sentences (1 year) are involved in this experiment. Fig. 3 shows the results. The horizontal axis consists of pairs of k and v. We first

[13]Table 1 only shows the best result for co-training.

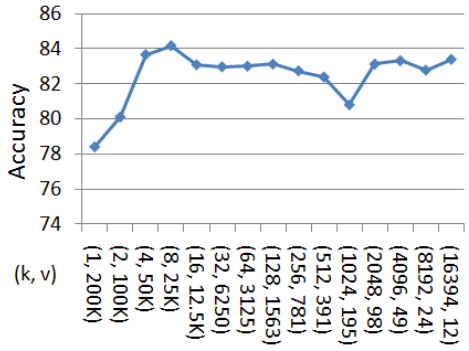

Figure 3: Trade-off between co-training parameters k and v with fixed amount of data

start with a very small ratio of k vs v ($k = 1$, $v = 200,000$), then we increase k exponentially such that $k * v$ is still equal to 200,000. We see that when $k = 8$ and $v = 25,000$, the system's performance reaches a peak accuracy of 84.2%. In addition, accuracy increases 6% from $k = 1$ to $k = 8$ which suggests that our co-training algorithm needs at least 5-10 iterations to achieve satisfactory results. We observe that there is a sudden drop when $k = 1024$ and $v = 195$; we explain this in section 4.4 and 4.3 when we test the impact of data diversity.

4.3 Influence of Leap Size

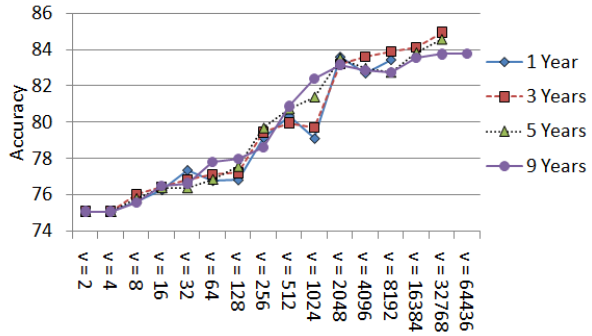

Figure 4: Performance varying leap size v with a fixed number of iterations $k = 10$

We evaluate the co-training leap size parameter v by fixing the number of iterations k to 10 and also experiment with the diversity of data by using unlabeled data drawn from different years. Fig. 4 shows that the system's performance improves significantly when using higher numbers of v. The best result is 85% accuracy when $v = 32,768$, compared to 75.1% accuracy obtained when $v = 2$. We also notice that using more diverse data from different years helps stabilize system performance and reduce the oscillation in the plot. In terms of efficiency, when using all 9 years of data, the corresponding runtime for v = 4 and v = 32768 are 15 minutes and 20 minutes, which indicates that increasing leap size is an efficient approach. Fig. 6 shows the comprehensive runtime costs from v = 2 to v = 2048. The runtime for varying v is almost a straight line, showing very little added cost as v increases.

4.4 Influence of the Iteration Parameter

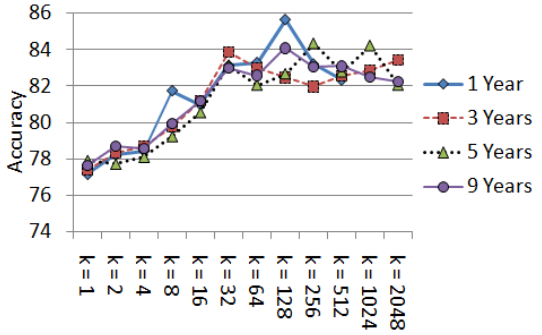

Figure 5: Performance varying the number of iterations k with fixed leap size $v = 500$

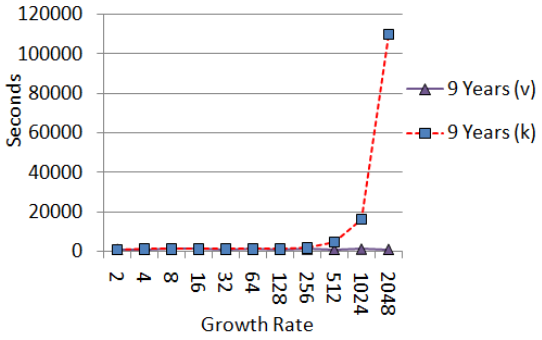

Figure 6: Average runtime costs when varying either k or v separately (and keeping the other fixed)

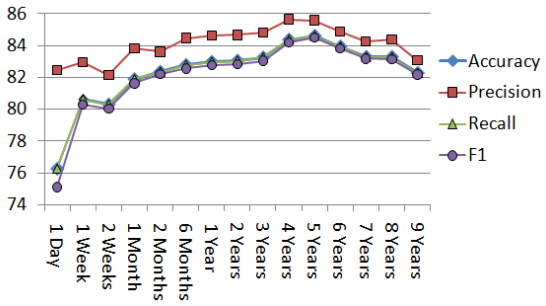

Figure 7: Performance varying the size and temporal range of the unlabeled dataset

We fix the leap size v to 500 and vary the number of iterations k to test its impact on the accuracy

and efficiency of our system. We notice (Fig. 5) that when increasing the number of iterations from k = 1 to 32, our system performance improves significantly. After 32 iterations, the performance reaches a stable state. The best performance of 85.6% accuracy is obtained when $k = 128$; however, the cost of system runtime grows exponentially as we increase the parameter k. For example, we note that the runtimes corresponding to k = {256, 512, 1024, 2048} are 28 minutes, 76 minutes, 270 minutes and 1829 minutes. Clearly, compared with the runtimes obtained by varying v, increasing k is not a good option. We also test impact of data diversity by using data from different years. Although using one year of data yields the best result, its overall performance is less stable than using 3, 5, or 9 years of input unlabeled data.

4.5 Influence of Size of Unlabeled Dataset

Experiments 4.3 and 4.4 show that increasing leap size v is an efficient method for introducing more data in co-training. Now, given different amounts of unlabeled news summary data from meaningful temporal time frames, we fix $k = 10$ and dynamically choose the best possible v to represent the amount of input data under consideration. Fig. 7 shows the precision and recall of the event-relevant class when co-training is performed using input unlabeled data of varying sizes (and temporal ranges). We observe that increasing the dataset size (and therefore drawing from older summaries) yields a dramatic improvement in recall accompanied by a slight decline in precision. Correspondingly, F1 generally increases when more data is added. The difference between minimum and maximum recall over the entire range is as high as 22% while precision drops by about 9%. These results suggest that introducing more unlabeled data in our co-training framework has the biggest impact on recall without sacrificing much precision.

5 Discussion

Our results show that an approach that only selects sentences with words that match the input query will not work well. As keyword matching might introduce a fair amount of noise, e.g. matched prepositional phrases that do not indicate the importance of the sentence, co-training together with a named entity based classifier can help reduce these errors. Thus when testing on unseen data, significantly better recall can be obtained via co-training. Our experiments also show that our co-training material, the nine years of news summary documents, is a reliable and effective source to augment the seed dataset, with minimum introduction of new noise or extra overhead.

The experiments show that increasing either the number of co-training iterations k or leap size v leads to improved performance; however, adding unlabeled data by increasing v adds much lower runtime overhead by avoiding repeated training iterations. The parameter trade-off experiment in section 4.2 indicates that beyond a minimum number of iterations k, unlabeled data can largely be introduced through v. This is useful in practice to maintain consistent runtime performance.

Despite the strong relative gains with co-training, the limited feature sets employed in both views (keyword and named entity) do not allow us to capture event-relevant sentences which don't share words with the event query. Although the relative gains offered by co-training are clear, we wonder if the requirement of agreement in annotation led to a corpus in which sentences that were labeled relevant tended to share keywords with the event query. Although not evident from our experiments, we nevertheless assume that query synonyms are likely occurrences in event-relevant sentences, as are sub-events which entail larger events and vice versa. Therefore, a consideration of semantic and ontological features would be a logical next step for further investigation of this task and may offer interesting new views through which co-training can be utilized.

6 Conclusion

In this paper, we aim at detecting event-relevant sentences in a news corpus given an event query. In contrast to previous work that needs expensive annotation for query-answer pairs, we use unlabeled news summaries that are readily available in large quantities online and design an efficient semi-supervised learning strategy for event identification based on co-training with Bayesian network classifiers. An analysis of different parameters in the co-training approach shows that increasing leap size is a better way to gain accuracy improvements than increase in number of iterations given efficiency costs. Our findings are applicable to question answering, summarization, and text mining domains where selection of event-relevant sentences is often critical and large-scale human annotated data is not always available.

Abstract

Since the present-day Japanese use of voiced consonant mark had established in the Meiji Era, modern Japanese literary text written in the Meiji Era often lacks compulsory voiced consonant marks. This deteriorates the performance of morphological analyzers using ordinary dictionary. In this paper, we propose an approach for automatic labeling of voiced consonant marks for modern literary Japanese. We formulate the task into a binary classification problem. Our pointwise prediction method uses as its feature set only surface information about the surrounding character strings. As a consequence, training corpus is easy to obtain and maintain because we can exploit a partially annotated corpus for learning. We compared our proposed method as a preprocessing step for morphological analysis with a dictionary-based approach, and confirmed that pointwise prediction outperforms dictionary-based approach by a large margin.

1 Introduction

Recently, corpus-based approaches have been successfully adopted in the field of Japanese Linguistics. However, the central part of the fields has been occupied by historical research that uses ancient material, on which fundamental annotations are often not yet available.

Despite the limited annotated corpora, researchers have developed several morphological analysis dictionaries for past-day Japanese. National Institute for Japanese Language and Linguistics creates Kindai-bungo UniDic,[1] a morphological analysis dictionary for modern Japanese literary text,[2] which achieves high performance on analysis for existing electronic text (e.g. Aozora-bunko, an online digital library of freely available books and work mainly from out-of-copyright materials).

However, the performance of morphological analyzers using the dictionary deteriorates if the text is not normalized, because these dictionaries often lack orthographic variations such as Okuri-gana,[3] accompanying characters following Kanji stems in Japanese written words. This is problematic because not all historical texts are manually corrected with orthography, and it is time-consuming to annotate by hand. It is one of the major issues in applying NLP tools to Japanese Linguistics because ancient materials often contain a wide variety of orthographic variations.

For example, there is an issue of voiced consonant marks. Any "Hiragana" character and "Katakana" character (called Kana character altogether) represent either consonant (k, s, t, n, h, m, y, r, w) onset with vowel (a, i, u, e, o) nucleus or only the vowel (except for nasal codas N). Furthermore, the characters alone can not represent syllables beginning with a voiced consonant (g, z, d, b) in current orthography. They are spelled with Kana and a voiced consonant mark (゛) to the upper right (see Figure 1). However, confusingly, it was not ungrammatical to put down the character without the mark to represent voiced syllable

[1] http://www2.ninjal.ac.jp/lrc/index.php?UniDic

[2] In historical linguistics, the phrase "modern Japanese" refers to the language from 1600 on to the present in a broad sense. However, most Japanese people regard the phrase to the Meiji and Taisho Era; we also use the phrase to intend the narrower sense.

[3] In Japanese Literature, both Kana (phonogramic characters) and Kanji (ideographic characters) are used together. Generally, conjugated form is ambiguous, given the preceding Kanji characters. However, the character's pronunciation can also be written using Kana characters. Thus, the pronunciation's tailing few syllables are hanged out (Okuri), using Kana (gana) characters for disambiguating the form. Although the number of Okuri-gana is fixed for each Kanji character now, it was not fixed in the Meiji Era.

until the Meiji Era, because Japanese orthography dates back to the Meiji Era. Consequently, modern Japanese literary text written in the Meiji Era often lacks compulsory voiced consonant marks. The mark was used only when the author deems it necessary to disambiguate; and it was not often used if one can infer from the context that the pronunciation is voiced.

Figure 2 shows characters which lack the voiced consonant mark even though we expect it to be marked in the text. Hereafter, we call such characters as "unmarked characters." Also, we call the characters to which the voiced consonant mark can be attached as "ambiguous characters." In Table 1, we present the statistics of the voiced consonants in "Kokumin-no-tomo" corpus which we will use for our evaluation. As you can see, 12% of the ambiguous characters are actually voiced but not marked. In addition, 44% of the voiced characters have the voiced consonant mark, showing the variation of using the voiced consonant mark in the corpus.

In the modern Japanese literary text, orthographic variations are not only the unmarked. However, unmarked characters appear a lot in the text and can be annotated easily by hand. Thus, we can get natural texts for evaluation of our method at low cost (in fact, it cost only a few weeks to annotate our above-mentioned test corpus). Therefore, we decided to begin with attaching voiced consonant mark for unmarked characters as a starting point for normalizing orthographic variations.

Basically, Kindai-bungo UniDic is created for a

今や廣島は其名大に内外國に顯はれ荷も時事を談 す るものは同地の形勢如何を知らんと欲せ さ るはあら す

(Today, the fame of "Hiroshima" has been broadly known in and outside Japan, and if you talk about current affairs, you want to know how the place has been established.)

Figure 2: Example of sentences that includes unmarked characters. This text is an excerpt from "The tide of Hiroshima": Katsuichi Noguchi, Taiyo, No.2, p.64 (1925). Wavy-underlined characters are ambiguous character, and gray-boxed characters are unmarked character.

fully annotated sentence that does not include unmarked characters, and thus if the target sentence includes unmarked character(s), the performance can degrade considerably.

There are two major approaches to handle this problem: a dictionary-based approach and a classification-based approach.

First, the dictionary-based approach creates a dictionary that has both original spellings and modified variants without the mark. For example, Kindai-bungo UniDic includes both entries "ず (zu)" and "す (zu)" for frequent words such as "ず (zu)" in auxiliary verb. This allows morphological analysis algorithms to learn the weights of both entries all together from a corpus annotated with part-of-speech tags in order to select appropriate entries during decoding.

Second, the classification-based approach employs a corpus annotated with unmarked characters to learn a classifier that labels the voiced consonant mark for unmarked characters. Unlike the dictionary-based approach, the classification-based approach does not require part-of-speech tagged nor tokenized corpora. Since it is easier for human annotators to annotate unmarked characters than word boundaries and part-of-speech tags, we can obtain a large scale annotated corpus at low cost.

Therefore, in this paper, we propose a classification-based approach to automatic labeling of voiced consonant marks as a preprocessing step for morphological analysis for modern Japanese literary language.

We formulate the task of labeling voiced con-

sonant marks into a binary classification problem. Our method uses as its feature set only surface information about the surrounding character strings with pointwise prediction, whose training data are available at low cost. We use an online learning method for learning large spelling variation from massive datasets rapidly and accurately. Thus, we can improve its performance easily by increasing amount of training data. In addition, we perform clustering of Kanji, which is abundant in the training data, and employ class n-grams for addressing the data sparseness problem. We compared our classification-based approach with the dictionary-based approach and showed that the classification-based method outperforms the dictionary-based method, especially in an out-of-domain setting. We also conducted an experiment to demonstrate that automatic labeling of unmarked characters as a pre-processing step improves the performance of morphological analysis of historical texts without normalization by a large margin, taking advantage of large scale annotated corpus of unmarked characters.

The rest of this paper is organized as follows: In section 2 we describe related work of automatic labeling of Japanese voiced consonant marks. Section 3 details our proposed classification-based method using pointwise prediction. We then explain experimental settings and results in section 4. Section 5 concludes our work and presents future work.

2 Related Work

If we assume an unmarked character as substitution error of one voiced consonant to one voiceless consonant, the task of detecting an unmarked character can be considered as a kind of error correction. In English, we can perform error correction for the one character's error by word-based approach. However, in Japanese, we cannot simply apply word-based approach because sentences are not segmented into words.

Nagata (1998) proposed a statistical method using dynamic programming for selecting the most likely word sequences from candidate word lattice estimated from observed characters in Japanese sentence. In this method, the product of the transition probability of words is used as a word segmentation model. However, most of the historical materials that we deal with are raw text, and there exist little, if any, annotated texts with words and part-of-speech tags. Thus, a word segmentation model learned from such a limited amount of data is unreliable. Unlike Nagata's method, our classification-based method does not rely on word segmentation and can exploit low-level annotation such as voiced consonant mark, which is available quite easily.

In addition, Nagata performed clustering of characters for smoothing confusion probability among characters to narrow down correction candidates. We also perform clustering on Kanji for addressing the data sparseness problem. Though Nagata uses character's shape for clustering, we instead use neighboring characters of the Kanji character. The intuition behind this is that whether to attach voiced consonant mark is affected by surrounding contexts, like sequential voicing.

On contrary, Shinnou (1999) proposed an error detection and correction method that does not perform word segmentation. He restricts the target to Hiragana characters and uses Hiragana n-gram that is a substring of the characters. In his method, error detection is determined by the Hiragana n-gram frequency. One counts each Hiragana n-gram frequency in training corpus and judges whether the string includes error by checking if the smallest frequency among them (minimum frequency of n-gram) is larger than a threshold value. After error detection, one enumerates candidate strings and corrects the input string to the string that has the largest minimum frequency of n-gram compared to other candidates.

The reason why Shinnou restricts targets to Hiragana characters is that it narrows down candidates of error correction. He used the fact that the number of Hiragana characters is 50 at most while the total number of distinct characters is more than 6,000 in Japanese. This method works well for present-day Japanese literary texts that contain relatively long Hiragana character strings. However, modern Japanese texts contain many Kanji characters and relatively short Hiragana character strings because modern Japanese texts are similar to Kanbun-kundokubun, or the Japanese reading of a Chinese text. Therefore, Hiragana n-grams fail to model error detection well for modern Japanese texts. Moreover, error correction of unmarked characters is much simpler than error correction of all the Hiragana. Our method differs from Shinnou's method in that we focus on automatic labeling of voiced consonant marks and em-

ploy a discriminative character n-gram model using a classification-based method. Although Shinnou's generative model is not capable of using overlapping features, our classification-based approach allows flexible feature design such as including character types that may help classification on unmarked characters. In addition, Shinnou's method requires a fully annotated corpus with unmarked characters even though there is a large amount of raw text in modern literary Japanese.

3 Detecting Unmarked Character with Pointwise Prediction

We formulate the task of automatic labeling of unmarked character into a binary-classification problem. More precisely, we build a binary classifier for detecting whether the target character is unmarked or not.

In our classifier, we use only surface information about one target character and its surrounding characters, and the classifier output is either unmarked (+1) or not (-1). Since proposed method does not require a corpus annotated with word boundaries or part-of-speech tags for learning, we take advantage of a large modern a Japanese corpus, Taiyo-Corpus,[4] which is based on Japanese magazines from the Meiji Era. This corpus is not annotated with neither word boundaries nor part-of-speech tags but is manually annotated with unmarked characters.

We employed pointwise prediction which makes a single independent decision at each point: ambiguous Hiragana character or Kunoji-ten[5].[6] Therefore, our method can learn from partially annotated corpora (Neubig and Mori, 2010) including raw corpora of modern Japanese literary text, and thus it is easy to obtain training data.

Neubig et al. (2011) extend the word segmentation method proposed by Sassano (2002) to Japanese morphological analysis using pointwise prediction. In our method, we adopt the binary features from (Sassano, 2002) to this task. Unlike Sassano and Neubig et al. who use an SVM, we use an online Passive-Aggressive algorithm for exploiting large datasets while achieving high accuracy.

3.1 Features for Classification

Our approach builds a binary classifier that uses binary features indicating whether the following n-grams exist or not (shown in Figure 3).

3.1.1 Character n-grams

These features correspond to character n-grams that surround the target character. Only characters within a window of three characters are used in classification ($n \leq 3$). These n-grams are referred with relative position from the target character.

If given sentence is $c_1 c_2 \cdots c_m$ and target character is c_i, character n-grams are $(-3/c_{i-3}c_{i-2}c_{i-1}$, $-2/c_{i-2}c_{i-1}c_i$, $-1/c_{i-1}c_ic_{i+1}$, $0/c_ic_{i+1}c_{i+2}$, $1/c_{i+1}c_{i+2}c_{i+3}$, $-3/c_{i-3}c_{i-2}$, $-2/c_{i-2}c_{i-1}$, $-1/c_{i-1}c_i$, $0/c_ic_{i+1}$, $1/c_{i+1}c_{i+2}$, $2/c_{i+2}c_{i+3}$, $-3/c_{i-3}$, $-2/c_{i-2}$, $-1/c_{i-1}$, $0/c_i$, $1/c_{i+1}$, $2/c_{i+2}$, $3/c_{i+3})$.

3.1.2 Character type n-grams

These features are similar to previously mentioned character n-grams with only the modification of replacing the character itself with the character type. We deal with eleven character types, Hiragana/H, Katakana/K, Kanji/C, Odoriji/O, Latin/L, Digit/D, dash/d, stop and comma/S, BOS ($\langle s \rangle$)/B, EOS ($\langle /s \rangle$)/E and others/o as the character types.

3.1.3 Markedness n-grams

These features are also similar to character n-grams with only the modification of replacing the character itself with 0 (voiced consonant mark cannot be attached), 1 (the mark can be attached) and 2 (it already has the mark).

3.2 Clustering on Kanji

In modern Japanese literary text, various Kanji characters were found commonly even in a sentence compared to nowadays. However, the frequency of each Kanji character varies. Learning tends to be sparse around a Kanji character that appears only several times in training corpus. For example, if "深" (deep) appeared only once in training corpus as in a word "深い" (is deep), then we will not be able to use the information "深" in a phrase "深けれは" (if it is deep) when we classify a character "は" in "深けれは."

[4] http://www2.ninjal.ac.jp/lrc/index.php?%C2%C0%CD%DB%A5%B3%A1%BC%A5%D1%A5%B9

[5] Kunoji-ten is a iteration mark, either "く" or "ぐ".

[6] Katakana characters had been used for specific words like adopted words and proper nouns. Thus, we excluded Katakana characters in this paper.

target character position

Markedness 3-gram:	-3/020 -3/010	-2/201 -2/101	-1/011	0/110	1/100		

Figure 3: Feature for classification of unmarked characters.

Therefore, we carry out clustering on Kanji characters and add character class n-gramin feature sets. For example, if "深" and "寒" (cold) belong to the same class X, and "寒" appears in training corpus as in a phrase "寒ければ" (if it is cold), then features corresponding to a phrase "X ければ" (if it is X) will be learned from "寒ければ." As a result, we will be able to exploit "深" as evidence of detecting "は" in "深ければ" as unmarked character.

Clustering was performed on Kanji characters with the subsequent and the previous two characters individually based on (Pereira et al. 1993).

A Kanji character that appears left of the target character is replaced with the class of the former-clusters and that appears right is replaced with the class of the latter-clusters.

4 Experiments

We conducted two experiments for evaluating our method as follows.

4.1 Experimental Settings

We compare three approaches for automatic labeling of unmarked character as a pre-processing to morphological analysis on historical texts.

First, we built a naive generative model as baseline for labeling voiced consonant mark. This method labels voiced consonant marks that maximize the likelihood of a sentence by using a character 3-gram model. One deficiency of the baseline method is that it requires a fully annotated corpus with the marks.

Second, for the dictionary-based approach, we created a dictionary and corpus from the same training corpus used by the Kindai-bungo UniDic (U-Train) with all the marks removed. We preserved the original orthography in the field of each entry. We then trained a morphological analyzer[7] using the dictionary and corpus. Finally, we added to the dictionary entries with which we partially (or completely) replaced voiced consonant marks. This method assigns voiced consonant marks and performs morphological analysis jointly. However, it requires an annotated corpus with both the marks, word segmentation and part-of-speech tags, which are scarce to obtain.

Third, we constructed a proposed classifier from an annotated corpus with the voiced consonant marks. Our method does not need the information of word segmentation and part-of-speech. There-

[7] http://mecab.sourceforge.net/

Training corpus	positive	negative	all
U-Train	25,910	111,511	137,421
T-Train	208,097	966,308	1,174,405
K-Train	24,185	-	24,185

Table 2: Number of instances in each training corpus.

Test corpus	positive	negative	all
T-Eval	899	93,022	93,921
K-Eval	3,843	25,461	29,304

Table 3: Number of instances in each test corpus.

fore we can take advantage of Taiyo-Corpus. We use only articles written in a literary style in the corpus (398,077 sentences). We use 10% of this corpus for evaluation (T-Eval, including 33,847 sentences), and the rest for training (T-Train, including 364,230 sentences).

For evaluation, we prepared a modern Japanese magazine "Kokumin-no-Tomo" corpus (85,291 sentences). It is not annotated with word boundaries nor part-of-speech tags. From the corpus, we use four numbers for testing, No.10, 20, 30 and 36, which we had finished annotating voiced consonant mark at the time (K-Eval, including 10,587 sentences), and the rest for training (K-Train, including 74,704 sentences).

4.2 Preparing Training and Test Corpus

We extract training instances from all ambiguous characters. We regard instances with the mark as positive instances and instances without the mark as negative instances. Note that we detach voiced consonant mark from target character when extracting training instances. Although we extract test instances in a similar manner, we do not count characters originally with the mark at testing. In other words, we evaluate the accuracy only on unmarked characters present in real world setting. We show per instance breakdown of training and evaluation instances in Tables 2 and 3.

4.3 Tools

In this paper, we use an online Passive Aggressive algorithm, specifically PA-I for learning a binary classifier with (Yoshinaga et al. 2010).[8] We use a linear kernel and set the iteration number to 20. Also, we optimized the regularization parameter C by performing 10-fold cross-validation on the training corpus.

[8]http://www.tkl.iis.u-tokyo.ac.jp/~ynaga/opal/

We performed clustering on Kanji with narrative sentences in training corpus. We used a clustering tool bayon[9] that implements the Repeated Bisection algorithm, which is a variant of the k-means algorithm. We use the product of probability of character bigram $P(char_1|char_{kanji})$ and trigram $P(char_2|char_{kanji}char_1)$ as distributions of two characters connecting to Kanji $P(char_1char_2|char_{kanji})$. Probabilities of character bigram and trigram are calculated by using the language modeling toolkit Palmkit.[10] We use Witten Bell smoothing. For computational efficiency, we replaced characters that are not Hiragana or Odori-ji with character type when creating the language model.

4.4 Experiment 1: intrinsic

In our first intrinsic experiment, we compared the precision, recall and F-measure of labeling voiced consonant mark with three approaches.

Table 4 presents the results of the intrinsic evaluation. The proposed method outperforms other methods in terms of precision and F-measure using the same training corpus. Moreover, by adding T-Train, the proposed method achieves the best performance in all evaluation metrics including recall. This is because our proposed method can benefit from a large-scale annotated corpus with voiced consonant marks, which is not possible for the dictionary-based method since it requires fully annotated corpus with words and part-of-speech tags. Although the baseline method can use corpora annotated with voiced consonant marks and achieves comparable performance to the proposed method regarding recall, its precision is inferior to the proposed method by a large margin. We suppose that this improvement comes from discriminative learning of the language model, which enables us to design flexible features. Generally, precisions are lower in T-Eval than in K-Eval over all methods. This is because T-Eval has relatively few positive instances and most of the instances are difficult to judge whether they are unmarked or not even for human.

In the baseline and the proposed method, performance is improved further by increasing amount of training data. By adding T-Train for U-Train, F-measure increases more than 10-points in T-Eval. We show in Figure 4 the change in recall

Table 4: Performance of intrinsic evaluation: labeling voiced consonant mark.

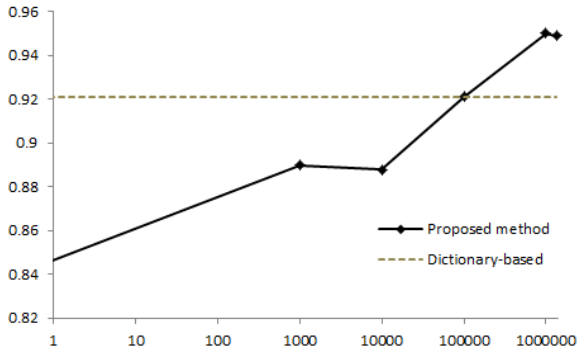

Figure 4: Improvement of recall with adding training instances.

when adding training instances from T-Train to U-Train in T-Eval (k=100). We confirmed that with just 1,000 instances added, recall increased 0.05 with the proposed method. Moreover, the proposed method's recall exceeded that of the dictionary-based approach after 100,000 instances were added. Although the F-measure was degraded by adding positive instances from K-Train, recall improved in K-Eval since positive instances add evidence for decision on voiced consonant marks. Apparently, it is effective to add instances from the same domain. However, the baseline and dictionary-based methods are not capable of using partially annotated corpora like K-Train. Our method employs pointwise prediction to make use of partially annotated corpus. Thus, we confirmed the effectiveness of using partially annotated corpora.

In addition, the proposed method shows the highest performance in k=1,000 for T-Eval and k=100 for K-Eval, respectively, when learned on T-Train and U-Train. In all settings, clustering improves precision while recall sometimes deteriorates. The performance gain is even larger when training data is scarce (See the results of U-Train). From this fact, we confirmed the effectiveness of clustering on Kanji for addressing the data sparseness problem.

Table 5 lists our features and their performance. Because the performance of detection degrades drastically when we subtract Character n-gram from All, this feature is crucial for determining unmarked characters. This is another piece of evidence that discriminative language model works quit well for this task. On the other hand, both Character type n-gram and Markedness n-gram contribute to improvement of precision. As a result, F-measure increases using those features.

We also investigated errors of the classification on our method. Although we found some errors which due to lack of training data, we found errors which are difficult to determine without discourse context, like "か"(ka) of binding particle or auxiliary verb and "が"(ga) of case-marking particle or auxiliary verb. However, these instances are difficult even for human to determine whether unmarked or not. Since the basic policy is to use the mark when there is ambiguity, the absence of the mark in an ambiguous case can be considered as evidence of non-unmarked character. Moreover,

Feature	Prec.[%]	T-Eval/K-Eval Rec.[%]	F
Character n-gram only	70.041/95.882	**95.439**/98.152	80.791/97.004
All − Character n-gram	2.521/20.000	1.001/ 0.156	1.433/0.310
All − Character Type n-gram	70.651/96.028	95.328/98.126	81.115/97.066
All − Markedness n-gram	69.764/95.884	95.217/**98.205**	80.527/97.031
All	**72.472/96.146**	94.883/98.022	**82.177/97.075**

Table 5: Performance of each feature and their combination.

our method can not refer the discourse information since we only employed local context of character n-grams. Therefore, our method excessively tend to classify characters into unmarked. On the other hand, we found instances for which both unmarked and marked form are acceptable, like "結び"(tie) and "結ひ"(tie). Note that "結び" and "結ひ" are pronounced differently as "musubi" and "yui," respectively. These instances seem to be the cause of degradation of precisions in T-Eval. For Odori-ji, it tends to fail classification because they not only depend on information of previous consonants but also on common practice such as "かえす ぐ (がえす)"(again and again).

4.5 Experiment 2: extrinsic

As a second extrinsic experiment, we investigated how effective these approaches are at improving accuracy of morphological analysis.

To create gold-standard annotation for morphological analysis, we take the result of morphological analysis for the corpus annotated with voiced consonant marks using the standard version of Kindai-bungo UniDic. Since the word and part-of-speech information are not available in Taiyo and Kokumin-no-Tomo corpus, this constitutes the upper bound of the morphological analysis performance on these data.

We evaluated the result of morphological analysis for two methods. First, we tested the dictionary-based method by performing morphological analysis using the same Kindai-bungo Unidic with additional entries that partially (or all) without voiced consonant marks as we described in section 4.1. Second, we evaluated the proposed method by pre-processing the unlabeled test corpus with the proposed method and performing morphological analysis using the standard version of Kindai-bungo Unidic. Then, we calculated the agreement rate between each method and the gold standard by counting how many sentences are identical to the gold standard. We compared each word's parts-of-speech tags and lexemes for the comparison.

	Taiyo	Kokumin-no-Tomo
Dictionary-based	91.479 [%]	88.968 [%]
Proposed method	99.016 [%]	96.647 [%]

Table 6: Performance of extrinsic evaluation: agreement rate of morphological analysis result.

Table 6 shows the results of the extrinsic evaluation. As you can see, the proposed method gives higher agreement with the gold standard in morphological analysis results than the dictionary-based approach, thanks to the large scale Taiyo corpus annotated with voiced consonant marks. In these experiments, we confirmed that pre-processing with the proposed method is effective for improving morphological analysis of unnormalized modern Japanese literary text.

5 Conclusion

In this paper, we proposed a pointwise approach to label voiced consonant marks for modern Japanese literary text. We confirmed that pointwise prediction outperforms the dictionary-based approach by a large margin. By using the proposed method as pre-processing, morphological analysis results become much closer to the gold standard than using the dictionary-based approach.

Also, we are using the method for annotating the modern Japanese literature. Thanks to the method, we are able to accelerate manual annotation with considerably small effort.

One limitation is that we only deal with unmarked characters in this work. In modern Japanese literary text, there are other orthographic variations such as Okuri-gana and Kana-usage as well. As our future work, we will work on normalizing these variations for improving accuracy of morphological analysis.

We hope this work will encourage further investigation into historical work.

$\mathcal{S}^3$ - Statistical Saṃdhi Splitting

Abhiram Natarajan and Eugene Charniak
Brown Laboratory for Linguistic Information Processing
Brown University, USA
abhiram.nat@gmail.com, ec@cs.brown.edu

Abstract

The problem of Saṃdhi-Splitting is central to computational processing of Sanskrit texts. Currently the best-known algorithm for this task, given a chunk, generates all possible splits and chooses the Maximum-a-Posteriori estimate as the final answer. Our contributions to the task of Saṃdhi-Splitting are two-fold. Firstly, we improve upon the current algorithm by proposing a principled modification of the posterior probability function to achieve better results. Secondly, we propose an algorithm based on Bayesian Word-Segmentation methods. We find that the unsupervised version of our algorithm achieves a better precision than the current algorithm with the original probabilistic model. We then present a supervised version of our algorithm that outperforms all previous methods/models.

1 Introduction

Sanskrit, considered to be among the oldest languages in the world, is elaborate in its oral specifications. It possesses a set of euphonic rules called Saṃdhi[1] rules, which when applied, cause phonological changes at word or morph boundaries. These rules are enumerated in Pāṇini's Aṣṭādhyāyī, and have been devised with the aim of achieving epigrammatic brevity. There are two kinds of Saṃdhi:

1. Internal Saṃdhi: Euphonic transformation at morph boundaries; $W_1x + yW_2 \Rightarrow W_1zW_2$, where x and y are the final and initial segments of W_1 and W_2, respectively, and z respresents the smoothed phonetic transformation of x and y together
   E.g: dīpena udvejayati ⇒ dīpenodvejayati
2. External Saṃdhi: Phonetic change at word boundaries; $W_1x + W_2 \Rightarrow W_1x' + W_2$, where the final segment of the first word x changes to x'
   E.g: utthitaḥ vidyādharaḥ ⇒ utthito vidyādharaḥ

We shall refer to the process of making the euphonic transformations as *Saṃdhising* and the text formed as a result as *Saṃdhied text*. The process of undoing the euphonic transformations shall be referred to as *Analysis* or *Saṃdhi-Splitting*[2], and the text formed as a result will be referred to as *Analysed text*.

It is easy to see that the task of *Saṃdhi-Splitting* is ambiguous. For instance, any of {(ca,api), (cā,api), (ca,āpi), (cā,āpi)} could have combined to form cāpi. Contextual knowledge is necessary for perfect *analysis* of Sanskrit text (Hellwig, 2009), and current methods have not evolved enough to be able to supply context. However the field of Statistical Machine Learning, by making reasonable assumptions, allows us to provide approximations of these processes. Previous work (Beesley, 1998; Hyman, 2007) indicates that Finite State Transducers (FST) could be used to generate morphologically valid splits. Mittal (2010) considers the FST approach as well as an approach based on Optimality Theory (Prince and Smolensky, 1993), by defining a posterior probability function to choose among all morphologically valid splits of a chunk (OT1). More recently, Kumar et al. (2010) report findings using a different posterior probability function with the same Optimality Theory approach (OT2).

Firstly, we derive our own posterior probability function, which is different from OT1 and OT2.

[1] Literally means "Putting Together".

[2] We shall use these terms interchangeably.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 301–308,
Chiang Mai, Thailand, November 8 – 13, 2011.

We observe better results. Secondly, and more importantly, we present a *Saṃdhi-Splitting* technique based on the Bayesian Word-Segmentation methods presented by Goldwater et al. (2006a). These methods in turn are based on the Dirichlet process. The Dirichlet process is a continuous multivariate distribution used in nonparametric Bayesian Statistics, often as a convenient prior distribution. Gibbs sampling is used to sample from the posterior distribution of *analysed* texts given the *Saṃdhied text*.

The paper is organised as follows. In Section 2, we discuss the Optimality Theory approach in detail. In Section 3, we introduce our framework for *Saṃdhi-Splitting*. We present both the unsupervised and supervised versions of our algorithm in this section. Section 4 then provides specific details of our implementations and Section 5 contrasts the results obtained by all the methods/models considered. Section 6 concludes the paper.

2 Current Methods

The literature on *Saṃdhi-Splitting* is too huge for us to do justice. We shall stick to the best published results so far, which have been obtained by the OT method (Kumar et al., 2010; Mittal, 2010). Procedure 1 is a pseudocode representation of the OT method.

Procedure 1 : Saṃdhi-Splitting using OT

1: **for each** $chunk \in \mathcal{D}$ **do**
2: $\mathbb{S} \leftarrow$ getAllPossibleSplits($chunk$)
3: $\mathbb{S}' \leftarrow \{x : x \in \mathbb{S}, x$ is morphologically valid$\}$
4: $l \leftarrow \arg\max_s \{\hat{P}(s) : s \in \mathbb{S}'\}$
5: **print** l

The procedure is quite straightforward. Each candidate chunk is recursively broken (Line 2) to generate all possible splits. Each split is passed through a morphological analyser and the splits that contain one or more invalid morphs are discarded (Line 3). Finally, the Maximum a posteriori (MAP) estimate is chosen as the answer (Line 4).

$\hat{P}(s)$ is the posterior probability function, which we derive as follows. Consider a morphologically valid split $s =< c_1, \ldots, c_m >$, where $c_1 \ldots c_m$ are its constituents, which was obtained after applying rules $r =< r_1, \ldots, r_{m-1} >$[3] on a chunk $\mathcal{C}$. We would need to find the most probable split, which is given by $\arg\max_{s \in \mathbb{S}'} P(s|\mathcal{C})$. Using the noisy channel model framework (Shannon, 1948), we get

$$\arg\max_{s \in \mathbb{S}'} P(s|\mathcal{C}) = \arg\max_{s \in \mathbb{S}'} P(\mathcal{C}|s) \times P(s) \quad (1)$$

We know that s is a result of applying r on $\mathcal{C}$ at specific points. Now, $P(\mathcal{C}|s)$ reads as the conditional probability of obtaining $\mathcal{C}$ given that r was applied at exactly those points. Clearly, this is 1. Thus the MAP estimate would be a split that maximises the probability of the prior

$$l = \arg\max_{s \in \mathbb{S}'} \hat{P}(s) \quad (2)$$

Note that we use the notation $\hat{P}$ instead of P because we can never know the true value of $P(s)$, but can only estimate it from our training set. Let us now turn our attention to $\hat{P}(s)$. We read $\hat{P}(s)$ as the probability of generating the morphs $< c_1, \ldots, c_m >$. Thus we get:

$$\begin{aligned} \hat{P}(s) &= \hat{P}(c_1) \times \hat{P}(c_2 \,|\, c_1) \times \hat{P}(c_3 \,|\, c_1, c_2) \times \ldots \\ &= \prod_{j=1}^{m} \hat{P}(c_j) \qquad \text{[Assuming Independence]} \end{aligned} \quad (3)$$

Equation 3 describes a generative model in that it shows us how we can generate the morphs $< c_1, \ldots, c_m >$. Mittal (2010) defines $\hat{P}(s)$ as

$$\frac{\prod_{i=1}^{m-1} \left(\hat{P}(c_i) + \hat{P}(c_{i+1})\right) \times \hat{P}(r_i)}{m} \quad (4)$$

Kumar et al. (2010) define $\hat{P}(s)$ as

$$\frac{\left(\prod_{i=1}^{m} \hat{P}(c_i)\right) \times \left(\prod_{j=1}^{m-1} \hat{P}(r_j)\right)}{m} \quad (5)$$

In each of these models, the maximum likelihood estimators for $\hat{P}(c_i)$ and $\hat{P}(r_j)$ are used, i.e. $\hat{P}(c_i)$ is set to the relative frequency of c_i in the training set, and $\hat{P}(r_j)$ to the relative frequency of the usage of r_j in the training set.

[3] Rule r_i is applied between c_i and c_{i+1}

Note that unlike Equation 4 and Equation 5, Equation 3 does not have rule probabilities. This can be explained by keeping in mind that Equation 3 describes a generative model. If we generated morphs and knew that they had to be combined to form a chunk, the rules are uniquely determined. In Section 5, we shall compare the results obtained by using each of Equations 3, 4 and 5 on standard datasets.

3 *Saṃdhi*-Splitting based on the Dirichlet Process

Our method is similar to the two-stage modelling framework described by Goldwater et al. (2006a; 2006b). The framework has two components, a morph *generator* which generates morphs likely to be found in a lexicon, from some probability distribution, and an *adaptor* which determines how often each of these morphs occur. Section 3.1 and Section 3.2 describe the unsupervised version of our algorithm while Section 3.3 describes the supervised version.

3.1 Foundations

In the realm of the framework, a *saṃdhied* chunk $\mathcal{C} = c_1 \ c_2 \ \ldots \ c_m$ can be viewed to be created as follows:

1. A *generator* P_s generates a super-set sequence of morphs[4]: $\mathbb{M} = M_1 \ldots M_n$ from a probability distribution P_s.

2. The *adaptor* P_γ generates a sequence of integers: $\mathbb{Z} = z_1 \ldots z_m$, each of which are identifiers of one particular item from $\mathbb{M}$. This means that $1 \leq z_i \leq n$, and $z_i = x \Rightarrow c_i = M_x$.

Once the morphs of a chunk are generated, *Saṃdhi* rules are applied between them to form $\mathcal{C}$. Henceforth $TwoStage(P_\gamma, P_s)$ shall be used to denote a two-stage framework with P_γ as the adaptor and P_s as the generator. Let us move to the Chinese Restaurant Process, which we use as our *adaptor*.

[4]In the case of *Internal Saṃdhi*, we consider morph boundaries and in the case of *External Saṃdhi*, we consider word boundaries. The theoretical foundations hold good for both cases. Thus the reader must always keep in mind that the concepts presented in this section apply at word boundaries too.

3.1.1 Chinese Restaurant Process

Having studied many corpora of natural language utterances, Zipf (1932) made a famous empirical observation that word frequencies follow a power-law distribution, i.e., the frequency of a word is inversely proportional to its frequency rank. This means that the most frequent word in a corpus occurs twice as often as the second most frequent word, thrice as often as the third most frequent word, and so on. Mathematically speaking, if w_r is the r-ranked word in a corpus, then

$$f(w_r) \propto \frac{1}{r^c} \tag{6}$$

where $f(w_r)$ denotes the frequency of occurrence of w_r, and $c \approx 1$. The veracity of this law has hence been verified by a study on present-day English (Kucera and Francis, 1967).

Typically, power-law distributions are produced by stochastic processes in which outcomes accrue probability based on the probability they already have. Such processes are called preferential attachment processes. Let us turn our attention to the Chinese Restaurant Process (Aldous et al., 1985) (CRP), which is one such process. The process is best explained by specifying how to draw a sample from it. Consider a restaurant with an infinite number of tables, each with infinite capacity. Customers enter the restaurant, one at a time, and seat themselves at a table of their choice. They choose an occupied table with probability proportional to the number of people already present at the table, or an unoccupied table with probability proportional to some real-valued scalar parameter α. The first customer always sits at the first table. Then onwards, the i^{th} customer sits at a table T_i, and T_i follows the distribution:

$$P\left(T_i = k \,|\, \text{Previous Customers}\right) = \begin{cases} \frac{n_k}{i-1+\alpha} & 1 \leq k \leq N_{i-1} \\ \\ \frac{\alpha}{i-1+\alpha} & k = N_{i-1}+1 \end{cases} \tag{7}$$

where n_k is the number of people occupying table k and N_{i-1} is total number of tables occupied by the previous $(i-1)$ customers.

When the CRP is combined with a morph *generator*, it can be used to generate a power-law distribution over morphs. Such a model can be described as $TwoStage(CRP(\alpha), P_s)$. We could

view this as restaurant where each table represents a morph. Every customer is also labelled with a morph and can either sit only at tables which are labelled with the same morph, or at an unoccupied table. A customer at a table represents one occurence of the morph that is represented by the table. To get the probability distribution of the i^{th} morph, we must sum over all the tables labelled with that morph:[5]

$$\begin{aligned} &P\left(c_i = c \mid c_{-i}\right) \\ &\quad = P(\text{assign customer to any of the } c \text{ tables}) \\ &\qquad + P(\text{assign customer to a new table}) \\ &\quad = \frac{n_c^{c_{-i}}}{i-1+\alpha} + P_s(c) \times \frac{\alpha}{i-1+\alpha} \\ &\quad = \frac{n_c^{c_{-i}} + \alpha \times P_s(c)}{i-1+\alpha} \end{aligned} \tag{8}$$

where $c_{-i} = c_1 \ldots c_{i-1}$ and $n_c^{c_{-i}}$ represents the number of occurrences of c in c_{-i}.

Let us examine Equation 8. It is in accordance with the principle of *preferential attachment*. This is because the probability of generating a morph that has already been generated increases as more instances of the morph are observed. Also note that the sparseness of the distribution generated increases with an increase in the value of the parameter α. This is explained by the fact that $\alpha \times P_s(c)$ is constant and it reduces w.r.t. the first summand over time. What this means is that the probability of generating a novel morph decreases (but never dissapears fully) as more data is observed.

Let us now turn our attention to the *generator*. For simplicity, we choose a unigram phoneme distribution for P_s. If a morph c_i contains the phonemes $a_1 \ldots a_d$

$$P_s(c_i) = p_\Phi (1-p_\Phi)^{d-1} \prod_{j=1}^{d} P(a_j) \tag{9}$$

where p_Φ is the probability of a *Saṃdhi* rule being applied at any juncture. The reasoning for the equation is quite straightforward - the *Saṃdhi* rule is not applied $(d-1)$ times, and applied at the d^{th} phoneme. The unsupervised version of the algorithm uses an uniform distribution over phonemes.

[5]Note that two different tables may represent the same morph.

3.1.2 Dirichlet Process Model

Given a coin with an unknown bias, say p, what would be a suitable distribution that reflects our expectations about p? It would be the Beta distribution. The Dirichlet distribution is a generalisation of the Beta distribution, in that it may have more than just two dimensions. The Dirichlet process is an infinite dimensional version of the Dirichlet distribution. Each sample from a Dirichlet process returns a distribution over an infinite set of random variables.

Let us consider a Dirichlet process with its parameters as α and P_s. A sample from this process, say G, will consist of a set of all possible morphs and their corresponding probabilities. Now, we can generate each morph c_i in the corpus from the distribution G. This can be represented as follows:

$$\begin{aligned} c_i &\sim G \\ G &\sim DP(\alpha, P_s) \end{aligned} \tag{10}$$

Following the argument in Goldwater (2006), it is not hard to find that the model described by $TwoStage(CRP(\alpha), P_s)$ is equivalent to the model represented by Equation 10.

We must also keep in mind that, analogous to Equation 8, the probability of i^{th} morph $c_i = c$ is given by

$$P(c_i = c \,|\, c_{-i}) = \frac{n_c^{c_{-i}} + \alpha \times P_s(c)}{i-1+\alpha} \tag{11}$$

where $c_{-i} = c_1 \ldots c_{i-1}$, and $n_c^{c_{-i}}$ denotes the number of occurrences of c in c_{-i}. Going ahead a little, we realise that our input corpus is a set of sentences, where each sentence contains a set of *Saṃdhied* chunks, where each chunk is in turn formed by *Saṃdhising* separate morphs. The program does not need to separate the chunks from each other, all it needs to do is to separate a chunk into its constituent morphs. Referring to Equation 3, we recall our generative model view of how a *Saṃdhied* chunk is generated. We describe the process by the following PCFG:[6]

$$\begin{aligned} P(r_i = r_{branch} \,|\, r_{-i}): &\quad S \rightarrow S\ C \\ P(r_i = r_{end} \,|\, r_{-i}): &\quad S \rightarrow C \\ P_s(c_i = c \,|\, c_{-i}): &\quad C \rightarrow c \end{aligned}$$

We shall derive an equation for $P(r_i = r_{branch} \,|\, r_{-i})$ in the next section.

[6]Probabilistic Context-Free Grammar

3.2 Gibbs Sampling for *Saṃdhi* Analysis

As suggested in Gilks et al. (1996), we use Gibbs Sampling to sample from the posterior distrubition of *Saṃdhi* Analyses. One iteration of the algorithm causes the program control to consider every possible splitting point in the data and form two hypotheses, say $\mathcal{H}_1$ and $\mathcal{H}_2$. These hypotheses contain the same structure, except at the point of consideration. If the point of consideration is part of a chunk c, $\mathcal{H}_2$ splits c into two individual morphs (say c_1 and c_2) while $\mathcal{H}_1$ does not. Let $\mathcal{H}^{\cap}$ denote the structure common to both $\mathcal{H}_1$ and $\mathcal{H}_2$.

Given the way Gibbs sampling works, we know that we only need the relative probabilities of $\mathcal{H}_1$ and $\mathcal{H}_2$. Also, we must recall that the order of arrival of customers in the metaphorical Chinese Restaurant does not affect seating probability, as shown by Aldous et al. (1985). This means that we could consider $\mathcal{H}^{\cap}$ to have already been generated. From Equation 11 we get

$$\begin{aligned} P\left(\mathcal{H}_1 \,|\mathcal{H}^{\cap}\right) &= P\left(c \,|\, \mathcal{H}^{\cap}\right) \\ &= \frac{n_c^{\mathcal{H}^{\cap}} + \alpha P_s(c)}{|\mathcal{H}^{\cap}| + \alpha} \end{aligned} \tag{12}$$

We also derive

$$\begin{aligned} &P\left(\mathcal{H}_2 \,|\mathcal{H}^{\cap}\right) \\ &= P\left(r_{branch} \cup c_1 \cup c_2 \,|\, \mathcal{H}^{\cap}\right) \\ &= P\left(r_{branch} \,|\, \mathcal{H}^{\cap}\right) \times \frac{n_{c_1}^{\mathcal{H}^{\cap}} + \alpha P_s(c_1)}{|\mathcal{H}^{\cap}| + \alpha} \\ &\quad \times \frac{n_{c_2}^{\mathcal{H}^{\cap}} + I(c_1 = c_2) + \alpha P_s(c_2)}{|\mathcal{H}^{\cap}| + 1 + \alpha} \end{aligned} \tag{13}$$

The extra '1' in the denominator of the third item of the product is because after c_1, we have an additional morph. Also, I is the indicator function, which is 1 when the expression inside its parathesis is true. Let us now examine $P\left(r_{branch} \,|\, \mathcal{H}^{\cap}\right)$. Clearly, each time we can choose only one among $\{r_{branch}, r_{end}\}$, so we have $P(r_{branch}) + P(r_{end}) = 1$. The number of r rules applied at the point of consideration would be $(|\mathcal{H}^{\cap}| + 1)$ - one each for the $|\mathcal{H}^{\cap}|$ morphs, and an extra one for the chunk under consideration. We apply a Beta($\frac{\rho}{2}, \frac{\rho}{2}$) prior to get:[7]

$$P\left(r_{branch} \,|\, \mathcal{H}^{\cap}\right) = \frac{n_{r_{branch}}^{\mathcal{H}^{\cap}} + \frac{\rho}{2}}{|\mathcal{H}^{\cap}| + 1 + \rho} \tag{14}$$

[7] Henceforth, please substitute this expression in Equation 13

The algorithm works as follows - we begin with a random *analysis* of the corpus. After that, using Equations 12 and 13, we sample every potential boundary point. An iteration is said to have completed when the sampler samples over the entire corpus. We run multiple iterations of this process, until convergence.

Simulated annealing (Aarts and Korst, 1989) is used to facilitate choosing of low probability transitions early in the algorithm, lest it gets stuck at a local maximum.

3.3 Supervised Version

As mentioned earlier, we use Gibbs Sampling to sample from the posterior distribution. Let us recall the relevant equations - Equations 12 and 13. In the supervised version of our algorithm, we use available training data (say D_{train}) to our advantage. Firstly, we define $\mathcal{H}^{\cap'} = \mathcal{H}^{\cap} \cup D_{train}$.

Also, instead of assuming a uniform distribution over phonemes, we infer phoneme probabilities from D_{train}:

$$P_s'(c_i) = p_{\Phi}(1 - p_{\Phi})^{d-1} \prod_{j=1}^{d} \hat{P}(a_j) \tag{15}$$

Let Π denote the set of all phonemes found in D_{train}. Given a phoneme a_x, we set $\hat{P}(a_x)$ to be the maximum likelihood estimate:

$$\hat{P}(a_x) = \frac{n_{a_x} + \alpha_0}{n_* + \alpha_0 |\Pi|} \tag{16}$$

where n_{a_x} is the number of times a_x occurs in D_{train}, $n_* = \sum_{p \in \Pi} n_p$, and α_0 is the unigram smoothing constant.

Thus we get

$$P\left(\mathcal{H}_1 \,|\mathcal{H}^{\cap'}\right) = \frac{n_c^{\mathcal{H}^{\cap'}} + \alpha P_s'(c)}{|\mathcal{H}^{\cap'}| + \alpha} \tag{17}$$

and

$$\begin{aligned} &P\left(\mathcal{H}_2 \,|\mathcal{H}^{\cap'}\right) \\ &= \frac{n_{r_{branch}}^{\mathcal{H}^{\cap'}} + \frac{\rho}{2}}{|\mathcal{H}^{\cap'}| + 1 + \rho} \times \frac{n_{c_1}^{\mathcal{H}^{\cap'}} + \alpha P_s'(c_1)}{|\mathcal{H}^{\cap'}| + \alpha} \\ &\quad \times \frac{n_{c_2}^{\mathcal{H}^{\cap'}} + I(c_1 = c_2) + \alpha P_s'(c_2)}{|\mathcal{H}^{\cap'}| + 1 + \alpha} \end{aligned} \tag{18}$$

The supervised version of the algorithm now works exactly the same way as the unsupervised version, except that Gibbs sampling is done using Equations 17 and 18.

4 Implementation Details

As a part of the Consortium project in India, a corpus of nearly 25000 parallel strings of *Saṃdhied* and *analysed* text has been formed (say D_1). OT trains on the 25000 string dataset and tests on a separate dataset of 2148 *Saṃdhied* Chunks (say D_2). We see that the test set used in OT only contains examples of *Internal Saṃdhi*. Thus, we merge the test set with the original 25000 string dataset ($D = D_1 \cup D_2$) and generate random samples of training data and test data. We use $\frac{3}{4}$ of the data for training (D_{train}) and $\frac{1}{4}$ for testing (D_{test}). Note that D_{test} can have instances of *Internal Saṃdhi*, *External Saṃdhi* as well as no *Saṃdhi*[8] at all. The scores we report are averaged over 5 random samples of D_{train} and D_{test} from D.

We also use the morphological analyser (Akshar Bharati, 2006) provided by the apertium group.

As for the parameters of the model, we fixed $\rho = 2$. We found that a decrease in p_Φ improved recall, but caused long words to get concatenated. At the same time higher values of p_Φ tended to cause over segmentation. It was also observed that higher α values resulted in higher lexicon recall, once again only up to a point. Although it was not possible to arrive a single best value for either α or p_Φ; we fixed them to be $p_\Phi = 0.5$ and $\alpha = 20$. The sampler is annealed with the following temperature schedule - $\frac{1}{\gamma} = 0.1$ to 1.0, in steps of 0.1.

For evaluation, standard statistical measures of Precision, Recall and F-Score were used. Precision indicates how many among the items found are correct; Recall indicates how many among the correct items are found. F-score is the harmonic mean of the Precision and the Recall.

Our implementations work with the Sanskrit Library Phonetic Basic format (SLP1). Since the morphological analyser uses the Hyderabad-Tirupati format (WX), we use the transcoding tools on the Sanskrit Library Website (Scharf and Hyman, 2010). One may refer Huet (2009) for more details about the formats.

[8]This explains why our implementations of OT achieve lower scores than what is reported in their paper. Readers must note that our implementation of OT, when trained on D_1 and tested on D_2, achieved nearly the same accuracy reported in their paper. Thus we believe our implementation of OT is accurate.

5 Results

Let OT1, OT2, OT3 denote versions of Procedure 1, using Equations 4, 5, 3 as the posterior probability functions, respectively. Precision is calculated as the percentage of correct segmentations among all the segmentations made by the algorithm. Recall is calculated as the percentage of correct segmentations made by the algorithm among all the correct segmentations that need to be made. F-Score is the harmonic mean of the Precision and Recall. Table 1 shows the scores obtained by our implementations of different versions of OT.

Method	Precision	Recall	F-Score
OT1	54.61	62.08	58.11
OT2	63.96	68.74	66.26
OT3	**70.52**	66.61	**68.51**

Table 1: Accuracies obtained by different versions of OT; OT3 outperforms OT1 and OT2 in Precision and F-Score

As we can see, using Equation 3 as the posterior probability function while obtaining the MAP estimate, we improve the previous best F-Score by nearly 3.5%. We shall now examine the results obtained by four different versions of the framework described in Section 3. Let these versions be denoted by NC1 ... NC4:

1. NC1 denotes the Two-Stage Framework in its most basic state. The algorithm possesses no linguistic knowledge whatsoever.

2. Kessler (1994) shows that each Sanskrit syllable must have only one Sonority peak. NC2 uses this knowledge to effect. The method is largely similar to NC1 except for the way in which sampling is done. We only sample when we are sure that the segments we generate do not violate Sonority Hierarchy. Refer Appendix A for more details about sonority hierarchy.

3. NC3 uses a morphological analyser. Sampling is only done when we know that the

segment we are leaving behind is morphologically valid.

4. NC4 uses a morphological analyser as well as training data. Sampling is done using Equations 17 and 18.

Method	Precision	Recall	F-Score
NC1	31.74	41.22	35.86
NC2	50.98	40.43	45.1
NC3	66.55	56.13	60.9
NC4	**76.21**	**64.84**	**70.07**

Table 2: Accuracies obtained by different versions of NC; NC4 Outperforms NC1...3, as well OT1...3 in Precision and F-Score

Results obtained by these versions are shown in Table 2. NC4 improves upon the F-Score achieved by OT2 by nearly 6%.

6 Conclusion

In this paper, we have presented an algorithm for *Saṃdhi*-Splitting which draws on expedients of Bayesian statistics. It is highly flexible in that it works even in the absence of (a) morphological analyser (b) training data. Also, one must remember that an entire corpus, as it is, can be fed to the algorithm, as opposed to OT which would require each *Saṃdhied* chunk separately. Finally, the fact that the algorithm runs in polynomial time, as opposed to OT which takes exponential time, further asserts the efficacy of the method.

A Sonority Hierarchy

Sonority hierarchy is as follows: Vowels $>$ Semivowels $>$ Nasals $>$ Spirants $>$ Voiced Stops $>$ Unvoiced Stops

- Vowels = AaEOeoiIuUfFxX
- Semivowels = yvrl
- Nasals = NYRnmM
- Spirants = hSzsH
- Voiced Stops = gGjJqQdDbB
- Unvoiced Stops = kKcCwWtTpP'

A syllable is said possess a sonority violation if it has more than one sonority peak (e.g. 'rjA'). However, at the beginning of a syllable, we must rate Spirants at the same level as Unvoiced Stops (e.g. 'sTApayati' is valid).

Improving Chinese Word Segmentation and POS Tagging with Semi-supervised Methods Using Large Auto-Analyzed Data

Abstract

This paper presents a simple yet effective semi-supervised method to improve Chinese word segmentation and POS tagging. We introduce novel features derived from large auto-analyzed data to enhance a simple pipelined system. The auto-analyzed data are generated from unlabeled data by using a baseline system. We evaluate the usefulness of our approach in a series of experiments on Penn Chinese Treebanks and show that the new features provide substantial performance gains in all experiments. Furthermore, the results of our proposed method are superior to the best reported results in the literature.

1 Introduction

In Chinese, most language processing starts from word segmentation and part-of-speech (POS) tagging. These two steps tokenize a sequence of characters without delimiters into words and predict a syntactic label (POS tag) for each segmented word. They are considered indispensable steps for higher-level NLP tasks such as parsing and information extraction. Although the performance of Chinese word segmentation and POS tagging has been greatly improved over the past years, the task is still challenging.

To improve the accuracy of NLP systems, one of the current trends is semi-supervised learning, which utilizes large unlabeled data in supervised learning. Several studies have demonstrated that the use of unlabeled data can improve the performance of NLP tasks, such as text chunking (Ando and Zhang, 2005), POS tagging and named entity recognition (Suzuki and Isozaki, 2008), and parsing (Suzuki et al., 2009; Chen et al., 2009; Koo et al., 2008). Therefore, it is attractive to consider adopting semi-supervised learning in Chinese word segmentation and POS tagging tasks.

In this paper, we present an approach to improve the performance of both segmentation and POS tagging by incorporating large unlabeled data. We first preprocess unlabeled data with our baseline models. We then extract various items of dictionary information from the auto-analyzed data. Finally, we generate new features that incorporate the extracted information for both word segmentation and POS tagging. We also perform word clustering on the auto-segmented data and use word clusters as features in POS tagging. In addition, we introduce lexicon features by using a cross-validation technique.

The use of sub-structures from the auto-annotated data has been presented previously (Noord, 2007; Chen et al., 2008; Chen et al., 2009). Chen et al. (2009) extracted different types of subtrees from the auto-parsed data and used them as new features in standard learning methods. They showed this simple method greatly improves the accuracy of dependency parsing. The idea of combining word clusters with discriminative learning has been previously reported in the context of named entity recognition (Miller et al., 2004; Kazama and Torisawa, 2008) and dependency parsing (Koo et al., 2008). We adapt and extend these techniques to Chinese word segmentation and POS tagging, and demonstrate their effectiveness in this task.

One of our criteria in this study was to achieve high accuracy with simple and easy-to-implement techniques. To meet this, the whole system is a pipeline with a character-based CRF for word segmentation and a word-based CRF for POS tagging. The information of unlabeled data is incorporated as additional new features without changing the learning algorithm.

To demonstrate the effectiveness of our approach, we conduct segmentation and POS tagging experiments on three versions of Penn Chinese Treebank, including the newly released CTB

version 7.0. We show that our semi-supervised approach yields improvements for all the test collections and achieves better results than the best reported results in the literature.

2 Segmentation and POS tagging Models

We implement our approach using sequential tagging models. Following the previous work (Zhao et al., 2006; Zhao et al., 2010), we employ the linear chain CRFs (Lafferty et al., 2001) as our learning model. Specifically, we use its CRF++ (version 0.54) implementation by Taku Kudo. [1]

2.1 Baseline Segmentation Model

We employ character-based sequence labeling for word segmentation. In addition to its simplicity, the advantage of a character-based model is its robustness to the unknown word problem (Xue, 2003). In a character-based Chinese word segmentation task, a character in a given sequence is labeled by a tag that stands for its position in the word that the character belongs to. Zhao et al. (2006) reported that a 6-tag tagset shown in Table 1 is the best choice among the tagsets tested for Chinese word segmentation under the CRF framework. Therefore we also use this 6-tag tagset.

The basic types of features of our word segmentation model are listed in Table 2. These basic feature templates are based on Zhao et al. (2006; 2010) and Low et al. (2005).

2.2 Baseline POS Tagging Model

Since we employ a pipelined method, the POS tagging can be performed as a word labeling task, where the input is a sequence of segmented words. We use a CRF here as well. The feature set of our baseline POS tagger, is listed in Table 3. These are adopted from Wu et al. (2008).

[1] Available from http://crfpp.sourceforge.net/

3 Our New Features

In this section, we describe our approach of effectively integrating useful information from unlabeled (and labeled) data into the above baseline models through features. We preprocess unlabeled data with our baseline models and obtain word-segmented sentences with POS tags, and generate new features from the auto-analyzed data. Although the focus of the paper is semi-supervised learning, we also extract a lexicon from the training corpus and use it to generate features. Figure 1 shows an overview of our approach. The rest of this section describes our features in detail.

3.1 New features for Word Segmentation

3.1.1 Semi-supervised *n*-gram features

In this section, we describe our approach of extracting character-level *n*-gram lists and generating *n*-gram features from unlabeled data. We followed the method of Chen et al. (2009), and modified the method for word segmentation and POS tagging. First, we preprocess unlabeled data using the baseline segmenter and obtain auto-segmented data. We then extract character *n*-gram lists from auto-segmented sentences. Finally, we generate *n*-gram features for word segmentation.

By using the baseline segmenter, each character c_i in the unlabeled data is labeled with a tag t_i. In other words, the output of auto-segmentation is a sequence $\{(c_i, t_i)\}_{i=1}^{L}$. Let g be a character *n*-gram (e.g., uni-gram c_i, bi-gram c_ic_{i+1}, tri-gram $c_{i-1}c_ic_{i+1}$ and so on)[2], and seg be a segmentation profile for n-gram g observed at each position. The segmentation profile can be tag t_i or the combination of tags. Take a bi-gram for example, seg may be t_i or t_it_{i+1}. Then,

[2] Note that there are several alternative ways for extracting n-grams at position i, for example $c_{i-1}c_i$ for a bi-gram. In this paper, we used the way as explained here.

Feature Type	Context Position	Description
Word Unigram	w_{-2},w_{-1},w_0,w_1,w_2	Word unigram
Nearing Word Bigram	($w_{-2}w_{-1}$),($w_{-1}w_0$),(w_1w_0),(w_1w_2)	Word bigram
Jump Word Bigram	(w_{-1},w_1)	Previous word and next word
First Character	$Fc(w_0)$	First character of current word
Last Character	$Lc(w_0)$	Last character of current word
Length	$Len(w_0)$	Length of current word

Table 3: Feature templates for POS tagging

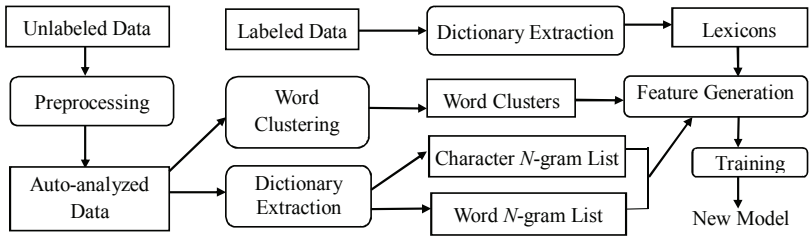

Figure 1: Overview of the proposed approach

we can extract a list of $\{(g, seg, f(g, seg))\}$ from the auto-segmented data. Here, $f(g, seg)$ is the frequency of the cases where n-gram g is segmented with the segmentation profile seg. Then, following Chen et al. (2009), we group entries in this list into three sets: high-frequency (HF), middle-frequency (MF), and low-frequency (LF). The sets are defined as follows: if (g, seg) is one of the top 5% most frequent entries, it is labeled as HF; if it is between top 5% and 20%, it is labeled as MF, otherwise it is labeled as LF. Finally the list can be transformed as a *n*-gram list $L_{ng} = \{(g, seg, FL(g, seg))\}$, with $FL(g, seg)$ being the frequency label determined as above.

We attempted to encode the information of the above *n*-gram list into a new type of features, called *n*-gram features. We tried several feature representations and generation methods and found that the feature derived from the bi-gram list with $seg = t_i$ was most effective.

We generate the feature for the current character c_0 as follows. We retrieve a set of entries, whose g part matches the bi-gram c_0c_1, from L_{ng}. Let this set be L_m. From an entry in L_m, we generate a feature string represented by

(a) $seg - FL(g, seg)$

Then, we concatenate the feature strings of all the entries in L_m as one n-gram feature. If there is no entry in L_m, the feature representation is "*ND*".

For example, consider that L_m is { (幸*(Xing)*/福*(Fu)*, *B*, *HF*), (幸*(Xing)*/福*(Fu)*, *B2*, *MF*), (幸*(Xing)*/福*(Fu)*, *E*, *LF*)} and we are processing c_kc_{k+1} = "幸*(Xing)*/福*(Fu)*"; consequently, the *n*-gram feature of c_k is represented as "*B-HF|B2-MF|E-LF*". Note that the concatenation is in lexicographic order of the feature strings for standardization.

3.1.2 Lexicon features

Although a character-based model is simple and robust to unknown words, a limitation is its inability to consider word-level information. If a sequence of characters matches a word in an existing dictionary, it may be a clue that the character sequence should be segmented as one word. Several studies showed that using a dictionary brings improvement for Chinese word segmentation (Low et al., 2005; Zhao et al., 2010). For a corpus-based word segmenter, a manually annotated corpus is essential. Thus we can easily compile a lexicon from a training corpus. We refer to the features related to this lexicon as lexicon features.

In this study, we extract a lexicon in the following way. We collect words and all possible POS tags of the words from the training corpus. For instance, for the word "交流(*JiaoLiu*)", the collected entry may be (交流(*JiaoLiu*), *NN-VV*). Here, "*NN-VV*" is a concatenation of all the observed POS tags. POS tags are in lexicographical order, as in "*NN-VV*". However, we were concerned that a lexicon compiled in this way could cause an overfitting problem and that meaningful weights for the lexicon features may not be learned. This concern was indeed confirmed by the preliminary experiments using the development set. To solve this problem, we used the following method to build and use lexicons. The method is based on the idea

of cross-validation.

- Divide the training corpus into ten equal-sized sets, as in the data preparation for 10-fold cross-validation.
- For each set, we compile a lexicon using the remaining nine sets and use this lexicon to generate features for this set.
- For the development and test sets, we collect a lexicon using the entire training corpus and use it for feature generation.

Because the lexicon is extracted from other sets, the weights for this feature will not be overestimated by the learning algorithm. This kind of cross-validation-like techniques are used in studies such as Collins (2002) and Martins et al. (2008) to avoid over-fitting to the training data. Our method can be considered as its application to lexicon extraction.

Using the extracted lexicon, we generate lexicon features as follows. If a character sequence starting with character c_0 matches some words in the lexicon, we greedily choose the longest such matching word w. Letting $LEN(w)$ be the length (the number of characters) of w, we add the following feature for each character c_k in $c_0, c_1, ..., c_{LEN(w)}$:

(b) $P(c_k)/LEN(w)\text{-}POSs(w)$

Here, $P(c_k)$ is the position number (i.e., k) of the character c_k in w and $POSs(w)$ represents the POS tags of w in the lexicon. After generating these features, we increment the current position by $LEN(w)$. If there is no matching word, we proceed to the next character. That is, the forward maximum matching is used.

For example, consider that the current character sequence c_0c_1= "幸*(Xing)*/福*(Fu)*" was matched with a lexicon entry (幸福*(XingFu), JJ-NN-VA*), the feature for c_0 "幸*(Xing)*" is "*1/2-JJ-NN-VA*" and the feature for c_1 "福*(Fu)*" is "*2/2-JJ-NN-VA*".

Several feature representations have been attempted: (i) using only position information, (ii) representing the position information in a 6-tag or 4-tag tagset, or (iii) representing only one POS tag with the highest frequency. Development experiments showed that the current encoding is more effective than others in word segmentation tasks.

Note that our lexicon feature uses POS tag information for word segmentation. The fact that this feature is very effective as reported in Section 4.3 is interesting, since this can be considered as "loose" information feedback from the later process. Although we need a POS tagged corpus even for segmentation, this will not be a big problem since we usually perform POS tagging as well in many applications.

3.2 New Features for POS Tagging

We generate *n*-gram and lexicon features for POS tagging as well. In addition, the features that incorporate word clusters derived from a large auto-analyzed corpus (referred to as cluster features) are introduced.

3.2.1 Semi-supervised *n*-gram features

We preprocess auto-segmented data using the baseline POS tagger and can generate word-level *n*-gram lists $L_{wg} = \{w, pos, FL(w, pos)\}$. Here, w is a word *n*-gram and pos is the POS tagging profile of the word *n*-gram. Different from segmentation, features generated from the word unigram list yielded the best results.

A feature of this type for the current word w_0 is generated as follows. We retrieve a set of entries, whose w part matches the uni-gram w_0, from L_{wg}. Let this set be L_m. In the error analysis, we found that some words were associated with several odd POS tags in the uni-gram list. For instance, in addition to (研究*(YanJiu), NN, HF*) and (研究*(YanJiu), VV, HF*), (研究*(YanJiu), VA, LF*) and (研究*(YanJiu), CD, LF*) may appear as entries in the word unigram list, due to mis-tagging by the baseline POS-tagger. Therefore we further impose a restriction based on the frequency as follows: if the number of entries with a HF label $\geq$ threshold, only the entries with HF will be selected, and if the sum of entries with a HF or MF label $\geq$ threshold, the entries with either HF or MF will be selected, otherwise, all of the entries in L_m will be selected. Here the threshold is set to 2 based on the development experiments. Let these selected entries be L_s. From an entry in L_s, we generate a feature string represented by

(c) $pos - FL(w, pos)$.

Then, we concatenate the feature strings of all entries in L_s as one n-gram feature. As for the previous instance, the feature for "研究*(YanJiu)*" is encoded as "$NN\text{-}HF|VV\text{-}HF$".

3.2.2 Semi-supervised cluster features

Following the work of Koo et al. (2008), we produced the clusters of various levels of granularity,

Data set	CTB chapter IDs
Dev	41-80,203-233,301-325,400-409,591,613-617,643-673,1022-1035,1120-1129,2110-2159,2270-2294,2510-2569,2760-2799,3040-3109,4040-4059,4084-4085,4090,4096,4106-4108,4113-4115,4121,4128,4132,4135,4158-4162,4169,4189,4196,4236-4261,4322,4335-4336,4407-4411
Test	1-40,144-174,271-300,410-428,592,900-931,1009-1020,1036,1044,1060-1061,1072,1118-1119,1132,1141-1142,1148,2000-2010,2160-2220,2295-2330,2570-2640,2800-2845,3110-3145,4030-4039,4060-4070,4086-4087,4091,4097,4109-4112,4118-4120,4127,4133-4134,4136-4139,4163-4168,4188,4197-4235,4321,4334,4337,4400-4406

Table 4: Dev-set and test-set of CTB7 data split

	Total	Dev-$_{LDC}$	Test-$_{LDC}$	Dev	Test
NS	107,14	561	981	2,084	2,028
NM	8,420	682	917	1,618	1,646
BN	10,079	836	898	2,067	2,038
BC	12,049	0	0	2,367	2,382
NW	10,181	0	0	2,000	2,086

Table 5: Statistics of each genre of CTB7 split (Dev(Test)-$_{LDC}$ are sets of LDC split)

by using the prefixes of the Brown cluster hierarchy at various lengths [3]. After experimenting with many different feature configurations, we eventually settled on the following features:

(d) full string prefixes for w_{-1}, w_0, w_1

6-bit string prefixes for w_{-1}, w_0, w_1

The clusters are best exploited when "anchored" to words or parts of speech (Koo et al., 2008). We found it useful to make the above features in Bigram template, in CRF++ with the first character "B". With this template, a combination of the current output tag and the previous output tag (bigram) is automatically generated. In this case, the combination of the current POS tag and the previous POS tag output is automatically generated.

3.2.3 Lexicon features

We use the same lexicon extracted for word segmentation for POS tagging. We add the following feature for the current word w_0:

(e) $POSs(w_0)$

Here, $POSs(w_0)$ are all possible POS tags of the current word w_0 in the lexicon. We also tried to use different lexicons, as well as representing the feature with only one POS tag with the highest frequency. However, the experimental results were not better than those by using the above simple method.

[3]We used the word clustering tool, available from http://www.cs.berkeley.edu/p̃liang/software/brown-cluster-1.2.zip, to produce word clusters.

4 Experiments

We conducted word segmentation and POS tagging experiments on Penn Chinese Treebanks incorporating up to 200-million-word unlabeled data.

4.1 Data Set

To compare with previous studies, we selected the widely used CTB5 (LDC2005T01), and defined the training, development and test sets according to Kruengkrai (2009a). In order to increase the reliability of our findings, we also used CTB6 (LDC2007T36) and CTB7 (LDC2010T07), which are larger than CTB5. For CTB6, we used the same data split as recommended in the CTB6 document [4]. Because CTB7 includes data from various sources and various genres, we made a new data split according to the following criteria:

• Put the test set and the development set data described in CTB7 documents [5] into each data set.

• Put the test set and the development set data of CTB5 into each set.

• Put all double checked files into the test-set. [6]

• Keep the data of different genres and sources in balance.

• Increase the size of the development and test sets to make the evaluation more reliable. [7]

The test set and development set of the CTB7 data split used in this paper are detailed in Table 4, and we used the rest as the training set. Table 5 provides the detailed statistics of each genre: NS (Newswire), NM (News magazine), BN (Broadcast news), BC (Broadcast conversation), NW (Newsgroups weblogs). Table 6 provides the statistics of our experimental settings on the treebanks. The out-of-vocabulary (OOV) is defined as

[4]list-of-files.pdf

[5]This is the same as the CTB6 data split.

[6]In CTB7, sentences checked twice are marked, and they are expected to have higher annotation quality.

[7]CTB5 and CTB6 data splits include small development and test sets.

	# of sent. training	# of sent. dev	OOV rate (word) dev	OOV rate(word & tag) dev	# of sent. test	OOV rate (word) test	OOV rate(word & tag) test

the words in the test set that are not in the training set (Sproat and Emerson, 2003). The development sets were used to obtain the optimal values of tunable parameters and feature configurations.

The unlabeled data for our experiments were taken from the XIN_CMN portion of Chinese Gigaword Version 2.0 (LDC2009T14), which has approximately 311 million words. Some of CTB data and Chinese Gigaword data are from the same source: Xinhua newswire between 1994 and 1998. In order to avoid overlap between the CTB data and the unlabeled data, we used only the articles published in 1991- 1993 and 1999-2004 as unlabeled data, with 204 million words.[8] Note that we only used one million words from this data for word clustering, because the clustering process is time-consuming and the amount is enough to show the impact of cluster feature.

4.2 Parameter Tuning

CRF++ has four major tunable parameters to control the training condition: *a*, the regularization algorithm; *c*, the balance between over-fitting and under-fitting; *f*, the cut-off threshold for the feature frequencies; and *p*, the number of threads. We used $a = CRF\text{-}L2$ (Gaussian regularization) and $f = 1$. We set p to 12 for all experiments to speed up the training. For the baseline segmentation model, we varied c in the range of [1.0, 5.0] and found that setting $c = 4.0$ yielded the best performance on the development set of CTB7. For our approach, we varied c in the range of [0.3, 5.0] and found that setting $c = 1.0$ yielded the best performance. For the POS tagging model, c was set to 4.0 in all of the methods . For the clustering tool, c (the number of clusters) was set to 1000.

4.3 Experimental Results

We evaluated both word segmentation (Seg) and joint word segmentation and POS tagging (Seg &Tag). We used recall (R), precision (P) and F_1 as evaluation metrics.

The experimental results of word segmentation on CTB5, CTB6 and CTB7 test sets are shown in Table 7, where (a) refers to the *n*-gram feature generated from the unlabeled data and (b) refers to the lexicon feature. The results show that the *n*-gram feature was very effective in all experiments and that the combination of (a) and (b) can provide further improvement.

The experimental results of segmentation and POS tagging on CTB5, CTB6 and CTB7 test sets are shown in Table 8 and Table 9. Table 8 shows the results when we used the baseline segmenta-

[8]This may be a too strict setting, but we wanted to test our approach in the fairest way.

Table 11: Comparison with previous studies on CTB6 and CTB7

tion model and Table 9 shows the results when we used our best segmentation model (i.e., (a)+(b)). The results show that the cluster features were the most effective ones and that a combination of three types of features achieves the best performance. This suggests that these features are relatively independent in feature characteristics.

The results of our best system are compared with the previous methods in the next section.

4.4 Comparative Results

In this section, we compare our approach with the best previous approaches reported in the literature. The performance scores of previous studies are directly taken from their papers, except for N&U 07 (Nakagawa and Uchimoto, 2007), which is taken from Kruengkrai et al. (2009b). Z&C 10 refers to Zhang and Clark (2010). Two methods in Kruengkrai et al. (2009a; 2009b) are referred to as K 09a and K 09b. Jiang 08a and Jiang 08b refer to Jiang et al. (2008a; 2008b). Table 10 compares F_1 results on CTB5.0. The best score in each column is in boldface. The results of our approach are superior to those of previous studies for both Seg and Seg&Tag.

	p-value		
Models	CTB5	CTB6	CTB7
Ours vs. K 09b(Seg)	0.8054	5.0e-08	≈ 0.0
Ours vs. K 09b(Seg&Tag)	0.7060	1.6e-14	≈ 0.0
Ours vs. Base(Seg)	4.0e-06	1.8e-11	≈ 0.0
Ours vs. Base(Seg&Tag)	2.1e-06	≈ 0.0	≈ 0.0

Table 13: Results of McNemar's test.

We also conducted experiments using the system implemented by Kruengkrai for comparison on CTB6 and CTB7 with two methods (K 09a and K 09b) and the F_1 results are shown in Table 11.

For reference, the results of the development set are also shown in Table 12. Although the Seg performances of CTB5 and CTB7 are lower than K 09a and K 09b , Seg&Tag achieves the best performance on all development sets.

4.5 Statistical Significance Tests

We evaluated statistical significance using McNemar's test [9]. With McNemar' test, we compared the correctness of the labeling decisions of the two models. The null hypothesis is that the disagreements (correct vs. incorrect) are due to chance. For Seg, a word in the system output is considered correct if the word boundary is correctly identified. For Seg &Tag, a word is considered correct only when both the word boundary and its POS tag are correctly identified. Table 13 summarizes the results on test sets. These tests suggest that although the difference from K 09b for CTB5 data is not statistically significant, all other differences are clearly statistically significant ($p < 10^{-5}$).

4.6 Comparison with Self-Training

An alternative method of incorporating unlabeled data is self-training, so we also compared our results to the self-training method. Because no existing research was found concerning the self-training method on word segmentation and POS

[9] We used the version with Yates' correction, using correction factor 0.5

Table 15: Comparison with self-training (POS)

tagging for Chinese, we tested the simplest self-training here. We analyzed the unlabeled data with the baseline models, added the newly auto-labeled data to the training corpus, and trained a new model. Since the manually labeled data should be considered more important than the unlabeled data (McClosky et al., 2006), we also adjusted the weight of the labeled data to the integer in the range of [1,5] in experiments. The results of all the experiments were not positive – we were not able to obtain any improvement over the baseline models in either word segmentation or POS tagging. Due to space limitation, we only include the results with the labeled data weight = 1. Other weights did not change the conclusion here. Table 14 shows the F_1 results on segmentation with different sizes of the additional data on the CTB7 test set. Table 15 shows the F_1 results on segmentation and POS tagging. The segmentation by the baseline model was used for all of the POS tagging experiments here.

5 Related Work

Our approach is to incorporate large unlabeled data in Chinese word segmentation and POS tagging.

For research using large unlabeled data, Suzuki and Isozaki (2008) and Suzuki et al. (2009) proposed semi-supervised learning algorithms on giga-word-scale unlabeled data and showed performance improvement in POS tagging, syntactic chunking, and named entity recognition. Instead of using specialized semi-supervised learning algorithms, Chen et al. (2009) used features based on sub-structures in auto-parsed data and demonstrated the effectiveness of these features. Koo et al. (2008) presented the use of cluster features. The advantage of the methods by Chen et al. (2009) and Koo et al. (2008) is their simplicity and flexibility. Our research applied these techniques to word segmentation and POS tagging rather than dependency parsing.

Yu et al. (2007) proposed a character-based joint method for word segmentation and POS tagging, in which they introduced an unsupervised method for unknown word learning. However, they only learned the unknown words from the test set. Zhao and Kit (2007; 2008) proposed an approach using unsupervised segmentation criteria as features for Chinese word segmentation. However, their features were only accumulated from the training and test data. Our approach differs in that we used features generated from large unlabeled data and provided richer information, which may be unseen from the training corpus.

Kruengkrai et al. (2009a; 2009b) presented a discriminative word-character hybrid model for joint Chinese word segmentation and POS tagging and achieved the state-of-the-art accuracy for the CTB test sets. Instead of using the hybrid model, we used conceptually simpler pipelined models built with standard CRF tools. Compared with their method, our approach achieved higher performance with the help of unlabeled data.

6 Conclusion

In this paper, we presented a simple yet effective semi-supervised approach to pipelined Chinese segmentation and POS tagging. Through a series of experiments, we demonstrated that our approach provides substantial improvement over the best previously reported methods as well as the baseline methods.

Abstract

Dialectal Arabic (DA) is the spoken vernacular for over 300M people worldwide. DA is emerging as the form of Arabic written in online communication: chats, emails, blogs, etc. However, most existing NLP tools for Arabic are designed for processing Modern Standard Arabic, a variety that is more formal and scripted. Apart from the genre variation that is a hindrance for any language processing, even in English, DA has no orthographic standard, compared to MSA that has a standard orthography and script. Accordingly, a word may be written in many possible inconsistent spellings rendering the processing of DA very challenging. To solve this problem, such inconsistencies have to be normalized. This work is the first step towards addressing this problem, as we attempt to identify spelling variants in a given textual document. We present an unsupervised clustering approach that addresses the problem of identifying orthographic variants in DA. We employ different similarity measures that exploit string similarity and contextual semantic similarity. To our knowledge this is the first attempt at solving the problem for DA. Our approaches are tested on data in two dialects of Arabic - Egyptian and Levantine. Our system achieves the highest Entropy of 0.19 for Egyptian (corresponding to 68% cluster precision) and Levantine (corresponding to 64% cluster precision) respectively. This constitutes a significant reduction in entropy (from 0.47 for Egyptian and 0.51 for Levantine) and improvement in cluster precision (from 29% for both) from the baseline.

1 Introduction

Arabic is the native tongue of over 300M people world wide. The Arabic language exhibits a relatively unique linguistic phenomena known as diglossia (Ferguson, 1959) where two forms of the language live side by side: a standard formal form known as Modern Standard Arabic (MSA) and an informal spoken form, the vernaculars used in everyday communication referred to as Dialectal Arabic (DA). MSA is the only language of education and is used in formal settings and Broadcast news. The only written standard is in MSA using the Arabic script. Technically there are no native speakers of MSA. On the other hand, DA is the mother tongue for all native speakers of Arabic however it is not traditionally a written form of the language and it differs significantly enough from MSA on all levels of linguistic representation that results in huge inconsistencies in orthography. This was not a problem a decade ago from an NLP perspective since all the resources were in MSA. Now with the proliferation of online media and informal genres, DA is ubiquitous online. Users of DA online write in different scripts (Arabic, Romanizations interspersed with digits), they also sometimes write phonemically. Similar to other languages (not unique to DA) in these informal genres, we observe rampant speech effects such as elongations and the use of emoticons within the text which compounds the problem further for processing DA. If NLP tools want to process real Arabic as spoken by its people, they need to address DA seriously. This paper presents an initial attempt at addressing the pervasive inconsistencies in DA orthography in informal media.

We cast the problem of lack of DA orthographic standards as an identification of spelling variants problem using unsupervised clustering techniques. We evaluate our results against a gold corrected set of data in two dialects: Egyptian (EGY) and

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 318–326,
Chiang Mai, Thailand, November 8 – 13, 2011.

Levantine (LEV). We focus our current efforts on identifying the orthographic variants in Arabic script though our work is extendible to the Romanizations as well. Such an identification is a necessary step for normalizing the variation which is useful for addressing the sparseness problem for DA. We contend that there are patterns in the variations that could be captured and processed. Also it is worth pointing out that this problem encompasses the spelling mistakes problem but it goes beyond it to address legitimate orthographic variants. Hence we attempt an approach that is generic enough to cover both scopes.

This paper is organized as follows: in Section 2 we show some of the variations between MSA and DA on different levels of linguistic representation; Section 3 discusses some related work; in section 4 we outline our approach and experimental conditions; in Section 5 we describe the data against which we evaluate our approach; we discuss the results and evaluation in Section 6; in Section 7 we discuss errors and performance of the system and approach proposed; finally, in Section 8 we conclude with some final remarks and a look at some future directions.

2 DA vs. MSA Phenomena

Most of the research effort, to date in creating tools and resources for Arabic has focused on MSA. In recent years we have seen a concentrated effort on making Arabic processing tools on par with English processing tools (Habash and Rambow., 2005; Diab et al., 2007; Kulick, 2010; Green and Manning., 2010). Researchers interested in handling realistic Arabic text have come to the realization that DA needs to be addressed. Applying state of the art MSA processing tools directly to DA yields very low performance proving the significant difference between the two varieties. For instance applying MSA tokenizers to DA yields a performance of 88% which is completely unacceptable as an initial processing tool performance. It is worth noting that state of the art MSA tokenization is at 99.2% (Diab et al., 2007). This low performance on DA can be explained by the genre differences (MSA tools are trained on newswire genres) but compared to English, we do not observe such a huge discrepancy between tokenizers trained on newswire when applied to informal genres. The significant drop in performance can be safely relegated to the inherent differences between the two varieties of Arabic. MSA differs from DA on the phonological, morphological, lexical, syntactic, semantic and pragmatic levels. The degree of variation depends on the specific dialect of Arabic. For instance, phonologically MSA would pronounce the word for dress as *fustAn* and spell it فستان while the same word in LEV is pronounced as *fusTAn*[1] with an emphatic T and could possibly be written phonemically in LEV as فوصطان. Morphologically, DA exhibits simpler inflectional morphology than MSA overall however cliticization is more nuanced rendering tokenization a more complex problem in DA than in MSA. For example, DA has lost all explicit marking of grammatical case and dual marking on verbal predicates. The MSA phrase *AlmwZfAn AklA*, الموظفان اكلا, meaning 'the employees_dual_nominative ate_dual', becomes *AlmwZfyn AlAtnyn AkAlw*, الموظفين الاتنين اكلو, 'the *two* employees_plural_no_case ate_plural'. Hence we note the loss of dual inflection marking and nominative case marking. On the other hand, clitization is more complex in DA as follows: EGY *mAHkytlhAlhw$*, ماحكيتلهالهوش, 'she did not recount it to him' is expressed in three words in MSA as *lm tHkyhA lh* لم تحكيها له. The lexical, syntactic, semantic and pragmatic variations abound between MSA and DA. The phonological and morphological differences lend themselves directly to the orthographic variation problem exhibited with DA. Writers of DA use a myriad of scripts to encode DA. All of which are used inconsistently even within the writings of the same author in the same post/article/blog. The most frequent scripts used are Arabic and Romanization. We note that people have use also Hebrew and Cyrillic scripts to write Arabic as well. For Arabic script we see inconsistencies in characters that exhibit regional variations such as the *qAf* sound ق. This letter is pronounced as a glottal stop ´ in EGY and LEV but as a *g* sound in the Gulf states and *q* sound in Tunisia, in most cases. Speakers and writers pertaining to these different dialects could render it in the orthography as it appears in a word such as *he said qAl* قال as *Ál* ال [EGY], *gAl* جال [Gulf] or *qAl* قال [Tunisian]. Moreover, we observe more severe variants in the Romanized script for the same word where the writers can render the EGY as *2Al*, *AAl*,

[1] We use the Buckwalter Arabic Transliteration standard for the Romanized Arabic throughout the paper. www.qamus.org

or *qAl*. For the purposes of this paper we will focus our discussion on identifying the orthographic variants only in the Arabic script leaving the handling of orthographic variants in Romanization for future work.[2]

3 Related Work

Most of the recent work in the area of orthographic variant detection and spelling correction has been towards resolving inconsistencies in spellings of Named Entities(NE). Huang et al. (2008) use NE spelling variant detection to improve the performance of Machine Translation (MT) and Information Extraction (IE) systems. (Habash and Metsky, 2008) cluster Urdu phrases mapping to the same English phrase to automatically learn morphological variation rules. Since Urdu is a morphologically rich language, such variations result in many OOV words. They use the these rules learned, as a part of MT system to replace OOV Urdu words with in-vocabulary words online. Raghavan and Allan (2005) use the edit distance metric along with generative models trained from Automatic Speech Recognition (ASR) output to cluster queries to improve performance of Information Retrieval (IR) systems. Bhagat and Hovy (2007) attempted to generate all possible spelling variations of a person's name. One method is supervised and uses CMU speech dictionary to train a phonetic model. Another is to cluster a large set of names that are known to sound similar using Soundex (Knuth, 1973). Although some earlier work related to spelling variations (Golding and Roth, 1999) dealt with the generalized problem, most of the recent work is confined to NEs.This is because of the relevance of the problem to NLP applications such as MT, IE, IR and ASR. Accordingly we note that the problem we try to solve is more generic since the lack of orthographic standard in DA affects the spellings of all kinds of words.

4 Approach

Our goal is to identify orthographic variations in textual DA. We build a system, CODACT, that aims at identifying and eventually normalizing such DA orthographic variants. We use techniques noted in the spelling correction literature. Our approach is mainly unsupervised. We view the problem as a clustering problem where our goal is to identify if two strings are similar, and hence cluster together. To that end we explore three basic similarity measures: (a) String based Similarity as direct Levenshtein Edit Distance; (b) String based Similarity Biased Edit Distance; and (c) Contextual String Similarity. We model the strings of interest in a vector space. We build a matrix for the string types of interest. We induce the clusters from the matrix by grouping the strings in the row entries together based on the similarity of their respective vectors in the matrix. We use Cosine Similarity between vectors and we use the implementation of the CLUTO Repeated Bisection (RB) algorithm with cosine similarity being the measure of similarity between vectors. (Zhao and Karypis, 2001). CLUTO is very suitable for clustering high dimensional datasets. CLUTO's repeated bisection partition method is used for clustering. In this method, for obtaining a *k* -way clustering, *k-1* repeated bisections are made. Each partition is made to the input dataset such that the clustering criterion function is optimized.

The row entries for the matrix are referred to as the focal string types of interest. We vary the dimensions as follows: (a) for N focal words, we have the same N focal words in the matrix dimensions, yielding an NxN matrix; or (b) the dimensions are all the string types in the corpus of interest yielding an NxM matrix. The cells of the matrix are populated based on one of the different similarity measures or a combination of them after normalization. We describe the different similarity measures next.

4.1 String Based Similarity Metrics

Strings that vary from each other minimally are likely to be orthographic variants of one another. Following this intuition, strings are grouped based on their string edit distance. We explore the basic known Levenshtein Edit Distance measure as in (Levenshtein, 1966) (LEDM). Moreover we extend the LEDM to account for known phonological variations on the character level. We refer to this as the Biased Edit Distance Metric (BEDM). BEDM has the same exact formulation as LEDM as a metric however it is more relaxed in that it treats letters that are considered similar as if they are the same, i.e. they are not *substitutions* of each

[2]It is worth noting that tools such as Yamli and Maren which transliterate Romanization to Arabic script serve as in interesting platform for handling the Romanization problem that could be easily leveraged.

other. The intuition behind adding such a bias is the fact that Arabic letters may have different pronunciations depending on the context. For example, the letter ا might have a sound equivalent to the any of letters أ, آ, و and ي. This is ignored by LEDM, and they are treated as different letters therefore incurring the substitution penalty. When BEDM is applied, any two letters that have the same sound are treated as a match. For example, (1) *fstAn*, 'dress', فستان, and the possible variants (2) *fstAn*, (3) *fSTAn*, (4) *fsTAn*, and (5) *fjTAn* would have the following calculations: (1) and (2) would be a perfect match, i.e. a distance of 0 according to both LEDM and BEDM; (1) and (3) would be penalized for substituting *S, T* for *s,t* in (1), therefore a distance of 0.4 according to LEDM, however for BEDM *s* and *S* are considered similar to each other and so are *t* and *T*, then the distance of (1) and (3) is 0. Similarily for (1) and (4) according to LEDM the distance is 0.2, but for BEDM the distance is 0. For (1) and (5) the LEDM will be 0.4 and for BEDM it will be 0.2. Hence, BEDM is a more nuanced and relaxed form of LEDM. The list of similar letters is taken from scholar seeded studies of phonological variations across different DA. The list is rendered in Table 1. We refer to this list as sound change rules (SCR).[3] The SCR are not always symmetric, for example a *v* can be replaced with a *S* but not vice versa.

4.2 Contextual String Similarity

We explore another relatedness measure of contextual string similarity (CSS). The intuition is that if two strings are variants of each other as they are semantically similar, they are bound to appear with similar contexts. Accordingly we model this notion via representing strings with their context co-occurrence vectors. In this framework , we represent the co-occurrence frequency of the focal string and dimensional string in all the sentences in the corpus within a window of 3 tokens. The observations are aggregated and used in the cell. If the focal string and the dimensional string never co-occur, then the cell value is set to 0. Contextual Similarity Metric (CSS) between two words is defined as a cosine similarity between their context vectors.

[3]We are aware that this list can be further refined to reflect the specific dialect under investigation. We plan to incorporate a better customized SCR depending on the variety of DA.

Letter	Similar Sounding Letters
A	{, <, >, ', &, }, w, y, |
'	A,{, }, <, >, |, y, &,w
}	A, y, &, ', {, <, >, |,w
&	A, y, }, ', {, <, >, |,w
|	A, y, ', {, <, >, }
{	A, y, &, ', }, <, >, |

4.3 Experimental Conditions

We experimented with each of these measures in isolation and in combination. In the case of combination, we normalized the values of metrics. Table 2 illustrates the values contained in the cells of the constructed matrices in the different conditions.

We have two different matrix dimension sizes depending on how extensive the feature space is. The first case is NxN, meaning that the set of words corresponding to both the rows and columns of the matrix are the focal words. The second case has all the unique words in the corpus representing the columns, making it NxM. This yields 6 isolated conditions and 8 combined conditions.

Metric	Cell Values
LEDM	1.0 - Normalized Levenshtein Distance
BEDM	1.0 - Normalized Levenshtein Distance biased by phonetic similarity across letters
CSS	Co-occurrence frequencies
LEDM+BEDM	Mean of LEDM and BEDM
CSS+LEDM	Mean of LEDM and Normalized CSS (both are in range $\{0, 1\}$)
CSS+BEDM	Mean of BEDM and Normalized CSS
CSS+LEDM+BEDM	Mean of LEDM, BEDM and Normalized CSS

Table 2: Matrix Cell Values

- LEDM-NxN where the similarity measure is a LEDM and the matrix size is NxN
- BEDM-NxN where the similarity measure is a BEDM and the matrix size is NxN
- CSS-NxN where the similarity measure is a CSS and the matrix size is NxN
- LEDM-NxM where the similarity measure is a LEDM and the matrix size is NxM
- BEDM-NxM where the similarity measure is a BEDM and the matrix size is NxM
- CSS-NxM where the similarity measure is a CSS and the matrix size is NxM
- LEDM-BEDM-NxN where the similarity measure is a combination of LEDM and BEDM and the matrix size is NxN
- LEDM-CSS-NxN where the similarity measure is a combination of LEDM and CSS and the matrix size is NxN
- BEDM-CSS-NxN where the similarity measure is a combination of CSS and BEDM and the matrix size is NxN
- LEDM-BEDM-CSS-NxN where the similarity measure is a combination of LEDM, BEDM, and CSS the matrix size is NxN
- LEDM-BEDM-NxM where the similarity measure is a combination of LEDM and BEDM and the matrix size is NxM
- LEDM-CSS-NxM where the similarity measure is a combination of LEDM and CSS and the matrix size is NxM
- BEDM-CSS-NxM where the similarity measure is a combination of CSS and BEDM and the matrix size is NxM
- LEDM-BEDM-CSS-NxM where the similarity measure is a combination of LEDM, BEDM, and CSS the matrix size is NxM

5 Evaluation Data

In order to measure the performance of this approach we need data that has the variants identified. We created such data by asking native speakers of DA to normalize variants into a standard conventionalized form in Arabic script. We targeted two dialects of Arabic: Egyptian (EGY) and Levantine (LEV). For EGY we specifically focused on Cairene Egyptian. For Levantine, we had a collection of Palestinian, Jordanian, Lebanese and Syrian Dialectal data. Most of the data is considered Syrian in our LEV collection however. Both data sets for both DA are derived from the web (Diab et al., 2010). The data is part of a larger collection we refer to in this paper as COMMENTDA collection. COMMENTDA comprises 3M token strings for EGY and 3M token strings for LEV. For EGY we had 2 annotators and an adjudicator, and for LEV we had 4 annotators and an adjudicator. The annotators were instructed to identify tokens that are considered incorrect orthographically according to a specific convention that we devised known as CODA (Conventionalized Orthography for Dialectal Arabic) after being trained on CODA (Habash et al., 2011). The annotators we asked to identify three different classes of variation from the CODA convention: (a) change in spelling of a string which included dealing with speech effects such as elongations, (b) introduction of spaces or splitting a string into multiple strings, and (c) deletion of spaces or merging strings. Many corrections included simultaneously both a spelling change and a split or merge of a string as well. Table 3 gives detailed statistics of the annotated data for EGY and LEV, respectively.

Category	EGY		LEV	
	Tokens	**Types**	**Tokens**	**Types**
Inspected	39328	12703	74450	19045
Spelling Changes Only	6835	3651	5877	3519
Splits	1373	751	1013	590
Splits Only	752	288	768	169
Merges	633	440	789	598
Two String Merges	72	61	119	109
More Than Two String Merges	561	379	670	489
Merges Only	374	211	357	264
Unique Changes	7961	4150	7002	3952
All Changes Including Overlaps	9248	4720	7913	4326
Unchanged	30080	7983	66537	14719
Common Strings Across Annotators	1541	843	3271	1759
Inter-Annotator Agreements	1080 (70.08%)	576 (68.33%)	2688 (82.18%)	1489 (84.65%)

Table 3: Annotation Statistics

It is worth noting that roughly 24% of the EGY data had changes of different types on the token level corresponding to 37% of changes to the types for EGY. For LEV, only 11% of the tokens were changed corresponding to 23% of the types that were changed. This suggests that the EGY data had a lot more variability. It was actually noted that a lot of the EGY data was not consistently EGY but rather from other DA compared to LEV that was considered relatively homogeneous. The last row in the table shows the number of cases where annotators agreed with each other on the correction. It also shows their percentages to the number of common annotations as shown by the row above it.

We created the gold data clusters of variants by grouping all the strings that are mapped to the same corrected CODA form. This data consisted of 290 clusters of strings in LEV with an average of 2.6 orthographic variants per cluster, and 312 string clusters in EGY with an average of 2.5 variant per cluster. All our experiments are conducted on surface forms of the strings with no preprocessing.

6 Evaluation

In order to derive statistics to build our matrices, we use two data sets: COMMENTDA and an augmented data set (RCorpora) which is double the size of COMMENTDA for each dialect. RCorpora comprises 6M strings for EGY, and 6M strings for LEV. In the NxN matrix conditions, the size of the corpora used to derive the statistics only affects the conditions involving CSS. In the NxM conditions, the corpora sizes affect the number of matrix dimensions as well as the cell values for the CSS conditions. Application of seven metrics to four class-data size combinations gives 25 distinct runs per dialect since in NxN case, augmenting the data does not change the metrics LEDM, BEDM, and LEDM+BEDM. It has to be noted that for NxM experiments this is not the case. Table 4 gives the various statistics on the different data sizes of unique string types.

Each clustering output is compared with the gold-standard clusters using Purity and Entropy measures (Zhao and Karypis, 2001). Every word in a given cluster in the output belongs to one or more gold clusters. These gold clusters are referred to as relevant gold clusters of the given output cluster. Purity or precision of a cluster is the fraction of its words in its relevant gold clusters. Entropy gives the measure of ambiguity in the clustering output. The larger the number of word in a relevant gold cluster, the higher the entropy value. In addition to these measures, the value of recall is also calculated. This equals the fraction of words in the relevant gold clusters that are in the given cluster. Together these three measures give a complete assessment of the quality of the output clusters. As a baseline for comparison, where strings are randomly assigned to clusters assuming the gold number of clusters per dialect. Table 5 shows the results of all the experiments described.

	COMMENTDA		COMMENTDA+RCorpora (C+R)	
	EGY	**LEV**	**EGY**	**LEV**
NxN	729	717	729	717
NxM	205088	237598	433697	410206

Table 4: Data Size Variations in the two dimensions conditions

7 Discussion

All the systems outperform the random baseline. The best results are presented in bold in Table 5.

Phonological Bias From the results, it can be seen that of the individual metrics, BEDM consistently performs better than LEDM. This shows that introducing a phonological bias while matching letters does have a significant positive effect in identifying spelling variants. We believe that this effect will be more pronounced if the SCR are more tailored to the specific dialect under study. We note that CSS has the worst performance of the three individual metrics in all cases. This may be attributed to the level of processing of the data. The data is dealt with specifically on the surface level and Arabic being a very rich morphological language results in a very sparse distribution of forms. This can be mitigated by using even larger corpora. Typically in such studies that rely on distributional similarity an order of magnitude larger than what we employed is exploited. We relegate this to future work.

Combined Metrics Combination of LEDM and BEDM showed better precision, recall, and entropy than each of them in isolation in every case for both dialects. Although adding CSS has shows improvement in LEDM, mainly in EGY, it actually worsened the performance of BEDM. This is more evident when CSS+LEDM+BEDM is compared with LEDM+BEDM. Almost all the quality measures show that CSS metric adds noise.

NxM vs. NxN Using a bigger class of words as a feature set for vector similarity significantly improves the performance of the system. This holds for all the metrics in both the dialects.

Data Augmentation Although there are slight improvements due to increase in data, on the whole this does not seem to affect the performance of the system significantly. We only see some effect in the CSS measures which is expected.

7.1 Error analysis

Cluster type	Members
Gold	<n$' w<n$' An$A'
LEDM	w<n$ w<n$' wgnY wgnYY
BEDM	<n$' An$A' w<n$'
LEDM+BEDM	<n$' An$A' w<n$'

The example above shows a comparison between LEDM and BEDM metrics. The clusters in second and third columns are the ones nearest to the gold cluster in first column. It can be observed that An$A' is not a part of the LEDM cluster since the word has more dissimilar letters. However, BEDM captures the fact that the words are phonologically similar. The example below shows a similar pattern too. LEDM differentiates ||mdh from the other words too much to identify it to be a potential variant.

Cluster type	Members
Gold	jAmddp ||mdh jAAmdp jAmdh
LEDM	jAmddp jAAmdp jAmdh
BEDM	jAmddp ||mdh jAAmdp jAmdh
LEDM+BEDM	jAmddp ||mdh jAAmdp jAmdh

The next example illustrates the advantage of combining metrics. BEDM gives both higher precision and recall than LEDM when compared to the gold cluster. However, both of them do not have perfect precision or recall while the combined metric has both.

Cluster type	Members
Gold	btAEtY btEty
LEDM	btAEtY bnt bt
BEDM	btAEtY btEty ty
LEDM + BEDM	btAEtY btEty

A relaxed similarity metric does not necessarily result in higher clustering recall. In the next example, BEDM gives a lower recall than LEDM. However, the combined metric does better than the individual edit distance metrics in this example too.

Cluster type	Members
Gold	byqwlw byqwlh byqwlwA byqlh
LEDM	byqwlw byqwlh byqwlwA yqwlp yqwlh
BEDM	byqwlw byqwlwA
LEDM + BEDM	byqlh byqwlh byqwlw byqwlwA

Table 5: Results

8 Conclusion and Future Work

We compared surface and contextual metrics for identifying spelling variants in DA. We also evaluated all the combinations of those metrics. We present an initial system CODACT. Our results hold clear cross-dialectal trends, showing that string similarity metric with a phonological bias, combined with simple edit distance as a similarity metric is better for this task than raw contextual similarity when the data is limited. The next step in this approach is to refine the co-occurrence model used in our approach. Using lemma forms instead of the surface forms can yield a potential improvement since Arabic is a morphologically rich language. Eventually we plan to develop a system that will automatically normalize orthographic variations in Dialectal Arabic to the CODA convention.

Abstract

In this paper, we propose a Localized Feature Selection (LFS) framework tailored to the HL-SOT approach to sentiment analysis. Within the proposed LFS framework, each node classifier of the HL-SOT approach is able to perform classification on target texts in a locally customized index term space. Extensive empirical analysis against a human-labeled data set demonstrates that with the proposed LFS framework the classification performance of the HL-SOT approach is enhanced with computational efficiency being greatly gained. To find the best feature selection algorithm that caters to the proposed LFS framework, five classic feature selection algorithms are comparatively studied, which indicates that the TS, DF, and MI algorithms achieve generally better performances than the CHI and IG algorithms. Among the five studied algorithms, the TS algorithm is best to be employed by the proposed LFS framework.

1 Introduction

With tens and thousands of review texts being generated online, it becomes increasingly challenging for an individual to exhaustively collect and study the online reviews. Therefore, research on automatic sentiment analysis on review texts has emerged as a popular topic at the crossroads of information retrieval and computational linguistics.

Sentiment analysis on product reviews aims at extracting sentiment information from texts. It includes two tasks, i.e., labeling a target text[1] with 1) the product's attributes it mentions (attributes identification task), and 2) the corresponding sentiments mentioned therein (sentiment annotation task). Recently, Wei and Gulla proposed the HL-SOT approach (Wei and Gulla, 2010), i.e., Hierarchical Learning (HL) with Sentiment Ontology Tree (SOT), that is able to achieve the two tasks in one hierarchical classification process. In the HL-SOT approach, each target text is encoded by a vector in a globally unified d-dimensional index term space and is respectively labeled by different nodes[2] of SOT in a hierarchical manner. Although the HL-SOT approach is reported with promising classification performance on tasks of sentiment analysis, its computational efficiency, especially as d increases, becomes very low. Furthermore, as d increases it will have more chance to index noisy term into the globally unified index term space so that the classification performance of the HL-SOT approach might be depressed. Hence, we argue that if a locally customized index term space could be constructed for each node respectively, both the computational efficiency and the classification performance of the HL-SOT approach would be improved.

In this paper, we propose a Localized Feature Selection (LFS) framework tailored to the HL-SOT approach. The rationale of the proposed LFS framework draws on the following two observations. Firstly, a feature term that is relevant to a node is usually irrelevant to nodes which stay at another branch of SOT. For example, "ergonomics" might be a feature term for the node "design and usability" (see Fig. 1) but it is irrelevant to the node "image quality". Secondly, a feature ter-

[1] Each product review to be analyzed is called target text in the following of this paper.

[2] If specified otherwise in the following of this paper the term "node" refers to the classifier of the node.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 327–335,
Chiang Mai, Thailand, November 8 – 13, 2011.

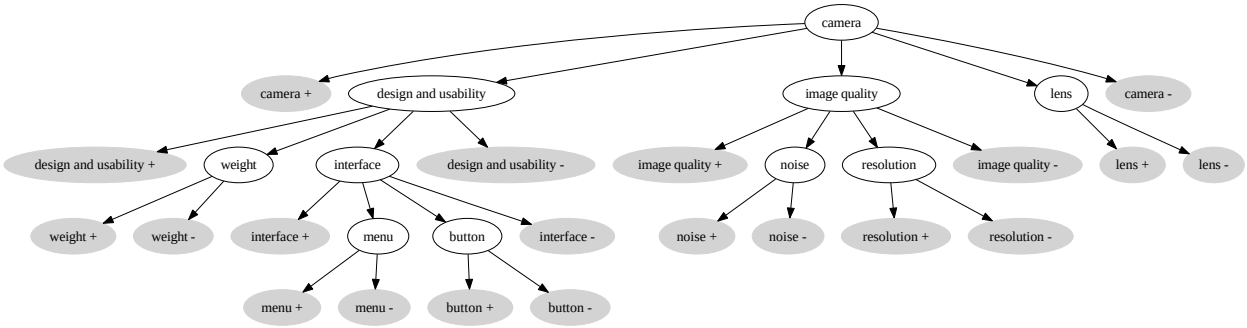

Figure 1: an example of part of a SOT for digital camera

m might become insignificant for child nodes of i even if the feature term is significant to i. For example, for a sentence commenting on a digital camera like "40D handles noise very well", terms such as "noise" and "well" are significant feature terms for the node "noise". However, the term "noise" becomes insignificant for its child nodes "noise +" and "noise -", since the hierarchical classification characteristic of the HL-SOT approach that a node only processes target texts which are labeled as true by its parent node ensures that each target text handled by the nodes "noise +" and "noise -" is already classified as related to "noise".

In the proposed LFS framework, the concept of "local hierarchy" is defined and introduced as delimitation of local scope of nodes. The localized feature selection process is conducted for each node within its local scope to generate the customized index term space for the node. The proposed LFS framework is empirically analyzed on a human-labeled data set. The experimental results show that with the proposed LFS framework the classification performance of the HL-SOT approach is enhanced and the computational efficiency is significantly improved. To test which is the best to be employed by the proposed LFS framework, we further comparatively study five classic feature selection algorithms respectively based on document frequency (DF) (Manning et al., 2008), mutual information (MI) (Manning et al., 2008; Church and Hanks, 1990), χ^2-statistic (CHI) (Manning et al., 2008), information gain (IG) (Mitchell, 1997), and term strength (TS) (Wilbur and Sirotkin, 1992). The comparatively experimental results suggest that the TS, DF, and MI algorithms achieve generally better performance than the CHI and IG algorithms. Among the five employed algorithms, the TS algorithm is the best to be employed by the proposed LFS framework. This paper makes the following contributions:

- We propose a LFS framework to enhance the classification performance and improve the computational efficiency of the HL-SOT approach;
- We conduct a comparative study on five feature selection algorithms that can be employed in the proposed LFS.

The remainder of the paper is organized as follows. In section 2, we discuss an overview of related work on sentiment analysis. In section 3, we review the HL-SOT approach proposed in (Wei and Gulla, 2010). In section 4, we present the proposed LFS framework. The empirical analysis and the results are presented in section 5. Finally, we conclude the paper and discuss the future work in section 6.

2 Related Work

Research on sentiment analysis was originally performed to extract overall sentiments from target texts. However, as shown in the experiments in (Turney, 2002), the whole sentiment of a document is not necessarily the sum of its parts. Recent work has shifted the focus from overall document sentiment to sentiment analysis based on product attributes (Hu and Liu, 2004; Popescu and Etzioni, 2005; Ding and Liu, 2007; Liu et al., 2005).

Document overall sentiment analysis is to summarize the overall sentiment in the document, which relies on two finer levels of sentiment annotation: *word-level sentiment annotation* and *phrase-level sentiment annotation*. The *word-level sentiment annotation* is to utilize the polarity annotation of words in each sentence and summarize the overall sentiment of each sentiment-bearing word to infer the overall sentiment within

the text (Hatzivassiloglou and Wiebe, 2000; Andreevskaia and Bergler, 2006; Esuli and Sebastiani, 2005; Esuli and Sebastiani, 2006; Hatzivassiloglou and McKeown, 1997; Kamps et al., 2004; Devitt and Ahmad, 2007; Yu and Hatzivassiloglou, 2003). The *phrase-level sentiment annotation* focuses sentiment annotation on phrases not words with concerning that atomic units of expression is not individual words but rather appraisal groups (Whitelaw et al., 2005). In (Wilson et al., 2005), the concepts of *prior polarity* and *contextual polarity* were proposed. This paper presented a system that is able to automatically identify the *contextual polarity* for a large subset of sentiment expressions. In (Turney, 2002), an unsupervised learning algorithm was proposed to classify reviews as recommended or not recommended by averaging sentiment annotation of phrases in reviews that contain adjectives or adverbs. However, the performances of these approaches are not satisfactory for sentiment analysis on product reviews, where sentiment on each attribute of a product could be so complicated that it is unable to be expressed by overall document sentiment.

Attributes-based sentiment analysis is to analyze sentiment based on each attribute of a product. In (Hu and Liu, 2004), mining product features was proposed together with sentiment polarity annotation for each opinion sentence. In that work, sentiment analysis was performed at the product attributes level. In (Liu et al., 2005), a system with framework for analyzing and comparing consumer opinions of competing products was proposed. The system made users be able to clearly see the strengths and weaknesses of each product in the minds of consumers in terms of various product features. In (Popescu and Etzioni, 2005), Popescu and Etzioni not only analyzed polarity of opinions regarding product features but also ranked opinions based on their strength. In (Liu et al., 2007), Liu et al. proposed Sentiment-PLSA that analyzed blog entries and viewed them as a document generated by a number of hidden sentiment factors. These sentiment factors may also be factors based on product attributes. In (Lu and Zhai, 2008), Lu et al. proposed a semi-supervised topic models to solve the problem of opinion integration based on the topic of a product's attributes. The work in (Titov and McDonald, 2008) presented a multi-grain topic model for extracting the ratable attributes from product reviews. In (Lu et al., 2009), the problem of rated attributes summary was studied with a goal of generating ratings for major aspects so that a user could gain different perspectives towards a target entity. In a most recent research work (Wei and Gulla, 2010), Wei and Gulla proposed the HL-SOT approach that sufficiently utilizes the hierarchical relationships among a product attributes and solves the sentiment analysis problem in a hierarchical classification process. However, the HL-SOT approach proposed in (Wei and Gulla, 2010) uses a globally unified index term space to encode target texts for different nodes which is deemed to limit the performance of the HL-SOT approach. Therefore, the LFS framework proposed in this paper aims at overcoming the weakness of the HL-SOT approach and consequently improving its performance by generating a locally customized index term space for each node.

3 The HL-SOT Approach Review

In the HL-SOT approach (Wei and Gulla, 2010), each target text is indexed by a vector $x \in \mathcal{X}, \mathcal{X} = \mathbb{R}^d$. Weight vectors $w_i (1 \leq i \leq N)$ define linear-threshold classifiers of each node i in SOT so that the target text x is labeled true by node i if x is labeled true by i's parent node and $w_i \cdot x \geq \theta_i$. The parameters w_i and θ_i are learned from the training data set: $D = \{(r, l) | r \in \mathcal{X}, l \in \mathcal{Y}\}$, where $\mathcal{Y}$ denotes the set of label vectors. In the training process, when a new instance r_t is observed, each row vector $w_{i,t}$ is updated by a regularized least squares estimator given by:

$$\begin{aligned} w_{i,t} = (I + S_{i,Q(i,t-1)} S_{i,Q(i,t-1)}^{\top} + r_t r_t^{\top})^{-1} \\ \times S_{i,Q(i,t-1)} (l_{i,i_1}, l_{i,i_2}, ..., l_{i,i_{Q(i,t-1)}})^{\top} \end{aligned} \quad (1)$$

where I is a $d \times d$ identity matrix, $Q(i, t-1)$ denotes the number of times the parent of node i observes a positive label before observing the instance r_t, $S_{i,Q(i,t-1)} = [r_{i_1}, ..., r_{i_{Q(i,t-1)}}]$ is a $d \times Q(i, t-1)$ matrix whose columns are the instances $r_{i_1}, ..., r_{i_{Q(i,t-1)}}$, and $(l_{i,i_1}, l_{i,i_2}, ..., l_{i,i_{Q(i,t-1)}})^{\top}$ is a $Q(i, t-1)$-dimensional vector of the corresponding labels observed by node i. The Formula 1 restricts that the weight vector $w_{i,t}$ of the classifier i is only updated on the examples that are positive for its parent node. Then the label vector $\hat{y}_{r_t}$ is computed for the instance r_t, before the real label vector l_{r_t} is observed. Then the current threshold vector θ_t is updated by:

$$\theta_{t+1} = \theta_t + \epsilon(\hat{y}_{r_t} - l_{r_t}), \quad (2)$$

where ϵ is a small positive real number that denotes a corrective step for the current threshold vector θ_t. After the training process for each node of SOT, each target text is to be labeled by each node i parameterized by the weight vector w_i and the threshold θ_i in the hierarchical classification process.

4 The Localized Feature Selection

In this section, we propose the LFS framework to generate a locally customized index term space for each node of SOT respectively. We first discuss why localized feature selection is needed for the HL-SOT approach. Then we define the concept of local hierarchy of SOT to introduce the local feature selection scope of a node, followed by a presentation on the local hierarchy based feature selection process.

4.1 Why Localized Feature Selection for the HL-SOT

One deficiency of the HL-SOT approach is that it uses a globally unified index term space to index target texts, which cannot efficiently encode feature information required by each local individual node of SOT. When we look into the detailed classification process of each node of SOT, we observe the following two types of phenomena. Firstly, SOT organizes domain knowledge in a tree like structure. Within a particular domain knowledge represented by SOT, nodes that stay in different branches of SOT represent independent different attributes in that domain. In this way, feature terms (e.g., the term "ergonomics") that are relevant to a node (e.g., the node "design and usability") might be irrelevant to other nodes (e.g., the node "image quality") that stay at another branches of SOT; Secondly, the HL-SOT approach labels each target text in a hierarchical order which ensures that each target text that comes to be handled by a node has already been labeled as true by its parent node. Due to this characteristic, feature terms (e.g., the term "noise") that are significant to a node i (e.g., the node "noise") might become a trivial term for i's child nodes (e.g., the nodes "noise +" and "noise -"). Therefore, the purpose of the localized feature selection is to filter out irrelevant terms that are insignificant to each individual node and build a locally customized index term space for the node so that the performance of the node can be improved.

4.2 Local Feature Selection Scope for a Node

In order to select locally customized feature terms for each individual node, we need to define a suitable scope, called local feature selection scope[3], within which the feature selection process can be effectively conducted for the node. Since the HL-SOT approach is a hierarchical classification process, before we introduce the local scope for a node we first give a formal definition on local hierarchy of SOT.

Definition 1 *[Local Hierarchy] A local hierarchy Δ_u of SOT is defined to be formed by all the child nodes of u in SOT, where the node u must be a non-leaf node of the SOT.*

By the Definition 1, we say all the child nodes of u are on the same local hierarchy under u which is denoted by Δ_u. For examples, in Fig. 2 nodes "camera +", "design and usability", "image quality", "lens", "camera -" are deemed on the same local hierarchy under the node "camera" and nodes "weight +", "weight -" are deemed on the same local hierarchy under the node "weight", etc. In the hierarchical labeling process of the HL-SOT approach, after a target text is labeled as true by a node i it will go further to the local hierarchy under i and is to be labeled by all nodes on the local hierarchy Δ_i. For a target text the labeling processes of nodes on Δ_i locally can be considered as a multi-label classification process where each node is a local label. Therefore, the measurement for selecting terms as features should be calculated among nodes on the same hierarchy. Hence, the local scope for a node is defined within the local hierarchy which the node is on.

4.3 Local Hierarchy Based Feature Selection

In the proposed LFS framework, local feature selection for a node i of SOT is performed within the *local scope* of the node i. Since nodes on the same local hierarchy share the same local scope, local feature selection process for all nodes of SOT is achieved in local hierarchy based manner. Specifically, for the feature selection process on a local hierarchy Δ, let $c_1, c_2, ..., c_K$ denote the K nodes on Δ. Let D denote the training data set for the HL-SOT approach. Let D_{c_k} denote the set of instances in D that contains the label of the node $c_k (1 \leqslant k \leqslant K)$. Let D_Δ denote the training corpus for the local hierarchy Δ which is the set of

[3] In this paper, we also call it "local scope" for short.

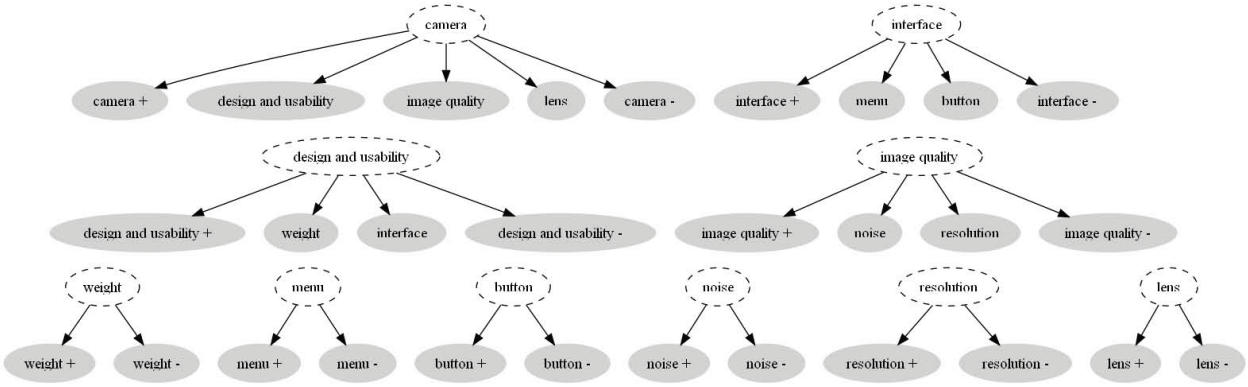

Figure 2: All local hierarchies of the example SOT: the grey nodes sharing the same parent node in dashed line are called on the same local hierarchy under the parent node

all instances in the training data set D that contain any label of nodes on the local hierarchy Δ: $D_\Delta = \bigcup_{k=1}^{K} D_{c_k}$. Let V_{c_k} denote the set of all the vocabularies that appears in D_{c_k}. Let $s_{c_k}(w)$ denote the term score that measures the suitability of w as a feature for node c_k. Let F_{c_k} denote the set of feature terms selected for c_k. Let d_{c_k} denote the number of features to be selected in F_{c_k}. A local feature selection process for nodes on the local hierarchy Δ is described in Algorithm 1.

Algorithm 1 Localized Feature Selection Algorithm

DATA INITIALIZATION:
for each node c_k on Δ **do**
  Establish D_{c_k} containing instances being labeled true by c_k;
  Establish the vocabulary set V_{c_k};
  Remove stop words from V_{c_k};
end for
Establish the training corpus: $D_\Delta = \bigcup_{k=1}^{K} D_{c_k}$;
BEGIN
for each node c_k on Δ **do**
  for each term $w \in V_{c_k}$ **do**
    with training corpus D_Δ and data instance set D_{c_k}:
    Calculate $s_{c_k}(w)$ with a specified feature selection algorithm;
  end for
  Establish feature space F_{c_k} with top d_{c_k} terms from V_{c_k};
end for
END

In the data initialization phase of the Algorithm 1, the data instance set D_{c_k} and vocabulary set V_{c_k} for each node on the local hierarchy Δ as well as the training corpus D_Δ are established. In a local feature selection process, a term score $s_{c_k}(w)$ for each term $w \in V_{c_k}$ can be calculated by a specified feature selection algorithm, taking D_Δ as the training corpus and D_{c_k} as the data instance set in the class c_k. The local feature selection process can employ any specific feature selection algorithm to calculate the term scores. After all terms in V_{c_k} are calculated, those terms with top d_{c_k} scores are selected to establish the feature space F_{c_k} for the node c_k. Since the number of terms in V_{c_k} varies from node to node, in order to produce a rational dimensionality d_{c_k} for the established feature space F_{c_k}, we introduce a feature selection rate, denoted by γ, to control d_{c_k} for each node c_k, i.e., $d_{c_k} = \ulcorner |V_{c_k}| \times \gamma \urcorner$.

After local feature selection processes for all the nods of SOT are accomplished, a locally customized index term space F_{c_k} for each node c_k is established. Each target text will be respectively indexed by a customized vector $x_{c_k} \in \mathcal{X}_{c_k} (\mathcal{X}_{c_k} = \mathbb{R}^{d_{c_k}})$ when it goes through the hierarchical classification process of the HL-SOT approach. In next section, we will present the empirical analysis on evaluating the proposed LFS framework.

5 Empirical Analysis

In this section, we conduct extensive experiments to empirically analyze the proposed LFS framework. Our experiments are intended to address the following questions: (1) can the classification performance of the HL-SOT approach be improved with the LFS framework; (2) how much computational efficiency can be gained for the HL-SOT to be implemented in the LFS framework; (3) how are the comparative performances produced by different feature selection algorithms when employed in the proposed LFS framework.

5.1 Data Set Preparation

We construct our data set based on the digital camera review data set used in the HL-SOT approach (Wei and Gulla, 2010). In total, the constructed data set contains 1500 snippets of customer reviews on digital cameras, where 35 attributes of a digital camera are mentioned in the

review data. We build an ontology structure to organize the mentioned attributes and label each review text with correspondent attributes as well as sentiments, which complying the rule that if a review text is assigned with a label of a node then it is assigned with a label of the parent node. We randomly divide the labeled data set into five folds so that each fold at least contains one example instance labeled by each attribute node. To catch the statistical significance of experimental results, we perform 5 cross-fold evaluation by using four folds as training data and the other one fold as testing data. All the experimental results presented in this section are averaged over 5 runs of each experiment.

5.2 Evaluation Metrics

Since the existing HL-SOT approach is a hierarchical classification process, we use the same three classic loss functions (Wei and Gulla, 2010) for measuring classification performance. They are respectively the One-error Loss (O-Loss) function, the Symmetric Loss (S-Loss) function, and the Hierarchical Loss (H-Loss) function[4]:

- One-error loss (O-Loss) function is defined as:

$$L_O(\hat{y}, l) = \mathfrak{B}(\exists i : \hat{y}_i \neq l_i), \tag{3}$$

  where $\hat{y}$ is the prediction label vector and l is the true label vector; $\mathfrak{B}(S)$ is a boolean function which is 1 if and only if the statement S is true, otherwise it is 0.

- Symmetric loss (S-Loss) function is defined as:

$$L_S(\hat{y}, l) = \sum_{i=1}^{N} \mathfrak{B}(\hat{y}_i \neq l_i), \tag{4}$$

- Hierarchical loss (H-Loss) function is defined as:

$$L_H(\hat{y}, l) = \sum_{i=1}^{N} \mathfrak{B}(\hat{y}_i \neq l_i \wedge \forall j \in \mathcal{A}(i), \hat{y}_j = l_j), \tag{5}$$

  where $\mathcal{A}$ denotes a set of nodes that are ancestors of node i in SOT.

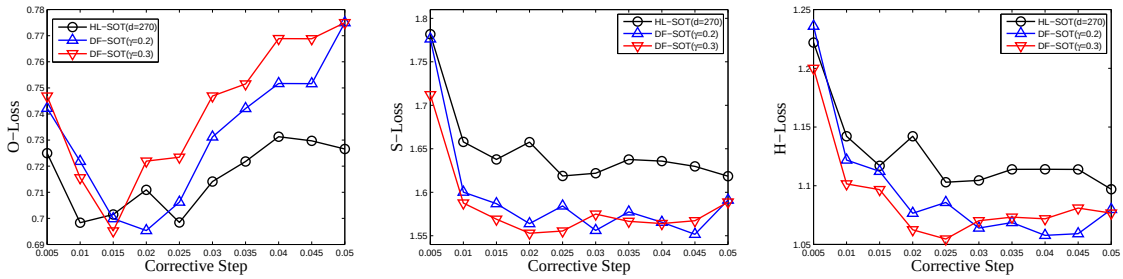
5.3 Performance Comparison

In this section, we conduct experiments to show performance improvement from the proposed LFS framework. The performance considered here include both classification performance and computational efficiency. We use the existing HL-SOT approach as a baseline. Since the HL-SOT approach used terms' document frequencies (DF) (Manning et al., 2008) algorithm to select features to build the globally unified index term space, employing the same DF feature selection algorithm we apply the proposed LFS framework on the HL-SOT approach and call the implemented method "DF-SOT". The only difference between HL-SOT and DF-SOT is the index term space for each node of SOT, i.e., in the HL-SOT all the nodes using the globally unified index term space while in the DF-SOT each node respectively using a locally customized index term space. In this way, the performance difference between the two methods will indicate the effect of the proposed LFS framework.

5.3.1 Comparison on Classification Performance

We conduct experiments to investigate whether the classification performance of the HL-SOT can be improved when it is implemented with the LFS framework. Fig. 3 presents the experimental results of classification accuracies between HL-SOT and DF-SOT. In the experiments, the dimensionality d of the globally unified index term space of the HL-SOT approach is set to 270, which is large enough for the HL-SOT approach to reach its best performance level. The feature selection rate γ for the locally customized index term space of the DF-SOT approach is set to 0.2 and 0.3, which brings respectively 80% and 70% vocabulary reduction. The value of the corrective step ϵ is set to varying from 0.005 to 0.05 with each step of 0.005 so that each running approach can achieve its best performance with a certain value of ϵ. From Fig. 3, we can observe that when $\gamma = 0.2$ the DF-SOT approach reaches its best performance with 0.6953 ($\epsilon = 0.02$) on O-Loss, 1.5516 ($\epsilon = 0.045$) on S-Loss, and 1.0578 ($\epsilon = 0.04$) on H-Loss, and that when $\gamma = 0.3$ the DF-SOT approach reaches its best performance with 0.6953 ($\epsilon = 0.015$) on O-Loss, 1.5531 ($\epsilon = 0.02$) on S-Loss, and 1.0547 ($\epsilon = 0.025$) on H-Loss, which outperforms the best performance of the HL-SOT approach on O-Loss 0.6984 ($\epsilon = 0.025$), on S-Loss 1.6188 ($\epsilon = 0.025$), and on H-Loss 1.0969 ($\epsilon = 0.05$). This indicates that with the proposed LFS framework, compared with the HL-SOT approach, the DF-SOT approach generally improves the classification performance.

[4]Since the three loss functions are respectively well-defined by each formula and self-explained by their names, due to the space limitation, we do not present more explanation.



(a) O-Loss (b) S-Loss (c) H-Loss

Figure 3: Classification Performance (A Smaller Loss Value Means Better Classification Performance)

5.3.2 Comparison on Computational Efficiency

We conduct further experiments to analyze computational efficiency gained through the proposed LFS framework. All the experiments are conducted on a normal personal computer containing an Intel Pentium D CPU (2.4 GHz, Dual Core) and 4G memory. Fig. 4 summarizes the computational time consumed by experiment runs respectively for HL-SOT ($d = 270$) and DF-SOT ($\gamma = 0.2$ and $\gamma = 0.3$). From Fig. 4, we can observe that the HL-SOT approach consumes 15917695 ms to finish an experimental run, although the DF-SOT approach only takes respectively 2.29% (with $\gamma = 0.2$) and 4.91% (with $\gamma = 0.2$) of computational time as the existing HL-SOT approach consumes and achieves even better classification performance than the HL-SOT approach (see Fig.3). This confirms that much computational efficiency can be gained for the HL-SOT approach to be implemented in the LFS framework while better classification performance is ensured. Since the computational complexity of each node classifier of DF-SOT is the same as HL-SOT, the computational efficiency gained from the proposed LFS framework should be attributed to the dimension reduction of the index term space.

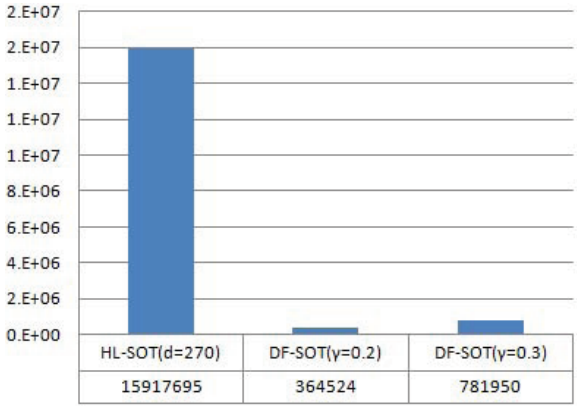


Figure 4: Time Consuming (ms)

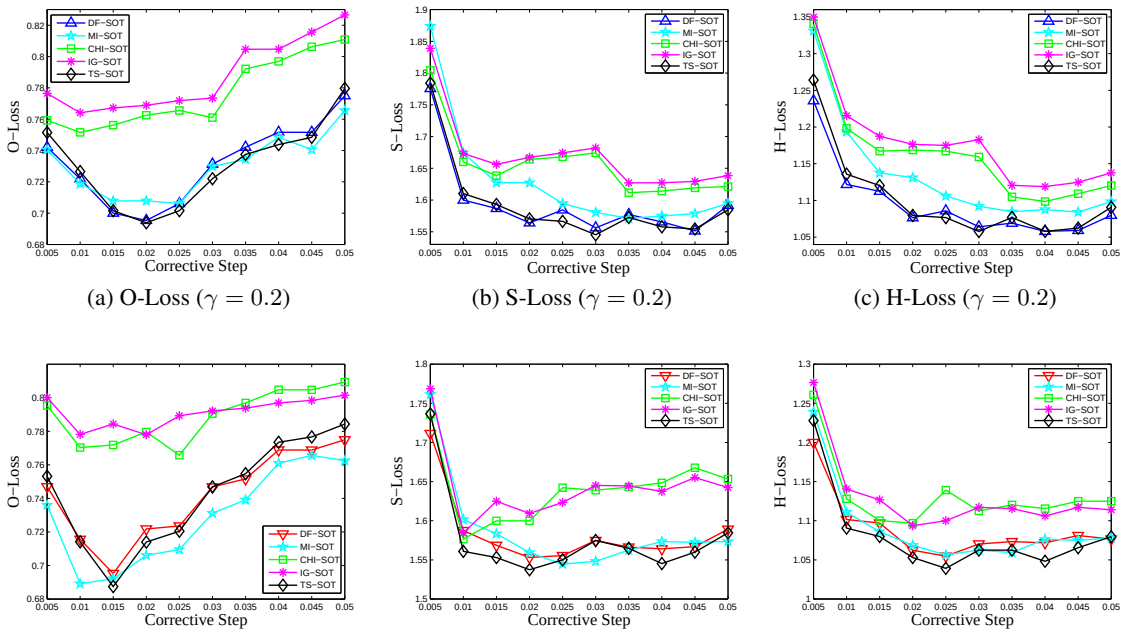
5.4 Comparative Study on Feature Selection Algorithms

The proposed LFS framework for the HL-SOT approach can employ various feature selection algorithms to select local features for each individual node. In this section, we conduct intensive experiments to comparatively study five classic feature selection algorithms employed within the LFS framework. The five employed feature selection algorithms are respectively document frequency (DF) (Manning et al., 2008) based feature selection algorithm, mutual information (MI) (Manning et al., 2008; Church and Hanks, 1990) based feature selection algorithm, χ^2-statistic (CHI) (Manning et al., 2008) based feature selection algorithm, information gain (IG) (Mitchell, 1997) based feature selection algorithm as well as term strength (TS) (Wilbur and Sirotkin, 1992) based feature selection algorithm[5].

In the experiments, the feature selection rate γ is set to 0.2 and 0.3 respectively. The value of the corrective step ϵ varies from 0.005 to 0.05 with each step of 0.005. The experimental results are summarized in Fig. 5. From Fig. 5 it is observed that DF, MI, and TS feature selection algorithms achieve generally better performances than CHI and IG feature selection algorithms when they are employed in the proposed LFS framework. Specifically, the TS algorithm is generally the best among the five employed algorithms while the DF algorithm can also achieve as

[5]Due to the space limitation, details of the studied feature selection algorithms are not reviewed here. The mechanism of each algorithm can be read in the related references.



(a) O-Loss ($\gamma = 0.2$) (b) S-Loss ($\gamma = 0.2$) (c) H-Loss ($\gamma = 0.2$)

(d) O-Loss ($\gamma = 0.3$) (e) S-Loss ($\gamma = 0.3$) (f) H-Loss ($\gamma = 0.3$)

Figure 5: Comparative Performances on the Employed Feature Selection Algorithms

comparable good performance as the TS algorithm does. This is due to that both the TS and the DF algorithms favor high frequency terms and vocabularies used in customer reviews on a specific product are usually overlapping. When $\gamma = 0.3$, it can be also observed that the MI algorithm achieves as comparable good performance as the TS algorithm does. This is because, in customer reviews, although some vocabularies are rarely used they always occur as significant features in some specific categories. For example, "ergonomics" is a rare term but almost always appears in the class of "design and usability". Therefore, the MI algorithm can also achieve relatively better performance through favoring rare terms that always co-occur with specific classes.

6 Conclusions and Future Work

In this paper, we propose a LFS framework tailored to the HL-SOT approach to sentiment analysis. In the proposed LFS framework, significant feature terms of each node can be selected to construct the locally customized index term space for the node so that the classification performance and computational efficiency of the existing HL-SOT approach are improved. The effectiveness of the proposed LFS is validated against a human-labeled data set. Further comparative study on five employed feature selection algorithms within the proposed LFS framework indicates that the TS, DF, and MI algorithms achieve generally better performance than the CHI and IG algorithms. Among the five employed algorithms, the TS algorithm is the best to be employed by the proposed LFS framework.

Although the proposed LFS framework shows its effectiveness of improving on the HL-SOT approach, its improvement on the classification performance is not so obvious compared with its much improvement on computational efficiency. Due to the limited number of instances in the training data set, the classification performance still suffers from the problem that unobserved terms appear in testing cases. This problem is inherently raised by the bag-of-word model. A concept-based indexing scheme that can infer concepts of unobserved terms might alleviate the problem. We plan to investigate on this issue in the future work.

Abstract

Sentiment analysis is the problem of determining the polarity of a text with respect to a particular topic. For most applications, however, it is not only necessary to derive the polarity of a text as a whole but also to extract negative and positive utterances on a more fine-grained level. Sentiment analysis systems working on the (sub-)sentence level, however, are difficult to develop since shorter textual segments rarely carry enough information to determine their polarity out of context. In this paper, therefore, we present a fully automatic framework for fine-grained sentiment analysis on the subsentence level combining multiple sentiment lexicons and neighborhood as well as discourse relations to overcome this problem. We use Markov logic to integrate polarity scores from different sentiment lexicons with information about relations between neighboring segments, and evaluate the approach on product reviews. The experiments show that the use of structural features improves the accuracy of polarity predictions achieving accuracy scores of up to 69%.

1 Introduction

Sentiment analysis systems have continuously improved the quality of polarity classifications of entire product reviews. For numerous real-world applications, however, classification on such a coarse level is not suitable. Even in their most enthusiastic reviews, users still tend to mention negative aspects of a particular product. Conversely, in very negative reviews there might still be mentions of several positive aspects of the product. Moreover, different opinions can even be uttered in the same sentence. Consider, for instance, the sentence "*Despite the pretty design I would never recommend it, because the sound quality is unacceptable*" which expresses both positive and negative opinions about a product. Thus, to determine both negative and positive utterances in product reviews, classification on the subsentence level is needed.

Sentiment Analysis on Subsentence Level. As basic classification unit for our fine-grained sentiment analysis system we choose discourse segments. There are various theories describing discourse, discourse segmentation and discourse relations. The most well-known theory aiming to describe some aspects of text coherence is the Rhetorical Structure Theory (RST) introduced by Mann and Thompson (1988). According to this theory, every text consists of elementary segments that are connected by relations. Segments joined by a relation form a unit, which is itself connected to other segments. This leads to a hierarchical tree structure that spans over the whole text. The example sentence given above could be divided into the three segments s_1 = *Despite the pretty design*, s_2 = *I would never recommend it* and s_3 = *because the sound quality is unacceptable*, with a CONCESSION relation[1] holding between s_1 and s_2 and a CAUSE-EXPLANATION-EVIDENCE relation holding between s_2 and s_3. As the segments form logical units, and parts of sentences bearing different polarities are contrastive and thus do not constitute a logical unit, we claim that the discourse segment level is appropriate for fine-grained sentiment analysis.

Integrating Neighborhood Relations. As discourse segments consist of only a few tokens, they

[1]Please note that in this work we do not distinguish between CONCESSION and CONTRAST relations and consider both as CONTRAST relations. In the following, we will refer to all other kind of relations as NO_CONTRAST relations.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 336–344,
Chiang Mai, Thailand, November 8 – 13, 2011.

rarely carry enough information to determine their polarity out of context. While it occurs that neighboring segments bear opposite polarities, like in the example given above, two segments following each other are mostly of the same polarity. Therefore, when determining the polarity of a discourse segment, we consider the polarity of the neighboring segments for the classification.

Leveraging Contrast Relations. Although mentioning positive and negative opinions next to each other constitutes a contrast, we cannot conclude that every contrast indicates a polarity change. We conducted a simple corpus study, focusing on the cue word *but* which is a strong indicator for contrast relations. Of all consecutive discourse segments connected by the word *but*, 40% express opposite and 60% express the same opinion. Of all the other discourse segment pairs, only 10% express differing opinions. From this experimental observation, we conclude that two neighboring segments not related by a contrast relation have a much higher probability of bearing opinions of the same polarity than segments connected by a contrast relation. In our experiments, we will investigate whether the distinction between CONTRAST and NO_CONTRAST relations will improve fine-grained sentiment analysis.

Collective classification. The challenge of fine-grained sentiment analysis is that shorter text segments pose a more difficult classification problem. There are various approaches to determining the polarity of text. One common approach is the look-up of terms in a sentiment lexicon with polarity scores. As discussed in the previous paragraphs, we claim that incorporating information about a segment's neighbors, the classification of small text segments can be improved on. Therefore, we simultaneously determine the most probable classification of all segments in a review. We use Markov logic to combine polarity scores from different sentiment lexicons with information about discourse relations between neighboring segments, and evaluate the method on product reviews.

2 Related Work

Methods for fine-grained sentiment analysis are developed by Hu and Liu (2004), Ding et al. (2008) and Popescu and Etzioni (2005). While the approaches of the former two operate on the sentence level, the system of the latter - Popescu and Etzioni (2005) - extracts opinion phrases on the subsentence level for product features. Their approaches have in common that they first extract features of a product, like the *size* of a camera or its *weight*. Then, they look for opinion words describing these features. Finally, the polarity of these terms and, thus, of the feature is determined. An even finer-grained system is presented in Kessler and Nicolov (2009). The approach aims at classifying both sentiment expressions as well as their targets using a rich set of linguistic features. However, they have not implemented the component that detects and analyses sentiment expressions, but focus on target detection.

Täckström and McDonald (2011) combine fully and partially supervised structured conditional models for a joint classification of the polarity of whole reviews and the review's sentences.

An approach based on assumptions similar to our intuition to integrate discourse relations is described in Kim and Hovy (2006) where the authors label sentences as reasons for or against purchasing a product. The system makes use of conjunctions like "and" to infer polarities and applies a specific rule to sentences including the word "but": if no polarity can be identified for the clause containing "but", the polarity of the previous phrase is taken and negated. In our system, we incorporate this information using discourse relations.

The impact of discourse relations for sentiment analysis is investigated in Asher et al. (2009). The authors conduct a manual study in which they represent opinions in text as shallow semantic feature structures. These are combined to an overall opinion using hand-written rules based on manually annotated discourse relations. An interdependent classification scenario to determine polarity as well as discourse relations is presented in Somasundaran and Wiebe (2009). In their approach, text is modeled as opinion graphs including discourse information. In Somasundaran et al. (2009) the authors try alternative machine learning scenarios with combinations of supervised and unsupervised methods for the same task. However, they do not determine discourse relations automatically but use manual annotations.

3 Statistical-Relational Representation

The basic idea of our approach is the integration of heterogeneous features such as polarity scores from sentiment lexicons and neighborhood relations between segments. We use concepts and algorithms from statistical relational learning and, in particular, Markov logic networks (Richardson and Domingos, 2006).

We briefly introduce Markov logic as a framework for combining numerical and structural features and describe how the problem of fine-grained sentiment analysis based on multiple lexicons and discourse relations can be represented in the language. Most probable polarity classifications are then derived by computing maximum a-posteriori (MAP) states in the ground Markov logic network.

3.1 Markov Logic Networks

Markov logic (Richardson and Domingos, 2006) can be as a first-order template language for log-linear models with binary variables. Log-linear models are parameterizations of undirected graphical models (Markov networks) which play an important role in the areas of reasoning under uncertainty (Koller and Friedman, 2009) and statistical relational learning (Getoor and Taskar, 2007). Please note that log-linear models are also known as maximum-entropy models in the NLP community (Manning and Schütze, 1999). The features of a log-linear model can be complex and allow the user to incorporate prior knowledge about what types of data are expected to be important for classification.

A Markov network $\mathcal{M}$ is an undirected graph whose nodes represent a set of random variables $\mathbf{X} = \{X_1, ..., X_n\}$ and whose edges model direct probabilistic interactions between adjacent nodes. More formally, a distribution P is a log-linear model over a Markov network $\mathcal{M}$ if it is associated with:

- a set of features $\{f_1(D_1), ..., f_k(D_k)\}$, where each D_i is a clique in $\mathcal{M}$ and each f_i is a function from D_i to $\mathbb{R}$,
- a set of real-valued weights $w_1, ..., w_k$, such that

$$P(\mathbf{X} = \mathbf{x}) = \frac{1}{Z} \exp\left(\sum_{i=1}^{k} w_i f_i(D_i)\right),$$

where Z is a normalization constant.

A Markov logic network is a set of pairs (F_i, w_i) where each F_i is a first-order formula and each w_i a real-valued weight associated with F_i. With a finite set of constants C it defines a log-linear model over possible worlds $\{\mathbf{x}\}$ where each variable X_j corresponds to a ground atom and feature f_i is the number of true groundings (instantiations) of F_i with respect to C in possible world $\mathbf{x}$. Possible worlds are truth assignments to all ground atoms with respect to the set of constants C. We explicitly distinguish between weighted formulas and *deterministic* formulas, that is, formulas that always have to hold.

Inference

There are two common types of inference tasks for a Markov logic network: Maximum a-posteriori inference and (conditional) probability inference. The latter computes the posterior probability distribution over a subset of the variables given an instantiation of a set of evidence variables. MAP inference, however, is concerned with finding a joint assignment to a subset of variables with maximal probability. Assume we are given a set $\mathbf{X}' \subseteq \mathbf{X}$ of instantiated variables and let $\mathbf{Y} = \mathbf{X} \setminus \mathbf{X}'$. Then, a most probable state of the ground Markov logic network is given by

$$\underset{\mathbf{y}}{\operatorname{argmax}} \sum_{i=1}^{k} w_i f_i(D_i).$$

Parameter Learning

Given a set of first-order formulas and a set of ground atoms, we wish to find the formulas' maximum a posteriori (MAP) weights, that is, the weights that maximize the log-likelihood of the hidden variables given the evidence. There exist several learning algorithms for Markov logic such as voted perceptron, contrastive divergence, and scaled conjugate gradient (Lowd and Domingos, 2007).

We employed the voted perceptron learner for the experiments (Richardson and Domingos, 2006; Lowd and Domingos, 2007; Riedel, 2008) which performs gradient descent steps to approximately optimize the conditional log-likelihood. In a MLN, the derivative of the conditional log-likelihood with respect to a weight w_i is the difference between the number of true groundings f_i of the formula F_i in the training data and the expected number of groundings according to the

model with weights $\mathbf{w}$

$$\mathrm{g}_i = \frac{\partial}{\partial w_i} \log P(\mathbf{Y} = \mathbf{y} | \mathbf{X}' = \mathbf{x}') = f_i - E_{\mathbf{w}}[f_i].$$

The expected number of true groundings $E_{\mathbf{w}}[f_i]$ is determined by (approximately) computing a MAP state with the current weights $\mathbf{w}$. The perceptron update rule for the set of weights $\mathbf{w}$ for epoch $t+1$ is then

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \eta \mathbf{g},$$

where η is the learning rate. Online learners repeat these steps updating the weight vector for a predetermined number of n epochs.

3.2 Markov Logic Formulation

Each discourse segment s is modeled with a constant symbol $c \in C$. The set C, therefore, models the discourse segments in the text under consideration and comprises the set of constants of the Markov logic network. The segments s_1, s_2, and s_3 depicted in Figure 1, for instance, would be modeled using the constant symbols c_1, c_2 and c_3. We represent the polarity of a segment using two non-observable predicates $positive$ and $negative$. Note that the state of variables modeling non-observable ground predicates is only known during weight learning. We first formulate the fact that a segment is positive or negative but cannot be $positive$ and $negative$ at the same time using the following deterministic formulas:

$$\begin{aligned} \forall x : \neg positive(x) &\Rightarrow negative(x) \\ \forall x : negative(x) &\Rightarrow \neg positive(x) \end{aligned}$$

Furthermore, the model incorporates several numerical *a-priori* features such as the polarity scores of individual segments provided by external lexical resources. We introduce these features in the experimental section in more detail. For each of these features ℓ we wish to include in the model, we first add the following deterministic equivalence formulas

$$\begin{aligned} \forall x : positive\_source_\ell(x) &\Leftrightarrow positive(x) \\ \forall x : negative\_source_\ell(x) &\Leftrightarrow negative(x) \end{aligned}$$

Now, in order to include a-priori polarity scores, we add the weighted formula $positive\_source_\ell(x)$ and *scale* the contribution of a *true* ground atom $positive\_source_\ell(s)$ with the a-priori polarity score of the particular segment s. This way, the parameter learning algorithm balances the contributions of the different sources according to their accuracy on the training data. The framework "Markov theBeast"[2] which we used for our experiments allows to add such real-valued features (Riedel, 2008).

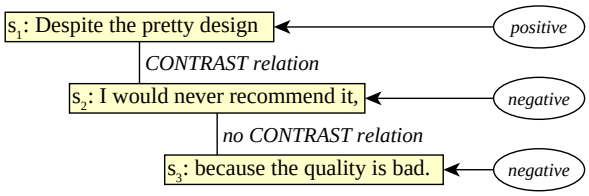

Figure 1: Sentiment polarities of and discourse relations between the segments of a sentence.

The novel contribution of the present paper, however, is the addition of *structural features*, that is, features that model specific dependencies holding between the segments of a review. We distinguish two different types of such features, namely, *neighborhood relations* and *discourse relations*.

3.2.1 Neighborhood Relations

The intuition behind *neighborhood relations* is that neighboring segments are more likely to have the same polarity. We model the fact that a segment *precedes* another segment with the observable predicate pre. Each sentence is represented as a set of ground predicates instantiated by constants modeling consecutive sentence segments. The sentence depicted in Figure 1, for instance, would be represented with the two ground atoms $pre(c_1, c_2)$ and $pre(c_2, c_3)$. The following formulas are included in the Markov logic formulation to model the dependency of preceding segments.

$$\begin{aligned} \forall x, y : pre(x, y) \wedge positive(x) \Rightarrow positive(y) \\ \forall x, y : pre(x, y) \wedge negative(x) \Rightarrow negative(y) \end{aligned}$$

The weights of the above formulas (a subset of the parameters of the model) are learned during training.

3.2.2 Discourse Relations

While there are numerous types of possible discourse relations we decided to only distinguish between contrast relations ($contrast$) and all other types of relations ($nconstrast$) due to their potential impact on polarity changes between discourse segments. In principle, however, it is possible to

[2]The code can be downloaded at `http://code.google.com/p/thebeast/`

Topic	p	n	total
Cell Phones & Service	1392	1785	3177
Gourmet Food	990	616	1606
Kitchen & Housewares	1188	1405	2593
Sum	3570	3806	7376

Table 1: Amount of positive (p) and negative (n) segments.

extend the model to also incorporate additional relations. The sentence shown in Figure 1, for instance, would be represented with the two ground atoms $contrast(c_1, c_2)$ and $ncontrast(c_2, c_3)$.

In order to leverage contrast relations, we included the following formulas in the Markov logic formulation, modeling how the absence of contrast relations between segments influences their potential polarity changes.

$$\begin{aligned}
\forall x, y : contrast(x, y) \ \wedge \ positive(x) \quad &\Rightarrow negative(y) \\
\forall x, y : contrast(x, y) \ \wedge \ negative(x) \quad &\Rightarrow \ positive(y) \\
\forall x, y : ncontrast(x, y) \wedge positive(x) \quad &\Rightarrow \ positive(y) \\
\forall x, y : ncontrast(x, y) \wedge negative(x) \quad &\Rightarrow negative(y)
\end{aligned}$$

Again, the weights of the above formulas are learned in the training phase.

The classification of a given set of segments is now equivalent to computing a maximum a-posteriori (MAP) state of the respective ground Markov logic network.

4 Experiments

In what follows, we describe the individual components of our sentiment analysis system and the data we used to experimentally evaluate it. For the evaluation, we first combine real-valued polarity scores derived from sentiment lexicons using Markov logic networks and classify all segments of a product review. We then investigate whether the addition of certain structural features improves the performance of the system.

4.1 Data

We chose a subset of the the Multi-Domain Sentiment Dataset arranged by Blitzer et al. (2007) and annotated it for our purpose. The Multi-Domain Sentiment Dataset consists of user-written product reviews downloaded from the web page `http://amazon.com`. The reviews are subdivided according to their topics. We included the three categories "Cell Phones & Service", "Gourmet Food" and "Kitchen & Housewares".

Each category consists of up to 100 reviews. A review is already classified as positive or negative according to the amount of stars the user has chosen for the product along with their review. To achieve a balanced corpus, we picked the 20 longest positive and the 20 longest negative reviews for each of the two topics, resulting in a complete amount of 120 reviews. Table 1 lists the three categories and their respective numbers of segments.

4.1.1 Gold Standard

Three independent annotators were instructed to label all passages of a review as `positive`, `negative` or `neutral`. Here, a passage is defined as a sequence of words sharing the same opinion. Each word of a review belongs to exactly one passage. The annotators were instructed to choose arbitrary passage boundaries independent of sentence or clause limits. The inter-annotator agreement among the three annotators varies from κ = 0.40 to κ = 0.45 for negative reviews, which is considered only fair agreement, and from κ = 0.60 to κ = 0.84 for positive reviews which is considered strong agreement according to Fleiss kappa (Fleiss, 1971). In our experiments, we only use the two classes `positive` and `negative`. Because of the individual segmentations, we processed the corpus word by word to determine the final polarity labels. For each word, we considered the three polarity labels the annotators had chosen for the respective passages containing the word. If one of the labels `positive` or `negative` was used in the majority, we chose this as the final label. Whenever the majority of the annotators picked `neutral` or each of the annotators chose a different label the general polarity of the entire review as given by the data set was taken as final label. This is because we estimate the user chose the star-rating according to his overall opinion on the product he is reviewing. This general opinion is expressed by the review text and, therefore, the "standard" label for the review represents the overall opinion. The numbers of positive and negative segments according to the gold standard are shown in Table 1.

The final output of our fine-grained sentiment analysis system are discourse segments labeled as positive or negative. To compare them to the gold standard, we determine the polarity labels of all tokens belonging to the segment in the gold standard and take the most-chosen label. Again, if there is

the same amount of positive and negative labels, we take the overall polarity of the whole review as label.

4.2 Polarity Features

For each segment, we estimate prior positivity and negativity scores using state-of-the-art sentiment classification methods. There are two basic ways to classify polarity. One of the most common approaches is to train a classifier on labeled data that works with a bag-of-words model or uses similar features. However, named approach will have difficulties with the short text segments our system is focused on.

Another method for polarity classification is to look up terms in a pre-compiled sentiment lexicon that lists terms and their polarities. We chose the latter method for several reasons. First, lexicon-based methods do not rely on large amounts of training data. Second, lexicons can easily be exchanged or added which makes the approach more flexible. Third, the use of Markov logic allows us to combine several lexicons without additional effort. To compute the positivity and negativity score for a segment according to a lexicon, we first look up the positivity as well as the negativity of each term of the segment in this lexicon. Then, we average the positivity as well as the negativity scores. This leads to one positivity score and one negativity score per lexicon for each segment. We use a simple heuristic to consider negated polarity terms such as in *not good*. To this end, we manually compiled a list of negation terms[3]. Every time we detect such a negation indicator within a segment, we switch the positivity and the negativity scores of all terms occurring after said negation. We employ the following lexicons:

- **SentiWordNet** (SWN)
  SWN (Esuli and Sebastiani, 2006) is a lexical resource that contains positivity-scores, negativity-scores and objectivity-scores for WordNet (Fellbaum, 1998) synsets. The scores are between 0.0 and 1.0 and all three scores for a synset sum up to 1.0. For our system, we only regard positivity scores and negativity scores. We use a part-of-speech tagger and take the first word sense.

- **Taboada and Grieve's Turney Adjective List** (TGL)
  Taboada and Grieve (2004) created a list containing adjectives and their polarities based on a method described by Turney (2002). They first query a search engine for the adjective together with some manually chosen clearly positive adjectives, using the `near`-operator, then they do the same with a list of negative adjectives. Finally, they calculate the point-wise mutual information (Church and Hanks, 1990) between the queries.

- **Unigram Lexicon** (UL)
  There are terms whose polarity depends on the context they are used in. Consider for instance the word *large*: a *large screen* is good while a *large cell phone* is likely bad. To take domain-dependence into account, we compile a list of common positive and negative unigrams as well as punctuation marks for each of the three topics separately. Since we need 40 reviews per topic for the evaluation only the remaining reviews are used to compile the unigram lexicon. From this data, we calculate the ratio of all occurrences of a unigram in positive reviews to its occurrences in negative reviews and use this ratio as the positivity and negativity scores, respectively.

4.2.1 Discourse Parsing

We employ the discourse parser HILDA developed by duVerle and Prendinger (2009). It performs two tasks: First, it splits the review text into discourse segments which constitute the basic entities our system classifies. Second, it determines the discourse relations between segments. The actual output of HILDA is the discourse tree of a text. We convert the tree structure to a linear sequence of relations between neighboring segments. HILDA uses the set of relation labels described by Soricut and Marcu (2003) which is coarser-grained than RST and consists of 18 labels. For the experiments, we distinguished two types of relations: relations labeled as $contrast$ and all other relations. We refer to this class as $ncontrast$. We model these two relations in the Markov logic framework as described in Section 3.2.

We want to investigate whether the use of a discourse parser is improving fine-grained sentiment analysis. The discourse segments determined by

[3] We used the negation indicators *no, cannot, not, none, nothing, nowhere, neither, nor, nobody, hardly, scarcely, barely* and all negations of auxiliaries modals ending on *n't*, like *don't* or *won't*.

	positive			negative			
	P	R	F	P	R	F	A
majority baseline	0.00	0.00	0.00	51.60	100.00	68.07	51.60
SVM	57.05	43.06	49.08	56.44	69.47	62.28	56.66
MLN_polarity	53.21	69.58	60.31	59.90	42.62	49.80	55.67
MLN_neighborhood	66.38	72.94	**69.50**	72.02	65.34	**68.52**	**69.02**
MLN_contrast	61.39	73.47	66.89	69.48	56.65	62.41	64.79

Table 2: Results (%) for the different systems. P = precision, R = recall, F = F-measure, A = accuracy

the discourse parser constitute the basic units for our sentiment classification system. Evaluating the correctness of discourse parsing is a hard task. However, it is not of prime importance for our task that the segments are correct according to any discourse theory but that they do not include passages containing differing labels according to the gold standard. An analysis of the data shows that only 3.2% of the segments contain contradictory labels. We therefore concluded that it is appropriate to use the discourse segments as basic units for the evaluation of our system.

4.3 Experimental Setting

The goal of our system is to label discourse segments of a review as `positive` or `negative`. We employed the Markov logic network implementation "Markov theBeast"(Riedel, 2008).

We compare three different Markov logic networks. First, we only take into account the real-valued polarity features. We consider this ML formulation ("MLN_polarity") a baseline to evaluate the quality of the evidence collected from the sentiment lexicons. To compare the performance of this system to the state of the art in classification algorithms, we train a Support Vector Machine (SVM) (Platt, 1998; Keerthi et al., 2001; Hastie and Tibshirani, 1998) on the polarity features. In a second Markov logic formulation (MLN_neighborhood), we incorporate structural information about neighboring segments using the formulas described in section 3.2.1. In order to assess the impact of explicitly distinguishing between `contrast` and `ncontrast` relations, we use the Markov logic formulation described in Section 3.2.2 (MLN_contrast).

We learn the weight parameters of the Markov logic networks by running the voted perceptron online learner for 20 epochs (Riedel, 2008). We then evaluate each of the classification algorithms with 10-fold cross validation.

4.4 Results

Table 2 lists the evaluation results for the different classifiers. To determine statistical significance of the relative effectiveness of two classifiers we applied a paired t-test at a significance level of $p < 0.01$. The classifiers exclusively using polarity features have comparable accuracy values. While the SVM is showing a bias towards classifying segments as negative ML_polarity shows the opposite trend. Although the accuracy of SVM is slightly higher the relative difference of the accuracy values is not statistically significant. Including neighborhood relations increases the effectiveness relative to both non-structure based classifiers significantly. MLN_neigborhood achieves an F-measure of 69.50% for positive segments and 68.52% for negative segments with an overall accuracy of 69.02%. It also significantly outperforms the majority baseline which achieves an accuracy of 51.60%. Contrary to our hypothesis, distinguishing between `contrast` and `ncontrast` relations did *not* improve the effectiveness relative to MLN_neigborhood. MLN_contrast achieves a slightly lower accuracy than MLN_neighborhood although the difference is not statistically significant. These results suggest that the correlation of `contrast` relations and polarity changes is not significant. Furthermore, the number of contrast relations in product reviews is too small to have a significant impact. Finally, employing a discourse parser as a component of a sentiment analysis poses the problem that misclassifications might as well be caused by erroneous decisions of the component. Figure 2 depicts the accuracy values for the different classifiers on each of the ten cross-validation folds.

To the best of our knowledge, there is no sen-

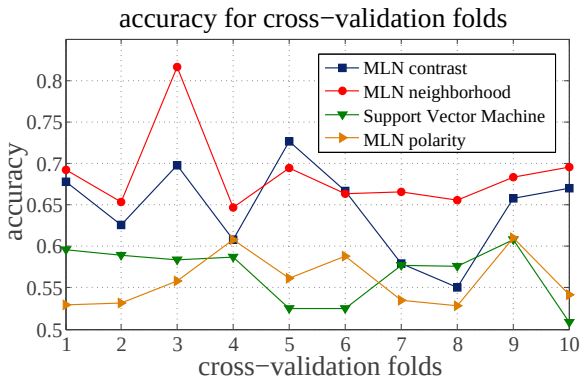

Figure 2: Accuracy values of the various algorithms for the 10 different cross-validation folds.

timent analysis system operating on the discourse segment level to which we could compare our results. However, the task is similar to that approached by Kim and Hovy (2006) whose system achieves an accuracy of 57% classifying whole sentences of reviews as positive or negative. In Täckström and McDonald (2011), the authors present a semi-supervised approach classifying sentences as positive, negative or neutral. Their approach achieves an accuracy of up to 59.1%. Considering the fact that our system is working on subsentence level we find our results promising.

5 Conclusion and Future Work

In this work, we addressed the problem of fine-grained sentiment analysis on subsentence level, achieving an accuracy of 69%. We proposed a sentiment classification method that uses Markov logic as a means to integrate polarity information from different sources and to explicitly use information about the structure of text to determine the polarity of text segments. The approach has a number of advantages. It is flexible enough to incorporate polarity scores from various sources. We used two pre-existing sentiment lexicons. To capture domain-dependent knowledge, we compiled an individual lexicon for each domain from training data. The presented approach, however, is not restricted to these sources and can include any source of polarity features. It allows for an easy combination of various existing methods into a single polarity judgement. Moreover, its major advantage is the inclusion of structural information. Again, this ability is more or less independent from a concrete method. In our work we used an existing discourse parser, however, other methods for determining the discourse structure could be used as well. Finally, the Markov logic representation can be used in a supervised and in an unsupervised setting. The experiments described in the paper are based on the supervised setting: we used a manually annotated corpus to learn weights for the formulas in the Markov logic model. In cases, where no annotated corpus is available, we could still set the weights by hand and experiment with different settings until a good setting is found.

Concerning fine-grained sentiment analysis the main result of our work is that the use of general structures found in the text systematically improves the results. As described in the paper, it turned out, however that the relation between the contrast relation and the change of polarity is not as close as we had expected. This means that the classical discourse relations are not necessarily the best choice concerning text structures to be taken into account. However, we think that focusing on cue words for discourse connectives is worth being investigated to determine features that allow us to more accurately predict such polarity changes. Further, in the work reported here, we only considered positive and negative polarity. This raises some questions concerning the treatment of segments that do not have a clear polarity. In future work, we will therefore extend our experiments to the case where segments can be classified as `positive`, `negative` or `neutral`.

Acknowledgments

We would like to thank Anette Frank for useful comments in the early phase of this work, and the annotators for annotating the product reviews.

Abstract

Syntactic structures have been good features for opinion analysis, but it is not easy to use them. To find these features by supervised learning methods, correct syntactic labels are indispensible. Two possible sources to acquire syntactic structures are parsing trees and dependency trees. For the annotation processing, parsing trees are more readable for annotators, while dependency trees are easier to use by programs. To use syntactic structures as features, this paper tried to annotate on human friendly materials and transform these annotations to the corresponding machine friendly materials. We annotated the gold answers of opinion syntactic structures on the parsing tree from Chinese Treebank, and then proposed methods to find their corresponding dependency relations on the dependency trees generated from the same sentence. With these relations, we could train a model to annotate opinion dependency relations automatically to provide an opinion dependency parser, which is language independent if language resources are incorporated. Experiment results show that the annotated syntactic structures and their corresponding dependency relations improve at least 8% of the performance of opinion analysis.

1 Introduction

Opinion analysis has drawn much attention in research communities of machine learning and natural language processing. In the early stages, words in documents were used as the main features (Pang *et al.*, 2002). Some opinion dictionaries were created for this demand (Ku *et al.*, 2007). However, researchers soon realized that word features were not sufficient for acquiring good performances, so they started to include syntactic structures and semantic information (Qiu *et al.*, 2008). Their researches showed that linguistic knowledge is helpful in determining opinions.

For various applications related to opinions, syntactic structures have become powerful tools for extracting useful clues. To find opinions in product reviews, modification relations were used to identify the product and their features (Lu *et al.*, 2009), e.g., a good *price* (feature) of this *camera* (product). To find opinion holders and targets, templates and linguistic rules were adopted (Breck *et al.*, 2007). To find more opinion words, dependency relations were utilized (Qiu *et al.*, 2011). Even when applying the basic negation rule that flips opinion polarity over, we need to find its modified word first by syntactic clues. However, we will show that syntactic relations do not directly suggest opinions.

Syntactic relations are obtained usually from all kinds of syntax trees. Parsing trees (phrase structured) and dependency trees (grammatical) are the most commonly seen ones. Parsing trees are in-order trees which keep the order of words in sentences, so they are more readable for people. Instead, nodes in dependency trees are displayed by the head-modifier relations, in which the sentence sequence probably is not remained. People could find the opinion passages if they can understand the whole sentence, i.e. from parsing trees. However, when the linguistic background is needed, it could be difficult for most people to reconstruct the whole sentence from the dependency trees in order to find the opinion passage. Therefore, if we want to find annotators to build a corpus which could be used to train an opinion relation recognizer, parsing trees are the better materials compared to dependency trees. However, compared to relations between words, complicated tree structures are more challenge to be utilized by algorithms (Doan *et al.*, 2008).

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 345–353,
Chiang Mai, Thailand, November 8 – 13, 2011.

This paper focuses on extracting opinionated dependency relations from relations generated by the Stanford parser. We design an annotation mechanism on the syntactic structures on the sentence from Chinese Treebank to create an annotation environment with a lower entry barrier so that sufficient annotations can be labeled. Then these annotations are aligned to the relations in the corresponding dependency trees generated by the same parser from the same sentence as the gold standard for training the automatic annotator of the opinion dependency relations. We conduct experiments on the annotated opinion syntactic structures in parsing trees, and on the opinion dependency relations corresponding to them. The proposed process demonstrates a feasible direction toward the development of an opinion dependency parser.

2 Problem Definition

Given a set of non-collapsed dependencies parsed from a specific sentence by the Stanford dependency parser (de Marneffe and Manning, 2008; Chang *et al.*, 2009), each associated with a dependency relation between two words in this sentence, our goal is to identify which of them are with sentiment, i.e., those which reveal a part of opinions or the aroused emotions. For example, in the sentence "活动 取得 了 圆满 成功 (Activities scored le perfect success)", the Stanford dependency parser gives three relations: nmod(成功 <success>, 圆满 <perfect>), nsubj(取 得 <scored>, 活 动 <activities>), dobj(取得 <scored>, 成功<success>), and asp(取得 <scored>, 了<le>). The goal is to identify the former three may bear sentiment or opinions. The corresponding dependency tree is shown in Figure 1. From Figure 1 we can also see that it is not easy to read the original sentence without the linguistic background.

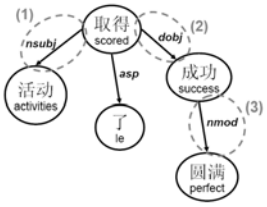

Figure 1. A sample dependency tree with three aligned opinion dependency relations.

Formally, the collection of the non-collapsed dependency relations of a sentence *S*, generated by the Stanford dependency parser, is denoted by $Rdep(S) = \{r_1, r_2, \ldots\}$, where each $r_i \in Rdep(S)$ is associate with an opinion judgment of *op(r)*.

Definition: Dependency Relation The dependency relation *r*, generated by the Stanford parser, is composed of the type of relation *rel*, the head word w_h and the modifier word w_m in the form of $rel(w_h, w_m)$. w_h and w_m are two individual words in *S*. For example, in one relation in Figure 1, *r* = nmod(成功 <success>, 圆满 <perfect>), where *rel* = nmod, w_h =成功 <success>, and w_m =圆满<perfect>. A list of *rel* is available in Stanford Parser Manual (de Marneffe and Manning, 2008; Chang *et al.*, 2009).

Definition: Opinion Judgment The opinion judgment *op(r)*, generated by the proposed system, indicates whether the corresponding dependency relation *r* is opinionated, and $op(r) \in \{true, false\}$. For example, when *r* = nmod(成功 <success>, 圆满<perfect>), *op(r)* = *true*.

Definition: Gold Opinion Judgment The gold opinion judgment, generated by mapping from manually annotated data, indicates whether the corresponding dependency relation *r* is opinionated, and $gop(r) \in \{true, false\}$.

The gold answers come from the annotations on Chinese Treebank 5.1. In a parsing tree *T* of the sentence *S*, generated by the Stanford parser, an in-ordered set of tree nodes $O = \{o_1, o_2, \ldots\}$ is used to draw a parsing tree for the annotation process, and its corresponding order, i.e., its index, is used as the node ID to record the annotations.

The way we annotate an opinion relation on a parsing tree is annotating an opinion trio (Ku *et al.*, 2009). An opinion trio $tri = (triID, o_{parent}, o_{left}, o_{right}, t) \in Tri$ is a structure containing a left node o_{left} and a right node o_{right} in a parsing tree, between them there is a syntactic inter-word relation $t \in Rpt$, and a nearest parent node o_{parent} of these two nodes. *Rpt* is an inter-word relation set where $Rpt \in \{$*Substantive-Modifier*, *Subjective-Predicate*, *Verb-Object*, *Verb-Complement*, *Other*$\}$. A sample parsing tree and opinion trios within the sentence in Figure 1 are shown in Figure 2. The literal output of opinion trios are shown in

Figure 3. In the trio *tri* = (*3, NP-OBJ,* 圆满, 成功, *Substantive-Modifier*), *triID = 3*, o_{parent} = *NP-OBJ*, o_{left} =圆满 (perfect), o_{right} =成功(success), and *t = Substantive-Modifier*.

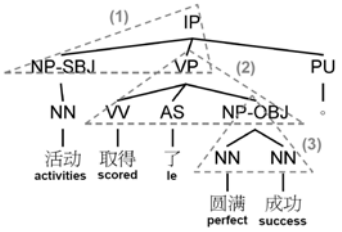

Figure 2. A sample parsing tree with trios.

1, IP, 活动, VP, Subjective-Predicate
2, VP, 取得, NP-OBJ, Verb-Object
3, NP-OBJ, 圆满, 成功, Substantive-Modifier

Figure 3. Opinion trios

Note that because the annotation of trios is on nodes of parsing trees, which appear inorderly, o_{left} will always appear before o_{right} in a sentence, and keeping this in mind will help understand the meaning of each inter-word relation *t*.

Now for the sentence *S*, we have its parsing tree *T*, the annotated opinion trios *Tri(S)* on it, and its dependency relations *Rdep(S)*. The next step is to mark the *op(r)* on *Rdep(S)* according to its corresponding *Tri(S)*. For each trio *tri*, if any descendent of its left node o_{left} and any descendent of its right node o_{right} together build a relation $r \in Rdep(S)$, the opinion judgment of *gop(r)* of the relation *r* is set to *true*. Otherwise, *gop(r)* is set to *false*. Now we have *gop(r)* for each *r* in *Rdep(S)*, our goal is to find good methods to generate *op(r)* so that it can predict *gop(r)* as precisely as possible. We propose methods to achieve this goal in Section 3.

3 Methods

As mentioned, our goal is to predict opinion dependency relations as precisely as possible. However, to use more readable materials, opinion trios are first annotated on Chinese Treebank 5.1, and then they are mapped to the corresponding dependency relations. Before the aligning process, we use the annotated trios for training to predict the opinion trios in Section 3.1. Using these predict trios for opinion analysis shall show the performance before the aligning process. After that, the aligned dependency relations, i.e., the gold opinion dependency relations are adopted for training to predict the opinion dependency relations in Section 3.2. Because the parsing tree and the dependency tree are generated by the same parser, we can always align them by the provided word ID numbers.

After prediction, the opinion dependency relations are available, and they can provide necessary information for many applications. However, we go one step further to test whether they benefit the opinion analysis. To fulfill this purpose, a basic method which uses the opinion dependency relations to extract opinionated sentences and determine their polarities is proposed in Section 3.3.

3.1 Predicting Opinion Trios

We predict the opinion trios by the sequential labeling model Conditional Random Field (*CRF*, Lafferty *et al.*, 2001*)*. In a parsing tree, the tag of the internal node is the syntactic structure of its sub-tree, and the tag of the leaf node contains its part of speech and the content word. For each node, tags of its first four children (the first level), first four children of them (the second level), and their three children are used as features of this node. Features of its siblings (the window size is five) are considered, too.

The labels ℓ we would like the *CRF* to predict labels for each node, which are *N* or labels of the form *t-C*, where $t \in Rpt$, $C = \{L, R\}$, *L* indicates that the current node is o_{left} in some opinion trio and *R* indicates o_{right}. The label *N* indicates that the current node does not belong to any $tri \in Tri$. The cardinality of the set *Rpt* is five, so that a total of 11 labels are used in *CRF*. *CRF++*[1] is selected for experiments.

3.2 Predicting Opinion Dependency Relations

After aligning the opinion trios to the dependency relations, we will have *gop(r)* for each one of them. In the previous research, usually only some relations were selected for opinion analysis. No statistical numbers showed the connection between the dependency relations and the opinions. We believe that it is because

[1] http://crfpp.sourceforge.net/

the opinion annotation on dependency relations is more difficult than on words, sentences, or documents. However, because of this alignment, we are able to see the distribution of different dependency relations in opinion sentences and opinion segments (opinion trios). We then predict opinion dependency relations based on these distributions: the *op(r)* of the relation *r* is set to *true* when its corresponding *gop(r)* appears massively frequently to be *true* in opinion sentences. To make this method reasonable, the assumption that *there are no opinion trios in non-opinionated sentences* must hold. A similar assumption that there are no opinion segments in non-opinionated sentences was made when annotating the NTCIR MOAT corpus, too (Seki *et al.*, 2008). Under this assumption, the relation that is in most case opinionated in opinion sentences is also in most case opinionated in all sentences. We believe that this assumption holds because intuitively if there is an opinion segment in one sentence, this sentence should be opinionated.

3.3 Using Syntactic Information for Opinion Extraction

In the previous research, relations were usually extracted automatically and then were used in various applications. As these relations are available after the prediction (or alignment) and as our purpose is to provide easy to use opinion dependency relations for further applications, we simply design rules for these relations in opinion analysis to show the baseline enhancement of using them.

3.3.1 Using opinion trios

In the past, Ku *et al.* (2009) have conducted rule based experiments for opinion trios. They designed formula for trios of each $t \in Rpt$. Therefore, we adopted their rules on our augmentative experiment materials. We define the opinion scoring function *S(.)*, and its output opinion score varies with the input variables. These rules are shown by trio types as follows.

- **Substantive-Modifier Type:** o_{left} of this trio type modifies o_{right}, so that the trio's opinion weight comes from the absolute opinion score of o_{left}, while the opinion polarity is determined by the occurrence of negative o_{left} or o_{right}. If at least one of them is negative, the trio is negative, else it is positive.

$$\begin{aligned}&\text{if } (S(o_{\text{left}}) \neq 0 \text{ and } S(o_{\text{right}}) \neq 0) \text{ then}\\ &\quad \text{if } (S(o_{\text{left}}) > 0 \text{ and } S(o_{\text{right}}) > 0) \text{ then } S(o_{\text{left}}o_{\text{right}}) = S(o_{\text{left}})\\ &\quad \text{else } S(o_{\text{left}}o_{\text{right}}) = -1 \times |S(o_{\text{left}})|\\ &\text{else } S(o_{\text{left}}o_{\text{right}}) = S(o_{\text{left}}) + S(o_{\text{right}})\end{aligned} \quad (1)$$

- **Subjective-Predicate Type:** o_{left} of this trio type is a subject and o_{right} is the action it performs, so that the action decides the opinion score of the trio. If the action is not an opinion or it is neutral, the subject determines the opinion score of this trio.

$$\begin{aligned}&\text{if } (S(o_{\text{right}}) \neq 0) \text{ then } S(o_{\text{left}}o_{\text{right}}) = S(o_{\text{right}})\\ &\text{else } S(o_{\text{left}}o_{\text{right}}) = S(o_{\text{left}})\end{aligned} \quad (2)$$

- **Verb-Object Type:** o_{left} of this trio type acts upon o_{right}. The effect depends not only on the action but on the target. The weight is determined by the action, but the polarity is the multiplication of the signs of opinion scores of o_{left} and o_{right}.

$$\begin{aligned}&\text{if } (S(o_{\text{left}}) \neq 0 \text{ and } S(o_{\text{right}}) \neq 0)\\ &\quad \text{then } S(o_{\text{left}}o_{\text{right}}) = |S(o_{\text{left}})| \times SIGN(S(o_{\text{left}})) \times SIGN(S(o_{\text{right}}))\\ &\quad \text{else } S(o_{\text{left}}o_{\text{right}}) = S(o_{\text{left}}) + S(o_{\text{right}})\end{aligned} \quad (3)$$

- **Verb-Complement Type:** The scoring function for trios of this type is defined the same as that of a Subjective-Predicate type in Formula (2). The complement node is the deciding factor of the opinion score.

3.3.2 Using opinion dependency relations

The *usages* of opinion dependency relations were seen in several researches (Bikel and Castelli, 2008). In these researches, rules for a small number of major dependency relations were proposed in different papers but they were not listed together for a better utilization. Some rules were not ever mentioned in pervious researches. Instead, all relations are analyzed in this paper. For each relation *r* of which *gop(r)* equals *true* (when gold opinion relations are used for opinion analysis) or *op(r)* equals *true* (when predicted opinion relations are used for opinion analysis), we calculate its opinion score *ops(r)*. Let *RM(w)* be a function to return the dependency relations of word *w*'s modifiers one at a time, *n* is the total number of relations *RM(w)* returns, and *S(.)* is also the defined opinion scoring function then *ops(r)* is defined as in Formula (4).

$$ops(r) = S(rel, w_h, w_m) + \frac{1}{n}\sum ops(RM(w_m)) \qquad (4)$$

That is, the opinion score of a dependency relation is an average of the aggregate scores of its descendent dependency relations. In practice, we design different rules for calculating opinion scores by the current relation type *rel* in *S(.)*. Here to simplify the problem, we adopted Formula (1) and treated w_m as o_{left} and w_h as o_{right} in it.

4 Experiments

Though there were researches which predicted opinion dependency relations, they did not predict directly from the parsing results. Instead, they predicted from documents or sentences according to the context and a large quantity of training instances were needed. They did not predict on all dependency relations either. Therefore, there is no existing dataset containing correct opinion labels on dependency relations. In this section, we describe how to generate opinionated syntactic dataset on parsing trees, and align the annotated labels to dependency trees. After that, qualitative and quantitative analyses of opinion dependency relations are provided. At the end, we discuss the evaluation results of the proposed methods.

4.1 Data Set and Preprocessing

To use the Stanford parser as our tool to generate dependency tree for experimental sentences and to avoid errors as possible, we adopted Chinese Treebank 5.1 as experiment materials. Sentences in Chinese Treebank are already segmented and part of speech tagged, and its tagging set is the same with the one Stanford parser uses. Therefore, the Stanford parser can take the data from the Chinese Treebank to generate more accurate dependency trees.

The dataset Chinese Treebank 5.1 contains 507,222 words, 824,983 Hanzi, 18,782 sentences, and 890 data files. For the opinion analysis experiments, opinionated labels, i.e., opinionated, non-opinionated, positive, neutral, negative, were annotated on all sentences in Chinese Opinion Treebank. Afterward 57,706 trios were annotated on the parsing trees of gold opinion sentences, i.e., sentences which were annotated as opinionated. Methods for generating the gold opinion sentences proposed by Ku *et al.* (2007) were adopted.

Next, the Stanford parser took all sentences in Chinese Treebank as input to generate their dependency trees. A total of 416,581 dependency relations were generated, and 284,590 of them were in opinion sentences. Then the annotated trios were aligned to their corresponding dependency relations, and because trios were only annotated on opinionated sentences, the *gop(r)* of these aligned relations were set to *true*. At the end, a total of 54,753 relations *gop(r)* were set to *true*.

	Opinion		
Polarity	Positive	Neutral	Negative
#	6,916	1,824	1,937
%	64.78	17.08	18.14
Total #	10,677		
Total %	56.84		

Table 1. Statistics of opinions.

Rpt	Number	Percentage
Substantive-Modifier	21,317	36.94
Subjective-Predicate	15,860	27.48
Verb-Object	18,010	31.21
Verb-Complement	1,208	2.09
Other	1,311	2.27
Total	57,706	100.00

Table 2. Statistics of structural trios.

Table 1 shows the distribution of the opinion and polarity labels. Table 2 shows the statistics of trios. Trios of the Substantive-Modifier and Verb-Object types are the majority in opinion sentences, while trios of the Verb-Complement type are few.

Table 3 further shows the distribution of dependency relations. It shows that previously the most adopted dependency relations for opinion analysis, e.g., *amod* (adjective modifier) or *advmod* (adverb modifier), do not certainly bear opinions or appear in opinion sentences. In Section 4.3, we will further test the performance of finding the opinionated relations with the help of the opinion word dictionary, which was also widely adopted by previous work (Feng *et al.*, 2009).

4.2 Evaluation of Opinion Trio Prediction

In this section, results of predicting opinion trios by CRF mentioned in Section 3.1 are shown. We first predicted the appearance of

o_{left} and o_{right} in trios, and then predicted the trio type $t \in Rpt$ for each trio.

The performance in Table 4 is not promising. Therefore, we consider the structure of trios, that is, o_{left} and o_{right} should appear as an ordered pair, and otherwise the label was viewed as illegal. The performance is shown in Table 5. Table 5 shows that all predicted trios were opinionated, and this tells that some opinion trios are of certain structures, but not all of them. We observed that the precisions 1.00 came from the collocations of specific words and structures, while the low recalls were from other trios which were not identified. However, these results still confirmed that we can find opinion trios by phrase structures and they may benefit in the opinion analysis process.

Table 3. Distributions of dependency relations and opinion dependency relations.

(A: type of dependency relations (*rel*); B: total occurrences in generated dependency trees; C: total occurrence in generated dependency trees of opinions; D: total occurrence in generated dependency trees of opinions when it bears opinions (*gop(r)* equals *true*); E: percentage that this relation appears in generated dependency trees of opinions; F: percentage that this relation appears in generated dependency trees of opinions when it bears opinions (*gop(r)* equals *true*).)

4.3 Evaluation of Opinion Dependency Relation Prediction

To predict which dependency relations are opinionated, we start with analyzing the distribution of them. Table 3 presented the distribution of dependency relations. The percentage of a relation appearing in dependency trees of opinion sentences when bearing opinions (*gop(r)* equals *true*), i.e., the value in F column, is taken as the support value. The support value indicates that in what degree this relation bears opinions. If the support value is high, it is confident to say that the relation is opinionated; otherwise, considering the content words is necessary. This idea conforms to the previous observation in Section 4.2: some of the opinions are structural, but not all of them.

According to the support value, dependency relations were divided into four categories. The Chinese opinion word dictionary *NTUSD* (Ku *et al.*, 2007) is involved to help identify opinion dependency relations when the support value is not high. The selecting criteria are listed as follows.

- **Very supportive**: with the support value above 0.8, e.g., *dvpmod*. Relations in this category are viewed as opinionated and their *gop(r)* are automatically set to *true*.
- **Supportive**: with the support value above 0.35 but lower than 0.8, e.g., *pass*, *dobj*, *npsubj*, *ba*, *top*, *nsubj*, *neg*, *amod*, *rcmod*. *RH(w)* is a function to return the word *w*'s

head in other relations of the same sentences, and *RM(w)* returns *w*'s modifier. For each $r = \{rel, w_h, w_m\}$ in this category:

$$\begin{aligned} &\textit{if any of } w_h, w_m, RH(w_h), RM(w_m) \textit{ is in NTUSD,} \\ &gop(r) = true, \\ &\textit{else } gop(r) = false. \end{aligned}$$

- **Minor supportive**: with the support value above 0.2, e.g., *rcomp*, *advmod*, *mmod*, *range*. For each $r = \{rel, w_h, w_m\}$ in this category:

$$\begin{aligned} &\textit{if all of } w_h, w_m, RH(w_h), RM(w_m) \textit{ is in NTUSD,} \\ &gop(r) = true, \\ &\textit{else } gop(r) = false. \end{aligned}$$

- **Not supportive**: with the support value less than 0.2. Relations in this category are viewed as non-opinionated and their *gop(r)* are automatically set to *false*.

Table 6. Performance of predicting opinion dependency relations.

The results of two experiment settings are listed: prediction performed on all dependency relations and on only modification-related dependency relations (in the form of *lex*-mod, e.g., *amod*, *rcmod*, etc.) The later are the relations adopted in many previous researches. Table 6 shows the performance of predicting opinion dependency relations. It indicates that if only modification related relations were considered, the f-score dropped nearly half because more than half of the opinion dependency relations were expelled in this case. In other word, results show that predicting on all relations instead of taking only modification-related dependency relations as clues can capture more opinion relations, and hence the prediction of opinion relations is necessary.

4.4 Evaluation of Opinion Extraction Using Predicted Opinion Trios and Dependency Relations

In this section, predicted opinion trios and predicted opinion dependency relations were utilized in an opinion extraction system. In order to make use of these structural cues, opinion analysis methods proposed by Ku *et al.* (2007) were selected. Their methods calculated opinion scores of sentences from characters and words accumulatively, so syntactic cues can be added in and function jointly.

Five settings for opinion analysis were experimented:

- **C+W+N**: characters, words, and negations were used as cues for calculating opinion scores. It was the original method proposed by Ku *et al.*
- **C+W+N+goldTrio**: annotated opinion trios were utilized additionally.
- **C+W+N+Trio**: predicted opinion trios were utilized additionally.
- **C+W+N+goldDep**: opinion dependency relations aligned from the annotated trios were utilized additionally.
- **C+W+N+Dep**: predicted opinion dependency relations were utilized additionally.

The results were shown in Table 7. The performance of the opinion extraction improves 10.40% (0.7162->0.7993) when utilizing opinion trios and 8.66% (0.7162->0.7782) when utilizing opinion dependency relations. These results clearly indicate that the syntactic information benefit opinion analysis. Because of

the possible information loss in the automatic alignment process, that the performance of using trios is a little better than using dependency relations matches our expectation.

Setting	f-Score
C+W+N	0.7162
C+W+N+goldTrio	0.7922
C+W+N+Trio	0.7993
C+W+N+goldDep	0.7784
C+W+N+Dep	0.7782

Table 7. Performance of using syntactic information for opinion analysis.

5 Related Work

For all we know, no previous work has annotated opinion information on all dependency relations, or mapped annotated opinionated structures to dependency relations on a large quantity of documents or sentences. Therefore, to the best of our knowledge, no statistically analysis of opinion dependency relations involving manually annotations has been conducted. Researchers designed ruled or extracted dependency relations as features for opinion analysis based on their linguistic knowledge (Qiu *et al.*, 2011).

Yet there are still several lines of related work, including (i) opinion analysis (ii) opinion corpora (iii) syntactic information. Several dozen papers have been published on the topic of opinion analysis. Two general approaches have been proposed previously. They are machine learning approaches and heuristic-rule approaches. For both approaches, syntactic structures could be utilized. For the former, they can be used as features (Abbasi *et al.*, 2008); for the later, rules can be designed according to them (Ku *et al.*, 2009). We can see from the previous work that syntactic structures can help to enhance the performance.

As to the experimental corpora, some researchers managed to generate annotated materials and gold standards under constraints. Somasundaran (2007) annotated discourse information from meeting dialogs to train a sentiment model. MPQA annotated opinions and their sources (Wiebe *et al.*, 2002). NTCIR annotated opinions, polarities, sources, and targets for its multilingual opinion analysis task (MOAT, Seki *et al.*, 2008). However, none of them were annotated on materials with syntactic structures, and it caused the lack of analysis of opinion syntactic structures.

Researchers have acquired syntactic structures (Zhou, 2008), but few of them have tried to associate syntactic structures with opinions. The most similar previous work to ours was proposed by Ku *et al.* (2009). Compared to it, the proposed process made the development of opinion dependency parser feasible. As dependency relations and the predicted opinion dependency relations are of the same form, no extra knowledge or integration is needed for the use of them.

6 Conclusions and Future Work

The proposed new process is the main contribution of this paper. It annotated opinion syntactic structures on phrase structure trees, which are more readable for annotators, and aligned these structures to grammatical structures, which facilitates their usage. Chinese Treebank was selected as the source of phrase structure trees, and dependency relations as the grammatical structures. They are both widely used in natural language processing.

Though the experiments were implemented on Chinese materials, this process is language independent. It can be applied to materials in different languages without modifications.

By predicting opinion dependency relations, we can say that a basic opinion dependency parser has been developed. Experiments have shown that the predicted opinion dependency relations are beneficial for opinion extraction. Although we still need a parser to generate syntactic structures, parsing is relatively a mature technique in natural language processing. For a comparably new research problem like opinion analysis, it is common that tools are not handy. The best of the proposed method is that it can function in a multilingual environment by incorporating a domain or language specific resources (here, NTUSD for Chinese).

Through the alignment, we made a large quantity of opinion dependency relations available. According to their distributions shown in this paper, researchers can select suitable relations to use according to their diverse needs, such as extracting evaluative features in product reviews or comments, opinions or their polarities.

Abstract

Sentiment detection of a given expression involves interaction with its component constituents through rules such as polarity propagation, reversal or neutralization. Such compositionality-based sentiment detection usually performs better than a vote-based bag-of-words approach. However, in some contexts, the polarity of the adjectival modifier may not always be correctly determined by such rules, especially when the adjectival modifier characterizes the noun so that its denotation becomes a particular concept or an object in customer reviews. In this paper, we examine adjectival modifiers in customer review sentences whose polarity should either be propagated (SHIFT) or not (UNSHIFT). We refine polarity propagation rules in the literature by considering both syntactic and semantic clues of the modified nouns and the verbs that take such nouns as arguments. The resulting rules are shown to work particularly well in detecting cases of 'UNSHIFT' above, improving the performance of overall sentiment detection at the clause level, especially in 'neutral' sentences. We also show that even such polarity that is not propagated is still necessary for identifying implicit sentiment of the adjacent clauses.

1 Introduction

Detecting the sentiment of a given grammatical unit such as phrase, clause or sentence has received much attention in opinion mining and sentiment analysis. While earlier work simply detected the overall polarity by computing the majority of the polarity of words within the expression, researchers are now looking more into the composition of polarity of words within the expression (Wilson et al., 2005; Moilanen and Pulman, 2007; Choi and Cardie, 2008). They have utilized either word features (e.g., 'Context Valence Shifters') or grammatical structures (e.g., 'the Principle of Compositionality'). It is shown that a machine learning approach with these features performs better than a vote-based bag-of-words approach. While the importance of salient features such as 'negation' or 'intensifier' is fully recognized, it is not yet clearly understood when the polarity of a particular word is propagated or is sacrificed.

The polarity of an adjectival modifier is often propagated to the polarity of the modified noun or noun phrases with no inherent polarity. However, sometimes the polarity is not propagated to that of the enclosing clause or sentence at all. For example, the polarity of the word 'real' is not propagated to that of the sentence "Real 501's are made of 14 oz canvas-like material." in a customer review of the pants, even though there is no salient sentiment word except for the word 'real'. Our observation shows that stopped propagation of this kind in customer reviews often appears because of the following reasons: 1) the word in question is mainly used to refer to the property or the identity of the product entity; 2) it is mainly used to describe certain processes about the author's experiences or to provide a useful guide for potential customers.

It is important to make the correct decision about the polarity propagation in particular regarding no propagation of the polarity of such an adjectival modifier, in order to detect the sentiment over customer reviews at a deeper linguistic level. For example, the word 'real' above is chosen to refer to the other comparative entity, which is regarded as a 'positive' entity, as opposed to the present one that is not 'real'. Hence, the 'positive' polarity should not be propagated to the polarity of the current reviewed product entity in the context. The benefit of this decision is that it will enhance the detection of the 'neutral' polarity of the sentences in a document. This decision can also be utilized in identifying

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 354–362,
Chiang Mai, Thailand, November 8 – 13, 2011.

the underlying 'negative' sentiment of the given sentence. Although it is still hard to detect the case by just looking into the sentiment of the words at the surface level, this will still work as a good clue for the detection because such a word is in contrast to the phrase 'these *Iconic Rigid* jeans' as in "These *Iconic Rigid* jeans are made of some sleazy, much lighter material", which is the sentence that follows. By considering these two sentences together, we can see that a 'negative' sentiment is conveyed. Previous work on sentiment detection from customer reviews mainly focuses on detecting sentiment of product features from the patternized sentences (Hu and Liu, 2004; Popescu and Etzioni, 2005; Titov and McDonald, 2008), so the sentences containing such implicit sentiment were not analyzed properly, despite of its importance.

In this paper, we examine adjectival modifiers in customer review sentences whose polarity should either be propagated (SHIFT) or not (UNSHIFT) when the modified noun has no inherent polarity. We refine the previous polarity propagation rules (Moilanen and Pulman, 2007) in order to enhance the performance of the propagation decision by considering both syntactic and semantic clues of the modified nouns and the verbs that take such modified nouns as arguments.

Our rules incorporating these clues into the previous rules have an important role in detecting the 'UNSHIFT' case. We found that our rules help the overall sentiment detection at the clause level especially regarding the 'neutral' cases but found also that even such polarity with no propagation is also necessary identifying the implicit sentiment of the adjacent clauses.

The rest of the paper is organized as follows. Section 2 introduces previous work analyzing the sentiment in customer reviews focusing on the detection of the polarity. Section 3 summarizes compositionality-based polarity detection in this paper. Sections 4 and 5 describe basic and refined polarity decision rules for adjectival modifiers. Section 6 analyzes our experimental results and Section 7 discusses its importance and limitation. Section 8 concludes the paper with future work.

2 Related Work

Previous work on the detection of the opinions and sentiments to a given product can be divided into three groups: graph-based method with polarity words, rule-based and machine learning-based methods focusing on sentiment detection in a compositional way. Hu and Liu (2004) identified the sentiment by counting the relevant adjectives that belong to each polarity class with a graph-based polarity lexicon. Popescu and Etzioni (2005) determined the polarity of opinion-containing phrases by identifying the polarity of the words based on relaxation labeling.

The rule-based sentiment identification methods are based on the Principle of Compositionality (Moilanen and Pulman, 2007; Neviarouskaya et al., 2009). Such methods determine the polarity of a given unit basically by composing the inherent polarity of its component lexical units or other linguistic constituents. In addition, a certain type of unit called 'valence shifters' works to contextually neutralize or intensify the polarity of the given phrase or sentence (Polanyi and Zaenen, 2004; Kennedy and Inkpen, 2006). Our work is also based on the polarity decision rules proposed by the previous work, and we modified some of them for our purpose. The benefit of rule-based approach is that it is easy to incorporate the additional rules into a rule-based framework for further detailed classification with additional categories.

Some researchers incorporated rule-based sentiment identification into machine learning techniques (Wilson et al., 2005; Choi and Cardie, 2008). Wilson and colleagues (2005) developed the classifier using AdaBoost.HM based on the idea of contextual valence shifters in order to identify contextual polarity at the phrase level. One of the features they considered is modification feature, *modifies* (parent with polarity), and *modified* (children with polarity), though they did not examine the context in which these types of feature may or may not contribute to the overall polarity. Choi and Cardie (2008) developed a machine-learning based sentiment detection method by adopting the Principle of Compositionality (Moilanen and Pulman, 2007) in order to examine whether such computational semantic-based idea can be made empirically effective. Their results show that the method incorporating compositionality performed best among all the methods. Our work is similar to their work in that we followed the idea of the Principle of Compositionality. However, our focus is on examining the characteristics of context surrounding a given adjectival modifier when its polarity is either propagated or not propagated and seeing how this propagation result affects the overall polarity of the clause.

3 Sentiment Detection based on Compositionality

Previous work on deciding the overall polarity of the given expression based on the Principle of Compositionality (Moilanen and Pulman, 2007; Neviarouskaya et al., 2009) takes into account how component lexical units are syntactically combined and develops rules to handle contextual polarity propagation, reversal, conflict or neutralization when combining the inherent polarities of the component lexical units.

We follow the polarity decision rules from previous work (Moilanen and Pulman, 2007; Shaikh et al., 2007; Neviarouskaya et al., 2009) as shown below. We apply the rules to each sentence with its dependency tree structure acquired from the Stanford parser (Klein and Manning, 2003; Marneffe et al., 2006).

- **Basic Propagation** (Moilanen and Pulman, 2007; Neviarouskaya et al., 2009): The polarity of the lexical unit at the upper level in the dependency structure of the text unit has a higher priority. If the word at the upper level has no inherent polarity, the polarity of its dependent word (at the lower level) is propagated to the polarity of the text unit.

- **OBJ/Comp domination for the case of transfer verbs** (Moilanen and Pulman, 2007): The polarity of the constituent as an object or a complement of the transfer verbs that "transmit sentiments among the arguments" (Neviarouskaya et al., 2009) is dominant when there is a polarity conflict among arguments of such verbs. (e.g., "My good old size started showing up too big or wouldn't shrink right.")

- **Reversal** (Moilanen and Pulman, 2007; Neviarouskaya et al., 2009): The negation words (e.g., 'not', 'no', 'hardly', 'reduce') reverse the polarity. We added more verb entries containing the meaning of 'reversal' from other existing review corpora.

- **Reversal for Conflict** (Both *negative* adverbs and *negative* verbs are combined from (Shaikh et al., 2007)): When two lexical units with 'negative' polarity are combined, the polarity of the unit covering both units is reversed. (e.g., "They are 501, it's hard to go wrong with these.": positive)

- **Neutralizing operators (**Condition operators (e.g., if) from Neviarouskaya et al., 2009): The polarity of the main clause or the sentence is neutralized when there are adverbial conditional clauses. We added the markers 'wh-words' or 'how' as well as the conditional marker 'if/unless'. (e.g., "How can I go wrong with the classic 501?")

4 Basic Rules for Adjectival Modifier

By following the compositionality-based polarity decision rules, the polarity of a noun or a noun phrase that has no inherent polarity is determined by its modifier's polarity. In other words, the polarity of the modifier is propagated to the upper level node in the dependency tree structure. For example, the noun phrase 'a perfect dryer' becomes to have 'positive' polarity by the result of polarity propagation. And such polarity may or may not be propagated depending on its syntactic role of the noun phrase at the clause level. If the phrase is a subject, it gets lower priority than the one that works as an object or a complement, but if the word at the upper level or the word with higher priority at the same level (i.e., object or complement) has no inherent polarity, its polarity can be propagated up to the root level by the 'Basic Propagation'. Figure 1 illustrates this case.

Sibling Xn: Children of the Verb with dependency relation R_2

Sibling Yn: Children of the Root with dependency relation R_3

Figure 1. Basic propagation

Nonetheless, we found that the polarity should not be propagated in some cases as shown in Example (1a).

(1) a. Real 501's are made of 14 oz canvas-like material.
b. It's a real 501's.

There is no word with inherent polarity except 'real' in (1a), so the overall polarity could be de-

cided as 'positive' by the rules just like (1b), but it is actually closer to 'neutral' sentence. The reason is that the adjective is utilized to refer to another product entity, which is 'the original Levis 501 Jean' in this context.

Interestingly, we see that such phrases often appear in the customer reviews of a product which is a steady seller and whose quality is already well known. To detect whether the polarity of the adjectival modifier is propagated or not is crucial especially when there are no other salient polarity words except for the adjective. It is mainly used to refer to the other product entity for contrastive purposes.

In this paper, we examine the types of clues that affect the propagation of the adjectival modifier's polarity at the clause level. We also refine the previous polarity decision rules by incorporating additional clues. With the refined rules, we define our problem as follows. For a given adjectival modifier modifying a noun or a noun phrase with no inherent polarity, we label it with 'SHIFT/UNSHIFT' tags depending on the nature of propagation. If it is propagated, we label it with the 'SHIFT' tag, and if not, we do it with the 'UNSHIFT' tag.

The basic rules for labeling by considering only syntactic clues from the previous polarity decision rules are as follows.

- SHIFT: 1) if the syntactic role of the noun phrase is complement; 2) if the syntactic role of the noun phrase is object of verbs or prepositions
- UNSHIFT: 1) if the syntactic role of the noun phrase is subject (e.g., (1a)); 2) if the syntactic role of the noun phrase is object of the verb whose syntactic type is either 'gerund (*Ving*)' or 'infinitive (*to V*)'

We also regarded the case as 'UNSHIFT' where the noun phrase has lower priority than its sibling phrases in the dependency tree; for example, if there is an object with non-neutral polarity and the syntactic role of the given noun phrase is subject, the labeling is done with 'UNSHIFT'. Example (2) shows 'SHIFT' and 'UNSHIFT' for the adjectival modifier 'good' and 'great', respectively.

(2) a. It's a <u>good</u> buy.
b. A <u>great</u> shave takes a little more commitment than just breaking out a can of foam and a disposable razor.

We decided not to use machine learning techniques with the following reasons. First, our goal is not to enhance the overall performance of sentiment detection in general but to examine what kinds of additional clues are called especially for the decision of the polarity propagation of the adjectives modifying the noun with no polarity. Following Kennedy and Inkpen (2006)'s work for measuring the impact of valence shifters on sentiment classification, we believe it is not straightforward to identify major factors for the improvement with a machine learning algorithm. Second, our work focuses on relatively small cases among all the cases in the whole review sentences (See Table 5), so it is reasonable to directly apply refined rules to each case without an unnecessary training process handling other cases. We believe that the rules of this kind by taking a closer look at the focused cases could be extended regarding scalability with the help of the machine leaning techniques in the future.

5 Rule Refinement

We refined the rules with additional clues as follows because the basic rules do not work properly in some context.

5.1 Phrase-level Clues

The basic rules mainly consider the syntactic types of the noun phrase and the verb taking the noun phrase as the argument. However, the following clues at the phrase level may also affect the propagation.

- Quoted / Capital Letters (UNSHIFT)
- Types of noun in the product reviews

Example (3) shows quoted adjectival modifiers. The quotes indicate that its inherent polarity is not effective. We can see that the author of the review intentionally used them to indicate such neutralization.

(3) a. The fit on these "<u>relaxed</u>" jeans is just that--relaxed but not loose.

b. If you love "<u>Happy</u> Hippy" shower gel, this fun bath product will impress you.

Examples (4) and (5) show the polarity propagation depending on the types of modified noun by the adjectives. While the polarities in Example (4) are propagated, those in Example (5) are not propagated.

(4) a. This product also arrived in good condition and in good time. (Delivery)
b. I will never order anything from Levi again until they come back to the original levi material. (Product feature)

(5) a. They were also not much cheaper than I would have paid from a real retailer. (Location & time)
b. People with healthy, not-so-damaged, and normal hair do not need to use this stuff. (User Information)
c. All it takes for a great shave is a good safety razor, a decent brush, shaving soap and a mug. (Purpose)
d. After a quick rinse my skin looked less dull, and helped clear blotches (Process).
e. Use with Chanel loose powder and Chanel concealer for a perfectly flawless finish. (Product name)

The types of noun in Example (4) are related to explicit sentiment of the product. On the other hand, the types of noun in Example (5) are related to implicit sentiment or additional background information provided for the potential customers. In order to distinguish SHIFT cases from UNSHIFT cases resulting from such different types of noun we built a lexicon for the noun type as shown in Table 1. We collected the words belonging to each type by utilizing three different methods. We first manually collected words belonging to each noun type from the sample review texts and extended the entries by including synonyms of the seed words in WordNet (Synonyms; Miller, 1995). Some synsets of WordNet such as 'body_part'/'illness' and 'shop' are appropriate for 'User information' and 'Location'. We combined several synsets for such type (WordNet Synsets). The noun types such as 'Product name', 'Product feature', 'Purpose', and 'Process' are domain dependent, we collected the words by utilizing Point-wise Mutual Information (PMI).

Propagation	Noun Type	Method
SHIFT	Delivery	Synonyms
	Deal	
	Product feature	PMI
UNSHIFT	Time	Synonyms
	Location (shop, store)	WordNet Synsets
	User info (body part/illness)	
	Product name	PMI
	Process/Purpose	

Table 1. Types of noun

5.2 Clause-level Clues

The main reason for the second rule of the 'UNSHIFT' basic rules in Section 4 is that we assumed the given phrase/clause could be regarded as a secondary concept or topic for the main concept or topic as shown in Example (6).

(6) a. Anyone who is that determined to make the best product on the market, obviously will do whatever it takes to make it happen.
b. Getting an outstanding shave from this razor should be a cinch.

However, the given phrase/clause should be regarded as the main concept or an independent concept as shown in Example (7).

(7) a. It *seemed* to have a rich sophistication which goes with horseback riding or polo.
b. It's wonderful doing everything I need, including making my hair nice and shiny, without the heaviness.

In order to capture these differences, we refined the rules as shown in Table 2.

Infinitive (*to V*)	Gerund (*Ving*)
IF the head of the infinitive has auxiliary characteristics such as 'seem' and 'need' THEN label it with SHIFT. Otherwise, label it with 'UNSHIFT'.	IF the phrase/clause including the gerund is clausal subject THEN label it with 'UNSHIFT'. Otherwise label it with 'SHIFT'.

Table 2. Refined rules for 'UNSHIFT'

The rule for the object of prepositions should also be refined. As we mentioned in Section 5.1, the reason for mentioning some particular types of object in the review is to explain additional background information as a guide for the potential customer as well as showing the sentiment about the product. The types of noun at the phrase level cannot always solely determine the polarity propagation because such decision is still affected by the presence of other constituents in the context at the clause level. For example, by comparing (5c) with the sentence "it provides a very close, smooth shave", the polarity of 'smooth' is propagated while that of 'great' is not propagated.

To handle this case properly, we consider 'Clause-level Semantic Label' at a shallow level by taking into account both some preposition

types and the noun types together that frequently appear as shown in Table 3. We named the labels by referring to 'Frame Index' from FrameNet data (Baker et al., 1998). This list of the pairs filters further 'UNSHIFT' cases from the 'SHIFT' labeled cases by the basic rules.

Semantic Label (FrameNet)	**Prep. & N.Type**	**Ex.**
Purpose (related to Shopping)	'for/with' & Purpose (Use)	(5c)
Body mark	'for/with' & User info (Body part)	(5b)
Process (related to Using)	'after' & Process	(5d)
Place (related to Shopping)	'on/from' & Time/ Location	(5a)

Table 3. Semantic Label for filtering 'UNSHIFT'

The last clue is about the sentence type. Even if the polarity of the adjectival modifier is propagated to the top node word at the clause level, the type of the sentence may block it for the overall polarity of the whole sentence. We consider three types of sentences that turn the 'SHIFT' label into the 'UNSHIFT' label as shown in Table 4.

Sentence Type	**Examples**
Condition	You will not be sorry *if* you are looking for the perfect brush to go with your perfect dryer (the featherweight)!
Experience (Perfect Tense & verb class)	*I have been searching* for what seems like forever for a nice cologne or perfume that is not all flowery and overpowering
Guide (Types of nominal subject)	The best *solution* for this is … A personal *tip* I would like to suggest …
Guide (Imperative sentence)	Make sure you shake the bottle before using for best color results (as mentioned on the packaging).

Table 4. Types of sentences for 'UNSHIFT'

As a number of previous researches also considered, we canceled the detected sentiment at the conditional clause. In addition, we considered two domain specific types of sentences, namely, *experiences sentences* and *guide sentences* as the clues for 'UNSHIFT' cases, because these types of sentences also give background information rather than explicitly mentioning the sentiment so that the polarity of the adjective tends not to be propagated. We defined *experience sentence* whose main subject is the author and which has present or past perfect tenses with purchase related verbs (e.g., buy, search, try or return). We also defined *guide sentence* that is an imperative sentence with no main subject or with the subject referring to the potential customer such as 'you' or 'people'.

The preprocessing steps before applying the rules above are as follows. First, we get the dependency relation pairs for each input sentence acquired from the Stanford parser (Klein and Manning, 2003; Marneffe et al., 2006), and constructed the dependency tree structure for tree traversal in order to process polarity propagation. Then we assigned each word to its inherent polarity (if it has one) by looking up the sentiment lexicon, 'Subjectivity Lexicon' (Riloff and Wiebe, 2003). We adapted the lexicon to product reviews by modifying the inherent polarity of 36 lexical entries (e.g., white, positive to neutral) and adding 105 additional words frequently used (e.g., small with neutral). In order to apply rules to particular types of adjective and verb such as transfer verbs or contextually polarized adjectives, we added an additional field such as 'type' into each lexical entry to show their identities (The original types of 22 entries in 'Subjective Lexicon' are modified). As for extracting clues, we utilized dependency relations for syntactic types of nouns and verbs. For semantic types of nouns and verbs, we utilized the semi-automatically constructed lexicon as mentioned in Section 5.1. In addition, in order to identify '*experience sentences*' and '*guide sentences*', we extracted tense information and noun subject by utilizing dependency parse tree.

6 Experimental Results

We performed two types of experiment in order to examine the performance of our refined polarity propagation rules and the contribution of the propagation results to the sentiment detection at the clause level.

Table 5 shows the data sets of customer reviews we used for the experiments. We first tested our rules with Set 1 (Beauty positive), a corpus utilized in (Blitzer et al., 2007) because all the reviews are classified as 'positive', so we assume that there are many adjectival modifiers with 'positive' polarity. We then performed both propagation decision and sentiment classification experiments with Set 2 (Levi's Jean), which is

crawled review data from Amazon.com by ourselves. The reasons why we chose this product are as follows. First, it is a steady-selling product so that most of the reviews are regarded as positive, which makes it more important to identify negative or neutral opinions than other kinds of reviews. Hence, it is crucial to consider correct decision of propagation of the adjectival modifiers with 'positive' polarity that is mostly not propagated. Second, after the initial observation, we found that a particular expression about 'changes in quality' frequently appears in such reviews (about 20%) and the adjectival modifiers with 'positive' polarity in such expression are mostly not propagated because it would refer to other particular entities or be used to describe a certain process.

Data Sets	**# for exp.**	**Total**	**%**
Beauty Positive set 1	444	6,126	7.2%
Levi's Jeans set 2	147	1,655	8.8%

Table 5. Data sets

Table 6 shows the numbers of propagation rules and Table 7 shows the propagation decision results. Compared to the results by the basic rules, the performance is enhanced in general. However, we notice that the rules related to VerbType are effective on recall but not on precision for 'SHIFT'. On the other hand, as for 'UNSHIFT' the rules are effective on precision but not on recall. Rules taking into account both noun types and prepositions slightly enhance the overall performance. The overall rules that include sentence type score the best precision and recall figures, which are both effective for 'SHIFT' and 'UNSHIFT'.

Next, we apply these rules to our data set 2. Table 8 shows the propagation decision results. The accuracy for the overall test clauses is almost similar to that for set 1. While precision for 'UNSHIFT' and recall for 'SHIFT' rose, precision for 'SHIFT' and recall for 'UNSHIFT' dropped. We analyzed False Negative errors of 'UNSHIFT' cases. Most of them are unknown cases for each rule except due to parsing errors. This also led to the drop of the precision for 'SHIFT'. The strong restriction for 'UNSHIFT' also affected the result of recall for 'SHIFT'.

Table 9 shows the sentiment detection results at the clause level for set 2. The performance of 'positive' label is not much enhanced but that of 'neutral' label is enhanced. We believe that this is because if the polarity of the top node word is explicitly 'positive' because of its inherent polarity the overall polarity of the clause is obviously 'positive' regardless of the result of the polarity propagation decision. On the other hand, in the case of 'neutral' clause, the correct polarity propagation decision for 'UNSHIFT' is critical for detecting the overall polarity. This confirms that our rules have a critical role in detecting the sentiment of 'neutral' sentences.

Rules	**SHIFT**		**UNSHIFT**	
	#	∑	#	∑
Basic rules (B)	3	3	2	2
B + PhClues	0	3	4	6
B + PhClues + VerbType	2	5	2	8
B + PhClues + VerbType + SemLabel	0	5	3	11
All	0	5	3	14

Table 6. Numbers of propagation rules

Rules	**SHIFT**		**UNSHIFT**		**All**
	P	**R**	**P**	**R**	**Acc.**
Basic rules (B)	0.84	0.83	0.72	0.73	0.79
B + PhClues	0.84	0.83	0.72	0.74	0.80
B + PhClues + VerbType	0.83	0.89	0.79	0.70	0.82

All	0.90	0.88	0.80	0.84	**0.86**

Table 7. Propagation decision results (set 1)

	SHIFT		**UNSHIFT**		**All**
	P	**R**	**P**	**R**	**Acc.**
Basic Rules	0.71	0.89	0.82	0.59	0.74
Refined Rules	0.78	0.90	0.85	0.69	**0.80**

Table 8. Propagation decision results (set 2)

	Basic Rules		**Refined Rules**	
	P	**R**	**P**	**R**
Positive	0.82	0.86	0.87	0.87
Negative	0.85	0.67	0.90	0.70
Neutral	0.45	0.56	**0.51**	**0.70**
All (Acc.)	0.74		0.79	

Table 9. Sentiment detection results

By the importance of 'neutral' polarity, we conducted an error analysis on 18 False Positive cases for 'neutral' polarity as shown in Table 10.

7 Discussion

Types	Description	#
Implicit sentiment	The overall sentiment should be detected by further deep linguistic analysis.	8
Incorrect 'UNSHIFT'	The 'UNSHIFT' result is incorrect.	3
Incorrect polarity	The polarity result is incorrect due to other lexical entries	3
Parsing errors	The propagation is made incorrectly due to incorrect dependency relation.	2
Others	Comparison without 'Positive/Negative' sentiment	2

Table 10. Error distribution

We note that the reason for considering specific sentence types as addressed in this paper is that we assume that these sentences are better suited to demonstrate the need for blocking the propagation of the polarity of the given adjectival modifier.

Although we considered certain types in a limited way, we haven't fully observed what types of sentence are actually involved in propagation. In addition, we found that some sentences in the data set we considered initially as having the sentence type that blocks the propagation of polarity of the adjectival modifier do not convey 'neutral' but convey 'positive' or 'negative' polarity implicitly as shown in Example (8).

(8) a. If there is a more perfect shampoo, I haven't found it.
b. *Previously*, I *had to* visit my favorite store more than once to get my size.
c. I've had it for a year and the *elastic is* totally *stretched out* with normal wear.

The main clause in (8a) conveys 'positive' polarity implicitly even though there is no polarity-bearing word. Further processing is necessary including a proper account of negation. The phrases in (8b) and (8c) are about product entities contrastive to the currently reviewed product so that the inherently assigned polarity of 'favorite' and 'normal' is not applicable to the currently reviewed product. In order to detect the implicit intention of this kind, we should also detect the clues for contrast such as 'previously' or the relation between the phrases 'elastic' and 'be stretched out'.

Although the propagation decision for 'UNSHIFT' itself is correct, such inherent polarity of the adjectival modifier may help to identify the implicit sentiment of the adjacent clause as shown in Example (9).

(9) a. I washed them repeatedly in my very *efficient* and eco-friendly Asko washer, but the smell remained.
b. I have paid much more for *inferior* brand jeans and I can say that I won't be doing that anymore.

The implicit polarity of the underlined clause in (9a) may be both 'negative' and 'positive' depending on the context. By utilizing both the inherent polarity of 'efficient' and the role of the conjunction 'but', the conventional polarity detection rule along with conjuncts (Meena and Prabhakar, 2007) can correctly detect its polarity as 'negative'. As for (9b), by the inherent polarity 'negative' of 'inferior' and negation on the underlined clause we can detect the 'positive' polarity of the underlined clause. However, the possibility of the correctness of the detection is still chancy, and a further analysis of the underlying meaning of the clause or the sentence is called for. For example, if we label the clause containing 'inferior' in (9b) as 'action for goal achievement', we can detect the polarity of the underlined clause as 'negative' by the rule taking such label and another label related to its continuity.

8 Conclusion

In this paper, we refined the previous polarity propagation rules in order to better decide whether the polarity of the adjectival modifier should be propagated or not. We considered both phrase-level and clause-level clues by considering syntactic and semantic types of nouns and verbs. Our rules incorporating these clues into the basic rules detected the 'UNSHIFT' case particularly well. The detection results of the overall sentiment at the clause level are meaningfully enhanced as compared to those based on the previous polarity propagation rules regarding especially 'neutral' sentences. However, despite the correct decision for 'UNSHIFT', we found that such polarity of the modifiers may also help to identify the implicit sentiment without further deeper linguistic analysis.

In order to detect implicit sentiment, we will examine the clues for detecting contrast among product entities or product features for the future work. We will also classify the roles of the clause at a fine-grained level that is related to the detection of the implicit sentiment.

Efficient induction of probabilistic word classes with LDA

Grzegorz Chrupała

Abstract

Word classes automatically induced from distributional evidence have proved useful many NLP tasks including Named Entity Recognition, parsing and sentence retrieval. The Brown hard clustering algorithm is commonly used in this scenario. Here we propose to use Latent Dirichlet Allocation in order to induce soft, probabilistic word classes. We compare our approach against Brown in terms of efficiency. We also compare the usefulness of the induced Brown and LDA word classes for the semi-supervised learning of three NLP tasks: fine-grained Named Entity Recognition, Morphological Analysis and semantic Relation Classification. We show that using LDA for word class induction scales better with the number of classes than the Brown algorithm and the resulting classes outperform Brown on the three tasks.

1 Introduction

Word classes automatically induced from distributional evidence have proved useful in a variety of tasks, including Named Entity Recognition (Miller et al. 2004, Ratinov and Roth 2009, Chrupała and Klakow 2010, Turian et al. 2010), parsing (Koo et al. 2008, Suzuki et al. 2009, Candito and Crabbé 2009) and sentence retrieval (Momtazi and Klakow 2009).

Brown et al. (1992) introduced an algorithm which assigns word types to disjoint clusters and it remains a common choice when a simple way to automatically obtain word classes is needed. We present a word class induction method using Latent Dirichlet Allocation (Blei et al. 2003) which has attractive properties compared to Brown:

- It induces a soft, probabilistic clustering on both word types and context features.
- It runs in time linear in the number of classes.

The model maps straightforwardly to the standard document topic model, and thus has the advantage of many existing high quality implementations. We evaluate the model's usefulness on fine-grained Named Entity Recognition (NER), Morphological Analysis (MA) and semantic Relation Classification (RC) and show that

- while the word classes obtained perform better than Brown classes,
- they can be induced in a fraction of the time necessary to run the equivalent Brown model.

2 Inducing word representations

There is a variety of approaches to inducing word representations from distributional information. In this section we briefly review the research most relevant to our proposed approach.

Hard classes Brown et al. (1992) introduced an early model which induces a mapping from word types to classes. It is an agglomerative clustering algorithm which starts with K classes for the K most frequent word types and then proceeds by alternately adding the next most frequent word to the class set and merging the two classes which result in the least decrease in the mutual information between class bigrams. The result is a class hierarchy with word types at the leaves. The overall runtime of the algorithm is $O(K^2V)$ where K is the number of classes and V the number of word types. Lin and Wu (2009) use a distributed version of K-Means to assign words and phrases to hard classes, and successfully use them as features in a NER task and in query classification.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 363–372,
Chiang Mai, Thailand, November 8 – 13, 2011.

Soft classes A limitation of the Brown model is that it performs hard clustering of word types, and cannot be used to disambiguate word occurrences based on context. Hidden Markov Models have been used to induce probabilistic (soft) word classes: training an HMM on unlabeled data one obtains classes which correspond to multinomial distributions over the vocabulary (Goldwater and Griffiths 2007, Gao and Johnson 2008). Griffiths et al. (2005) propose a model factored into an HMM which generates function words and an LDA topic models which generates content words. Learning the parameters of a bigram HMM takes $O(K^2N)$ time where N is the number of word tokens in the corpus.

Other approaches Other approaches to inducing word representations do not rely on the notion of word class. Distributed word embeddings can be learned using a neural network-bases language models (Bengio et al. 2006, Collobert and Weston 2008, Mnih and Hinton 2009). Dimensionality reduction techniques such as SVD (Schütze 1995, Lamar et al. 2010) and LSA (Deerwester et al. 1990) have also been found useful for generating word representations.

3 Using word representations

Our main motivation for studying word class induction methods is to use them in a semi-supervised learning scenario, where word representations are induced from a large unlabeled corpus and subsequently used as a source of features for a supervised model. Turian et al. (2010) compare the effect of using representations based on Brown classes, the Collobert and Weston (2008) embeddings and the Mnih and Hinton (2009) embeddings in learning English syntactic chunking (CoNLL 2000) and English coarse-grained Named Entity Recognition (CoNLL 2003). For both tasks the best representation is fine-grained Brown classes (3200 and 1000 classes respectively). Combining the Brown features with distributed embeddings further improves performance on NER but not on chunking. Lin and Wu (2009) use induce word and phrase classes and report results on NER which are higher than Turian et al. (2010)'s Brown scores, but this research used 700 billion words of web text and needed a cloud computing infrastructure with 1000 CPUs to run. It is evident that the Brown clustering algorithm still provides an extremely competitive baseline nearly 20 years after it was proposed.

We thus compare the performance of the LDA word class model to the Brown model on three NLP tasks: fine grained Named Entity Recognition, Morphological Analysis, and Relation Classification. The first two tasks are difficult due to the large number of labels and high potential for ambiguity. The third task is challenging for a different reason: it involves highly abstract semantic relations, often not obviously inferable from surface lexical clues.

4 LDA model for word class induction

We propose an LDA-based model for word class induction and contrast its structure, efficiency, and performance to those exhibited by the Brown model.

4.1 Weaknesses of Brown

Here we address what we see as two related weaknesses of the Brown model. The algorithm's quadratic dependence on K makes it inconvenient to induce more than a few hundred classes: running a 1.000 class model with a 400.000 vocabulary took over 100 hours. Second, the induced clustering is hard, and the only way to model ambiguous word types is to have a separate class for each kind of ambiguity. This in turn means that we need to learn a large number of classes, which exacerbates the problem with inefficiency. Very fine-grained Brown classes are typically needed for good performance as shown by Turian et al.'s results. Our model for word class induction addresses both of the weaknesses.

4.2 LDA for word class induction

Latent Dirichlet Allocation (LDA) was initially introduced by Blei et al. (2003) in the context of topic modeling, i.e. finding coherent topics shared among subsets of a collection of documents. LDA is a generative, probabilistic hierarchical Bayesian model which induces a set of latent variables which correspond to the topics. The topics themselves are multinomial distributions over words. The graphical model is shown in plate notation in Figure 1. The generative structure of the LDA model is as follows:

$$\begin{aligned}
&\phi_k \sim \text{Dirichlet}(\beta), && k \in [1, K] \\
&\theta_d \sim \text{Dirichlet}(\alpha), && d \in [1, D] \\
&z_{n_d} \sim \text{Multinomial}(\theta_d), && n_d \in [1, N_d] \\
&w_{n_d} \sim \text{Multinomial}(\phi_{z_{n_d}}), && n_d \in [1, N_d]
\end{aligned} \tag{1}$$

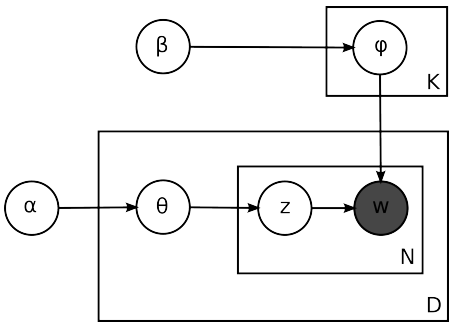

Figure 1: LDA plate diagram

The document collection is generated by drawing, for each topic k, a distribution over words ϕ_k from a Dirichlet prior with parameters β. Then for each document d we draw a multinomial distribution over topics θ_d from a Dirichlet prior parametrized by α. To generate the n^{th} word in document d we draw the topic id z_{n_d} from the document-specific topic distribution θ_d, and then draw the word from the word distribution corresponding to the chosen topic $\phi_{z_{n_d}}$. Thus each document is a mixture of different topics, giving the model the flexibility needed to reflect the topical structures in real-world document collections. This flexibility has contributed to the popularity of LDA as a common choice in a wide range of domains beyond topic modeling. Another important reason for LDA's success is the availability of efficient and well-understood estimation methods such as Variational EM (Blei et al. 2003), and Gibbs sampling (Griffiths and Steyvers 2004). For both methods efficient, well engineered and well tested implementations are readily available. These advantages have led us to try to use a model equivalent to an LDA topic model in order to induce word classes based on distributional clues.

We associate each word type with a distribution over latent classes. Each class is in turn a distribution over contextually co-occurring features. In principle the contextual features could be arbitrary functions of the context, but to make our model use exactly the same information as the Brown model, we will restrict them to the word's immediate left and right neighbors. A direct mapping to document topic model can be seen:

Topic model	Word class induction
Document	Word type
Word	Context feature
Topic	Word class

An example "document" in our scenario, corresponding to the word type *Krzysztof* looks like the following:

> **Bledkowski**$_R$ **Kieslowski**$_R$ **Kieslowski**$_R$ **Rutkowski**$_R$ **Sikorski**$_R$ **and**$_L$ **argues**$_L$ **argues**$_R$ **director**$_L$ **director**$_L$ **edits**$_R$ **said**$_R$

The subscript on the word indicates whether it is a left or right context feature, i.e. whether it appears to left or to the right of *Krzysztof* in the corpus.

Thus, strictly speaking our model does not generate the actual sequence of words in the corpus, but rather a collection of "documents" such as the above, or equivalently, a table listing bigram co-occurrence counts for each word type.

The generative structure of the model corresponds exactly to a standard LDA topic model in equation 1. Now K is the number of latent classes, D is the vocabulary size, and N_d is the number of left and right contexts in which word type d appears, z_{n_d} is the class of word type d in the n_d^{th} context, and f_{n_d} is the n_d^{th} context feature of word type d.

Once trained, the parameters provide two types of word representations. Each θ_d gives the latent class probability distribution given a word type. Each ϕ_k gives the feature distribution given a latent class. Thus the model provides a probabilistic representation for word types independently of their context, and also for contexts independently of the word type. This is a more powerful representation than hard word clustering: (i) soft clustering allows the modeling of ambiguity, (ii) additional source of information is available which helps determine the class of a word from its context.

Figure 2 shows an example of how the classes discovered by the model deal with ambiguity. The pie charts depict the induced class distributions for two word types *Martin* and *Cameron*. These words are ambiguous in a similar way: they are mostly used as (i) first names or (ii) family names, and (iii) additionally can appear as part of a name of a company or place. This similarity of usage is reflected in closeness of the distributions over the induced classes for those words. Thus the first class (colored red) is associated with many family names, the second (blue) with titles and first names, and the third (green) with companies and locations. This correspondence is certainly not

perfect (e.g. the first class is also associated with the word *chief*) but it is suggestive that soft LDA-based clustering can successfully model and discover this type of systematic shared ambiguities.

We can use the same three classes to illustrate the second advantage of LDA word classes mentioned above: we can obtain information about the class of a particular token based on its context. Thus even for a rare word which did not appear in the corpus used for word class induction, we can still find out what word classes it is associated with just by consulting the ϕ table and retrieving the classes strongly associated with the context features. Figure 3 shows the left and right context features which co-occurred most frequently with the same three classes illustrated in Figure 2. For example the second (blue) class, which contains titles and first names, is associated with left contexts such as *says* and *Chairman* and right contexts such as *Clinton* and *Dole*.

5 Experimental evaluation

In order to evaluate the LDA word class induction model we assess two of its aspects: (i) we compare its efficiency to that of Brown clustering, and (ii) we compare the performance of the induced word classes to those obtained by Brown clustering in two difficult sequence labeling tasks and one classification task.

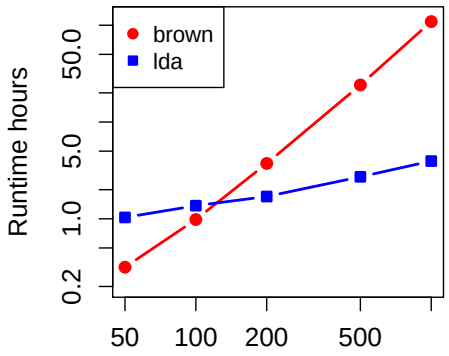

Figure 4: Brown and LDA run times

5.1 Efficiency

Two main approaches have been used to train LDA topic models: variational EM (Blei et al. 2003) and Gibbs sampling (Griffiths and Steyvers 2004). Both scale linearly with the number of topics. This property is one of the main advantages of the LDA word class induction model over HMM or Brown clustering. In this section we show that also in practice this means that LDA word classes can be induced much faster than equivalently performing Brown classes.

As training data for both models we use the North American News Text Corpus (over 60M words). For both models we only keep bigrams which occur at least 3 times. The resulting vocabulary is over 380K word types. The LDA class induction model scales as $O(KN)$ where N is the sum of all feature counts. Since we discard rare bigrams with frequencies under m, we can scale the remaining feature counts by $1/m$ and obtain an equivalent model, while reducing runtime by m times. For both models we induce 50, 100, 200, 500 and 1000 classes. For Brown we run the implementation of Liang (2005) until termination. For LDA we run 1000 iterations of a collapsed Gibbs sampler from Mallet (McCallum 2002). Figure 4 shows how the models scale with growing value of K on a log-log plot. Brown terminates in 20 minutes for K=50, but takes over 110 hours for K=1000, while LDA takes between 1 hour for K=50 and 4 hours for K=1000.

5.2 Performance

Another advantage of LDA word classes over hard clusters is the increased representational power. Ambiguity can be modeled more compactly, and there are two sources of information to draw on when deciding on the most likely class of a word in context: the word type identity, and the local context features. In this section we show that these theoretical advantages translate into performance on fine-grained Named Entity Recognition, Morphological Analysis and on semantic Relation Classification.

In each of the tasks we tried to use the Brown classes and the LDA classes in an optimal way by taking advantage of the strength of each type of representation, and also to adapt the feature sets to the specifics of the task. We followed previous work when available and ran exploratory experiments with different feature combinations on the development data. The details of the final feature sets are given in the respective sections but in general we make use of the hierarchical nature of Brown classes by using them at several levels of granularity. For LDA classes we exploit their probabilistic softness by including feature probability or rank, and include classes inferred from context words when appropriate.

5.2.1 Named entity recognition

Named-entity recognition is one of the most commonly needed NLP task. Many evaluations have focused on learning the coarse-grained CoNLL and MUC entity labels (person, organization and location). Here we evaluate on the more challenging fine-grained entities from the BBN corpus (Weischedel and Brunstein 2005). We use sections 2 to 21 as training data, section 22 for development and section 23 for final evaluation. We keep all labels appearing at least 100 times in training data. Less frequent labels we map to an existing more generic label if possible (e.g. LOCATION:LAKE_SEA_OCEAN $\mapsto$ LOCATION:OTHER), otherwise we discard them. We also discard all **description** labels which are not proper named entities. We are left with 40 labels, shown in Table 1.

We convert the labeling to the BIO format which encodes chunking information into token-level labels: each label is prefixed with B if it starts a new chunk, I if it continues the previous chunk, or O if it does not belong to a named entity chunk. Thus we end up with 81 labels after conversion.

lowercase	Map all characters to lower case
wordshape	Encodes spelling of a token by mapping sequences of upper case letters to `X`, lower case letters to `x`, digits to `0`, hyphens and underlines to themselves. For example *IJCNLP-2011* maps to `X-0`
suffix_n	The n characters from the end of the token
$\text{rank}_z^n f(z)$	The n^{th} class in the ranking ordered by the value of the function f
prefix_n	The first n characters from the start
z	Class id

Table 2: Meaning of feature functions

Baseline As a baseline we use a sequence-perceptron labeler (Collins 2002) with the following features: $\{w_{-2}, w_{-1}, w_0, \text{lowercase}(w_0), \text{wordshape}(w_0), \text{suffix}_1(w_0), \text{suffix}_2(w_0), \text{suffix}_3(w_0), w_1, w_2\}$. For the explanation of the feature functions see Table 2.

For inducing classes for this task we use the North American News Text Corpus described in section 5.1. When evaluating word classes we add to this feature set the Brown or LDA word class features:

Brown Class IDs encode the path in the class hierarchy, we thus use ID prefixes of different lengths to include classes at several levels of granularity. We also add feature conjunctions. The additional Brown class features are thus: $\text{prefix}_n(z(w_m))$ (for tokens at positions $m \in \{-1, 0, 1\}$, class id prefix of length n for $n \in \{4, 6, 10, 20\}$) and feature conjunctions $\{\text{prefix}_{20}(z(w_0))\} \times \{\text{lowercase}(w_0), \text{wordshape}(w_0), \text{suffix}_1(w_0), \text{suffix}_2(w_0), \text{suffix}_3(w_0)\}$. The class ID prefix sizes we adopted were shown to be effective in Ratinov and Roth (2009) and Turian et al. (2010).

LDA We rank the classes according to posterior probability and take the 3 top ranked classes given the current word d, the 1 top ranked class given the previous word w_{-1}, and 1 top ranked class given the next word w_{+1}: $\{\text{rank}_z^1 P(z|d), \text{rank}_z^2 P(z|d), \text{rank}_z^3 P(z|d), \text{rank}_z^1 P(z|w_{-1}), \text{rank}_z^1 P(z|w_{+1})\}$. We add the following feature conjunctions: $\{\text{lowercase}(w_0), \text{wordshape}(w_0), \text{suffix}_1(w_0), \text{suffix}_2(w_0), \text{suffix}_3(w_0)\} \times \{\text{rank}_z^1 P(z|d),$

Table 1: BBN named entity labels

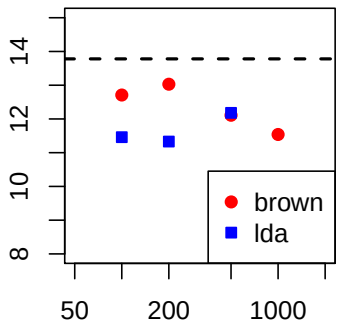

Figure 5: F1 error on NER dev. set with word classes

$$\text{rank}^1_z P(z|w_{-1}), \text{rank}^1_z P(z|w_{+1})\}.$$

Figure 5 shows the F1 error on section 22 for the baseline and for Brown and LDA classes of different granularity. A large number of classes (500 or 1000) is needed to achieve low error with Brown classes. With LDA, a lower number (100 or 200) is sufficient, and in fact the error rates are lower for LDA word class features than for Brown. The results for the test set (section 23) using Brown with 1000 classes and LDA with 200 classes are shown in the *NER* column of Table 5. We are unaware of previous published results on BBN at a comparable level of NE label granularity.

5.2.2 Morphological analysis

We next evaluate the induced word classes on a morphological analysis task. The goal is to learn to assign morpho-syntactic descriptors (MSD) (roughly speaking, fine-grained POS tags) and lemmas to tokens in sentences. The MSD tags encode all relevant inflectional features of a token such as gender, case and number for nouns or tense, aspect, person and number for verbs. A morphological tagger which performs this type of analysis is an important component for processing languages with rich inflectional morphology. Figure 6 shows example morphological annotation of a short sentence in Spanish.

Token	Lemma	MSD	Gloss
Pero	pero	`cc`	but
cuando	cuando	`cs`	when
era	ser	`vsii3s0`	he was
niño	niño	`ncms000`	boy
le	el	`pp3csd00`	to him
gustaba	gustar	`vmii3p0`	it pleased

Figure 6: Morphosyntactic annotation of a Spanish which translates as *When he was a boy he liked it.*

As the supervised model we use the Morfette system (Chrupała et al. 2008)[1]. Morfette trains two classifiers, one for morphological tags (i.e. fine-grained POS tags) and one for lemmatization classes. The classifiers are trained separately; their output is combined during decoding. For the baseline we used the default features (see Chrupała et al. 2008) and trained the POS and lemma models for 10 and 3 iterations respectively. We added word-class features to the POS model.

Brown We use class id prefixes for the focus word: $\text{prefix}_n(z(w_0)),\ \ n \in \{4, 6, 10, 20\}$

LDA Morfette can use real-valued features and initial tests on this task with class distributions showed that using them directly works as well as discretizing them. We use classes for the focus token (w_0) and set probabilities below 0.15 to 0 for sparseness.

Data sets We chose two data sets for evaluation:

- Spanish Ancora corpus (Taulé et al. 2008): portion corresponding to data used by Chrupała et al. (2008), 188.803 tokens, 10.000 dev. and 10.000 test, 279 tags.

[1] Available at `http://code.google.com/p/morfette/`

CAUSE-EFFECT INSTRUMENT-AGENCY PRODUCT-PRODUCER CONTENT-CONTAINER ENTITY-ORIGIN ENTITY-DESTINATION COMPONENT-WHOLE MEMBER-COLLECTION COMMUNICATION-TOPIC

Table 3: Relation classification labels

- French Treebank (Abeillé et al. 2003), 351.873 tokens, 36.297 dev. and 37.967 test, 214 tags.

For inducing word classes we used (i) Spanish Europarl (Koehn 2005), 50M words and (ii) Est Republicain[2] 147M words.

We optimized the number of classes on the development set: for Brown the best was 500 for both languages, for LDA the best setting was 50 for Spanish and 100 for French.

Table 5 (columns *MA es* and *MA fr*) shows the joint morphological tagging-lemmatization scores on the test set. Word classes give a moderate performance boost and in both cases LDA improves more. We do not know of published results on the French data with this level of granularity. However Seddah et al. (2010) show that Morfette on French data with a reduced tagset compares well to state-of-the-art, and thus can be assumed to be a strong baseline. For Spanish, our baseline error is almost identical to the error reported by Chrupała et al. (2008) (4.98 vs 5.00): thus the word classes give 10% relative error reduction over previous results.

5.2.3 Classification of semantic relations

The last task on which we evaluate induced word classes is multi-way classification of abstract semantic relations between nominals (RC). This task appeared at the Semeval 2007 and 2010 workshops. We use the task definition and the training and testing data from 2010.

The relation inventory is shown in Table 3. For example in the sentence *The bowl was full of apples, pears and oranges* the nominal *pears* is in a CONTENT-CONTAINER relation with the nominal *bowl*.

The training set consists of sentences annotated with the relations and their directionality. The arguments (nominals) participating in the relations are marked in both the training and test examples. We used the 2010 training set of 8000 sentences and the test set of 2717 sentences. During development, we split the training set in half, and trained on the first half, while validating on the second half. For the final evaluation we trained on all the 8000 training sentences.

arg_1	The first argument
arg_2	The second argument
between_n	Each of the tokens between arg_1 and arg_2
before_m	Each of the 3 tokens before arg_1
after_m	Each of the 3 tokens after arg_2

Table 4: Description of features for RC

We evaluated with the scoring script provided, using the official macro-averaged F1 score.

Baseline For our baseline system we used the Weka (Hall et al. 2009) implementation of the Sequential Minimal Optimization algorithm to train an SVM classifier (Platt 1999), with the default linear kernel. We treat each combination of the relation label and the direction label together as a single atomic class to be learned.

Table 4 describes the features we extracted from each sentence for the RC task.

Corpus For this task we initially used the word classes induced from The North American News Text Corpus described in section 5.1. The improvements we achieved were smaller than we expected. We suspected that the reason for this was that the training data for the RC task come from a variety of Web sources and are much less restricted in genre than the text in the NANT corpus. We thus decided to retrain word classes on the more balanced 100M-word BNC corpus (BNC Consortium 2001). As expected, the word classes from the BNC worked better. Due to time constraints, for Brown we were able to induce only up to 500 classes.

Brown With Brown classes we use class ID prefix $\text{prefix}_n(z(f))$, $n \in \{4, 6, 10, 20\}$, for each of the baseline features f listed in Table 4.

LDA For this task we use the probabilities of the classes as real-valued features, and we took classes for each of the baseline features f listed Table 4.

We optimized the number of classes on the development data (second half of training data). We found 500 classes for Brown and 100 classes for

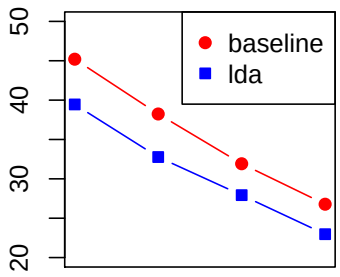

Figure 7: Relation classification error as a function of the number of training examples. The x-axis is plotted on a logarithmic scale.

LDA to give the best results, and we used these values for the final evaluation.

The impact of adding word classes can be appreciated in Figure 7, which plots the test error with and without word classes while varying the number of training examples (1000, 2000, 4000 and 8000). It can be seen that adding LDA word class features corresponds to almost doubling the amount of training data.

Table 5 (column labeled *RC*) shows the macro-averaged F1 error on test data. Similarly to the previous tasks, the improvement is larger with LDA than with Brown classes.

For comparison, during the Semeval 2010 evaluation the F1 error of the top-scoring system (Rink and Harabagiu 2010) was 17.81%; the system ranked second (Tymoshenko and Giuliano 2010) achieved 22.37%.

Both these systems used large amounts of external resources and heavy-duty linguistic processing tools. Rink and Harabagiu (2010) extracted features from dependency parses, from PropBank and FrameNet parses, from WordNet and NomLex as well as using Google n-grams and the output of TextRunner[3]. Tymoshenko and Giuliano (2010) extracted features from syntactic parses and from the massive semantic knowledge database Cyc (Lenat 1995).

In comparison, our system is extremely resource-light since our features do not rely on any manually created databases or linguistic processing tools (not even POS tags). It is thus satisfying that by automatically and efficiently inducing simple word class features we can achieve results

[3] A system for open information extraction from the Web (Yates et al. 2007).

	%Error			
Model	NER	MA es	MA fr	RC
Baseline	13.42	5.00	7.80	26.78

LDA	**11.70**	**4.50**	**7.39**	**22.97**

Table 5: Test set results on NER, MA, RC

which are close to state-of-the-art.

6 Discussion

To our knowledge LDA word class induction has not been previously used in this particular scenario. LDA variants have been proposed in other settings: Brody and Lapata (2009) use LDA to induce latent variables corresponding to word senses; Toutanova and Johnson (2007) propose an LDA-inspired model where induced word-classes are used for semi-supervised POS tagging; Dinu and Lapata (2010) use LDA-induced word-classes for measuring word similarity in context. Rather than focus on adapting LDA to a particular task, we instead induce generic word classes that can be plugged in as features in a number of NLP applications.

We show that the LDA word clustering algorithm is an attractive choice for semi-supervised learning. It is efficient to train and beats a competitive baseline provided by Brown clustering.

Abstract

The abundance of user-generated content comes at a price: the quality of content may range from very high to very low. We propose a regression approach that incorporates various features to recommend short-text documents from Twitter, with a bias toward quality perspective. The approach is built on top of a linear regression model which includes a regularization factor inspired from the content conformity hypothesis - documents similar in content may have similar quality. We test the system on the Edinburgh Twitter corpus. Experimental results show that the regularization factor inspired from the hypothesis can improve the ranking performance and that using unlabeled data can make ranking performance better. Comparative results show that our method outperforms several baseline systems. We also make systematic feature analysis and find that content quality features are dominant in short-text ranking.

1 Introduction

More and more user-generated data are emerging on personal blogs, microblogging services (e.g. Twitter), social and e-commerce websites. However, the abundance of user-generated content comes at a price: there may be high-quality content, but also much spam content such as advertisements, self-promotion, pointless babbles, or misleading information. Therefore, assessing the quality of information has become a challenging problem for many tasks such as information retrieval, review mining (Lu et al., 2010), and question answering (Agichtein et al., 2008).

In this paper, we focus on predicting the quality of very short texts which are obtained from Twitter. Twitter is a free social networking and microblogging service that enables its users to send and read other users' updates, known as "Tweets". Each tweet has up to 140 characters in length. With more than 200 million users (March 2011), Twitter has become one of the biggest mass media to broadcast and digest information for users. It has exhibited advantages over traditional news agencies in the success of reporting news more timely, for instance, in reporting the Chilean earthquake of 2010 (Mendoza et al., 2010). A comparative study (Teevan et al., 2011) shows that queries issued to Twitter tend to seek more temporally relevant information than those to general web search engines.

Due to the massive information broadcasted on Twitter, there are a huge amount of searches every day and Twitter has become an important source for seeking information. However, according to the Pear Analytics (2009) report on 2000 sample tweets, 40.5% of the tweets are pointless babbles, 37.5% are conversational tweets, and only 3.6% are news (which are most valuable for users who seek news information). Therefore, when a user issues a query, recommending tweets of good quality has become extremely important to satisfy the user's information need: how can we retrieve trustworthy and informative posts to users?

However, we must note that Twitter is a social networking service that *encourages* various content such as news reports, personal updates, babbles, conversations, etc. In this sense, we can not say which content has better quality without considering the value to the writer or reader. For instance, for a reader, the tweets from his friends or who he

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 373–382,
Chiang Mai, Thailand, November 8 – 13, 2011.

follows may be more desirable than those from others, whatever the quality is. In this paper, we have a special focus on finding tweets on news topics when we construct the evaluation datasets.

We propose a method of incorporating various features for quality-biased tweet recommendation in response to a query. The major contributions of this paper are as follows:

- We propose an approach for quality-biased ranking of short documents. Quality-biased is referred to the fact that we explore various features that may indicate quality. We also present a complete feature analysis to show which features are most important for this problem.
- We propose a content conformity hypothesis, and then formulate it into a regularization factor on top of a regression model. The performance of the system with such a factor is boosted.
- It is feasible to plug unlabeled data into our approach and leveraging unlabeled data can enhance the performance. This characteristics is appealing for information retrieval tasks since only a few labeled data are available in such tasks.

The rest of the paper is organized as follows: in Section 2 we survey related work. We then formulate our problem in Section 3 and present the hypothesis in Section 4. Various features are presented in Section 5. The dataset and experiment results are presented in Section 6 and Section 7, respectively. We summarize this work in Section 8.

2 Related Work

2.1 Quality Prediction

Quality prediction has been a very important problem in many tasks. In review mining, quality prediction has two lines of research: one line is to detect spam reviews (Jindal and Liu, 2008) or spam reviewers (Lim et al., 2010), which is helpful to exclude misleading information; the other is to identify high-quality reviews, on which we will focus in this survey. Various factors and contexts have been studied to produce reliable and consistent quality prediction. Danescu-Niculescu-Mizil et al. (2009) studied several factors on helpfulness voting of Amazon product reviews. Ghose and Ipeirotis (2010) studied several factors on assessing review helpfulness including reviewer characteristics, reviewer history, and review readability and subjectivity. Lu et al. (2010) proposed a linear regression model with various social contexts for review quality prediction. The authors employed author consistency, trust consistency and co-citation consistency hypothesis to predict more consistently. Liu et al. (2008) studied three factors, i.e., reviewer expertise, writing style, and timeliness, and proposed a non-linear regression model with radial basis functions to predict the helpfulness of movie reviews. Kim et al. (2006) used SVM regression with various features to predict review helpfulness.

Finding high-quality content and reliable users is also very important for question answering. Agichtein et al. (2008) proposed a classification framework of estimating answer quality. They studied content-based features (e.g. the answer length) and usage-based features derived from question answering communities. Jeon et al. (2006) used non-textual features extracted from the Naver Q&A service to predict the quality of answers. Bian et al. (2009) proposed a mutual reinforcement learning framework to simultaneously predict content quality and user reputation. Shah and Pomerantz (2010) proposed 13 quality criteria for answer quality annotation and then found that contextual information such as a user's profile, can be critical in predicting the quality of answers.

However, the task we address in this paper is quite different from previous problems. First, the document to deal with is very short. Each tweet has up to 140 characters. Thus, we are going to investigate those factors that influence the quality of such short texts. Second, as mentioned, high-quality information on Twitter (e.g., news) is only a very small proportion. Thus, how to distill high quality content from majority proportions of low-quality content may be more challenging.

2.2 Novel Applications on Twitter

Twitter is of high value for both personal and commercial use. Users can post personal updates, keep tight contact with friends, and obtain timely information. Companies can broadcast latest news to and

interact with customers, and collect business intelligence via opinion mining. Under this background, there has been a large body of novel applications on Twitter, including social networking mining (Kwark et al., 2010), real time search[1] , sentiment analysis[2], detecting influenza epidemics (Culotta, 2010), and even predicting politics elections (Tumasjan et al., 2010).

As Twitter has shown to report news more timely than traditional news agencies, detecting tweets of news topic has received much attention. Sakaki et al. (2010) proposed a real-time earthquake detection framework by treating each Twitter user as a sensor. Petrovic et al. (2010) addressed the problem of detecting new events from a stream of Twitter posts and adopted a method based on locality-sensitive hashing to make event detection feasible on web-scale corpora. To facilitate fine-grained information extraction on news tweets, Liu et al. (2010) presented a work on semantic role labeling for such texts. Corvey et al. (2010) proposed a work for entity detection and entity class annotation on tweets that were posted during times of mass emergency. Ritter et al. (2010) proposed a topic model to detect conversational threads among tweets.

Since a large amount of tweets are posted every day, ranking strategies is extremely important for users to find information quickly. Current ranking strategy on Twitter considers relevance to an input query, information recency (the latest tweets are preferred), and popularity (the retweet times by other users). The recency information, which is useful for real-time web search, has also been explored by Dong et al. (2010) who used fresh URLs present in tweets to rank documents in response to recency sensitive queries. Duan et al. (2010) proposed a ranking SVM approach to rank tweets with various features.

3 Problem Formulation and Methodology

Given a set of queries $Q = \{q_1, q_2, \cdots, q_n\}$, for each query q_k, we have a set of short documents $D_k = \{d_k^1, d_k^2, \cdots\}$ which are retrieved by our built-in search engine. The document set D_k is partially labeled, i.e., a small portion of documents in D_k were annotated with a category set C={1, 2, 3, 4, 5} where 5 means the highest quality and 1 lowest. Therefore, we denote $D_k = D_k^U \cup D_k^L$, where D_k^U indicates the unlabeled documents, and D_k^L the labeled documents. Each document in D_k is represented as a feature vector, $d_i = (x_1, x_2, \cdots, x_m)$ where m is the total number of features.

The learning task is to train a mapping function $f(\mathcal{D}) : \mathcal{D} \rightarrow \mathcal{C}$, to predict the quality label of a document given a query q. We use a linear function $f(\mathbf{d}) = \mathbf{w^T d}$ for learning and where $\mathbf{w}$ is the weight vector. Formally, we define an objective function as follows to guide the learning process:

$$\Theta(\mathbf{w}) = \frac{1}{n}\sum_{k=1}^{n}\frac{1}{\mid D_k^L \mid}\sum_{\mathbf{d_i}\in D_k^L}\ell(\mathbf{w}^T\mathbf{d_i}, \hat{y}_i) + \alpha\mathbf{w}^T\mathbf{w} \tag{1}$$

where $\ell(.,.)$ is the loss function that measures the difference between a predicted quality $f(\mathbf{d_i}) = \mathbf{w}^T\mathbf{d_i}$ and the labelled quality $\hat{y}_i$, D_k^L is the labeled documents for query q_k, $\hat{y}_i$ is the quality label for document $\mathbf{d_i}$, n is the total number of queries, and α is a regularization parameter for $\mathbf{w}$. The loss function used in this work is the square error loss, as follows:

$$\ell(\mathbf{w}^T\mathbf{d_i}, y_i) = (\mathbf{w}^T\mathbf{d_i} - \hat{y}_i)^2 \tag{2}$$

It's easy to see that this problem has a closed-form solution, as follows:

$$\widehat{\mathbf{w}} = \arg\min_{\mathbf{w}}\Theta(\mathbf{w}) = (\sum_{i=1}^{N_l}\mathbf{d_i}\mathbf{d_i}^T + \alpha N_l\mathbf{I})^{-1}\sum_{i=1}^{N_l}\hat{y}_i\mathbf{d_i} \tag{3}$$

where $\mathbf{I}$ is an identity matrix of size m (the dimension of feature vector), and N_l is the total number of labeled documents in all the queries. As mentioned, there are a large number of documents retrieved for each query while we only sample a small number of documents for manual annotation. Thus there are much more unlabeled documents yet to be utilized.

4 Content Conformity Hypothesis

To make quality prediction more consistent and to utilize the unlabeled data, we propose the content conformity hypothesis which assumes that the quality of documents similar in content should be close to each other. This hypothesis can be formulated as a regularization factor in the objective, as follows:

$$\Theta_1(\mathbf{w}) = \Theta(\mathbf{w}) + \beta\sum_{k=1}^{n}\sum_{\substack{d_i, d_j\in D_k \\ \wedge IsSim(d_i,d_j)}}(\mathbf{w^T d_i} - \mathbf{w^T d_j})^2 \tag{4}$$

[1] http://twittertroll.com/

[2] http://twittersentiment.appspot.com/

where $IsSim(d_i, d_j)$ is a predicate asserting that two documents are similar, and β is an empirical parameter. Note that D_k is usually all labeled data but it may also include *unlabeled* documents for query q_k. In this way, we can utilize the unlabeled documents as well as the labeled ones. There are various ways to determine whether two documents of the same query are similar. One way is to use TF*IDF cosine similarity to find similar documents with a threshold, and another way is to use clustering where two documents in the same cluster are similar. We use the first means in this paper and leave the second for future work.

To obtain the closed-form solution of Eq. 4, we define an auxiliary matrix $A = (a_{ij})$ where each a_{ij} is 1 if document d_i is similar to document d_j for some query. Then, Eq. 4 can be re-written as follows:

$$\Theta_1(\mathbf{w}) = \Theta(\mathbf{w}) + \beta \sum_{i<j} a_{ij}(\mathbf{w^T d_i} - \mathbf{w^T d_j})^2 \quad (5)$$

Let $\mathbf{D} = [\mathbf{d_1}, \mathbf{d_2}, \ldots, \mathbf{d_N}]$ be an $m \times N$ matrix in which each $\mathbf{d_i}$ is a column feature vector for a document. Note that this matrix includes both labeled and unlabeled documents, and N is the total number of documents. Then the last term in Eq. 5 can be re-written as

$$\sum_{i<j} a_{ij}(\mathbf{w^T d_i} - \mathbf{w^T d_j})^2 = \mathbf{w^T D \Lambda_A D^T w} \quad (6)$$

where $\Lambda_A = \Delta_A - A$ and Δ_A is a diagonal matrix with $(\Delta_A)_{ii} = \sum_j a_{ij}$. By some mathematical manipulations, the problem in Eq. 6 has the following closed-form solution (Zhu and Goldberg, 2009):

$$\widehat{\mathbf{w}} = (\sum_{i=1}^{N_l} \mathbf{d_i} \mathbf{d_i}^T + \alpha N_l I + \beta N_l \mathbf{D \Lambda_A D^T})^{-1} \sum_{i=1}^{N_l} \hat{y}_i \mathbf{d_i} \quad (7)$$

5 Features

We design several groups of features to indicate the quality of tweets from different perspectives. These features include: content quality, user profile and authority, sentiment polarity, query relevance, and Twitter specific features.

5.1 Content Quality

Documents with higher quality in content will be more desirable for users in search. We thus exploit several features to respect quality:

Tweet's length: longer tweet may be more informative as each tweet has been limited to up to 140 characters.

Average term similarity: each tweet d has a score of $\frac{1}{|D_i|} \sum_{d_i \in D_i} sim(d, d_i)$ where D_i is the document set for query q_i, and $sim(.,.)$ is a cosine TF*IDF similarity measure for two documents.

Ratio of unique words: in some tweets, the same word is repeated many times while there are only few unique words. Tweets with more unique words may have more information. The number of unique words is normalized by the total number of words.

Ratio of POS tags: We compute the ratio of nouns, verbs, adverbs, adjectives, etc. in a tweet. Each POS tag corresponds to one dimension in the feature vector.

5.2 User Profile and User Authority

A user with a real and complete profile may post tweets responsibly and accountably. Authoritative users (particularly celebrity users) are more probably to post high-quality tweets.

Profile integrity: we have several features for measuring this property: whether the user of a tweet has a description field, whether the description field contains a url, whether the user verifies her account via the registered email, and whether the user provides the location information.

User Activeness: the average number of tweets that the user posted per day and how many days a user has registered.

User authority: In the spirit of (Duan et al., 2010), we utilize follower score (the number of followers) , mention score (the number of times a user is referred to in tweets), popularity score to measure the authority of a user. The popularity score is obtained with the PageRank algorithm based on retweet relationship (two users have an edge in the graph if a tweet posted by one user is retweeted by another user).

5.3 Sentiment

As mentioned, Twitter has become a popular site for expressing opinions and personal sentiment towards public persons or events. Thus we believe that a tweet with clear sentiment polarity will be more favorable for users. Therefore, we adopt a sentiment lexicon (SentiWordNet) and collect the top 200 frequent emoticons from our tweet corpus to identify positive and negative sentiment words.

Positive sentiment: the ratio of positive sentiment words or emoticons in a tweet.

Negative sentiment: the ratio of negative sentiment words or emoticons.

Sensitive words: the number of sensitive words. We manually collect 458 offending or pornographic words.

The emoticon lexicon and the sensitive word lexicon will be available to public.

5.4 Twitter-Specific Features

Tweet has its own characteristics which may be used as features, such as whether a tweet contains a common url

(such as http://www.google.com), whether the url is a tinyurl (Twitter has a service which shortens urls to very short url), the number of hashtags (topical terms leading by a '#') in a tweet, how many users are mentioned in the tweet (a user is mentioned if the tweet contains a term like @user_name), and how many times the tweet has been re-posted (so-called 'retweeted').

5.5 Query-specific Features

As our task is to supply quality-biased ranking of tweets for an input query, query-specific features will favor those tweets relevant to the input query.

Query term frequency: the frequency of the query term (exact matching) in a tweet.

BM25 score: the BM25 score is used to quantify the overall relevance of a tweet to the query.

Recency: the time lag (in days) between the current tweet and the earliest tweet in the collection for the query. In this case, the more recent tweets may contain latest information, which will be more desirable for users.

6 Dataset

To investigate the factors that influence the quality of short texts, we use the Edinburgh Twitter Corpus (Petrovic et al., 2010)[3] in which each tweet has up to 140 characters. The corpus contains 97 million tweets, and takes up 14 GB of disk space uncompressed. The corpus was collected through the Twitter streaming API from a period spanning November 11th 2009 until February 1st 2010. Each tweet has some meta-data: the timestamp of the tweet, an anonymized user name, the textual content, and the posting source (via web, mobile, etc.).

We collect a set of news queries using Google Trends. Intuitively, those hot queries in Google Trends will also have high possibility to be discussed on Twitter. The top 10 queries per day captured by Google Trends for the period 11th November, 2009 to 1st February, 2010 are collected. We then randomly sample 60 hot queries from these queries. And for each query, we use our own built-in search engine (based on BM25) to retrieve a set of tweets for manual annotation. To minimize the labeling cost, for each query, we sample 150-200 tweets for annotation as each query may return thousands of results, which makes the complete annotation impossible. These queries are grouped into four categories: thing (10 queries), person (15), event (30) and place (5). Table 1 shows some example queries of each type. For all these queries, there are about 9,000 unique tweets to be annotated.

[3]Though the corpus is not available now on the original website due to licensing problems, readers are encouraged to request a copy from us. We are downloading a new dateset for further evaluation.

Then, two computer science students were asked to annotate the tweets. The quality of a tweet was judged to a 5-star likert scale, according to the relevance, informativeness, readability, and politeness of the content. If the label difference of two tweets is larger than 1, the tweets were re-annotated until the quality difference is within 1.

Thing	**Person**
haiti relief effort	adam james
newegg	tiger woods mistress
flight 253	jennifer jones
groupon	john wall
Event	**Place**
obama ambulance	google headquarters
boeing 787 first flight	solomon islands
eureka earthquake	humanitarian bowl
shaq retires	college of charleston

Table 1: Sample queries for each query type.

6.1 Evaluation Metrics

We adopt information retrieval metrics to measure the performance since the task can be viewed as a ranking task (ranking document according to its quality). $nDCG$ (Järvelin and Kekäläinen., 2000) is used to evaluate the ranking performance, as follows:

$$nDCG(\Omega, k) = \frac{1}{|\Omega|} \sum_{q \in \Omega} \frac{1}{Z_q} \sum_{i=1}^{k} \frac{2^{r_i^q} - 1}{log(1+i)}$$

where Ω is the set of test queries, k indicates the top k positions in a ranked list, Z_q is a normalization factor obtained from a perfect ranking (based on the labels), and r_i^q is the relevance score (the annotated quality label) for the *i-th* document in the predicted ranking list for query q. We also evaluate the system in terms of MAP [4] where the document whose quality score is larger than 3 is viewed as relevant and otherwise irrelevant.

Note that the ranking task is approached as a regression problem, mean square error is thus adopted to measure the learning performance:

$$MSE(\mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{d_j \in \mathcal{D}} (f(d_j) - \hat{y}_j)^2$$

where $\mathcal{D}$ is the test document collection, $f(d_j)$ is the predicted label, and $\hat{y}_j$ is the annotated label.

$nDCG$ and MSE have a significant difference in that $nDCG$ only considers the top k documents for each

[4]http://en.wikipedia.org/wiki/Information_retrieval

query while MSE takes into account all documents in the test collection.

7 Experiment and Evaluation

In this section, we will first assess whether the proposed hypothesis holds on our labeled data. We then evaluate whether the performance of the model with the regularization factor (as defined in Eq. 4) can be enhanced. We next compare the regression model with several baselines: BM25 model, Length Model (tweets containing more words may have better quality), ReTweet Model (tweets of higher quality may be re-posted by more users), and a Learning-to-Rank model (L2R) as used in (Duan et al., 2010)(a ranking SVM model). Finally, we investigate the influence of different feature groups on the performance. We conduct five-fold cross validation in the following experiments (3/5 partitions are for training, 1/5 are used as a validation set, and the left for test).

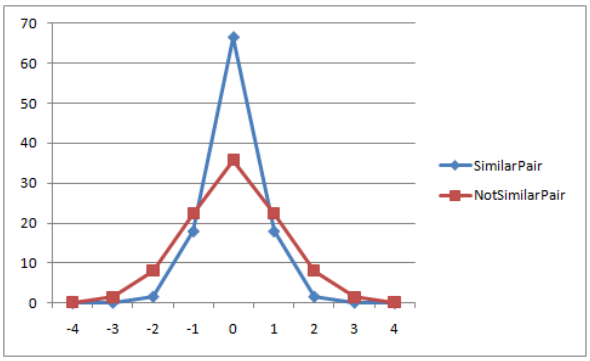

Figure 1: The hypothesis holds on the annotated dataset. y-axis is the percentage of pairs and x-axis is the quality difference between two documents in a pair.

7.1 Hypothesis Evaluation

We will evaluate whether the content conformity hypothesis holds on our manually annotated dataset. To define the similarity predicate ($IsSim$ in Eq. 4), we assume two documents are similar if their TF*IDF cosine similarity is no less than 0.6. We then compute the statistics of the quality difference of similar pairs and that of dissimilar pairs. We find that more than 53% similar pairs have exactly identical quality labels, out of all similar pairs. And more than 93% similar pairs have a quality difference within 1. For dissimilar pairs, only 35% pairs have identical quality labels. This shows that if two documents are similar, there is high probability that their quality labels are close to each other, and that if two documents are dissimilar, it's more likely that they have more divergent quality scores. These statistics are shown in Figure 1.

As shown in the figure, we can see that the hypothesis holds. Therefore, we can safely formulate the hypothesis into a regularization factor in the subsequent experiments.

7.2 Parameter Tuning

We explain here how the parameters (α, β) are chosen. In Table 2, we can see clearly that the best performance is obtained when $\alpha = 1e-8$. In Table 3, the model that utilizes only labeled data obtains most of the best nDCG scores when $\beta = 0.001$. For the MAP metric, the scores when $\beta = 0.001$ and $\beta = 0.0001$ are very close. Unlike MSE that considers all documents in the test collection, nDCG only considers the top ranked documents, which are more desirable for parameter choosing since most users are only interested in top ranked items. In Table 4, the model that utilizes unlabeled data obtains best performance when $\beta = 0.0001$. These optimal parameters will be used in our subsequent experiments.

7.3 Influence of the Regularization Factor

In this section, we address two issues: (1) whether the regularization factor inspired by content conformity hypothesis (Eq. 4) can improve the performance; and (2) whether the performance can be improved if using unlabeled data (see D_k in Eq. 4).

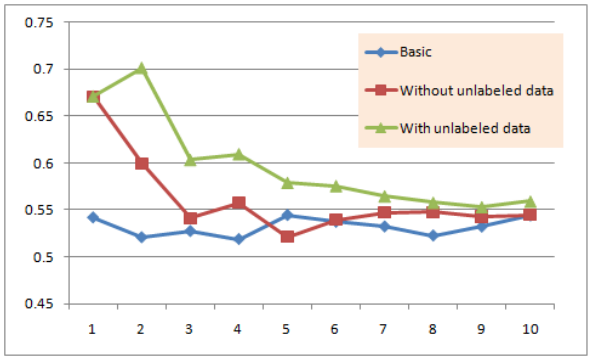

Figure 2: nDCG performance (y-axis) for top k ranks. The similarity predicate ($IsSim(a, b)$ in Eq. 4) is implemented with TF*IDF cosine similarity.

As shown in Figure 2, under the hypothesis the ranking performance is boosted compared to the basic model. As shown in Eq. 4, unlabeled data can be included in the regularization factor, thus we add the same number of unlabeled documents[5] for each query. We conduct experiments with and without such unlabeled data respectively. Adding unlabeled data can improve the ranking performance. This is appealing for most IR applications since

[5]Arbitrary number of documents may be added but we will evaluate this as future work.

most IR problems only have a small number of labeled data available.

7.4 Comparison to Baselines

To demonstrate the performance of our approach, we compare our system to three unsupervised models and one supervised model. The unsupervised models are: the BM25 model, the Length model which ranks tweets by the document length in tokens, and the RTNum model which ranks tweets by the frequency of being re-posted. The supervised model is a ranking SVM model (L2R) that was used in (Duan et al., 2010). In this experiment, the model (as indicated by "Full" in Fig. 3) is the best model presented in the preceding section.

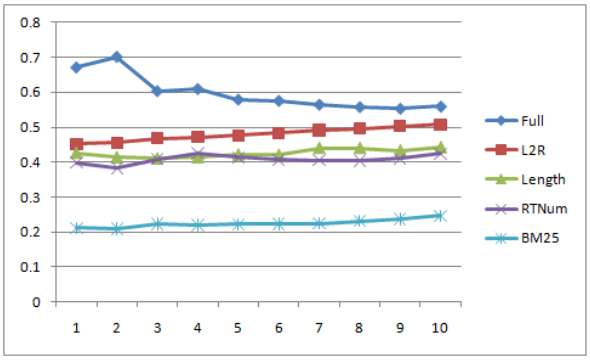

Figure 3: nDCG performance (y-axis) with different approaches. x-axis is the top k ranks. The Full model used unlabeled data with the regularization factor.

We can see that the proposed approach outperforms those unsupervised models remarkably, and it also performs better than the L2R model (Ranking SVM). Noticeably, the Length model is strong in performance, which shows the document length is a good indicator of quality. The RTNum model takes advantage of a Twitter specific property - a document of higher quality may be posted repeatedly by other users with higher probability. This is a special property for Twitter documents. Not surprisingly, the supervised methods outperform all unsupervised methods.

To further demonstrate that our approach outperforms the baselines, we list the results (in terms of $nDCG@k = 1, 5, 10$, and MAP) in Table 5 which clearly shows the advantages of our proposed approach. Note that our performance shown in Table 5 is significantly better than all the baselines (p-value$<$0.001 by t-test). We choose the significance level of 0.01 through the paper.

nDCG @k	Full	L2R	Length	RTNum	BM25
k=1	**0.671**	0.442	0.466	0.398	0.212
k=5	**0.579**	0.477	0.422	0.413	0.222
k=10	**0.559**	0.508	0.442	0.424	0.247
MAP	**0.427**	0.315	0.253	0.225	0.126

Table 5: Performance comparison between systems. Our results are significantly better than the baselines.

7.5 Feature Study

To investigate the influence of different features on performance, we perform a feature ablation study. As shown in Section 5, we classify features into different groups. In this experiment, we first train the basic model (as defined in Eq. 1) with all the features, and then remove one group

of features each time. We also experiment with only content features to justify the effectiveness of these features.

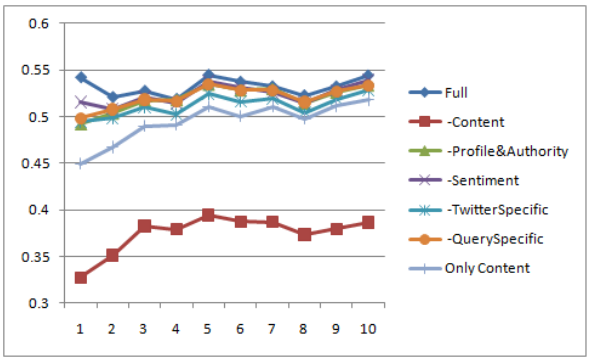

Figure 4: $nDCG@k$ performance with different feature groups. 'Full' means all the features. '-' means removing that feature group from the full feature set.

We can see that when removing content features, the performance drops substantially, which indicates that content is the most important indicator of quality. When using only content features, the performance is also fairly good (but significantly worse than the Full model, p-value<0.01 by t-test), showing that content is reliable features for this task. When removing Twitter specific features, there is a significant drop in performance (p-value<0.01). This indicates that such prior knowledge on tweets is helpful for ranking such documents. However, removing user profile and authority features does not affect the system much. Similar observation can be seen when removing sentiment features and query-specific features respectively. For query-specific features, it seems that such features play a light-weighted role. There may be two reasons for this: First, the documents are obtained from the BM25 model in our approach, thus all documents are more or less relevant to the query while our approach can be treated as a re-ranking process; Second, the document is very short, thus query-specific features may not be as important as in retrieving longer documents, more specifically, the query term frequency may not be as accurate as in longer documents.

To further investigate which specific content features are important, we conduct a further feature ablation study on content features. We find that the average term similarity (p-value<0.01), ratio of unique words (p-value=0.08), and ratio of POS tags (p-value<0.02) play more roles in performance. Not as expected, removing the length features does not lead to as a remarkable drop as removing other features (p-value=0.12). However, as shown in Figure 3, the Length model is strong in performance. This may infer that the length feature may be complemented by other content features.

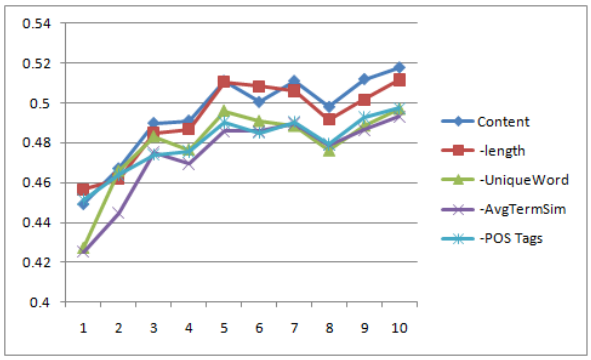

Figure 5: $nDCG@k$ performance with different content features. '-' means removing the feature group from the full content features.

Note that these experiments are performed with the basic model (Eq. 1). We also conduct similar feature studies with the regularization factor and similar observations are seen.

8 Conclusion

We presented a regression model which incorporates various features for suggesting quality-biased short-text documents. We proposed a content conformity hypothesis and formulated it into a regularization factor. The performance was boosted with such a factor. Moreover, unlabeled data can be used seamlessly in this approach, and leveraging such data leads to improvements in ranking performance. The comparative results demonstrate the effectiveness of finding high-quality tweets.

Short-text ranking is still in its infancy. There is still much work to do. For example, it is feasible to plug other hypotheses in this approach. As an instance, celebrity users may be more likely to post responsible tweets than common users. We also note that the quality of a tweet is not only determined by the text itself, but also by the external resources it points to (via a tiny URL) or it attaches (a picture or a video). Therefore, considering these factors would also be helpful in finding high-quality posts.

Abstract

The effort required to build a classifier for a task in a *target* language can be significantly reduced by utilizing the knowledge gained during an earlier effort of model building in a *source* language for a similar task. In this paper, we investigate whether unlabeled data in the target language can be labeled given the availability of labeled data for a similar domain in the source language. We view the problem of labeling unlabeled documents in the target language as that of clustering them such that the resulting partitioning has the *best* alignment with the classes provided in the source language. We develop a cross language guided clustering (CLGC) method to achieve this. We also propose a method to discover concept mapping between languages which is utilized by CLGC to transfer supervision across languages. Our experimental results show significant gains in the accuracy of labeling documents over the baseline methods.

1 Introduction

The last few years have seen a rapid growth in the development of machine learning applications for non-English languages. This growth can be attributed to several factors such as increased Internet penetration (especially in non-English speaking countries) and wide adoption of Unicode standards that allow people to generate content in their own language.

A key guiding principal in the development of such applications for a new language (referred to as the target or resource-poor language) has been to leverage the existing models and linguistic resources available for a popular language such as English (also called source or resource-rich language). Existing literature examines two ways of utilizing this knowledge. The first way is to adapt an existing statistical model for a new target language. Examples of this is the problem of cross-lingual sentiment classification (Xiaojun Wan 2009), or in a more general setting for cross language domain adaptation for classification (Peter Prettenhofer and Benno Stein 2010). The second way is to develop linguistic resources for a target or resource-poor language by leveraging the resources available in a source or resource-rich language. An example of this is the work done for automatically transferring syntactic relations (in WordNet) from a source language (English) into a target language (Romanian) (Verginica Barbu Mititelu and Radu Ion 2005).

In this paper, we investigate another way of utilizing the knowledge gained in one language for building machine learning applications in an another language. Our work focuses on generating training data (in contrast to adapting models and language resources) in the target language, given in-domain training data for the source language. The labeled data in the source language could be used to guide the grouping of unlabeled data in the target language, where each group *aligns* to a class label from the source language. We assume that the domain for both the source and target language data is similar and therefore the set of class labels across the two languages will be shared (but may not be exactly the same). As an example consider a real world scenario from a call routing application. A call routing application maps natural language utterances (typically a caller's response to an open ended question such as "how may I help you") to one of a given set of classes also called call types. Figure 1 shows examples of a few ut-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 383–391,
Chiang Mai, Thailand, November 8 – 13, 2011.

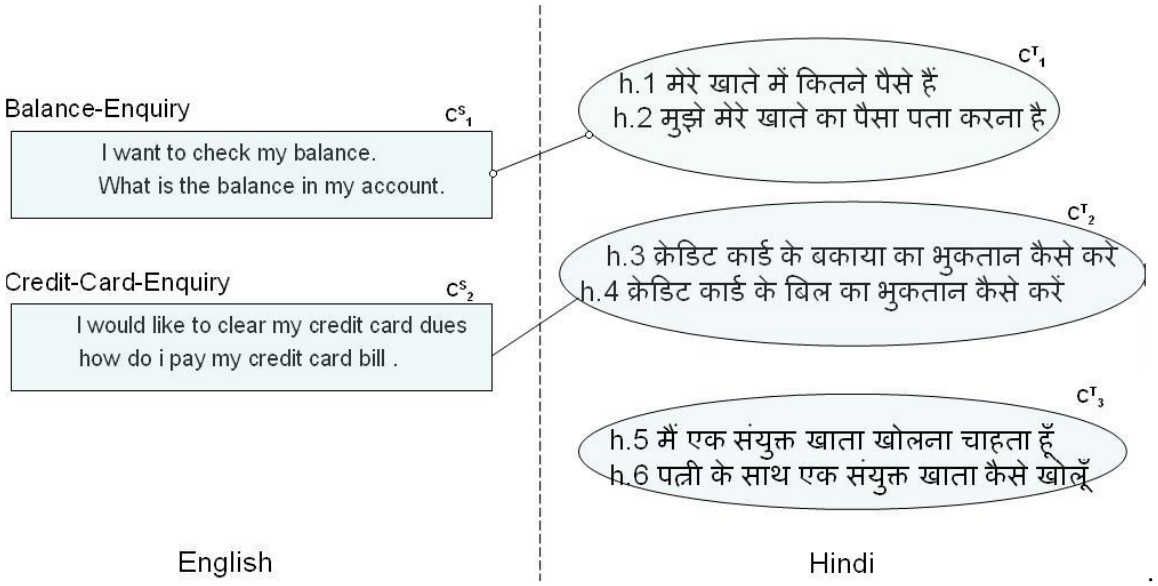

Figure 1: Utterances and class labels in source and target languages

terances (in English) along with associated class labels from the banking domain. These labeled utterances could be used as training data for building a call-routing classifier for the two class labels namely "Balance-Enquiry" and "Credit-Card-Enquiry". Let us assume that we now have utterances in a new language (in Hindi) which are unlabeled. Given that these utterances belong to the same domain, they can be labeled using the same label set as the one used for the source language. This is shown in the Figure 1 where utterances $h.1$ and $h.2$ are grouped together and labeled as "Balance-Enquiry" and utterance $h.3$ and $h.4$ is labeled as "Credit-Card-Enquiry". The labeled data can then be used to train a classifier in the target language.

To label the target language documents automatically we propose a method called cross-language guided clustering (CLGC). This method is built upon a recently proposed approach called cross guided clustering (CGC). CGC guides clustering of documents in a target domain given clusters/classes in a source domain (Bhattacharya et al. 2009). This is achieved by discovering a partitioning in the target domain that is most "similar" or "aligned" to a given partitioning in the source domain. In CLGC we view the problem of labeling unlabeled documents in the target language as that of clustering them such that the resulting partitioning has the *best* alignment with the classes provided in the source language. Since in our case the source and target data are in different languages, we extend the CGC framework to transfer supervision across different languages. We develop cross language similarity measures that use word level and concept level mappings to guide the clustering across languages. We also develop methods to discover concept level mapping between languages. Our experimental results show significant gains in the accuracy of labeling documents over the baseline methods.

One could argue that if the final goal is to classify documents in the target language, this could be achieved by either of the following approaches - (1) by adapting the source language classifier (Peter Prettenhofer and Benno Stein 2010) or (2) by translating unlabeled documents from the target language to the source language and then applying a source language classifier (Mckeown et al. 2003). We claim that our approach is more general and has several advantages over both these approaches. First, building a classifier given a training dataset is a well studied and understood problem. Several off-the-shelf machine learning tools exist that can readily be used for tasks such as feature construction, and building classifiers, provided a training dataset is available (Hall et al. 2009). Our approach can be used to generate a training dataset for the target language which enables use of existing approaches not only for building classifiers, but also for feature engineering tasks such as feature construction and feature selection. This cannot be done using either of the above mentioned approaches.

Second, a key assumption made in both these approaches is that the class labels across languages

are completely shared. This may not be true in several cases as there could be categories that are specific to the target language dataset. As an example, while most of the Hindi utterances in the Figure 1 can be grouped and aligned with a class label in the source language, there exist utterances ($h.5$,$h.6$) which do not belong to any of the existing labels in the source language. Our method allows such groupings to be discovered which can then be used to build target language specific class labels. Moreover, it is worth mentioning that apart from these advantages our proposed method is more efficient than machine translation based methods as it does not require a complete machine translation system.

The specific contributions made by us in this paper are two fold. First, we introduce the problem of labeling documents in one language using the set of labeled documents in another language and show that it is not only feasible but also better than other competitor techniques. Second, we extend the CGC framework to transfer supervision across languages. For this we develop methods to discover concept level mapping between languages that is utilized to guide the clustering across languages.

The rest of the paper is organized as follows. In Section 2 we present related work. We formulate the problem in Section 3. We describe the cross-language guided clustering framework in Section 4. In Section 5, we describe the cross language similarity measure that is used in the CLGC framework. We provide the experimental results in Section 6 and conclude in Section 7.

2 Prior Work

The two research areas that are related to our work are, (1) cross lingual classification and clustering, and (2) semi-supervised clustering.

Cross Lingual Classification and Clustering : Traditional approaches to cross language text classification use linguistic resources such as bilingual dictionaries or parallel corpora to induce correspondences between two languages (Olsson 2005). Some of these methods employ latent semantic analysis (LSA) (Dumais et.al. 1997) or kernel canonical correlation analysis, CCA (Fortuna and Shawe-Taylor 2005). The major limitations of these approaches are their computational complexity and dependence on a parallel corpus. Cross-lingual clustering aims to cluster a heterogeneous (a collection of documents from different languages) document collection. Initial work done in cross-lingual document clustering employed an expensive machine translation (MT) system to fill the gap between two languages (Mckeown et al. 2003). Later work (Wu 2007) done in this area demonstrated that it was possible to achieve comparable performance to the direct MT method using simple linguistic resource such as bilingual dictionaries.

Semi-supervised clustering: Semi-supervised clustering aims to improve clustering performance by limited supervision in the form of a small set of labeled instances. Alternatively, a small set of labeled instances can be used to learn a parameterized distance function (M. Bilenko and R. J. Mooney 2003), (Klein et al. 2002). The co-clustering approach (Dhillon et al. 2003), (N. Slonim and N. Tishby 2000) clusters related dimensions simultaneously through explicitly provided relations between them, such as words and documents, or people and reviews.

The problem that we address in this paper differs significantly from the above mentioned work. Unlike others, our objective is to cluster target language documents such that the resulting clusters are most *'similar'* or best *'aligned'* to the given source language classes. This problem is an instance of semi-supervised clustering in a bilingual setting, which to the best of our best knowledge has received very little attention. Our work builds upon Cross Guided Clustering (CGC) work (Bhattacharya et al. 2009) where supervision is discovered in the form of cluster level similarities obtained from labeled instances from a different domain, having different but related labels. In our work we extend the CGC framework to transfer supervision across different languages.

3 Problem Formulation

Let $T^S = \{< d_1^S, l_1^S >, < d_2^S, l_2^S >, \ldots, < d_n^S, l_n^S >\}$ denote a training dataset in the source language S for a classification task γ. Here $d_i^S \in D^S$ denotes a document that has an associated class label $l_i^S \in L^S$ where, L^S denotes the set of class labels used in T^S. Note, that L^S induces a partitioning of D^S, where each class label l_i^S can be seen as a cluster containing documents d_i^S that have l_i^S as the class label. We are also given a set of unlabeled documents $D^T = \{d_1^T, d_2^T, \ldots, d_m^T\}$ where all the documents are from a similar domain as in T^S but are from a different language T. Our objective is to generate a training dataset using D^T

for the classification task γ. We pose this as a clustering problem over document set D^T, where the resulting clusters are *aligned* with the given classes in the source language dataset. The alignment is achieved by taking the supervision from the partitioning of D^S, which is induced by the label set L^S, to guide the clustering of document set D^T. We refer to this clustering method as *cross-language guided clustering*. In the next section, we describe cross-language guided clustering in detail.

4 Cross-Language Guided Clustering

In this section, we modify the cross guided clustering framework as described in (Bhattacharya et al. 2009) to transfer supervision across languages. Let $Dis(d_i^T, d_j^T)$ provide a distance measure between documents d_i^T and d_j^T in the target language T. A clustering method partitions the given document set into k clusters denoted by centroids $C^T = \{C_1^T, C_2^T, \ldots, C_k^T\}$ such that the total divergence $Div(C^T)$ also referred to as *target only divergence* is minimized. This is defined as follows.

$$Div^T(C^T) = \sum_{C_i^T} \sum_{d_j^T} \delta(C_i^T, d_j^T) Dis(C_i^T, d_j^T)^2 \quad (1)$$

Here $\delta(C_i^T, d_j^T)$ returns 1 if d_j^T is assigned to the centroid C_i^T else returns 0. This is a standard formulation used in the K-Means algorithm (Hall et al. 2009).

In our problem setting, we are additionally provided with a labeled dataset in the source language where the label set induces a partitioning $C^S = \{C_1^S, C_2^S, \ldots, C_l^S\}$ of D^S in the source language. Our objective is to discover partitioning of D^T such that each resulting cluster is aligned with *at most* one class label from the source language and vice-versa. This enables discovery of clusters in the target language that are aligned with the classes in the source language while simultaneously allowing for discovery of any additional concept in the target language. To do this, we require a cross-language similarity function $Sim^X(..)$ that given two documents from different languages, returns a similarity score. This is non-trivial as documents in different languages are represented in entirely separate attribute/feature space. We develop a cross-language similarity measure to achieve this in Section 5. For now, we assume that we have access to such a measure.

To find a cross-language alignment between the source partition and the target partition we construct a bipartite cross language graph G_x that has one set of vertices C^S corresponding to source centroids, and another set C^T corresponding to target centroids. An edge is added between every pair of vertices (C_i^S, C_j^T) where the weight of the edge is given by $Sim^X(C_i^S, C_j^T)$. Now finding the best cross language alignment is equivalent to finding the maximum weighted bipartite match in the graph G_x. Recall that a matching is a subset of the edges such that any vertex is spanned by at most one edge. The score of a matching is the sum of the weights of all the edges in it. In our implementation, we use the 'Hungarian method' to determine the matching (Kuhn 1955).

The matching provides an alignment between the source classes and the target clusters. We only consider those edges in the matching whose weight is more than some predefined threshold. To measure the goodness of cross-language alignment we define a cross-language divergence measure:

$$Div^X(C^S, C^T) = \sum_{C_i^S} \sum_{C_j^T} \delta^X(C_i^S, C_j^T)(1 - Sim^X(C_i^S, C_j^T))^2 |C_j^T| \quad (2)$$

Here, $\delta^X(C_i^S, C_j^T)$ returns the weight of the edge between node C_i^S and node C_j^T if these nodes are matched, else it returns 0. Here $|C_j^T|$ denotes the size of the cluster for which C_j^T is the centroid. The weighing by $|C_j^T|$ is done to make $Div^X(C^S, C^T)$ comparable to $Div(C^T)$. Now the combined divergence between the source partition and the target partition is computed by taking a weighted sum of target-only divergence and cross-language divergence.

$$Div(C^S, C^T) = \alpha * Div^T(C^T) + (1 - \alpha) * Div^X(C^S, C^T) \quad (3)$$

Here α captures the relative importance of the two divergences.

We now provide an algorithm (see Figure 2) that minimizes the objective function given in Equation 3. The algorithm starts by selecting k random data points as centroids from the target language and then executes the following two steps in each iteration. It first assigns points to their nearest centroids and then re-estimates the target centroids to minimize cross-language divergence as given in Equation 3. This is achieved by the

Procedure CrossLanguageGuidedClustering

Select k centroids randomly from D^T
% Initialize target clusters
Iterate n times or until convergence
  Iterate m times
    Assign each $d_i^T \in D^T$ to the nearest centroid
    Recompute the centroids

  % Start CLGC
  Create cross language similarity graph G_x using Sim^X
  Compute maximum bipartite graph matching over G_x
  Iterate over k target centroids in C^T
    Update centroid using the cross language update rule
    Assign each $d_i^T \in D^T$ to the nearest centroid
Return k centroids

Figure 2: Procedure for Cross Language Guided Clustering

following update rule that is obtained by differentiating the divergence function in Equation 3 with respect to the current target centroids.

$$C_i^T = \frac{\alpha \sum_{d_i^T \in C_i^T} d_i^T + (1-\alpha) \sum_j \delta^x(C_i^T, C_j^S)\phi(C_j^S)}{\alpha|C_i^T| + (1-\alpha)|C_i^T| \sum_j \delta^x(C_i^T, C_j^S)\phi(C_j^S)} \quad (4)$$

Here the δ^X function captures the current matching of target clusters with source classes. Intuitively, there are two factors contributing to the update rule. The first factor tries to move the current target centroid towards the center of the cluster computed using the currently assigned data points. This is similar to the standard K-means approach. The second factor that arises due to cross-language alignment tries to move the centroid towards the currently matched source class. Since the feature space used to represent source classes and target centroids are different, we use the function ϕ that projects source classes in the feature space used by the target language. We provide more details regarding the projection function and cross-language similarity in the next section.

5 Cross Language Similarity

In order to perform cross language guided clustering we need a similarity function Sim^X that given two documents d_i^S and d_j^T from source and target languages, computes a similarity score. Let V^S and V^T be the vocabularies used to represent documents in source and target language respectively. Given a word $w_i^S \in V^S$, let the function $proj(w_i^S)$ return a probability distribution $P = \{p_1, p_2, \ldots, p_{|V^T|}\}$ where p_j represents the probability of the word w_i^S being translated to the word w_j^T in target dictionary. The function $proj(..)$ has access to a statistical dictionary $\mathcal{D}_T^S$ for doing this. The dictionary could be constructed using some large general purpose parallel corpus. We now present three different methods to compute the similarity function $Sim^X(d_i^S, d_j^T)$.

Projection based Method: Let M represent a matrix of dimension $|V^S| * |V^T|$ where each i^{th} row contains the probability distribution returned by $proj(w_i^S)$ for $1 \leq i \leq |V^S|$. Given a source document d_i^S, let $\bar{d}_i^S$ refer to its vector representation using the feature space V^S. Then the projection function $\phi(\bar{d}_i^S) = (\bar{d}_i^S)' M$ and the similarity function Sim^X can be defined as follows, where $'$ denotes transpose of a matrix:

$$Sim^X(d_i^S, d_j^T) = \phi(\bar{d}_i^S)\bar{d}_j^T = (\bar{d}_i^S)' M \bar{d}_j^T \quad (5)$$

Weighted Projection based Method: The function $proj(w_i^S)$ returns a probability distribution that captures the likelihood that w_i^S gets translated to a word w_j^T in the target dictionary. Since, this function uses a general purpose bi-lingual statistical dictionary it does not capture domain specific translations. For example, the English word "bank" may have equal probabilities for being translated as "बैंक" or "किनारा" however, given a corpus from the banking domain, it is more likely that the word "bank" translates to "बैंक". Therefore, given a source term we weigh the probability values of the target terms that it translates to, by the frequency of the target terms computed over the target corpus. We then normalize these values again to obtain a probability distribution.

Semantic Mapping based Method: There are multiple words that are synonymous to each other and can be used to represent the same meaning. For example, the word "games" and "sports" are synonymous English words and can be used to represent the same meaning as "खेल" or "गेम्स". The matrix M used in the previous methods, captures the translation probabilities at the word level. In this method we first discover the concepts in each language and then find translation probabilities at the concept level. We refer to this as semantic mapping between the two languages.

To discover the concepts, words from the source and target vocabulary are clustered into *term clusters* based on the words that occur in its *context*. For this a word-by-word co-occurrence matrix is built for the given language. The entry (i, j) in the matrix contains the number of times the word w_i and w_j occur within a fixed window of L

words in the corpus. Thus, each word is represented by a vector called "context vector" that captures words occurring in the context of the given word. We then use an off-the-shelf clustering algorithm (Hall et al. 2009) to obtain term clusters in a language. These term clusters are referred to as concepts. The Figure 3 shows examples of concepts identified in English and Hindi languages. Let $G^S = \{G_1^S, G_2^S, \ldots, G_l^S\}$ and $G^T = \{G_1^T, G_2^T, \ldots, G_m^T\}$ be the source and target concepts obtained by clustering. To find the semantic relationship across concepts from different languages, we construct a bipartite graph that has one set of vertices G^S corresponding to the source concepts, and another set G^T corresponding to the target concepts. Now for each word $w^S \in G_i^S$, we determine the set of target words T_{w^S} that it translates to along with the corresponding translation probabilities. For each word $w^T \in T_{w^S}$, we find the concept G_j^T that contains w^T and add a weight p on the edge between the vertex G_i^S and G_j^T, where p is the probability of w^S being translated to w^T. After repeating this process for all the source concepts, we normalize the edge weights such that for each G_i^S, the sum of weights corresponding to the edges connecting G_i^S and any concept in the target language equals to 1. Thus for each source concept the normalized bipartite graph contains a distribution over the target concepts. We call this normalized bipartite graph as the semantic mapping between the two languages. Note, that the normalized bipartite graph can be seen as a matrix M_{map} where the rows and columns correspond to source and target concepts respectively and the entry (i, j) denotes the probability that the i^{th} source concept corresponds to j^{th} target concept.

Now using the matrix M_{map}, the similarity function $Sim^X(d_i^S, d_j^T)$ can be defined as follows:

$$Sim^X(d_i^S, d_j^T) = (\bar{c}_i^S)' M_{map} \bar{c}_j^T \qquad (6)$$

Here, $\bar{c}_i^S$ and $\bar{c}_i^T$ denote the concept vector representation of d_i^S and d_j^T respectively. The concept vector for a document is obtained by replacing the occurrence of each word w_i in the document by its concept.

6 Experimental Evaluation

There are three key questions for which we seek an answer through our experimental evaluation. First, whether the availability of labeled data in a source language is helpful for labeling unlabeled documents in the target language. Second, whether discovery of concepts and concept mapping between languages improves the CLGC performance. Third, given that the target language contains exactly the same classes as the source language (which is not an assumption for CLGC), whether labeling documents using CLGC gives comparable performance to computationally more expensive method that uses a machine translation system. We next describe the dataset, baselines and evaluation metrics that we use to answer these questions.

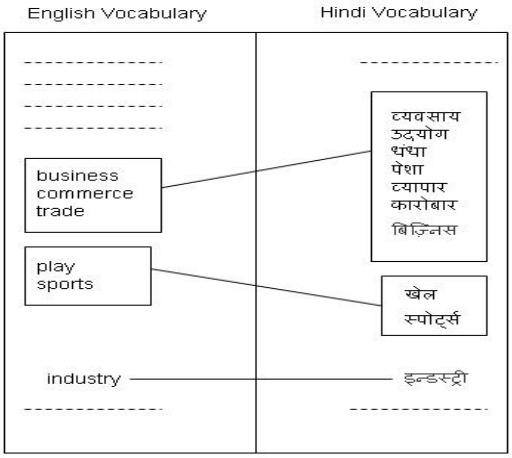

Figure 3: Vocabulary after Semantic Projection

Dataset and Resources: To evaluate the performance of our method, we constructed a dataset of news articles by crawling an English and a Hindi news site. The crawled news articles are from a four month period and belong to the following five categories, *viz*, (1) Economy and Finance - these are news reports on macro-economic events (such as cuts in interest rates, stock market and increase in taxes), (2) Healthcare and BioTech - these are business reports from the Healthcare and Biotechnology industry (mergers and acquisition, patents lawsuits , expansion etc), (3) Energy - these are news reports from the energy and utility sector, (4) sports and (5) Auto. The number of documents for each language and category are shown in Table 1. As mentioned earlier, the CLGC method does not assume that the same set of categories are present in both the languages, to verify this claim we have an additional category, viz, "Auto" in our Hindi dataset which is absent in the English dataset. Even though both English and Hindi news articles are from the same time frame these articles are not aligned.

Language	Economy	BioTech	Energy	Sports	Auto
English	1012	510	500	268	0
Hindi	412	300	350	275	153

Table 1: News Dataset used for Experimentation

	English	Hindi
Number of Unique Words	18128	14521
General Dictionary coverage	11061 (61%)	9344 (64%)
Domain Dictionary coverage	14969 (82.5%)	11767 (81%)

Table 2: Dictionary Statistics

Dictionary	Method	F1	Purity
	K-Means	0.45	0.61
General dictionary	PB	0.49	0.63
	WPB	0.56	0.66
	SM	0.62	0.71
Domain Dictionary	PB	0.57	0.64
	WPB	0.61	0.69
	SM	0.64	0.73

Table 3: Comparison of k means with CLGC using different cross lingual similarity measures

In our experiments, we use an English-Hindi statistical dictionary which was built using the Moses toolkit (Koehn 2007). The training data for the dictionary was a collection of 150,000 English and Hindi parallel sentences sourced from a general corpus. The dictionary built using this corpus is referred to as a "general dictionary" (GD). We further collected 10,000 parallel sentences on the topics present in our news dataset. These were then used along with the earlier set of parallel sentence to learn a dictionary that contains domain specific words and their translations. We refer to this dictionary as a "domain dictionary" (DD). The statistics for these dictionaries in terms of word coverage is shown in Table 2. The objective of creating these two dictionaries is to observe the performance of CLGC when a general purpose dictionary is used in contrast to a domain specific dictionary.

Baselines: One of the objective of experimental evaluation is to see if the availability of source classes helps in clustering documents in the target language. In order to measure gains achieved by the availability of source class information, we compare the performance of CLGC against the standard k-means algorithm. We refer to this as *k-means baseline*.

Another objective of the experimental evaluation is to see whether labeling documents using CLGC gives comparable performance to computationally more expensive method that uses a machine translation system. For this we train a classifier using the English news articles referred to as source classifier. We then translate Hindi new articles into English using Google's machine translation system and then label them using the source classifier. We refer to this as *NB baseline*.

Evaluation Metric The objective of the CLGC approach is to label the unlabeled target dataset. We use the following approach for evaluating this. As the true class-labels for the target news articles are known we assign to each cluster the class-label which is the most frequent in the cluster. All articles in the cluster are now labeled with the corresponding cluster-label. Based on this labeling strategy and the available ground truth we report the accuracy/purity measure which is computed by dividing the correctly labelled documents by the total number of documents. We also evaluate clustering quality by considering the correctness of clustering decisions over all document pairs. We report the standard F1 measure over the pairwise clustering decisions. The F1 measure is the harmonic mean of precision and recall over pairwise decisions.

Experiment 1: In our first experiment, We compare the performance of k-means with the projection based method, referred to as PB, weighted projection based method referred to as WPB and semantic mapping based method, referred to as SM. For this experiment we use the English dataset as the source dataset and Hindi dataset as the target dataset with 4 and 5 categories respectively. For the semantic mapping based method, we discover concepts using the word clustering. The word clustering algorithm uses k-means algorithm. We set k to a large value (we set it to 1000) and use only the first 100 best clusters where goodness of a cluster is measured in terms of its divergence. For each word that is not covered by the first best 100 clusters, we create singleton clusters for the word. We use this procedure for both the source and target dataset. We then use the method described in Section 5 to discover concept mappings.

Since the results obtained for both the k means and all the variations of CLGC depends on the choice of initial centroids, in each experimental run all the methods are seeded with the same set of centroids. The reported results are averaged

over 10 runs with random initialization. We set the value of k equal to the actual number of categories in each dataset for both k-means as well as for CLGC. The value of α in Equation 4 is set to 0.5 and value of n and m in the procedure given in the Figure 2 is kept 20 and 5 respectively.

The results are reported in Table 3. The results show that there is a significant gain that is achieved by CLGC methods over K-means. This shows that the presence of labeled data in the source language helps in the clustering of documents in the target language. We further note that the SM methods, both using "general dictionary" (GD) and "domain dictionary" (DD) outperforms all other methods in their class. This happens because words that do not get translated using the statistical dictionary, are taken into account as they become part of concept mappings that have correspondence across languages. Thus, these terms get accounted in the computation of the SM similarity measure. These terms were not being considered in the PB and WPB similarity computations. As an example the statistical dictionary did not have the translation for the word "bharti" , which is the name of a company from the telecommunication and retail sector. However the word "bharti" mapped to a concept from the source language which contained words such as "communication", "retail" and "ipo". This cluster mapped to a concept in Hindi which had words such as "सँचार", "रिटेल" and "भारती" where the first two words are translations for the words "communication" and "retail" respectively. As a result of this correspondence between the two concepts the words "bharti" and "भारती" get associated. Another key point to note is that the performance of Semantic Mapping using General Dictionary is only slightly worse than Semantic Mapping using the Domain Dictionary. This shows that the semantic mapping based method is able to achieve good performance even when it does not have access to a domain specific dictionary.

Experiment 2: In our second experiment, we compare the performance of SM method which is the best performing CLGC method with the NB baseline. We use the rainbow package (McCallum 1996) to train a naïve Bayes classifier using the English dataset. For translating Hindi documents to English, we use Google [1] translation engine. The accuracy results for this experiment are provided in Table 4.

[1] http://code.google.com/p/google-api-translate-java

Method	Accuracy
NB	0.71
SM	0.73

Table 4: Comparison of naïve Bayes with CLGC (SM using General Dictionary)

We note that the performance of SM is slightly higher than the naïve Bayes approach. We investigated the reasons behind this and found that there are a few important features that are specific to the Hindi dataset. As the naïve Bayes classifier is trained using the English dataset only, it does not have access to these features and therefore incorrectly classifies the documents that contain such features. While classification techniques such as those based on Support Vector Machines can be expected to perform better than simple NB, our aim here is only to demonstrate that in a resource poor language, where building such classifiers may not be possible (due to the lack of a good machine translation system etc), CLGC can prove to be a useful method.

7 Concluding Remarks

In this paper, we presented cross language guided clustering (CLGC) that utilizes the labeled data from a source language to label unlabeled data from a target language. CLGC tries to cluster unlabeled target language documents such that the resulting clusters are most 'similar' or best 'aligned' to the given source language classes. To achieve this alignment we defined a cross-language similarity measures that returns a similarity score between two documents in different languages. We presented and compared three cross-language similarity measure namely Projection Based, Weighted Projection Based and Semantic Mapping and demonstrate their effectiveness on real-world data-sets. Our Semantic Mapping method, which discovers concepts and their associated mapping across languages, shows the maximum gain in the accuracy of labeling documents over the baseline methods.

Abstract

In this paper we study a novel relation extraction problem where a general relation type is defined but relation extraction involves extracting specific relation descriptors from text. This new task can be treated as a sequence labeling problem. Although linear-chain conditional random fields (CRFs) can be used to solve this problem, we modify this baseline solution in order to better fit our task. We propose two modifications to linear-chain CRFs, namely, reducing the space of possible label sequences and introducing long-range features. Both modifications are based on some special properties of our task. Using two data sets we have annotated, we evaluate our methods and find that both modifications to linear-chain CRFs can significantly improve the performance for our task.

1 Introduction

Relation extraction is the task of identifying and characterizing the semantic relations between entities in text. Depending on the application and the resources available, relation extraction has been studied in a number of different settings. When relation types are well defined and labeled relation mention instances are available, supervised learning is usually applied (Zelenko et al., 2003; Zhou et al., 2005; Bunescu and Mooney, 2005; Zhang et al., 2006). When relation types are known but little training data is available, bootstrapping has been used to iteratively expand the set of seed examples and relation patterns (Agichtein and Gravano, 2000). When no relation type is pre-defined but there is a focused corpus of interest, unsupervised relation discovery tries to cluster entity pairs in order to identify interesting relation types (Hasegawa et al., 2004; Rosenfeld and Feldman, 2006; Shinyama and Sekine, 2006). More recently, open relation extraction has also been proposed where there is no fixed domain or predefined relation type, and the goal is to identify all possible relations from an open-domain corpus (Banko and Etzioni, 2008; Wu and Weld, 2010; Hoffmann et al., 2010).

These different relation extraction settings suit different applications. In this paper, we focus on another setting where the relation types are defined at a general level but a more specific relation description is desired. For example, in the widely used ACE[1] data sets, relation types are defined at a fairly coarse granularity. Take for instance the "employment" relation, which is a major relation type defined in ACE. In ACE evaluation, extraction of this relation only involves deciding whether a person entity is employed by an organization entity. In practice, however, we often also want to find the exact job title or position this person holds at the organization if this information is mentioned in the text. Table 1 gives some examples. We refer to the segment of text that describes the specific relation between the two related entities (i.e., the two arguments) as the *relation descriptor*. This paper studies how to extract such relation descriptors given two arguments.

One may approach this task as a sequence labeling problem and apply methods such as the linear-chain conditional random fields (CRFs) (Lafferty et al., 2001). However, this solution ignores a useful property of the task: the space of possible label sequences is much smaller than that enumerated by a linear-chain CRF. There are two implications. First, the normalization constant in the linear-chain CRF is too large because it also enumerates the impossible sequences. Second, the restriction to the correct space of label sequence per-

mits the use of long-range features without an exponential increase in computational cost.

We compare the performance of the baseline linear-chain CRF model and our special CRF model on two data sets that we have manually annotated. Our experimental results show that both reducing the label sequence space and introducing long-range features can significantly improve the baseline performance.

The rest of the paper is organized as follows. In Section 2 we review related work. We then formally define our task in Section 3. In Section 4 we present a baseline linear-chain CRF-based solution and our modifications to the baseline method. We discuss the annotation of our data sets and show our experimental results in Section 5. We conclude in Section 6.

2 Related Work

Most existing work on relation extraction studies binary relations between two entities. For supervised relation extraction, existing work often uses the ACE benchmark data sets for evaluation (Bunescu and Mooney, 2005; Zhou et al., 2005; Zhang et al., 2006). In this setting, a set of relation types are defined and the task is to identify pairs of entities that are related and to classify their relations into one of the pre-defined relation types. It is assumed that the relation type itself is sufficient to characterize the relation between the two related entities. However, based on our observation, some of the relation types defined in ACE such as the "employment" relation and the "personal/social" relation are very general and can be further characterized by more specific descriptions.

Recently open relation extraction has been proposed for open-domain information extraction (Banko and Etzioni, 2008). Since there are no fixed relation types, open relation extraction aims at extracting all possible relations between pairs of entities. The extracted results are (*ARG-1*, *REL*, *ARG-2*) tuples. The TextRunner system based on (Banko and Etzioni, 2008) extracts a diverse set of relations from a huge Web corpus. These extracted predicate-argument tuples are presumably the most useful to support Web search scenarios where the user is looking for specific relations. However, because of the diversity of the extracted relations and the domain independence, open relation extraction is probably not suitable for populating relational databases or knowledgebases. In contrast, the task of extracting relation descriptors as we have proposed still assumes a pre-defined general relation type, which ensures that the extracted tuples follow the same relation definition and thus can be used in applications such as populating relational databases.

In terms of models and techniques, we use standard linear-chain CRF as our baseline, which is the main method used in (Banko and Etzioni, 2008) as well as for many other information extraction problems. The major modifications we propose for our task are the reduction of the label sequence space and the incorporation of long-range features. We note that these modifications are closely related to the semi-Markov CRF models proposed by Sarawagi and Cohen (2005). In fact, the modified CRF model for our task can be considered as a special case of semi-Markov CRF where we only consider label sequences that contain at most one relation descriptor sequence.

3 Task Definition

In this section we define the task of extracting relation descriptors for a given pre-defined class of relations such as "employment." Given two named entities occurring in the same sentence, one acting as *ARG-1* and the other as *ARG-2*, we aim to extract a segment of text from the sentence that best describes a pre-defined general relation between the two entities. Formally, let $(w_1, w_2, \ldots, w_n)$

denote the sequence of tokens in a sentence, where w_p is *ARG-1* and w_q is *ARG-2* ($1 \leq p, q \leq n$, $p \neq q$). Our goal is to locate a subsequence $(w_r, \ldots, w_s)$ $(1 \leq r \leq s \leq n)$ that best describes the relation between *ARG-1* and *ARG-2*. If *ARG-1* and *ARG-2* are not related through the pre-defined general relation, *Nil* should be returned.

The above definition constrains *ARG-1* and *ARG-2* to single tokens. In our experiments, we will replace the original lexical strings of *ARG-1* and *ARG-2* with the generic tokens `ARG1` and `ARG2`. Examples of sentences with the named entities replaced with argument tokens are shown in the second column of Table 1.

4 Method

4.1 Representation

The relation descriptor extraction task can be treated as a sequence labeling problem. Let $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ denote the sequence of observations in a relation instance, where x_i is w_i augmented with additional information such as the POS tag of w_i, and the phrase boundary information. Each observation x_i is associated with a label $y_i \in \mathcal{Y}$ which indicates whether w_i is part of the relation descriptor. Following the commonly used BIO notation (Ramshaw and Marcus, 1995) in sequence labeling, we define $\mathcal{Y} = \{\textit{B-REL}, \textit{I-REL}, \textit{O}\}$. Let $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)$ denote the sequence of labels for $\boldsymbol{x}$. Our task can be reduced to finding the best label sequence $\hat{\boldsymbol{y}}$ among all the possible label sequences for $\boldsymbol{x}$.

4.2 A Linear-Chain CRF Solution

For sequence labeling tasks in NLP, linear-chain CRFs have been rather successful. It is an undirected graphical model in which the conditional probability of a label sequence $\boldsymbol{y}$ given the observation sequence $\boldsymbol{x}$ is

$$p(\boldsymbol{y}|\boldsymbol{x}, \Lambda) = \frac{\exp\Big(\sum_i \sum_k \lambda_k f_k(y_{i-1}, y_i, \boldsymbol{x})\Big)}{Z(\boldsymbol{x}, \Lambda)}, \quad (1)$$

where $\Lambda = \{\lambda_k\}$ is the set of model parameters, f_k is an arbitrary feature function defined over two consecutive labels and the whole observation sequence, and

$$Z(\boldsymbol{x}, \Lambda) = \sum_{\boldsymbol{y'}} \exp\Big(\sum_i \sum_k \lambda_k f_k(y'_{i-1}, y'_i, \boldsymbol{x})\Big) \quad (2)$$

is the normalization constant.

Given a set of training instances $\{\boldsymbol{x}_j, \boldsymbol{y}_j^*\}$ where $\boldsymbol{y}_j^*$ is the correct label sequence for $\boldsymbol{x}_j$, we can learn the best model parameters $\hat{\Lambda}$ as follows:

$$\hat{\Lambda} = \arg\min_{\Lambda} \Bigg(-\sum_j \log p(\boldsymbol{y}_j^*|\boldsymbol{x}_j, \Lambda) + \beta \sum_k \lambda_k^2 \Bigg). \quad (3)$$

Here $\beta \sum_k \lambda_k^2$ is a regularization term.

4.3 Improvement over Linear-Chain CRFs

We note that while we can directly apply linear-chain CRFs to extract relation descriptors, there are some special properties of our task that allow us to modify standard linear-chain CRFs to better suit our needs.

Label sequence constraint

In linear-chain CRFs, the normalization constant Z considers all possible label sequences $\boldsymbol{y}$. For the relation descriptor extraction problem, however, we expect that there is either a single relation descriptor sequence or no such sequence. In other words, for a given relation instance, we only expect two kinds of label sequences: (1) All y_i are *O*, and (2) exactly one y_i is *B-REL* followed by zero or more consecutive *I-REL* while all other y_i are *O*. Therefore the space of label sequences should be reduced to only those that satisfy the above constraint.

One way to exploit this constraint within linear-chain CRFs is to enforce it only during testing. We can pick the label sequence that has the highest probability in the *valid* label sequence space instead of the entire label sequence space. For a candidate relation instance $\boldsymbol{x}$, let $\tilde{\mathbf{Y}}$ denote the set of valid label sequences, i.e., those that have either one or no relation descriptor sequence. We then choose the best sequence $\hat{\boldsymbol{y}}$ as follows:

$$\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y} \in \tilde{\mathbf{Y}}} p(\boldsymbol{y}|\boldsymbol{x}, \hat{\Lambda}). \quad (4)$$

Arguably, the more principled way to exploit the constraint is to modify the probabilistic model itself. So at the training stage, we should also consider only $\tilde{\mathbf{Y}}$ by defining the normalization term $\tilde{Z}$ as follows:

$$\tilde{Z}(\boldsymbol{x}, \Lambda) = \sum_{\boldsymbol{y'} \in \tilde{\mathbf{Y}}} \exp\Big(\sum_i \sum_k \lambda_k f_k(y'_{i-1}, y'_i, \boldsymbol{x})\Big). \quad (5)$$

The difference between Equation (5) and Equation (2) is the set of label sequences considered. In other words, while in linear-chain CRFs the correct label sequence competes with all possible label sequences for probability mass, for our task the correct label sequence should compete with only other valid label sequences. In Section 5 we will compare these two different normalization terms and show the advantage of using Equation (5).

Adding long-range features

In linear-chain CRF models, only first-order label dependencies are considered because features are defined over two consecutive labels. Inference in linear-chain CRFs can be done efficiently using dynamic programming. More general higher-order CRF models also exist, allowing long-range features defined over more than two consecutive labels. But the computational cost of higher-order CRFs also increases exponentially with the order of dependency.

For our task, because of the constraint on the space of label sequences, we can afford to use long-range features. In our case, inference is still efficient because the number of sequences to be enumerated has been drastically reduced due to the constraint. Let $g(\boldsymbol{y}, \boldsymbol{x})$ denote a feature function defined over the entire label sequence $\boldsymbol{y}$ and the observation sequence $\boldsymbol{x}$. We can include such feature functions in our model as follows:

$$p(\boldsymbol{y}|\boldsymbol{x}, \Theta) = \frac{1}{\tilde{Z}(\boldsymbol{x}, \Theta)} \Bigg[\exp\Big(\sum_i \sum_k \lambda_k f_k(y_{i-1}, y_i, \boldsymbol{x}) + \sum_l \mu_l g_l(\boldsymbol{y}, \boldsymbol{x}) \Big) \Bigg], \quad (6)$$

where $\Theta = \{\{\lambda_k\}, \{\mu_l\}\}$ is the set of all model parameters. Both $\{\lambda_k\}$ and $\{\mu_l\}$ are regularized as in Equation (3). Note that although each $f(y_{i-1}, y_i, \boldsymbol{x})$ may be subsumed under a $g(\boldsymbol{y}, \boldsymbol{x})$, here we group all features that can be captured by linear-chain CRFs under f and other real long-range features under g. In Section 5 we will see that with the additional feature functions g, relation extraction performance can also be further improved.

4.4 Features

We now describe the features we use in the baseline linear-chain CRF model and our modified model.

Linear-chain features

The linear-chain features are those that can be formulated as $f(y_{i-1}, y_i, \boldsymbol{x})$, i.e., those that depend on $\boldsymbol{x}$ and two consecutive labels only. We use typical features that include tokens, POS tags and phrase boundary information coupled with label values. Let t_i denote the POS tag of w_i and p_i denote the phrase boundary tag of w_i. The phrase boundary tags also follow the BIO notation. Examples include *B-NP*, *I-VP*, etc. Table 2 shows the feature templates covering only the observations. Each feature shown in Table 2 is further combined with either the value of the current label y_i or the values of the previous and the current labels y_{i-1} and y_i to form zeroth order and first order features. For example, a zeroth order feature is "y_i is *B-REL* and w_i is `the` and w_{i+1} is `president`", and a first order feature is "y_{i-1} is *O* and y_i is *B-REL* and t_i is `N`".

Long-range features

Long-range features are those that cannot be defined based on only two consecutive labels. When defining long-range features, we treat the whole relation descriptor sequence as a single unit, denoted as `REL`. Given a label sequence $\boldsymbol{y}$ that contains a relation descriptor sequence, let $(w_r, w_{r+1}, \ldots, w_s)$ denote the relation descriptor, that is, y_r = *B-REL* and y_t = *I-REL* where $r + 1 \leq t \leq s$. The long-range features we use are categorized and summarized in Table 3. These features capture the context of the entire relation descriptor, its relation to the two arguments, and whether the boundary of the relation descriptor conforms to the phrase boundaries (since we expect that most relation descriptors consist of a single or a sequence of phrases).

5 Experiments

5.1 Data Preparation

Since the task of extracting relation descriptors is new, we are not aware of any data set that can be directly used to evaluate our methods. We therefore annotated two data sets for evaluation, one for the general "employment" relation and the other for the general "personal/social" relation.[2]

The first data set contains 150 business articles from New York Times. The articles were crawled from the NYT website between November 2009

[2] `http://www.mysmu.edu/faculty/jingjiang/data/IJCNLP2011.zip`

Description	Feature Template	Example
single token	w_{i+j} $(-2 \leq j \leq 2)$	w_{i+1} (next token) is *president*
single POS tag	t_{i+j} $(-2 \leq j \leq 2)$	t_i (current POS tag) is *DET*
single phrase tag	p_{i+j} $(-2 \leq j \leq 2)$	p_{i-1} (previous phrase boundary tag) is *I-NP*
two consecutive tokens	$w_{i+j-1}\&w_{i+j}$ $(-1 \leq j \leq 2)$	w_i is *the* and w_{i+1} is *president*
two consecutive POS tags	$t_{i+j-1}\&t_{i+j}$ $(-1 \leq j \leq 2)$	t_i is *DET* and t_{i+1} is *N*
two consecutive phrase tags	$p_{i+j-1}\&p_{i+j}$ $(-1 \leq j \leq 2)$	p_i is *B-NP* and p_{i+1} is *I-NP*

Table 2: Linear-chain feature templates. Each feature is defined with respect to a particular (current) position in the sequence. i indicates the current position and j indicates the position relative to the current position. All features are defined using observations within a window size of 5 of the current position.

Category	Feature Template Description	Example
Contextual Features	word w_{r-1} or POS tag t_{r-1} preceding relation descriptor	`, REL`
	word w_{s+1} or POS tag t_{s+1} following relation descriptor	`REL PREP`
Path-based Features	word or POS tag sequence between `ARG1` and relation descriptor	`ARG1 is REL`
	word or POS tag sequence between `ARG2` and relation descriptor	`REL PREP ARG2`
	word or POS tag sequence containing `ARG1`, `ARG2` and relation descriptor	`ARG2 's REL , ARG1`
Phrase Boundary Feature	whether relation descriptor violates phrase boundaries	1 or 0

Table 3: Long-range feature templates. r and s are the indices of the first word and the last word of the relation descriptor, respectively.

and January 2010. After sentence segmentation and tokenization, we used the Stanford NER tagger (Finkel et al., 2005) to identify PER and ORG named entities from each sentence. For named entities that contain multiple tokens we concatenated them into a single token. We then took each pair of (PER, ORG) entities that occur in the same sentence as a single candidate relation instance, where the PER entity is treated as *ARG-1* and the ORG entity is treated as *ARG-2*.

The second data set comes from a Wikipedia personal/social relation data set previously used in (Culotta et al., 2006). The original data set does not contain annotations of relation descriptors such as "sister" or "friend" between the two PER arguments. We therefore also manually annotated this data set. Similarly, we performed sentence segmentation, tokenization and NER tagging, and took each pair of (PER, PER) entities occurring in the same sentence as a candidate relation instance. Because both arguments involved in the "personal/social" relation are PER entities, we always treat the first PER entity as *ARG-1* and the second PER entity as *ARG-2*.[3]

[3]Since many personal/social relations are asymmetric, ideally we should assign *ARG-1* and *ARG-2* based on their semantic meanings rather than their positions. Here we take a simple approach.

We go through each candidate relation instance to find whether there is an explicit sequence of words describing the relation between *ARG-1* and *ARG-2*, and label the sequence of words, if any. Note that we only consider explicitly stated relation descriptors. If we cannot find such a relation descriptor, even if *ARG-1* and *ARG-2* actually have some kind of relation, we still label the instance as *Nil*. For example, in the instance "he is the son of `ARG1` and `ARG2`", although we can infer that *ARG-1* and *ARG-2* have some family relation, we regard this as a negative instance.

A relation descriptor may also contain multiple relations. For example, in the instance "`ARG1` is the CEO and president of `ARG2`", we label "the CEO and president" as the relation descriptor, which actually contains two job titles, namely, CEO and president.

Note that our annotated relation descriptors are not always nouns or noun phrases. An example is the third instance for personal/social relation in Table 1, where the relation descriptor "married" is a verb and indicates a spouse relation.

The total number of relation instances, the number of positive and negative instances as well as the number of distinct relation descriptors in each data set are summarized in Table 4.

Data Set	total	positive	negative	distinct descriptors
NYT	536	208	328	140
Wikipedia	700	122	578	70

Table 4: Number of instances in each data set. Positive instances are those that have an explicit relation descriptor. The last column shows the number of distinct relation descriptors.

5.2 Experiment Setup

We compare the following methods in our experiments:

- **LC-CRF**: This is the standard linear-chain CRF model with features described in Table 2.
- **M-CRF-1**: This is our modified linear-chain CRF model with the space of label sequences reduced but with features fixed to the same as those used in LC-CRF.
- **M-CRF-2**: This is M-CRF-1 with the addition of the contextual long-range features described in Table 3.
- **M-CRF-3**: This is M-CRF-2 with the addition of the path-based long-range features described in Table 3.
- **M-CRF-4**: This is M-CRF-3 with the addition of the phrase boundary long-range feature described in Table 3.

For the standard linear-chain CRF model, we use the package CRF++[4]. We implement our own version of the modified linear-chain CRF models.

We perform 10-fold cross validation for all our experiments. For each data set we first randomly divide it into 10 subsets. Each time we take 9 subsets for training and the remaining subset for testing. We report the average performance across the 10 runs.

Based on our preliminary experiments, we have found that using a smaller set of general POS tags instead of the Penn Treebank POS tag set could slightly improve the overall performance. We therefore only report the performance obtained using our POS tags. For example, we group *NN*, *NNP*, *NNS* and *NNPS* of the Penn Treebank set under a general tag *N*.

[4] http://crfpp.sourceforge.net/

We evaluate the performance using two different criteria: overlap match and exact match. Overlap match is a more relaxed criterion: if the extracted relation descriptor overlaps with the true relation descriptor (i.e., having at least one token in common), it is considered correct. Exact match is a much stricter criterion: it requires that the extracted relation descriptor be exactly the same as the true relation descriptor in order to be considered correct. Given these two criteria, we can define accuracy, precision, recall and F1 measures. Accuracy is the percentage of candidate relation instances whose label sequence is considered correct. Both positive and negative instances are counted when computing accuracy. Because our data sets are quite balanced, it is reasonable to use accuracy. Precision, recall and F1 are defined in the usual way at the relation instance level.

5.3 Method Comparison

In Table 5, we summarize the performance in terms of the various measures on the two data sets. For both the baseline linear-chain CRF model and our modified linear-chain CRF models, we have tuned the regularization parameters and show only the results using the optimal parameter values for each data set, chosen from $\beta = 10^{\gamma}$ for $\gamma \in [-3, -2, \ldots, 2, 3]$.

First, we can see from the table that by reducing the label sequence space, M-CRF-1 can significantly outperform the baseline LC-CRF in terms of F1 in all cases. In terms of accuracy, there is significant improvement for the NYT data set but not for the Wikipedia data set. We also notice that for both data sets the advantage of M-CRF-1 is mostly evident in the improvement of recall. This shows that a larger number of true relation descriptors are extracted when the label sequence space is reduced.

Next we see from the table that long-range features are also useful, and the improvement comes mostly from the path-based long-range features. In terms of both accuracy and F1, M-CRF-3 can significantly outperform M-CRF-1 in all settings. In this case, the improvement is a mixture of both precision and recall. This shows that by explicitly capturing the patterns between the two arguments and the relation descriptor, we can largely improve the extraction performance. On the other hand, neither the contextual long-range features nor the phrase boundary long-range features exhibit any

New York Times	Overlap Match				Exact Match

Table 5: Comparison of different methods on the New York Times data set and Wikipedia data set. Accu., Prec., Rec. and F1 stand for accuracy, precision, recall and F1 measures, respectively. † indicates that the current value is statistically significantly better than the value in the previous row at a 0.95 level of confidence by one-tailed paired T-test.

significant impact. We hypothesize the following. For contextual long-range features, they have already been captured in the linear-chain features. For example, the long-range feature "*is REL*" is similar to the linear-chain feature "w_{i-1} = *is* & y_i = *B-R*". For the phrase boundary long-range feature, since phrase boundary tags have also been used in the linear-chain features, this feature does not provide additional information. In addition, we have found that a large percentage of relation descriptors violate phrase boundaries: 22% in the NYT data set, and 29% in the Wikipedia data set. Therefore, it seems that phrase boundary information is not important for relation descriptor extraction.

Overall, performance is much higher on the NYT data set than on the Wikipedia data set. Based on our observations during annotation, this is due to the fact that the "employment" relations expressed in the NYT data set often follow some standard patterns, whereas in Wikipedia the "personal/social" relations can be expressed in more varied ways. The lower performance achieved on the Wikipedia data set suggests that extracting relation descriptors is not an easy task even under a supervised learning setting.

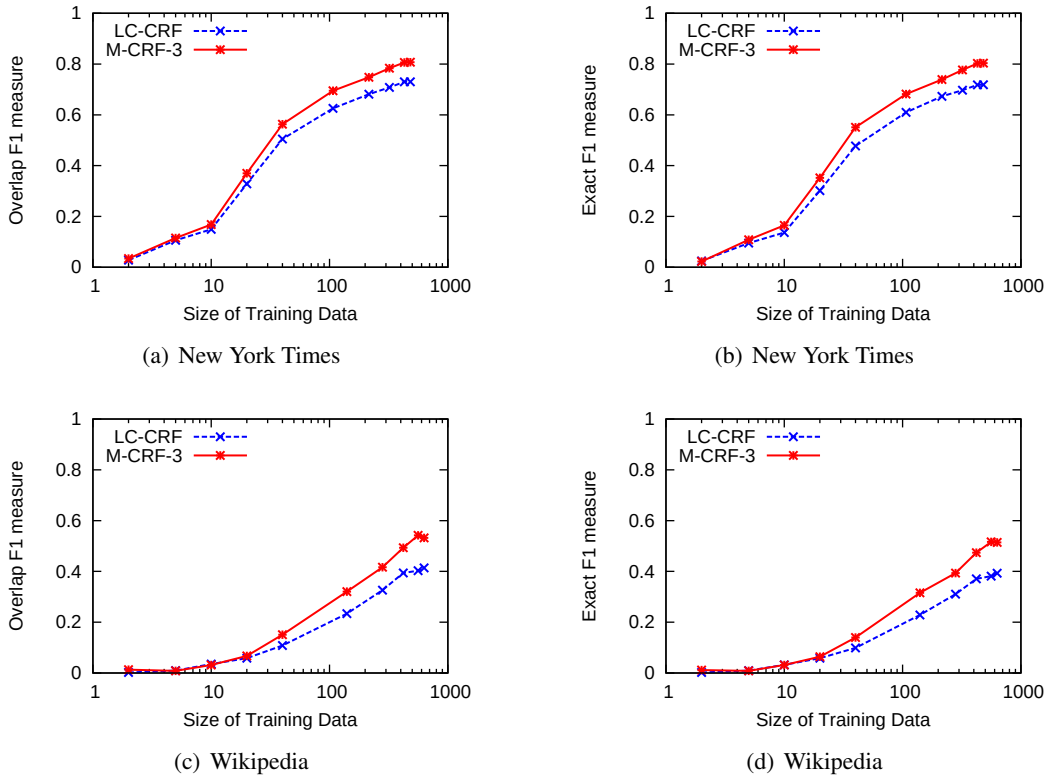
Presumably relation descriptors that are not seen in the training data are harder to extract. We would therefore also like to see how well our model works on such unseen relation descriptors. We find that with 10-fold cross validation, for the NYT data set, on average our model is able to extract approximately 67% of the unseen relation descriptors in the test data using exact match criteria. For the Wikipedia data set this percentage is approximately 27%. Both numbers are lower than the overall recall values the model can achieve on the entire test data, showing that unseen relation descriptors are indeed harder to extract. However, our model is still able to pick up new relation descriptors.

5.4 The Effect of Training Data Size

In the previous experiments, we have used 90% of the data for training and the remaining 10% for testing. We now take a look at how the performance changes with different numbers of training instances. We vary the training data size from only a few instances (2, 5, and 10) to 20%, 40%, 60% and 80% of the entire data set. The results are shown in Figure 1.

As we can expect, when the number of training instances is small, the performance on both data sets is low. The figure also shows that the Wikipedia data set is the more difficult than the NYT data set. This is consistent with our observation in the previous section.

The modified linear-chain CRF model consistently outperforms the baseline linear-chain CRF model. For similar level of performance, the modified linear-chain CRF model requires less training data than the baseline linear-chain CRF model.



(a) New York Times (b) New York Times

(c) Wikipedia (d) Wikipedia

Figure 1: Performance of LC-CRF and M-CRF-3 as the training data size increases.

For example, Figure 1(b) shows that the modified linear-chain CRF model achieve 0.72 F1 with about 215 training instances, while the baseline linear-chain CRF model requires about 480 training instances for a similar F1.

6 Conclusions

In this paper, we studied relation extraction under a new setting: the relation types are defined at a general level but more specific relation descriptors are desired. Based on the special properties of this new task, we found that standard linear-chain CRF models have some potential limitations for this task. We subsequently proposed some modifications to linear-chain CRFs in order to suit our task better. We annotated two data sets to evaluate our methods. The experiments showed that by restricting the space of possible label sequences and introducing certain long-range features, the performance of the modified linear-chain CRF model can perform significantly better than standard linear-chain CRFs.

Currently our work is only based on evaluation on two data sets and on two general relations. In the future we plan to evaluate the methods on other general relations to test its robustness. We also plan to explore how this new relation extraction task can be used within other NLP or text mining applications.

Attribute Extraction from Synthetic Web Search Queries

Marius Paşca
Google Inc.
Mountain View, California 94043
mars@google.com

Abstract

The accuracy and coverage of existing methods for extracting attributes of instances from text in general, and Web search queries in particular, are limited by two main factors: availability of input textual data to which the methods can be applied, and inherent limitations of the underlying assumptions and algorithms being used. This paper proposes a weakly-supervised approach for the acquisition of attributes of instances from input data available in the form of synthetic queries automatically generated from submitted queries. The generated queries allow for the acquisition of additional attributes, leading to extracted lists of attributes of higher quality than with comparable previous methods.

1 Introduction

Motivation: The availability of larger textual data sources has allowed research in information extraction to shift its focus towards robust methods that require little or no annotated data, operate at large scale with lower computational costs, and acquire open-domain information (Banko and Etzioni, 2008). The information is usually targeted at three levels of granularity: classes (e.g., *giant planets*), class elements or instances (e.g., *jupiter*, *uranus*, *saturn*), and relations among instances. Since these types of information would form the backbone of knowledge bases acquired automatically from text (Mooney and Bunescu, 2005), their acquisition has received increased attention over recent years.

Among other types of relations targeted by various extraction methods, attributes (e.g., *escape velocity*, *diameter* and *surface gravity*) have emerged as one of the more popular types, as they capture quantifiable properties of their respective classes (*giant planets*) and instances (*jupiter*). A variety of attribute extraction methods mine textual data sources ranging from unstructured (Tokunaga et al., 2005) or structured (Cafarella et al., 2008) text within Web documents, to human-compiled encyclopedia (Wu et al., 2008; Cui et al., 2009) and Web search query logs (Alfonseca et al., 2010), attempting to extract, for a given class or instance, a ranked list of attributes that is as comprehensive and accurate as possible. The accuracy and coverage of existing methods (Raju et al., 2008; Alfonseca et al., 2010) for extracting attributes of instances are limited by two main factors: availability of input textual data to which the methods can be applied; and inherent limitations of the underlying assumptions and algorithms being used. For example, a simple but effective method was proposed in (Paşca and Van Durme, 2007) for extracting attributes of an instance, by applying a small set of extraction patterns (e.g., *A of I*) to Web search queries (e.g., *"escape velocity of jupiter"*). If the input set of queries increased, additional candidate attributes would be extracted.

Contributions: This paper introduces a weakly-supervised approach for the acquisition of attributes of instances from query logs, by automatically expanding the set of known (organic) queries from which attributes are extracted with additional, inferred (synthetic), not-yet-submitted queries. The focus on expanding the input textual data gives a generally-applicable approach, which can be applied to existing methods for attribute acquisition from query logs, to increase coverage. In particular, the application of previously-proposed extraction patterns (Paşca and Van Durme, 2007)

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 401–409,
Chiang Mai, Thailand, November 8 – 13, 2011.

to the expanded set of queries allows for the acquisition of additional attributes that would otherwise not be acquired only from the set of known queries.

In order to infer new queries, known queries are aggregated into query templates (e.g., *"lyrics of ⋆ beatles"*) associated with known phrase fillers (e.g., ⋆→{*yesterday*, *hey jude*}). The known phrase fillers of each query template are then expanded into new candidate phrase fillers. In contrast to previous work on query generation (Mitkov and Ha, 2006; Heilman and Smith, 2010), new queries are generated based on query analysis alone, as opposed to individual document analysis. This has the potential advantages of scalability and robustness when applied to arbitrary, inherently-noisy queries. Among the inferred queries, the ones of higher interest to attribute extraction are those derived from a query template that fixes either a potential attribute (e.g., *"surface gravity of ⋆"*) or a potential instance (e.g., *"⋆ of jupiter"*). In experiments using a large set of anonymized search queries, the inferred queries allow for the acquisition of accurate attributes over an evaluation set of 75 instances introduced in previous work (Alfonseca et al., 2010).
Applications: Attributes are useful in information retrieval, e.g., for suggesting related queries (Bellare et al., 2007) and recommending products (Probst et al., 2007). They plan an important role in knowledge acquisition and representation (Guarino, 1992), for example as building blocks in the manual compilation of infoboxes in Wikipedia (Remy, 2002). Furthermore, the availability of a larger number of more accurate attributes allows for the development of better search interfaces geared towards structured search. Examples of such interfaces are Wolfram Alpha and Google Squared, two search tools that can take as input instances and return lists of attributes and their values.

2 Attribute Extraction

2.1 Intuitions and Scope

Intuitions: Our attribute extraction method is inspired by several intuitions. First, phrases of the same class (car models, search engines, baseball players etc.) share similar properties or attributes, enter similar relations and satisfy similar constraints. For example, car models have replacement parts, are assembled by some maker in some year, and have an estimated current value. Consequently, known queries that refer to similar phrases may overlap significantly, or even become equal once the phrases have been replaced by a common slot filled by the phrases. Thus, *"kelley blue book value of 2008 dodge charger"* and *"kelley blue book value of 2008 honda civic"* can be grouped into a shared query template *"kelley blue book of 2008 ⋆"*, whose slot ⋆ is filled by the names of car models. Second, known queries that can be grouped into a shared query template often provide a small sample of, rather than comprehensive coverage of, all phrases that would meaningfully fill the template. Therefore, new queries can be generated by filling the slots of query templates with new phrase fillers similar to known fillers. For instance, *"kelley blue book value of 2008 chrysler sebring"* can be inferred as a new candidate query if *chrysler sebring* is known to be similar to *dodge charger* and/or *honda civic*. Third, a new candidate query is meaningful if the new phrase filler is similar to the known fillers not only statically, but also in the context of the query template. This is particularly important for query templates with few, ambiguous phrase fillers. Consider the query template *"lyrics of ⋆ beatles"*, with the known fillers *come together*, *hey jude* and *yesterday*. Although phrases such as *gather together*, *earlier today* and *last friday* are highly similar to the known fillers, they are not meaningful new fillers for *"lyrics of ⋆ beatles"* and would therefore produce spurious new queries. In contrast, *lovely rita* and *here comes the sun* are similar to the known fillers both statically and in the context of the query template.

Scope: Following the above intuitions, attributes can be extracted from generated queries. In turn, generated queries are inferred by essentially replacing phrases from known queries with meaningful, similar phrases. The form (e.g., long and complex, vs. short and simple) and scope (e.g., open-domain vs. domain-specific) of known queries determine the form and scope of inferred queries. While this prevents arbitrarily complex queries from being generated, it has the advantage of homogeneity of new queries relative to known queries. Also, this should have little, if any, impact on extracted attributes, since the latter are actually extracted from queries whose form is relatively simple rather than complex. The scope of new queries is further influenced by the availabil-

ity of new phrases that are similar to phrases from known queries. For example, *chrysler sebring* must be available as a phrase similar to *dodge charger* and/or *honda civic*, in order to potentially generate *"kelley blue book of 2008 chrysler sebring"* from the known queries *"kelley blue book of 2008 dodge charger"* and *"kelley blue book of 2008 honda civic"*.

2.2 Extraction from Generated Queries

Aggregation into Query Templates: The input to the method is a set of Web search queries. As described in (Paşca, 2011), the sequence of terms available in each query is split into all combinations of triples of a prefix, non-empty infix and postfix. Queries that share a common prefix and common postfix are aggregated into a query template, where the input infixes are the known phrase fillers of the template. For example, queries such as *"lyrics of yesterday beatles"* and *"lyrics of come together beatles"* are aggregated into the template *"lyrics of* $\star$ *beatles"*, where the template filler $\star$ corresponds to the set of known phrase fillers, i.e., infixes from the input queries: {*yesterday*, *come together*}. An input query may contribute to the creation of multiple query templates, via different infixes. For example, another template created from *"lyrics of yesterday beatles" "lyrics of yesterday toni braxton"* is *"lyrics of yesterday* $\star$*"*.

Like the subsequent stages of processing, generating all possible infixes of all input queries, especially for large input sets of queries, is a non-trivial computational challenge. However, the computation can be translated into parallelizable operations in a distributed computing framework such as Hadoop (White, 2010) or MapReduce (Dean and Ghemawat, 2004). In particular, the aggregation of queries into templates can be performed in a single MapReduce step. The mapper takes as input queries, and splits them into one or more mappings from a query template (key) to a corresponding infix, i.e., a known phrase filler (value). For each query template, the reducer simply aggregates its phrase fillers into a set.

Generation of Candidate Phrase Fillers: In order to generate new queries, the set of known phrase fillers is expanded into additional candidate phrases that may fill the query template. As a prerequisite to generating candidate phrase fillers, distributionally similar phrases (Lin and Pantel, 2002; Lin and Wu, 2009; Pantel et al., 2009) and their scores are collected in advance. The assumption is that phrases that appear in similar contexts have similar meanings. A phrase is represented as a vector of its contextual features. A feature is a token, collected from windows of three tokens centered around the occurrences of the phrase in sentences across Web documents (Lin and Wu, 2009). Alternatively, the context could be approximated via linguistic dependencies detected with noun chunking (Pantel et al., 2009) and syntactic parsing (Lin and Pantel, 2002). In the contextual vector of a phrase, the weight of a feature is the pointwise-mutual information (Lin and Wu, 2009) between the phrase P and the feature F:

$$PMI(P,F) = \log \frac{Freq(P,F) \times N}{Freq(P) \times Freq(F)} \quad (1)$$

where $Freq(P,F)$ is the frequency of the feature F occurring with the phrase P, and N is the feature vocabulary size. The distributional similarity score between two phrases P_1 and P_2 is the cosine similarity between the contextual vectors of the two phrases. Alternatively, vector similarity could be computed via the Jaccard or Dice coefficients (Pantel et al., 2009). The lists $DS(P)$ of most distributionally similar phrases of a phrase P are thus compiled offline, by ranking the similar phrases of P in decreasing order of their $DSscore$ relative to P.

The most distributionally similar (Lin and Pantel, 2002; Pantel et al., 2009) phrases, of a known phrase filler K_i from a query template T, are considered to be candidate phrase filler U of the respective query template. The score of a candidate relative to the entire set of known fillers is the average of the distributional similarity scores between the candidate and each known filler. For each template T, its candidate phrase fillers U are ranked in decreasing order of their scores. Known phrase fillers of T are discarded from the resulting list of candidate phrase fillers of T.

The generation of candidate phrase fillers translates into two MapReduce steps. The first step rearranges the mappings from a query template to a set of known phrase fillers, into mappings from a known phrase filler to a set of query templates. Concretely, the mapper takes as input mappings from a query template (key) to its set of known phrase fillers (value), as they were output after the aggregation into query templates. The mapper emits mappings from a known phrase filler (key)

to a query template (value). For each phrase filler, the reducer aggregates its query templates into a set. The second MapReduce step takes this data, and joins it with distributional similarity data. The latter is available as mappings from a phrase (key) to a list of scored similar phrases (value). The mapper selects similar phrases as candidate phrase fillers for the template, as explained earlier. The output of the second step consists in mappings from a query template (key) to its set of known phrase fillers, as well as to a list of scored candidate phrase fillers (value).

Filtering of Candidate Phrase Fillers: Candidate phrase fillers generated via distributional similarities are similar to known phrases only statically. To also take the context of the query template into account, the candidates are filtered using the input queries. More precisely, the list of candidate phrases of a query template T is filtered, by retaining only known phrases of some other templates T' that are equivalent to T. Templates are deemed equivalent if they become identical after removal of stop words and other linking particles (prepositions, conjunctions etc.), term stemming and term reordering. For example, if the unfiltered candidate phrase *eleanor rigby* for the template *"lyrics of ⋆ beatles"* appears as a known phrase filler of the template *"lyrics for ⋆ by the beatles"*, then *eleanor rigby* is retained after filtering for the template *"lyrics of ⋆ beatles"*.

The filtering of candidate phrases using equivalent templates is modeled as two MapReduce steps. The first step takes as input mappings from a query template (key) to its set of known phrase fillers and list of scored candidate phrase fillers (value), as they were output after the generation of candidate phrase fillers. The mapper converts the query template into the corresponding equivalent template that contains the individual terms in lexicographic order. It emits mappings from an equivalent template (key), to a query template with its set of known phrase fillers and its list of scored candidate phrase fillers (value). For each equivalent template, the reducer simply aggregates this data. The second step takes as input mappings from an equivalent template (key) to its query templates with their sets of known phrase fillers and lists of scored candidate phrase fillers (value). For each equivalent template, the mapper iterates over its query templates. It checks which of its candidate phrase fillers occur among the known phrase fillers of the other query templates. The candidate phrase fillers that pass this test are retained as filtered phrase fillers. The mapper emits mappings from a query template (key) to its set of known phrase fillers, list of scored unfiltered phrase fillers, and list of scored filtered phrase fillers. The reducer merely emits its input, without modifications.

The relative ranking of candidate phrases from the list of inferred unfiltered phrase fillers (before filtering) is preserved in the list of inferred filtered phrase fillers (after filtering). Each filtered phrase filler inferred for a query template corresponds to a new query, generated by filling the phrase into the slot filler of the query template.

Attribute Extraction: Extraction patterns such as *"A of I"*, introduced in previous work (Paşca and Van Durme, 2007) to extract a candidate attribute A for a candidate instance I from queries, can be immediately applied to inferred queries. Thus, additional candidate attributes can be extracted from inferred queries, where the inferred queries are obtained via two types of query templates:

• query templates that specify a potential instance, and leave the attribute (e.g., A in *"A of I"*) as a phrase filler being inferred:

surface gravity of jupiter
europa of jupiter
composition of atmosphere of jupiter
father of jupiter

} "⋆ of jupiter"

Each inferred phrase filler (e.g., *core temperature*, *luminosity*) is collected as a candidate attribute of the phrase specified in the query template (*jupiter*). In this case, attribute extraction is equivalent to transferring an instance associated with a noisy set of attributes that are known phrase fillers of a template, to be associated with new attributes that are inferred phrase fillers of the template.

• query templates that specify a potential attribute, and leave the instance (e.g., I in *"A of I"*) as a phrase filler being inferred:

mass of positronium
mass of planets in order
mass of steel beams
mass of planet uranus

} "mass of ⋆"

For each inferred phrase filler (e.g., *cesium 137*, *water drop*), the phrase specified in the query template (*mass*) is collected as a candidate attribute. In this case, attribute extraction is equivalent to transferring an attribute associated with a noisy set

Phrase	Ranked List Available in Data Repository
caesium	[cesium, rubidium, strontium, barium, thallium, lanthanum, potassium, cerium, yttrium, bismuth, indium, gallium, europium, cadmium, antimony, ammonium,..]
ch3br	[ch3cl, ch4, nh3, ch 4, c2h4, ch3i, nh 3, ch3oh, c2h2, ch3f, c2h6, hcho, no2, h2s, hcn, ch30h, n2o, n20, ch3cn, hcooh, ethane, cc14, ethene, propene, hzo, c02, ch3sh, chbr3,..]
exxon valdez	[torrey canyon, amoco cadiz, sea empress, braer, 1989 exxon valdez, valdez oil, exxon valdez oil tanker, chernobyl nuclear, cosco busan, valdez oil spill, chernobyl,..]

medal	[congressional medal of honor, navy cross, distinguished service cross, victoria cross, distinguished flying cross,air force cross, bronze star, purple heart, soldier's medal, medal honor, military cross,..]
men and women	[women and men, men and woman, males and females, men & women, young men, women, people, men, individuals, boys and girls, girls and boys, adults, sexes, females and males,..]
nerve	[ganglion, preganglionic, postganglionic, peripheral nerve, sciatic, sciatic nerve, axon, afferent, nerve root, dorsal root, ganglionic, vagus, trigeminal, median nerve,..]
yesterday	[last week, earlier today, last friday, last night, two days ago, yesturday, last thursday, earlier this week, just yesterday, last wednesday, yesteday, last monday, last month, two weeks ago,..]
whey	[protein powder, whey protein isolate, whey protein powder, soy protein, whey isolate, protein whey, casein protein, creatine, creatine monohydrate, isopure,..]

Table 1: Examples of ranked lists of similar phrases, available in the phrase similarity repository for various phrases

of instances that are known phrase fillers of a template, to be associated with new instances that are inferred phrase fillers of the template.

Regardless of whether they are specified manually or derived automatically, extraction patterns used in information extraction are imperfect (Kozareva et al., 2008). The pattern *A of I* for attribute extraction is no exception. The two types of query templates from above have known phrase fillers that are not true attributes (e.g., *europa* for the instance *jupiter*) and instances (e.g., *planets in order* for the attribute *mass*) respectively. This phenomenon is not a defect of this particular approach, but is inherited from and shared with any methods using such patterns for attribute extraction, as well as with any methods that rely on seed attributes, when the seeds are noisy rather than clean.

Attribute Ranking: As explained earlier, the score of an inferred phrase filler is computed as the average of similarity scores relative to known phrase fillers. The score is assigned to the pair of an attribute and instance extracted from the phrase filler. Attributes extracted for an instance are ranked in decreasing order of the scores.

3 Experimental Setting

Textual Data Sources: The acquisition of instance attributes relies on a random sample of around 100 million fully-anonymized queries in English submitted by Web users in 2010. Each query is accompanied by its frequency of occurrence in the query logs.

A phrase similarity repository is derived following (Pantel et al., 2009), from unstructured text available within a sample of around 200 million documents in English. The repository provides data for each of around 1 million phrases that occur as full-length queries in the input query logs. It contains ranked lists of the top 200 phrases computed to be the most distributionally similar, for each phrase. Table 1 illustrates the actual

aaa, ac compressors, acheron, acrocyanosis, adelaide cbd, african population, agua caliente casino, al hirschfeld, alessandro nesta, american fascism, american society for horticultural science, ancient babylonia, angioplasty, annapolis harbor, antarctic region, arlene martel, arrabiata sauce, artificial intelligence, bangla music, baquba, bb gun, berkshire hathaway, bicalutamide, blue jay, boulder colorado, brittle star, capsicum, carbonate, carotid arteries, chester arthur, christian songs, cloxacillin, cobol, communicable diseases, contemporary art, cortex, ct scan, digital fortress, eartha kitt, eating disorders, file sharing, final fantasy vii, forensics, habbo hotel, halogens, halophytes, ho chi minh trail, icici prudential, jane fonda, juan carlos, karlsruhe, kidney stones, lipoma, loss of appetite, lucky ali, majorca, martin frobisher, mexico city, pancho villa, phosphorus, playing cards, prednisone, right to vote, robotics, rouen, scientific revolution, self-esteem, spandex, strattera, u.s., vida guerra, visual basic, web hosting, windsurfing, wlan

Table 2: Set of 75 target instances, used in the evaluation of instance attribute extraction

ranked lists available in the repository for various phrases. The underlying similarity score between two phrases is the cosine between their vectors of context windows.

Target Instances: The performance of attribute extraction is computed over a standard set of 75 instances, previously introduced in (Alfonseca et al., 2010). As shown in Table 2, the set of instances ensures varied experimentation across multiple domains.

Experimental Runs: The experiments consist of several individual runs. Runs R_U and R_F acquire attributes from queries inferred via the first type of target query templates (e.g., *"⋆ of jupiter"*), before filtering (R_U) and after filtering (R_F). Run R_I uses queries inferred via the second type of target query templates (e.g., *"mass of ⋆"*), after filtering.

In order to compare with existing work, a previous extraction method from (Paşca and Van Durme, 2007), which uses extraction patterns, is implemented in a baseline run R_P. For consistency, the data source to the run R_P is the same set of input queries described at the beginning of the section.

Label	Value	Examples of Attributes
vital	1.0	capsicum: calorie count
		cloxacillin: side effects
		lucky ali: album songs
okay	0.5	jane fonda: musical theatre contributions
		mexico city: cathedral
		robotics: three laws
wrong	0.0	acheron: kingdom
		berkshire hathaway: tax exclusion
		contemporary art: urban institute

Table 3: Correctness labels manually assigned to attributes extracted for various instances

The per-instance ranked lists of attributes produced by the individual runs from above are concatenated in a series of combination runs. For example, run R_{FP} concatenates the attributes output by R_F and by R_P, in this order.

Evaluation Procedure: The evaluation focuses on the assessment of accuracy of the ranked list of attributes generated for each instance. To remove any undesirable bias towards higher-ranked attributes, the attributes of each list to be evaluated are sorted alphabetically into a merged list. Each attribute of the merged list is manually assigned a correctness label relative to its respective instance. In accordance with previously introduced methodology, an attribute is *vital* if it must be present in an ideal list of attributes of the instance (e.g., *side effects* for *cloxacillin*); *okay* if it provides useful but non-essential information; and *wrong* if it is incorrect (Paşca, 2007). Thus, a correctness label is manually assigned to a total of 4,833 attributes extracted for the 75 target instances.

To compute the precision score over a ranked list of attributes, the correctness labels are converted to numeric values (*vital* to 1, *okay* to 0.5 and *wrong* to 0), as shown in Table 3. Precision at some rank N in the list is measured as the sum of the correctness values of the attributes extracted up to rank N, divided by the number of those attributes.

4 Evaluation Results

Attribute Accuracy: Table 4 compares precision at various ranks, in the ranked lists of attributes

Run	Precision of Ranked Attributes				
	@1	@5	@10	@20	@50
Average (over all):					
R_P	0.61	**0.65**	**0.65**	**0.67**	**0.65**
R_I	0.61	0.62	0.60	0.61	0.60
R_U	0.45	0.37	0.33	0.31	0.30
R_F	0.64	0.58	0.57	0.55	0.51
R_{IP}	0.68	0.68	0.67	0.67	0.66
R_{IF}	0.64	0.64	0.63	0.64	0.62
R_{FP}	**0.77**	**0.69**	**0.68**	**0.65**	**0.62**
R_{FI}	**0.77**	**0.69**	**0.68**	**0.65**	**0.62**
Average (over non-empty):					
R_P	0.66	0.71	0.71	0.73	0.71
R_I	0.67	0.67	0.65	0.67	0.65
R_U	0.59	0.48	0.43	0.41	0.38
R_F	**0.83**	**0.75**	**0.74**	**0.71**	**0.66**
R_{IP}	0.69	0.69	0.67	0.68	**0.67**
R_{IF}	0.68	0.68	0.66	0.67	0.66
R_{FP}	**0.83**	**0.74**	**0.72**	**0.70**	**0.67**
R_{FI}	0.81	0.73	**0.72**	0.69	0.65

Table 4: Comparative accuracy of the ranked lists of attributes extracted in various runs, as an average over the entire set of 75 instances; and as an average over the (variable) subsets of instances for which some attributes were extracted

extracted by various runs. In the upper half of the table, average precision scores penalize instances for which no attributes are extracted. In contrast, the average scores in the lower half of the table only consider the instances for which some attributes are extracted.

The runs R_I, R_U and R_F operate directly over generated queries. One of the two types of query templates that produce attributes performs better, as illustrated by lower scores with R_F than with R_I. The difference in scores between R_U and R_F, which are about twice as high at rank 50 for the latter, illustrates the positive impact of filtering the candidate phrase fillers inferred from the query templates.

The benefit of combining the output from individual runs is illustrated by the generally higher scores given by combination runs in Table 4, relative to individual runs that they combine. Among combination runs, R_{FP} gives the highest scores at most ranks. When considering the accuracy of all runs, the highest scores over the entire evaluation set of instances are given by the combination run R_{FP}. Over subsets of instances with non-empty attribute lists, the accuracy of the individual run R_F is higher than all other individual runs, at par with the combination run R_{FP}. Table 5 shows the ranked lists of attributes extracted by R_F for a sample of instances.

Instance	[Ranked List of Inferred Attributes]
aaa	[symptoms, epidemiology, differential diagnosis, mortality, risk, surgical repair, stenting, resection, benefits, stent placement,..]
ac compressors	[manufacturer]
berkshire hathaway	[net asset value, closing price, total assets, dividend yield, par value, fair value, shares outstanding, class a shares, current price, common stock,..]
martin frobisher	[time line, routes, voyage, bibliography, explorations, ships, discoveries, travel,..]
scientific revolution	[negative effects, social impacts, social impact, theories, positive effects, accomplishments, long term effects, influences, cause and effects, scientific discoveries,..]
wlan	[limitations, risks, architectures, benefits, configurations, throughput, concepts, config, physical layer, security vulnerabilities,..]

Table 5: Examples of ranked lists of attributes extracted in run R_F from inferred filtered queries. None of these attributes are extracted for the respective instances in the baseline run R_P

5 Related Work

Previous work on attribute extraction uses a variety of types of textual data as sources for mining attributes. Taking advantage of structured and semi-structured text available within Web documents, the method introduced in (Yoshinaga and Torisawa, 2007) assembles and submits list-seeking queries to general-purpose Web search engines, and analyzes the retrieved documents to identify common structural (HTML) patterns

around class labels given as input, and potential attributes. Similarly, layout (e.g., font color and size) and other HTML tags serve as clues to acquire attributes from either domain-specific documents such as those from product and auction Web sites (Wong et al., 2008) or from arbitrary documents, optionally relying on the presence of explicit itemized lists or tables (Cafarella et al., 2008). As an alternative to Web documents, articles within online encyclopedia can also be exploited as sources of structured text for attribute extraction, as illustrated by previous work using infoboxes and category labels (Suchanek et al., 2007; Nastase and Strube, 2008; Wu and Weld, 2008) associated with articles within Wikipedia.

Working with unstructured text within Web documents, the method described in (Tokunaga et al., 2005) applies manually-created lexico-syntactic patterns to document sentences in order to extract candidate attributes, given various class labels as input. The candidate attributes are ranked using several frequency statistics. If the documents are domain-specific, such as documents containing product reviews, additional heuristically-motivated filters and scoring metrics can be used to extract and rank the attributes (Raju et al., 2008). In (Bellare et al., 2007), the extraction is guided by a small set of manually-provided seed instances and attributes rather than manually-created patterns, with the purpose of generating training data and extract new pairs of instances and attributes from text.

Web search queries have also been considered as a textual data source for attribute extraction, using extraction patterns (Paşca and Van Durme, 2007) or seed attributes (Paşca, 2007) to guide the extraction, and leading to attributes of higher accuracy than those extracted with equivalent techniques from Web documents. If the input data includes query sessions in addition to sets of search queries, extracted attributes have higher quality (Paşca et al., 2010). Given an instance (e.g., *nissan gt-r*) and a numerical attribute (e.g., *width*) extracted with a method like ours, the acquisition of the corresponding values (e.g., *1.9m*) is the aim of other research endeavors (Davidov and Rappoport, 2010; Bakalov et al., 2011).

6 Conclusion

The role of Web search queries in information extraction has been previously explored. In this paper, synthetic search queries inferred from existing queries are used to acquire attributes. The queries lead to ranked lists of attributes whose accuracy is higher than with equivalent methods operating over queries. Current work investigates alternative methods for combining attributes from multiple individual runs; the expansion of the target query templates used to extract attributes; and further applications of the inferred queries, in information extraction and beyond.

Abstract

A novel reranking method has been developed to refine web search queries. A label propagation algorithm was applied on a clickthrough graph, and the candidates were reranked using a query language model. Our method first enumerates query candidates with common landing pages with regard to the given query to create a clickthrough graph. Second, it calculates the likelihood of the candidates, using a language model generated from web search query logs. Finally, the candidates are sorted by the score calculated from the likelihood and label propagation. As a result, high precision and coverage were achieved in the task of Japanese abbreviation expansion, without using handcrafted training data.

1 Introduction

The query expansion technique has been widely used in recent web-search engines. Query expansion significantly improves recall in information retrieval operations. It uses a thesaurus or synonym dictionary to reformulate a query, or to correct spelling errors in search queries.

In the early days of the speller, the dictionary was manually compiled by lexicographers. However, it is time consuming to construct a broad coverage dictionary, and domain knowledge is required to achieve high quality. Moreover, the rapid growth of the web makes it even harder to maintain an up-to-date dictionary for the web.

To alleviate this problem, web-search engines often exploit web search query logs to automatically generate a thesaurus. A web search query is a query that a web user types into a web search engine to find information. It is noisy and sometimes ambiguous to detect query intent, but it is a great way to create a fresh web dictionary at low cost. Hence, the web search queries are widely used in the NLP field. For instance, Hagiwara and Suzuki (2009) used them for a query alteration task, and Sekine and Suzuki (2007) leveraged them for acquiring semantic categories.

More recently, web search clickthrough logs have been explored in the field of lexical acquisition. A web clickthrough is the process of clicking a URL and going to the page it refers. This ensures that the landing page is appropriate since the web user follows the hyperlink after checking the information displayed, such as 'title', 'URL', and 'summary' of their search. Two distinct queries landing on the same 'URL' are possibly input for the same purpose, meaning that they are likely to be related. In the NLP literature, clickthrough logs have been used to learn semantic categories (Komachi et al., 2009) and named entities (Jain and Pennacchiotti, 2010).

The main contribution of this work is two fold:

- We propose a novel method to combine web search query logs and clickthrough logs.
- To the best our knowledge, this work is the first attempt to automatically recognize full spellings given Japanese abbreviations.

This is a very first step of Japanese abbreviation expansion task using search logs.

For evaluation of query expansion method, it is desirable to use a set of queries for evaluation.

However, it is difficult to obtain them beforehand, because we have to check query logs to find incorrect queries and make necessary changes to define their corrections.

Therefore, in this paper, we focus on query abbreviation and evaluate our proposed approach in an abbreviation expansion task. Abbreviation expansion itself is difficult for many query expansion methods based on edit distance, because the input and output have only a few, if any, characters in common. Our clickthroughlog-based approach can expand even queries that do not share any characters at all with the abbreviated ones [1]. Since our method does not rely on any language, it is applicable to any other languages including Chinese and English.

The rest of this paper is organized as follows. Section 2 describes previous works in query expansion tasks. In Section 3, we formulate a query expansion task in a noisy channel model framework. In Section 4, we show that label propagation on a clickthrough graph can be used as a query abbreviation model and extract candidates for query correction without preparing correct candidates. Section 5 explains the query language model we use. In Section 6, we evaluate our method in an abbreviation expansion task and show its efficiency. Section 7 offers conclusions and directions for future work.

2 Related Work

Query expansion for a web-search query has to handle neologisms and slang on the web. Thus, it is labor-intensive to maintain a list of correctly spelled words for search queries. Additionally, Japanese query expansion includes several tasks, such as word segmentation, word stemming, and acronym expansion. Much of the previous work has focused on each individual task (Ahmad and Kondrak, 2005; Chen et al., 2007; Bergsma and Wang, 2007; Li et al., 2006; Peng et al., 2007; Risvik et al., 2003).

Cucerzan and Brill (2004) clarified problems of spelling correction for search queries, addressing them using a noisy channel model with a language model created from query logs. Gao et al. (2010) and Sun et al. (2010) applied a reranking method applying neural net to the search-query spelling correction candidates obtained from the Cucerzan's method. Their reranking method had the advantageous ability to incorporate clickthrough logs to a translation model learned as a ranking-feature. However, their methods are based on edit distance, and thus they did not deal with the task of synonym replacement and acronym expansion.

Wei et al. (2009) addressed synonym extraction using similarity based on Jensen-Shannon divergence of commonly clicked URL distribution between queries. Their approach is similar to our proposed method, except that they did not use a language model. Also, their method is not scalable and cannot be applied to our task using large-scale data.

Jain and Pennacchiotti (2010) proposed an unsupervised method for named entity extraction from web search query logs. They performed a clustering method using a combination of features based on query logs, web documents, and clickthrough logs. They showed that clickthrough logs give higher accuracy than query logs as a corpus.

Guo et al. (2008) proposed a unified approach for query expansion using a discriminative model. They extended feature function of CRFs (Lafferty et al., 2001) by adding 'operation' to the triplet variables: 'feature', 'label', and 'operation'. 'Operation' represents a process for query expansion. For example, 'operation' can take four states ('deletion', 'insertion', 'substitution', and 'transposition') on spelling correction. However, their method needs supervised data for training and cannot deal with a word that does not occur in the corpus. In fact, they used only 10,000 queries to learn the query expansion model. Unlike their method, our approach takes advantage of an enormous amount of clickthrough logs for learning the query abbreviation model.

Query suggestion is another task that uses search logs (Mei et al., 2008; Cao et al., 2008). Query suggestion differs from our task in that it allows queries to be suggested that are different from the one that the search user types.

Furthermore, some previous works have addressed acquiring a Japanese abbreviation task. Murayama and Okumura (2008) formulated the process of generating Japanese abbreviations by noisy channel model but they did not handle abbreviation expansion. Okazaki et al. (2008) dealt with recognizing Japanese abbreviation tasks as a binary classification problem. They extracted

[1] Note that our method can be applied to query expansion as well.

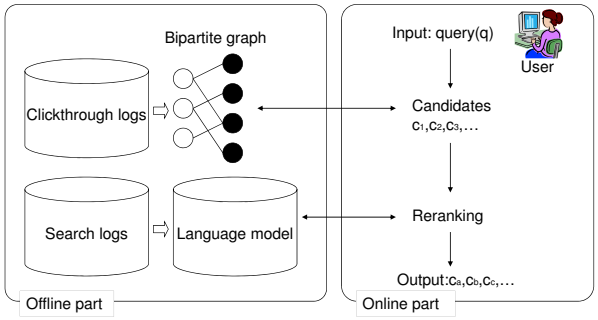

Figure 1: Combining clickthrough logs and search logs for query abbreviation expansion

pairs of words from the newspaper corpus using a heuristic and then classified them as "abbreviation" or "not-abbreviation". However, their heuristic for obtaining abbreviation candidates cannot be applied to web search queries.

3 Noisy Channel Model for Abbreviation Expansion

In this section, we explain our noisy channel based approach to query expansion. We define the query expansion problem as follows: Given a user's query q and a set of search logs L, find a correct query $c \in C$ that is most relevant to the input q. In a probabilistic framework, this can be formulated as finding the $\mathrm{argmax}\, P(c|q)$. Applying Bayes' Rule and dropping the constant denominator, we obtain a unnormalized posterior: $\mathrm{argmax}\, P(c)P(q|c)$(Eq.1). We now have a noisy channel model for query expansion, with two components: the source model $P(c)$ and the channel model $P(q|c)$.

$$\begin{aligned} c^* &= \underset{c}{\mathrm{argmax}}\, P(c|q) \\ &= \underset{c}{\mathrm{argmax}}\, \frac{P(c)P(q|c)}{P(q)} \\ &= \underset{c}{\mathrm{argmax}}\, P(c)P(q|c) \end{aligned} \quad (1)$$

We use a language model estimated from search query logs as the source model, thus $P(c)$ represents likelihood of c as a query. As for the channel model, we use a label propagation method on a clickthrough graph as proposed by Komachi et al. (2009). Figure 1 shows the framework of our approach.

To find candidates to the input query, we construct a bipartite graph from a query and a clicked URL using the web search logs. We calculate the relatedness between the queries on this graph to select a set of candidates C. Since the label propagation is mathematically identical to the random walk with restart, probability of the label propagation can be regarded as the conditional probability $P(q|c)$. If we assume that the relatedness score represents the conditional probability of the typed query q given a candidate $c \in C$, $P(q|c)$, the c^* is calculated by $\mathrm{argmax}\, P(c) \times P(q|c)$. As a consequence, we propose reranking in accordance with the follow equation using two probabilistic models P_{QLM} and P_{LP} and then output ranked candidates. In this paper, we will define P_{LP} interchangeably as a query abbreviation model, P_{QAM}.

$$score(q, c) = P_{QLM}(c) \times P_{QAM}(q|c) \quad (2)$$

An advantage of our proposed method is that it can correct a query by only using search logs without a manually labeled-corpora or any heuristics. Our approach is a versatile framework for query expansion and thus is not specialized for any tasks. We explain the label propagation algorithm on a clickthrough graph and the query language model below.

4 Query Abbreviation Model from Clickthrough Logs

In this section, we describe a label propagation algorithm on a clickthrough graph. It is based on a previous work by Komachi et al. (2009). The main difference between their method and ours is that we use the normalized pointwise mutual information and the 1-step approximation of a clickthrough graph.

Graph-based semi-supervised methods such as label propagation can performance well with only a few seeds and scale up to a large dataset. Figure 2 illustrates the process of label propagation using a seed term "abc".

This is a bipartite graph whose left-hand side nodes are terms and right-hand side nodes are patterns. Starting from "abc", the label propagates to other term nodes through the pattern "http://abcnews.go.com" that is strongly connected to "abc" and thus the label "abc" will be propagated to "american broadcasting corporation".

In this way, label propagation gradually propagates the label of the seed instance to neighboring

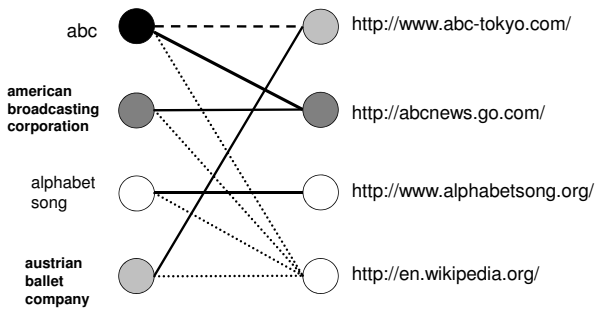

Figure 2: An illustrative example of Instance-Pattern co-occurrence graph and label propagation process.
The strength of lines indicates relatedness between each node, whereas the depth of the color of nodes represents relatedness to the seed. The darker a left-hand side node, the more likely it is similar to "abc". The darker a right-hand side node, the more likely it is the characteristic pattern of "abc".

nodes, and optimal labels are given as the labels at which the label propagation process has converged.

However, the seed instance like that in Figure 2 possibly causes a result to be worse in a task of lexical acquisition, due to an ambiguous instance "abc", which belongs to more than one domain, e.g. "mass media" and "dance". It is expected that the label propagates to unrelated instances if we have highly frequent ambiguous nodes. This problem is called "semantic drift" and has received a lot of attention in NLP research (Komachi et al., 2008).

Komachi et al. (2008) have reported that bootstrapping algorithms like Espresso (Pantel and Pennacchiotti, 2006) can be viewed as Kleinberg's HITS algorithm (Kleinberg, 1999) and the "semantic drift" problem on the graph is the same phenomenon as "topic drift" in HITS, which converges to the eigenvector of the instance-instance similarity graph created from instance-pattern co-occurrence graph as described in the next subsection.

Our label propagation method based on Komachi et al. (2009) can be used as a relatedness measure that returns a similarity score relative to the seed instance, and thus is suitable for a query correction task.

Input：
Seed instance vector $F(0)$
Instance similarity matrix A
Output：
Instance score vector $F(t)$
1: Construct the normalized Laplacian matrix
$L = I - D^{-1/2}AD^{-1/2}$
2: Iterate
$F(t+1) = \alpha(-L)F(t) + (1-\alpha)F(0)$
until convergence

Figure 3: Laplacian label propagation

4.1 One-step approximation of clickthrough graph

In this paper, we extract queries landing on the same URL as the one related with input query by stopping label propagation after 1-hop. These queries are possibly synonyms with the input query and thus possible to correct without semantic transformation.

Figure 3 shows the label propagation algorithm on a clickthrough graph.

Given an instance set $\mathcal{X} = \{x_1, \ldots, x_l, x_{l+1}, \ldots, x_n\}$ and a label set $\mathcal{L} = \{1, ..., c\}$, the first l instances x_i $(i < l)$ are labeled as $y_i \in \mathcal{L}$. The goal is to predict the labels of the unlabeled instances x_u $(l+1 \leq u \leq n)$.

Let $\mathcal{F}$ denote the set of $n \times c$ matrices with nonnegative entries. A matrix $F = [F_1, \ldots, F_n]^T \in \mathcal{F}$ corresponds to a classification on the dataset $\mathcal{X}$ by labeling each instance x_i as a label $y_i = argmax_{j \leq c} F_{ij}$. Define F_0 as the initial F with $F_{ij} = 1$ if x_i is labeled as a label $y_i = j$ and $F_{ij} = 0$ otherwise. The (i,j)-th element of the final matrix F represents a similarity to the labeled instances. We use these similarities as $P(q|c)$ in Equation 2, where q is a seed instance, c is a labeled instance by label propagation.

The instance-instance similarity matrix A in Figure 3 is defined as $A = W^T W$ where W is an instance-pattern matrix. The (i,j)-th element of W_{ij} contains the relative frequency of occurrence of instance x_i and pattern p_j.

D is a diagonal degree matrix of A where the (i,j)-th element of D is given as $D_{ii} = \sum_j A_{ij}$. Label propagation has a parameter α $(0 \leq \alpha \leq \lambda^{-1}$, where λ is a principal eigenvalue of normalized Laplacian matrix $L)$ that controls the effect of clamping the label distribution of labeled data.

4.2 Normalized PMI

Komachi et al. (2009) suggested that the normalized frequency causes semantic drift (Jurafsky and Martin, 2009), and we confirmed this phenomenon in our preliminary experiment. They suggested using relative frequency such as pointwise mutual information (PMI) and log-likelihood ratio as countermeasure against semantic drift. Therefore, we used pointwise mutual information (PMI) shown below to handle the aforementioned semantic drift problem.

$$PMI(x,p) = ln\frac{P(x,p)}{P(x)P(p)} \tag{3}$$

PMI assigns high scores to low-frequency events. Moreover, using PMI naively makes sparse matrix W dense. Therefore, we used normalized PMI (NPMI) (Bouma, 2009) below as the relative frequency and cut off the values lower than a threshold θ ($\theta \geq 0$).

$$NPMI(x,p) = \left\{ ln\frac{P(x,p)}{P(x)P(p)} \right\} \Big/ -lnP(x,p) \tag{4}$$

$$W_{ij} = \begin{cases} NPMI(x_i,p_j) & (NPMI(x_i,p_j) > \theta) \\ 0 & (NPMI(x_i,p_j) \leq \theta) \end{cases}$$
$$, (\theta \geq 0) \tag{5}$$

NPMI prevents low-frequency events from being assigned scores that are too high by dividing by $-lnP(x,p)$ and heads off excess label propagation through them. By cutting off negative values, the range of W_{ij} can be normalized to [0,1]. Additionally, this prevents sparse matrix W from being dense and reduces the noise in the data.

5 Query Language Model

In this paper, we use a character n-gram language model to obtain the likelihood of the candidates for query expansion in Equation 2.

$$\begin{aligned} P(c) &= \prod_{i=0}^{N-1} P(x_i | x_{i-N+1}, \ldots, x_{i-1}) \\ &= \prod_{i=0}^{N-1} \frac{freq(x_{i-N+1}, \ldots, x_i)}{freq(x_{i-N+1}, \ldots, x_{i-1})} \end{aligned} \tag{6}$$

where consider c is a contiguous sequences of N characters $c = \{x_0, x_1, \ldots, x_{n-1}\}$.

In the web search, neologims appear continuously, which make it hard to compute the likelihood of queries by a word n-gram language model. Moreover, characters themselves carry essential semantic information in Chinese and Japanese. Therefore, we build a character language model for the search query logs following observations of the usefulness of character n-grams for Japanese (Asahara and Matsumoto, 2004) and Chinese (Huang and Zhao, 2006). Asahara and Matsumoto used a window of two characters to the right and to the left of the focus character, which results in using character 5-grams. We also used 5-grams for a query language model from the preliminary experiment.

6 Experiment

6.1 Test Set

We collected abbreviations of *'Acronym'*, *'Kanji'*, *'Kana'* from the Japanese version of Wikipedia, and then removed single letters and duplications. Finally, we gathered 1,916 terms and used them in our evaluation.

6.2 Construction of a Clickthrough Graph

We used queries and clicked links in Japanese clickthrough logs as instances and patterns, respectively. We tallied them in the below conditions.

1. Query and clickthrough are unique with respect to each cookie each day.
   If a user input the same query and clicked the same URL any number of times, we do not count it as occurring multiple times, i.e. we do not increase the number of clickthrough.

2. Alphanumeric characters in a query are unified to one-byte lower-case characters

3. A sequence of white space in a query is unified to single one-byte white space character

4. All the URLs included in clickthrough logs are unique, i.e., we did not generalize URLs as Tseng et al. (2009) did.

The Japanese clickthrough logs were collected from October 22 to November 9, 2009 [2] and from January 1 to 16 in Yahoo Japan web search logs.

[2] A storage device in our experimental environment became full when tallying clickthrough logs. As a result, we were not able to use clickthrough logs of some periods.

Links clicked less than 10 times were removed for efficiency reasons. Finally, we obtained 4,428,430 nodes, 16,841,683 patterns, and 16,988,516 edges.

The threshold θ of elements W_{ij} was set to 0.1 on the basis of preliminary experimental results.

The parameter α for label propagation was set to 0.0001.

6.3 Construction of Query Language Model

We used web search query logs for constructing a language model. The search query logs were collected from August 1, 2009, to January 27, 2010, in Yahoo Japan web search logs. We removed queries that occurred fewer than 10 times. Finally, we obtained 52,399,621 unique queries as a training corpus.

In this experiment, we constructed a character 5-gram language model using the query logs, all normalized by the length of the candidate's string.

6.4 Evaluation

The system output was shown to five search evaluation specialists. We evaluated all systems using *precision* and *coverage at k*. Coverage is defined as the percentage of queries for which the system returned at least one relevant query. Precision at k is the number of relevant queries amongst the top k returned. They are computed as follows:

$$precision = \frac{\text{\# of correct output at rank } k}{\text{Number of output at rank } k},$$
$$coverage = \frac{\text{\# of queries for which the system gives at least one correct output}}{\text{Number of all input queries}} \quad (7)$$

In our experiment, the average number of candidates for each query is about 53. Therefore, we extracted 50 candidates from clickthrough logs and then reranked using three methods:

1. Ranking using abbreviation model (AM) only
2. Ranking using language model (LM) only
3. Ranking using both language model and abbreviation model.

Micro average of edit distance between input abbreviations and its correct expansions is 4.03, while the average length of queries is 3.01. These statistics show that input queries should be replaced by totally different characters and it is difficult to use edit distance for extracting correct candidates from web search logs. This is another reason clickthrough logs are essential to the query abbreviation task.

6.4.1 Judgment Guideline

We describe our guidelines to judge system outputs below. We defined four correction patterns for abbreviation expansion:

1. acronym for its English expansion
2. acronym for its Japanese orthography [4]
3. Japanese abbreviation for its Japanese orthography
4. Japanese abbreviation for its English orthography

We collected abbreviation/expansion pairs if and only if they were one of these three types: (1) named entity, (2) common expression, (3) Japanese meaning of the common expression.

Table 1 shows examples of each correction pattern along with its output type.

Ambiguous cases were discarded in the study as exceptions after discussion with experts. To calculate the agreement rate, system outputs for a hundred randomly sampled queries from test set were evaluated by two judges. The agreement rate of judgment of abbreviation/expansion pair is 47.0 percentage and Cohen's kappa measure $\kappa = 0.63$. Thus, it is considered as an upper bound of the system, and the abbreviation expansion is not considered to be a trivial task.

6.5 Experimental Results

Table 2 shows *precision at k* and coverage for three systems with *k* ranging from 1 to 50. Table 3 shows examples of inputs and outputs. The baseline without reranking is shown at the bottom line (k=50). The result of using only QAM in Table 2 is equivalent to the method of Komachi et al. (2009) using NPMI instead of raw frequency as elements of an instance-pattern matrix. To

[3] Underlined words are correct.

[4] Some corrections were dealt with as exceptions. For example, acronym for its Japanese *Hiragana* was treated as incorrect, but acronym for its Japanese meaning was treated as correct.

Table 1: Abbreviations and its correction

abbreviation	correct candidates（descending order of rank）	output type	correction pattern
adf	asian dub foundation	Named Entity: Organization	acronym for its expansion
ana	全日空，全日本空輸株式会社 (All Nippon Airways)	Named Entity: Organization	acronym for its Japanese orthography
ny	ニューヨーク (New York)	Named Entity: Location	acronym for its Japanese orthography
tos	テイルズオブシンフォニア (Tales of Symphonia)	Named Entity: Product	acronym for its Japanese orthography
イラレ	illustrator	Named Entity: Product	Japanese abbreviation for its English orthography
ハンスト	ハンガーストライキ (Hunger Strike)	Common expression	Japanese abbreviation for its Japanese orthograpy
阪神	阪神タイガース	Named Entity: Organization	Japanese abbreviation for its Japanese orthograpy
fyi	for your information	Common expression	acronym to its expansion

p-value	0.055	$7.79e^{-10}$

our knowledge, their algorithm is the state-of-the-art algorithm in acquiring synonyms using web search logs.

The proposed ranking method using a query language model and abbreviation model learned from clickthrough logs shows the best precision and coverage within $1 \leq k \leq 10$. This is because the language and abbreviation model use different sources of information to complement each other.

The language model estimates probability of the candidate as a query, and it assigns high probability to candidates that appear frequently in query logs. Those candidates tend to co-occur with many clickthrough patterns, which results in creating generic patterns that may cause semantic drift (Komachi et al., 2009). Because we used NPMI instead of raw frequency, our label propagation method assigns high weight to instances connected to a seed instance through a few specific patterns. Consequently, low-frequency instances tend to be ranked in higher positions.

Table 4 shows the significance level between two baselines and the proposed model. We applied Wilcoxon's signed rank test to compare harmonic mean between precision and coverage of each model with *k* ranging from 1 to 50. The improvement of adding QAM to QLM is made statistically significant by the Wilcoxon's signed rank test at level $p < 0.00001$. Our approach outperforms the QAM without QLM although not as significant ($p < 0.06$). These mean that the ranking of our methods is similar to that of QAM. We consider the reason or this result to be that QLM introduces more information about queries under this experimental setting because the reranking process is performed after narrowing candidates down

to 50 by QAM, even though we do not use QAM scores at all when evaluating QLM.

Due to time constraints and human resources for evaluation, we were unable to compare NPMI with raw frequency. There is still much room for improvement for assigning appropriate weights to edges in a clickthrough graph.

6.6 Error Analysis

We conducted error analysis of our proposed method and found that errors can be divided into three types: (1) a partial correct query, (2) a correct query but with an additional attribute word, and (3) a related but not abbreviated term.

A partial correct query The main reason for this error is that the likelihood of the partial query becomes higher than that of its correct spelling. Although we normalized the likelihood of candidates by their string length, we still fail to filter fragments of queries. We consider that this issue can be solved by modeling popularity of candidates using PageRank from web search logs. Partial correct queries do not co-occur with attribute words frequently, while correct queries co-occur with diverse attribute words. Therefore, PageRank on a query graph whose edges represent common co-occurring words between queries, will assign higher scores to correct queries than a query language model and abbreviation model.

A correct query but with an additional attribute word Examples of this error type include the combination of correct queries and commonly used attribute words in the search (e.g.“* とは”*(what does * mean?)*, “* 意味”*(* meaning)*,“* 使い方” *(how to use *)*, etc.). There were 857 queries that were classified as incorrect that co-occurred with these attribute words. The similarity of these candidates and input query tend to be higher than that of others because these attribute words frequently appear in search query logs, so the likelihood of these candidate being calculated by a language model tends to be higher too.

We consider that this issue can be solved at some level by generating a language model using the first term only, after splitting queries separated by a space in search query logs. However, attribute words are not always separated by a space, and sometimes appear as the first term in the query[5]. Another way to handle this problem is to use PageRank described earlier to decrease likelihood of candidates including attribute words.

Related but not abbreviated term A number of abbreviations coincide with other general nouns (e.g. “dog”[6]). It is hard to expand these abbreviations correctly at present. In future work, session logs and geo-location information from IP address and GPS can be used to disambiguate the intent of the query.

Besides above reasons, 280 out of 1,916 queries did not exist in clickthrough logs, resulting in our system not being able to extract the correct query. To solve this problem, we will increase clickthrough logs to improve the coverage of our corpus.

7 Conclusion

We have proposed a query expansion method using the web search query and clickthrough logs.

Our noisy channel based method uses character 5-gram of query logs as a language model and label propagation on a clickthrough graph as a channel model. In our experiment, we found that a combination of label propagation and language model outperformed other methods using either label propagation or language model in reranking of query abbreviation candidates extracted from the web search clickthrough logs.

In fact, a modified implementation of this method is currently in production use as an assistance tool for making a synonym dictionary at Yahoo Japan.

In evaluation of IR systems, Mizzaro (2008) has proposed a normalized mean average precision (NMAP) for considering difficulty of topics in data sets. However, identifying topics in our test set queries and measuring their difficulty are beyond the scope of this paper. Evaluation criteria are important for making production services.

In the future, we are going to address this task using discriminative learning as a ranking problem.

Abstract

We propose a content-based approach to mine parallel resources from the entire web using cross lingual information retrieval (CLIR) with search query relevance score (SQRS). Our method improves mining recall by going beyond URL matching to find parallel documents from non-parallel sites. We introduce SQRS to improve the precision of mining. Our method makes use of search engines to query for target document given each source document and therefore does not require downloading target language documents in batch mode, reducing computational cost on the local machines and bandwidth consumption. We obtained a very high mining precision (88%) on the parallel documents by the pure CLIR approach. After extracting parallel sentences from the mined documents and using them to train an SMT system, we found that the SMT performance, with 29.88 BLEU score, is comparable to that obtained with high quality manually translated parallel sentences with 29.54 BLEU score, illustrating the excellent quality of the mined parallel material.

1 Introduction

Parallel resources such as bilingual lexicon and sentence translations are typically obtained from translated parallel documents. The web has now grown into an archive of trillions of URLs, heterogeneous in nature, in the last decade. There is a need to readdress the problem of how to mine parallel documents from the web.

We suggest that parallel documents can be mined with high precision from web sites that are not necessarily parallel to each other.

Parallel resources reside on a diverse range of websites which can be classified into the following categories:

Parallel websites: single website with structurally aligned bilingual pages. Typically they are websites of institutions, governments and commercial companies. (e.g. Financial Times Chinese/English, Wall Street Journal Chinese/English). Structure based methods were previously proposed to mine parallel documents from these websites:

Resnik and Smith (2003) used (1) parent pages containing links to versions of one document in different languages and (2) sibling pages contains link to translation of the current documents. They also rely on the URL and anchor text to spot language specific version of documents.

A structural alignment using DOM tree representation was proposed by Shi et al. (2006) to align parallel documents by using HTML structure. They identify the translational equivalent texts and hyperlinks between two parallel DOM trees to find parallel documents.

However, the web is a heterogeneous collection of documents that extend far beyond bilingual and comparable pages with obvious structural features, such as similar URLs or common titles. Structural features only work for bilingual websites or document pairs that are already linked by editors.

Comparable websites: websites that contain parallel content in different languages without any structural relation between document pairs. Press agencies have independent content management systems and editors for publishing news

Chiang Mai, Thailand, November 8 – 13, 2011.

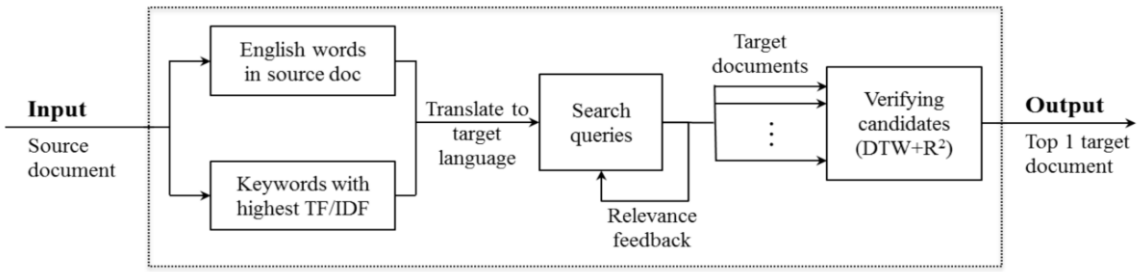

Figure 1. Parallel Document Mining using CLIR with Relevance Feedback

in different languages. (e.g. Reuters China vs. Reuters)

Quasi-comparable websites: independent websites that somewhere contain translated parallel contents. They may contain stories, documentations and books chapters in many languages on different websites. (e.g. Forbes, Fortune)

Instead of structural cues such as URLs, hyperlinks and HTML trees, content based approach are applied to find extra parallel resources from comparable and quasi-comparable websites.

Nie et al. (1999) proposed to download all source language and target language documents and then perform Cross Language Information Retrieval (Grefenstette, 1998) to extract candidate parallel documents. Munteanu and Marcu (2005, 2006) also focused on mining parallel documents from a downloaded collection of news articles, using time stamp alignment and content matching. More recently, Jiang et al. (2009) proposed an adaptive pattern-based bilingual data mining method to mine bilingual web pages for parallel phrases and terms.

Uszkoreit et al. (2010) aligned parallel documents by querying n-gram index built from translation of multilingual documents. All these approaches require a huge local achieve of both source and target documents. This can be very costly when we want to query the entire web.

Moreover, Uszkoreit et al. (2010) makes use of statistical machine translation (SMT) system to translate all documents into target language to build a query index. Due to the complexity of machine translation algorithms, it is still resource wasteful to download all target language documents, machine translate them, then select the desired candidate parallel documents.

Web content is being updated continuously. The above methods need to crawl for all documents in the target language. This is costly in terms of CPU consumption, bandwidth usage and disk storage utilization. This step can be replaced with search engine APIs by several search queries generated from source documents to save CPU and bandwidth consumption.

As most research institutions interested in mining parallel documents do not possess a large number of CPUs or storage on the scale of the world's top search companies, it is also desirable that any site can scale the mining speed and volume according to the computing resources available to them.

To this end, we propose a low bandwidth CLIR method to on the one hand complement structural matching, and on the other hand reduce the complexity of content matching.

Hong et al. (2010) proposed a mining approach on selected Chinese news article containing cue phrases. In non-oracle queries, 45% of the parallel or comparable documents were found among top search results. This is a benchmark in mining precision.

As the parallel resources mined are often times used to improve SMT systems or yield bilingual lexicons, it is desirable that the mining output is of high precision.

2 The Low Bandwidth High Precision Content Based Approach

Our proposed approach (Figure 1) primarily aims to discover parallel documents from all kinds of parallel, comparable or quasi-comparable websites on the World Wide Web. We take advantage of online search engines to find candidate documents thereby saving bandwidth, computational cost and dispenses with crawling for and storing all documents in the target language in an archive.

Content based approach queries the document in target language using keywords from documents in the source language. In our approach, queries are generated from source documents and expanded dynamically by search result quality as feedback. Neither machine translation of the full

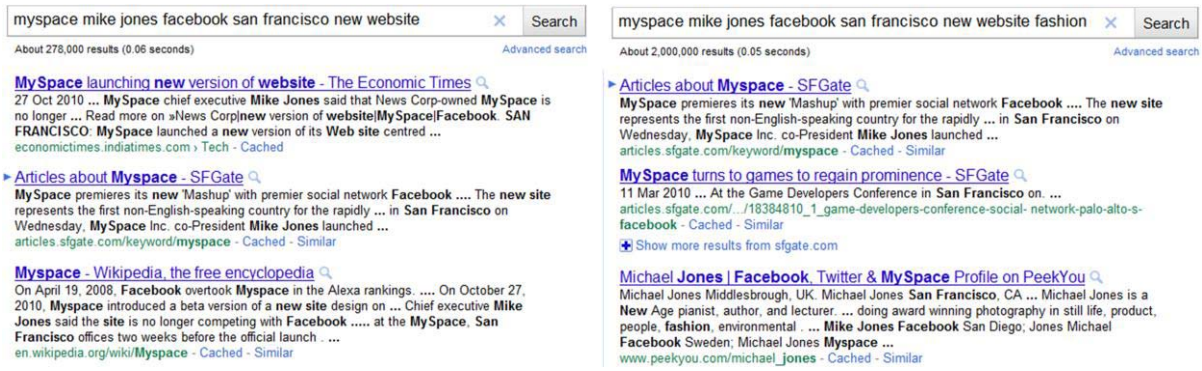

Figure 2. Search Result of Query 1 (Left) and 2 (Right) on Google.com

text no downloading of target documents is needed.

We suggest query expansion feedback score is the key in improving the precision of target documents found. If a source document is found to have no translation in the target language, the system simply returns <not-found>.

2.1 Representing Source Document

We cannot enter documents with thousands of words directly into an online search engine. We need to convert full text into keywords to perform automated queries. A keyword may exist in multiple articles. However, several keywords cam uniquely identify a document if they are grouped together as a keyword set (Jiang et al., 2009).

We then translate each keyword to target language to form the initial query.

There are several reasons why using the translated keyword set as query directly, as proposed by Hong et al. (2010), does not always yields the desired target document:

1) Keyword translation might not correspond to the actual words in the target document;
2) Certain keywords in the target document might have been removed by content editors;
3) There are errors in keyword translation or selection.

It is essential to select appropriate keywords to find the desired target document in a search engine. Two conditions that an appropriate keyword set should satisfy are: (1) they should represent the document exclusively (Jiang et al., 2009) (2) they should have unique or common translation in both languages.

We suggest that words with high TF-IDFs and English words in Chinese text are usually keywords that fulfill both conditions above.

$$K = K_T \bigcup K_E$$

K_T: set of words with high TF-IDF score
K_E: set of English words in Chinese documents

To obtain TF-IDFs that are representative of the keyword in the source document, they are trained from all source documents under the same domain name (e.g. www.ftchinese.com).

Keywords in K_E are more important because most of them are words used in the target document. However, in many cases, there are additional words in K_E so that we cannot find any document by directly searching for K_E. Our method removes keywords with the lowest TF-IDF score from K_E until a non-empty result is obtained.

2.2 Translating Source Documents with Search Query Relevance Score (SQRS)

Search engines use multiple criteria, such as keyword significance, domain popularity, date, popularity, page rank and etc., to return the most relevant documents that match the query. For mining a translated document pair, we need to somehow overcome the impact of page popularity and rank, and aim for content matching only.

Instead of ranking keywords locally and send single query, we take the above search engine criteria into account to amend queries.

To avoid adding erroneously translated keywords and further reduce the amount of undesirable documents downloaded, we introduced the *search query relevance score (SQRS),* defined in Equation 1, that describes how well the search result is and how we can refine the query. The score is determined by comparing the query with highlighted keywords in search result. Generally, a webpage has higher SQRS if the summary contains more keywords that match the query.

Commercial search engines omit some keywords when there is no document in their index

containing all the keywords. In such cases, the rank of documents usually changes significantly.

The following example shows search results of two search queries (Figure 2) generated from the Chinese version of *My Space launching new version of website*[1]. "|" indicates separation of keywords.

Query 1:
myspace | mike jones | facebook | san francisco | new | website

Query 2:
myspace | mike jones | facebook | san francisco | new | website | fashion

In Query 1, the oracle (known) target document was the topmost in search result. The short summary contains every keyword we entered in the query. Rank and SQRSs are shown in Table 1.

SQRS	Search engine omitted kwd	Rank
7.742	-	1*
5.174	web(site)	3
4.951	web(site)	2
4.663	web(site)	4
4.545	web(site)	5

* Target document

Table 1. SQRS of Query 1

In Query 2, we added *fashion* which is the English translation of "新潮" (but the actual English version used *hottest*). The rank of search result changed and each summary omitted at least one keyword in the query (Table 2).

SQRS	Search engine omitted kwd(s)	Rank
6.155	fashion	5*
3.951	web(site) | fashion	1
5.867	website	3
0.871	mike | new | website | fashion	4
-2.921	mike jones | new | website | fashion	2

Table 2. SQRS of Query 2

This phenomenon suggests that the document with all keywords in Query 2 does not exist on the web. The recently added keyword *fashion* must be erroneously translated.

In many similar cases, an erroneously translated keyword can pollute the query quality and decrease the rank of target document. Parallel document mining cannot rely on the document rank of search engine. The system must have a mechanism to detect the problem when expanding the query. Otherwise, a batch of irrelevant documents will be downloaded and need to be filtered out.

We ran experiments to find target documents of 112 randomly selected source documents and compare their SQRSs. 81 or 72.3% target documents have the highest SQRS among other URLs in the search results. It implies the SQRS are an effective measure of query formation and keyword translation.

Source documents	Target documents have largest SQRSs	%
112	81	72.3

Table 3. Result quality and SQRS

Although the query may include multiple translations of a keyword in a bilingual lexicon, the SQRS ensures that there is minimum adverse effect from incorrect translations.

2.3 Query Expansion using SQRS

To improve the precision of the keyword set, we further use SQRS for relevance feedback as shown in Figure 3.

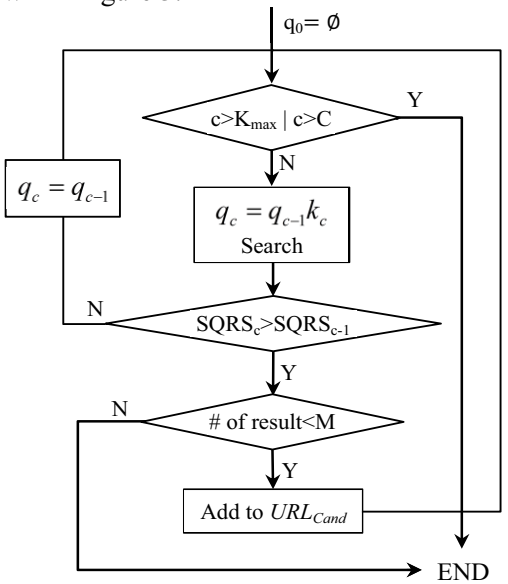

Figure 3. Flowchart of Query Expansion Algorithm

First, we rank the keywords in K_T by their TF-IDF scores. Next, the query is expanded by SQRS. When keyword w is added to current query, we compare the maximum $SQRS_c$ among top n results with the previous highest score $SQRS_p$ without w. w will be discarded from the keywords if $SQRS_c<SQRS_p$ or simply caused an

[1] Source: http://cn.reuters.com/article/CNTechNews/idCNCHINA-3233720101027 on May 10, 2011

$$Q = (k_1 k_2 ... k_C) \quad k_i = (w_{i1} w_{i2} ... w_{iJ}) \quad \Gamma K_i = \{(w_{ia} ... w_{ib}) \mid 0 < a < b \le J\}$$

$$count(c,t) = \#\text{ of occurrence of } c \text{ in } t, \quad \delta(c,t) = \begin{cases} 0 & \text{if } count(c,t) > 0 \\ 1 & \text{if } count(c,t) = 0 \end{cases}$$

$$SQRS(Q,T) = \sum_{c=1}^{C} \left[\sum_{s \in \Gamma K_c} [\log(count(s,T)+1)] - \delta(k_c,T) \right]$$

where Q is the query, k is keyword, w is English word and T is the short text with highlighted keywords in search result.

Equation 1. Definition of SQRS

empty search result. Otherwise, query will be expanded by adding w.

The search engine returns the total number of target documents for each query. If this number is less than a threshold M, we will add the URL of top-ranked documents to the URL_{Cand} list for verification.

To save network bandwidth, the system only considers the top K_{Max} words with the highest TF-IDF scores.

2.4 Document Verification

All candidate document pairs are subjected to a parallelness verification process before output. The system returns <not-found> if a pair failed the verification process. We propose using both dynamic time warping (DTW) and R^2 regression as in (Cheung and Fung, 2004) on every pair of the source and targets document to evaluate their parallelness.

2.4.1 Dynamic Time Warping (DTW) Score

DTW alignment is faster than machine translation (MT). We measure the word level DTW score between source document and target document with local constrain of 5 (Equation 2). Stop words are removed from the English text before DTW processing.

If the there is an entry in the bi-lexicon for a pair of i-th Chinese word and j-th English respectively, the cost of point (i,j) is 0, otherwise 1. The total cost is normalized by maximum number of steps (moves) from (0,0) to (m,n) to convert DTW score to a number between 0 and 1.

Parallel document pairs tend to have a path close to the diagonal line with high DTW score.

$$DTW(i_m, i_n) = c + \min \begin{pmatrix} DTW(i_m, i_n) & \cdots & DTW(i_m - 5, i_n) \\ \vdots & \ddots & \vdots \\ DTW(i_m, i_n - 5) & \cdots & DTW(i_m - 5, i_n - 5) \end{pmatrix}$$

Equation 2. DTW with local distance of 5

Figure 4 shows the DTW paths of a parallel document pair and a non-parallel pair. The parallel documents are aligned and the path with minimum cost is shown along the diagonal of the graph.

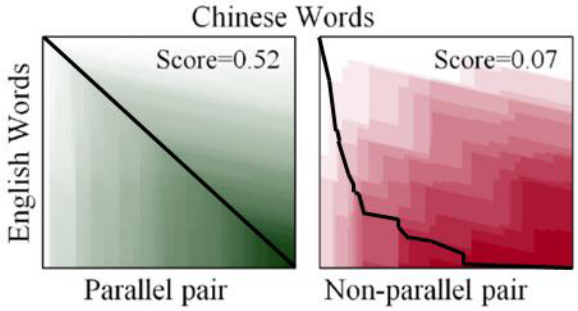

Figure 4. DTW of Parallel and Non-Parallel Pair

Table 4. is the relationship between DTW score and precision of candidate pairs. The precision of output sentences increases if the DTW score threshold is set higher.

DTW	# Pairs	# Parallel	Precision %
>0.45	122	121	99.18
>0.40	224	219	97.77
>0.35	298	288	96.64
>0.30	354	337	95.20
>0.28	389	364	93.57
>0.26	429	389	90.68
>0.25	456	403	88.38
>0.24	488	415	85.04
>0.22	545	417	76.51
>0.20	627	426	67.94

Table 4. DTW and Precision of Candidates Pairs

2.4.2 R^2 Regression

The parallel documents contain parallel sentences that may have different word orders, especially in the case of English and Chinese. The DTW score may be affected by different word order. We propose to use R^2 regression as an additional score to measure the deviation of the matching path of shared words in both documents from the diagonal. (Figure 5)

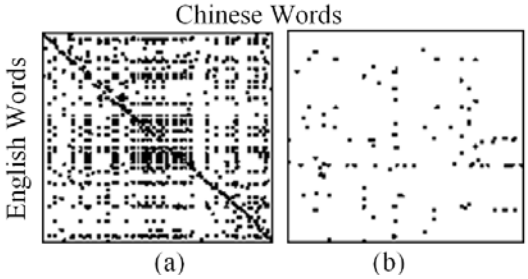

Figure 5. R^2 of Parallel and Non-Parallel Document Pairs

R^2 are normalized by the slope:

$$R^2 = R^2_{score} / Slope$$

2.4.3 Combining DTW and R^2

DTW score helps filter out non-parallel pairs and R^2 is introduced as a supplementary feature to improve the precision of extracted parallel documents.

A comparison of using these measures is shown in Table 5.

	DTW (>0.22)	R^2 (1.0E-5,1)	DTW+R^2
# Pairs	545	534	481
# Parallel	417	403	399
Precision %	76.51	75.47	82.95

Table 5. Mining Precision of DTW and R^2

2.4.4 Structural Features

The final step of verification uses structural features of the document pair candidates:

- **Language:** mined document should be in the target language
- **Absolute size:** mined documents should not have too small/large in file length
- **Size difference:** source and target documents must have similar size
- **Document type:** both documents must be content page in a website

2.5 Find One Get More

Since search engines rank target documents by various criteria, such as the popularity-based page rank, some legitimate bilingual website documents might not be found by our proposed content based method, content based approach using search engines. We propose to supplement our approach with URL matching patterns if the content based method has found several pairs of source and target documents under the same hostname.

Source	# Chinese Docs
ftchinese.com	11,009
cn.wsj.com	3,327
cn.reuters.com	8,570
forbeschina.com	6,281
fortunechina.com	593
Total	**29,780**

Table 6. Source Documents for Pure CLIR Approach

We examine the pairs found by the content based method and look for any parallel pairs coming from the same hostname or whether a pattern can be generalized from these URLs.

We apply this URL pattern to all Chinese pages under this domain.

All pairs found by both methods are subjected to pass the verification process in Section 2.4.

3 Experimental Setup

We evaluate our approach on two sets of experiments.

3.1 Baseline

As a baseline of the content base method, we directly use English words in the original Chinese document as keyword. Then, we add keywords ranked by TF-IDF to query the target document but not perform SQRS to expand query.

Finally, SQRS is used to refine each keyword to get better results.

We use both Google and Bing Search APIs to search the keyword sets. Results from different search engines are merged together by URLs. For each query, we consider eight URLs which is the default number of search engine APIs.

We generalize URL patterns (if any) from document pairs when we find some document pairs by content based method on parallel websites. By *Find One Get More*, we extract more parallel webpages that follow those URL patterns.

3.2 Parallel Document Extraction Accuracy

Source (Chinese) documents in our experiments are news from the following 5 agencies:

Parallel (bilingual) websites:

(1) Financial Times Chinese (ftchinese.com)
(2) Wall Street Journal Chinese (cn.wsj.com)

Parallel website contain both Chinese and English document under the same host and can be aligned with URL matching.

Comparable/quasi-comparable websites:

(3) Reuters China (cn.reuters.com)
(4) Forbes China (forbeschina.com)
(5) Fortune China (fortunechina.com)

Documents on quasi-comparable or comparable websites may have target documents on either the corresponding agencies' global site (e.g. cn.reuters.com and www.reuters.com) or somewhere else. Parallel documents from such websites cannot be found by URL matching.

We applied our content based approach to the above sites to find target documents and evaluate the mining precision.

The percentage of parallel documents that we can successfully find is highly dependent on the type of documents and search engine index. Calculating recall, on the other hand, is only possible for sites we already knew. For comparable or quasi-comparable sites, it is not possible to have the oracle target documents for evaluation because:

1) Some source documents may not have translation in the target language
2) Target language pages may not be indexed by search engines
3) Manual evaluation of all documents for recall calculation is not feasible

In the verification process, we discard the document pairs if:

- DTW score>0.25 (88% precision)
- R^2 score>1.0E-5
- Article size is too small
- Size of source and target too different
- URL is root (/) under hostname
- Text in wrong language

We manually evaluate the effectiveness of our method on randomly selected document pairs. Only parallel document pairs are considered as *correct*.

3.3 Parallel Sentence Extraction

In order to obtain a sentence alignment for pairs of document, we first need to extract the proper content of each page and remove the header and footers that are of little interest and are unlikely to be parallel anyway.

We first segment the documents in sentences and filter out improper ones, such as English sentence containing Chinese characters, or Chinese sentence containing roman characters only. We then use DTW again to find a continuous path in the documents and extract the longest one. The header and footer will generally not align and will be discarded; only the chunk of true alignable content will be preserved.

Using this method, we manage to find the beginning and the end of source and target content and extract it. Then discard pairs of document whose number of extracted sentences are too different. Sentence alignment is performed on the remaining documents using the Champollion ToolKit (Ma, 2006), which is already trained for Chinese-English document pairs.

Finally, we filter all the sentences using a simple word overlap score. Sentences whose lengths are too different or whose word overlap score is too low are discarded, to ensure a high precision at the end.

4 Experimental Results

4.1 Comparison of different methods

	Src doc	Doc pairs	Sent.	Improvement
i	1000	153	2483	Baseline
ii	1000	217	2907	+17.08%
iii	1000	243	3068	+23.56%

i. Direct Search of K_E
ii. Top ranked keywords without SQRS
iii. With SQRS

Table 7. Comparison of different methods

We directly search all English keywords in Chinese documents and found 153 target documents (baseline). Then we search translation of top ranked TF-IDF keywords (ii). With SQRS further improved 23.56% of output sentences comparing to baseline (Table 7). The precision in the three experiments are the same.

4.2 Parallel Document Extraction Accuracy

Among the 29,680 Chinese documents retrieved from the five news agencies, we obtained 7,253 parallel document pairs with 88% precision by content based approach alone.

In many such cases, parallel document pairs are on different websites and be found neither by URL matching nor by content-based methods that use times stamps for matching.

4.3 Find One Get More

With the *Find One Get More* approach, we increase the output of parallel documents from

parallel websites. Table 8 shows that using URL matching can improve the output quantity a lot, compensating for the missing target documents with low page ranks.

Source	# of Doc	CLIR	CLIR+URL
FTChinese	11,009	2,968	9,066
WSJ	3,327	1,002	3,120
Reuters	8,570	1,911	1,911
Forbos	6,281	1,166	1,166
Fortune	593	206	206
Total	**29,780**	**7,253**	**15,469**

Table 8. Output Document Pairs of 4.2 & 4.3

For parallel bilingual websites, the pure content based method can find about 1/3 of the target documents compared to the CLIR+URL method. It shows that, however, our query expansion with relevance feedback approach has higher recall than the 18% produced by the local ranked keywords in Hong et al. (2010).

4.4 Parallel Sentence Extraction for SMT

Among the 15,469 Chinese-English document pairs, we extracted 225,374 parallel sentence pairs with mining precision of over 97% based on human evaluation on randomly selected sentence pairs . We evaluate the quality of those sentences for training machine translation with the Moses SMT engine. We compare the BLEU score obtained with a 4,097,357 sentence pairs corpus, manually aligned (baseline) and the BLEU score obtained with the same corpus, replacing 225,374 sentence pairs by the ones we extracted (CLIR). Results are presented in Table 9, they are evaluated on the NIST MT06 evaluation set.

	BLEU
Baseline	29.54
CLIR	29.88

Table 9. BLEU score obtained for SMT

These results show that our set of sentences, together with a larger parallel corpus, yield results similar to the one obtained with manually aligned sentences only.

The extracted sentences have been processed for rare word translation extraction. (Prochasson and Fung, 2011)

4.5 System Performance and Scalability

We carried out our mining experiments on workstation with 8 states of arts CPU cores. The average time taken for each source document is 30 seconds which is only bottle-necked by the usage limitation of search engine APIs.

As the TF/IDF scores are pre-trained only from the source documents, and our CLIR approach mines target document for each source document individually. Our system can be easily scaled to run in parallel on multiple servers.

5 Conclusion

In this paper, we have proposed a content based CLIR approach to search any part of the Web to find parallel documents without the limitation of URL-matched bilingual web sites. Our method transforms an input source document into a target language query set, then it makes use of search engine APIs, and a proposed query relevance feedback mechanism, and finds the target language document if it exists on the web. We propose a search query relevance score (SQRS) that checks for precision of the query keywords we use to represent the source document. Our proposed method does not require machine translation, nor does it require downloading all documents in the target language into an archive for document matching, thereby saving computational resources.

The query expansion and relevance feedback by SQRS which measures translation correctness ensures high precision in the target document found. Using a verification process, the web documents are further filtered by dynamic time warping and regression scores.

Experimental results show an 88% mining precision on the parallel documents extracted from parallel, comparable and quasi-comparable web sites.

Another experiment on extracting bilingual sentences from the mined documents shows that the sentence extraction adds another layer of verification which further improves the precision from 88% to 97%.

SMT experiments on using our mined parallel sentences, together with a larger baseline training set, to train an SMT system show comparable performances from using our data to that of using manually aligned bilingual sentences. Our system is scalable to run on multiple servers simultaneously and is linear in time to the number of input source documents. It can also be run continuously to discover and mine for newly added web documents that were not there previously. It is also extendable to mine for parallel documents in multiple target languages at the same time.

Abstract

This paper presents a novel crawling strategy to locate bilingual sites. It does so by focusing on the Web graph neighborhood of these sites and exploring the patterns of the links in this region to guide its visitation policy. A sub-task in the problem of bilingual site discovery is the job of detecting bilingual sites, i.e., given a Web site, verify whether it is bilingual or not. We perform this task by combining supervised learning and language identification. Experimental results demonstrate that our crawler outperforms previous crawling approaches and produces a high-quality collection of bilingual sites, which we evaluate in the context of machine translation in the tourism and hospitality domain. The parallel text obtained using our novel crawling strategy results in a relative improvement of 22% in BLEU score (English-to-Spanish) over an out-of-domain seed translation model trained on the European parliamentary proceedings.

1 Introduction

Parallel texts are translations of the same text in different languages. Parallel text acquisition from the Web has received increased attention in the recent years, especially for machine translation (Melamed, 2001) and cross-language information retrieval (Grossman and Frieder, 2004). For many years, the European Parliament proceedings (Koehn, 2005a) and official documents of countries with multiple languages were the only widely available parallel texts. Although these are high-quality corpora, they have some limitations: (1) they tend to be domain specific (e.g., government related texts); (2) they are available in only a few languages; and (3) sometimes they are not free or there is some restriction for using them. On the other hand, Web data is free and comprises data from different languages and domains.

Previous research in the area of parallel Web data acquisition has mainly focused on the problems of document pair identification (Jiang et al., 2009; Uszkoreit et al., 2010; Munteanu and Marcu, 2005; Resnik and Smith, 2003; Melamed, 2001) and sentence alignment. Typically, document pairs are located by issuing queries to a search engine (Resnik and Smith, 2003; Hong et al., 2010). The sentences in the matched documents are then aligned using standard dynamic programming techniques. In this work, we model the problem of obtaining parallel text in two subtasks. First, locate the sites that contain bilingual data (bilingual sites). Here we assume that parallel texts are present in the same site (Chen and Nie, 2000). Second, extract parallel texts within these sites. While the latter problem of extracting of parallel text from bilingual Web sites has received a lot of attention, the former problem of automatically locating high quality parallel Web pages is still an open problem.

In this paper, we propose a crawling strategy (Olston and Najork, 2010) to discover bilingual sites on the Web. Previous work on focused crawlers (Chakrabarti et al., 1999; Diligenti et al., 2000) has been used to locate different kinds of Web sources such as Web pages in a topic (Chakrabarti et al., 2002), geographic information (Ahlers and Boll, 2009) and Web forms (Barbosa and Freire, 2007) by following outlinks. In contrast to these approaches, we explore the idea of using not only forward links but also backlinks. *Backlinks* of a page p are the links that point to p and *outlinks (forward links)* are the links that p points to. The reason for that is a single backlink page sometimes refers to many related pages, a phenomenon known as co-citation. Kumar et al. (Kumar et al., 1999) showed that co-

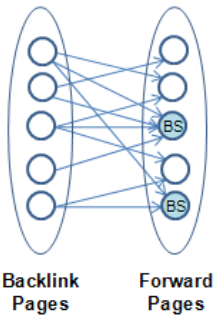

Figure 1: Bipartite graph representing the graph neighborhood visited by the crawler. Backlink pages point to pages in bilingual sites (BS) and other pages (forward pages).

citation is a common feature of Web communities and, as a result of that, Web communities are characterized by directed bipartite subgraphs. Based on that, we implemented our crawling strategy by restricting the crawler's search for bilingual sites in the bipartite graph composed by backlink pages (BPs) of the bilingual sites that were already discovered by the crawler, and pages pointed by BPs. This scheme is illustrated in Figure 1. Our assumption, therefore, is that the Web region represented by this bipartite graph is rich in bilingual sites since backlink pages typically point to multiple bilingual sites (co-citation). Finally, to focus on the most promising regions in this graph, the crawler explores the patterns in the links to guide its visitation policy.

A sub-task in the problem of bilingual site discovery is the job of detecting bilingual sites, i.e., given a Web site, verify whether it is bilingual or not. A simple approach to this task is to search the entire Web site for parallel text. However, this is computationally expensive since Web sites might contain hundreds/thousands of pages. We propose a low-cost strategy that visits very few pages in the Web site to make its prediction regarding the presence of bilingual text. Given a Web site's page, we use supervised learning to identify links on the page that are good candidates to point to parallel text within the site. Subsequently, our strategy verifies whether the pages pointed by the candidate links are in fact in the languages of interest.

The main contributions of this paper can be summarized as follows:

- A new focused crawling strategy that explores the concept of co-citation by restricting the search for targeted sources (bilingual sites in this paper) in the bipartite graph composed by the backlink pages of the targeted sources already discovered by the crawler, and the forward links pointed to by the backlink pages. The crawler uses link classifiers specialized in each set of the URLs of the pages (backward and forward pages) of the bipartite graph to focus on the most promising regions in this graph;
- A high-precision and efficient approach to detecting bilingual sites based on supervised learning and language identification.

The remainder of the paper is organized as follows. In Section 2, we present our approach to locating and detecting a bilingual site. We present experimental results in Section 3 and demonstrate the efficacy of our approach in the context of machine translation in Section 4. We review related work in Section 5 and conclude in Section 6.

2 Bilingual Site Crawler

A naive approach to collect parallel text would be to check for every pair of pages on the Web. However, this is computationally prohibitive given the scale of the Web. To make the search for parallel text more feasible, previous approaches made the assumption that parallel texts mainly occur within Web sites (Chen and Nie, 2000). Thus, the search for parallel text can be comprised of two steps. First, locate bilingual sites, and then, extract the parallel text from them. While previous approaches (Resnik and Smith, 2003; Zhang et al., 2006) have mainly focused on the latter problem of extracting sentence aligned parallel text from web, we are interested in the former problem of locating such sites.

The architecture of our crawler is presented in Figure 2. The crawler downloads a page, p and sends it to the bilingual site detector (BS Detector). If the BS Detector predicts that the site represented by p contains parallel text (see Section 2.1), the Backlink Crawler collects the backlinks of p, i.e., links that point to p, by using a search engine backlink API. The Backlink Classifier predicts the relevance of these links (see Section 2.3), and adds them to the queue that represent these links in the Frontier (backlink queue). The most promising backlink is then sent by the Frontier Scheduler to the Crawler, which downloads its content. Next, the Page Parser extracts the forward links of the backlink page and adds the most promising forward links (as identified by Forward-Link

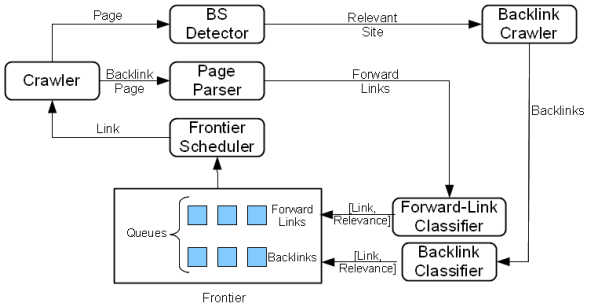

Figure 2: Architecture of our crawling strategy to locate bilingual sites.

Classifier) to the forward-link queue. The Frontier Scheduler then decides the next link to be sent to the crawler. We present the core elements of the crawler in the sections below.

2.1 Bilingual Site Detection

The performance of the bilingual site detection is essential to obtain a high-quality collection of bilingual sites. Zhang et al. (Zhang et al., 2006) perform this task by extracting the anchor text and image alt text from pages in the Web sites and match them with a pre-defined list of strings in the languages of interest. If the Web site contains at least two matched links in the different languages then it is considered as bilingual. The approach suffers from the drawback of low recall since bilingual sites that contain patterns outside the list may be missed. Another approach (Ma and Liberman, 1999) verifies the presence of bilingual text at pages of the top 3 or 4 levels of the Web site by using a language identifier. This approach can be very expensive as one might need to download a considerable portion of the Web site to make a decision.

Our solution to detecting parallel sites has some similarities with these previous approaches but tries to address their main limitations. First, instead of using a pre-defined list of patterns to detect bilingual sites, we use supervised learning to predict if a given page has links to parallel data (Link Predictor). Second, to avoid downloading a great portion of the Web site, the BS Detector only verifies whether the pages whose URLs are considered relevant by the Link Predictor are in different languages.

Link-Based Prediction. The role of the Link Predictor is to identify links that point to parallel text in a Web site. Our assumption is that pages of bilingual sites contain some common link patterns. For instance, pages in English might have a link to its version in Spanish, containing words such as "espanol" and "castellano" in its anchor, URL, etc. However, there are cases whereby the link does not provide any visible textual information to the user. Instead, only an image (usually a country flag) might represent the link. In these cases, textual information in the fields of the img html tag (e.g. alt and src) might be helpful. In order to be able to handle different types of patterns in the links, the Link Predictor uses features in 5 different contexts: tokens in the URL, anchor, around, image alt and image src. For this paper, we built the training data from non-bilingual and bilingual sites in English/Spanish. It was compiled by manually labeling 560 URLs (236 relevant and 324 non-relevant). We use probabilistic SVM (Platt, 1999) as the learning algorithm to create the Link Predictor. Probabilistic SVM is a suitable choice for this classification as it performs well on text data, and we are also interested in the class likelihood of the instances.

In essence, the Link Predictor works as a low-cost filter, its cost is associated with the link classifications which is very low. It also considerably prunes the search space for subsequent steps that are typically more expensive computationally.

Language Identification. In the second step of the bilingual site detection, the BS Detector verifies if the pages whose links were considered relevant by the Link Predictor are in the languages of interest. The motivation behind the use of language identification for our problem is, since we are interested in bilingual text, only looking at individual links of these sites might not suffice. In addition to identify the language of the pages of candidate links identified by the Link Predictor, language identification is also performed on the page that contains such links, i.e., the page that was provided as input to the BS Detector. This handles cases in which a page in a given language only contains a link to its translation in other language but not links to both versions. The language identification is then performed in all pages of that candidate list and if different pages are in the language of interest, the site is considered as bilingual. To detect the language of a given page, we use the textcat (Cavnar and Trenkle, 1994) Language Identifier.

Even though there is some cost in downloading the pages to perform this step, we show later in this section that it is only necessary to download

Min. Likelihood	Link Predictor			BS Detector			Cost (Downloads per site)

0.9	0.77	0.8	0.78	0.66	0.97	0.78	2

Table 1: Results obtained by the BS Detector (Link Predictor + language identification) and the Link Predictor only.

on average 2 to 3 pages per site, since the Link Predictor prunes the search space considerably.

Evaluation. To measure the quality of the BS Detector, we manually labeled 200 Web sites (100 positive and 100 negative) from the dmoz directory in topics related to Spanish speaking countries. A site was considered as relevant if it contained at least a pair of parallel pages. Our approach is similar to that employed by (Resnik and Smith, 2003) to label parallel text.

Since the Link Predictor outputs the likelihood of a relevant link, we varied the minimum likelihood for a link be considered as relevant. For each value, we measured its quality (precision, recall and F-measure), as well as its cost (number of downloaded pages per site in the language identification step). Table 1 presents the results for the BS Detector and the Link Predictor (first step of the BS Detector). When the minimum likelihood is 0, the language identification process checks all the links in the given pages for pairs of languages, i.e., the Link Predictor considers all the links as relevant. In this scenario, an average of 29 pages per Web site were downloaded and the recall of the BS Detector was 0.86. This implies that the language identifier was not able to detect pairs of languages in 16% of the relevant sites. As expected, the minimum likelihood is directly proportional to the precision and inversely proportional to the recall. It is interesting to note that between 0.5 and 0.8, these values do not change for the BS Detector besides the decreasing of cost. The Link Predictor shows a similar behavior. Another important observation to glean is that adding the language detection on top of the Link Predictor improves the overall precision of the bilingual site detection. For instance, when the minimum likelihood is set to 0.5, the Link Predictor's precision is 0.75 whereas that of the BS Detector is 0.95. The high precision of the BS Detector is very important to build a high-quality set of bilingual sites.

2.2 Crawling Policy

In this section, we focus our attention to our solution to locating bilingual sites on the Web. Previous work (Ma and Liberman, 1999) tries to perform this task by restricting the crawler in a top-level internet domain where it is supposed to contain a high concentration of these sites. For instance, Ma and Liberman (Ma and Liberman, 1999) focused the crawler in .de domain since they were interested in German/English language pairs. In this work, we do not restrict the crawler to any particular internet domain or topic. Our objective is to allow the crawler to perform a broad search while avoiding visits to unproductive Web regions.

We implemented this strategy by imposing the constraint that the crawler stays in the Web neighborhood graph of the bilingual sites that were previously discovered by the crawler. More specifically, the crawler explores the neighborhood graph defined by the bipartite graph composed by the backlink pages (BPs) of bilingual sites and the pages pointed by BPs (forward pages), see Figure 1. As we mentioned before, this strategy is based on the findings that Web communities are characterized by directed bipartite subgraphs (Kumar et al., 1999). Thus, our assumption is that the Web region comprised by this bipartite graph is rich in bilingual sites as backlink pages typically point to multiple bilingual sites. Finally, as we are looking for Web sites and not for single Web pages, the crawler only considers out-of-site links, i.e., it excludes from the bipartite graph links to internal pages of the sites.

The steps of our algorithm are shown in Algorithm 1. Initially, the user provides a set of seed URLs that are added to the frontier. The crawler then starts to download the links in the frontier. If the BS Detector identifies a page in a bilingual site, the backlinks to this page are collected and added back to the frontier. Backlink information can be retrieved through the "link:"

Algorithm 1 Crawling Policy

```
1: Input: seeds, BS_Detector
   {seeds : seeds provided by the user, BS_Detector: the
   Bilingual Site Detector.}
2: frontier = ∅
   {Create the empty frontier.}
3: frontier.addLinks(seeds)
   {Add the seeds to the frontier.}
4: repeat
5:    link = frontier.next()
      {Retrieve from the frontier the next link to be vis-
      ited.}
6:    page = download(link)
      {Download the content of the page.}
7:    if BS_Detector.isRelevant(page) then
8:       backlinks = collectBacklins(page)
         {Collect the backlinks to the given page provided
         by a search engine API.}
9:       frontier.addLinks(backlinks)
         {Add the backlinks to the frontier.}
10:   end if
11:   if link.isBacklink() then
12:      outlinks = extractOutlinks(page)
         {Extract the outlinks of a backlink page.}
13:      frontier.addLinks(outlinks)
         {Add the outlinks to the frontier.}
14:   end if
15: until frontier.isEmpty()
```

API provided by search engines such as Google and Yahoo! (Bharat et al., 1998). In the next step, pages represented by the backlinks (backlink pages) are downloaded, their outlinks are extracted and added to the frontier. Notice that only the outlinks from the backlink pages are added to the frontier. The crawler does not explore outlinks of forward pages (forward pages are pages pointed by backlink pages, see Figure 1).

2.3 Forward-Link and Backlink Classifiers

Retaining the crawler in the graph neighborhood of bilingual sites (the bipartite graph) is our first attempt towards an effective search for such sites. However, there may be many links in the graph that do not lead to relevant sites. In order to identify promising URLs in the two different page sets of the bipartite graph, we employ supervised learning. For each set (backlink and forward sets), the crawler builds a classifier that outputs the relevance of a given link in that particular set. Relevant links in the forward pages' set represent URLs of bilingual sites, i.e., links that give immediate benefit, whereas relevant links in the backlink pages' set are URLs of backlink pages that contain outlinks to bilingual sites (delayed benefit).

Previous approaches for focused crawling (Chakrabarti et al., 2002; Rennie and McCallum, 1999; Barbosa and Freire, 2007) also use patterns on links to prioritize them. But instead of using link classifiers specialized in different link layers, they build a single classifier. The advantage of having multiple classifiers is that it decomposes a complex problem into simpler subproblems in which each classifier is dedicated to a subset of more homogeneous hypothesis (Gangaputra and Geman, 2006). Diligenti et al. (Diligenti et al., 2000) also proposed the use of multiple classifiers to guide the crawler. But instead of looking at link patterns, they use the content of the pages.

In summary, the Forward-Link Classifier predicts the most promising links for the forward pages, whereas the Backlink Classifier identifies the most promising links for the backlink pages. Both classifiers use as features the neighborhood of links. The link neighborhood is composed by four contextual categories: URL (without the host), host, anchor, and text around the link. Since the number of extracted features tends to be large (and most of them have very low frequency), we remove stop-words and stem the remaining words. Note that features are associated with a context. For example, if the word "hotel" appears both in the URL and anchor text of a link, it is added as a feature in both contexts. It is important to note that words in the host context have an important role, since many parallel corpus sites are in a country's internet domain, e.g., es, de, etc. In fact, as we mentioned before, some previous approaches (Ma and Liberman, 1999) restrict the crawl within these domains to collect parallel data. But instead of pre-defining a set of domains, the crawler in our work automatically identifies the most important ones during its crawling process.

As one can expect, the two classifiers perform a different role. For the Backlink Classifier, features such as "link" and "directory" in the URL obtained have high frequency in the training data. These words usually occur in the URL of pages that point to many different sites, e.g., http://www.rentaccomspain.com/links.asp. The Forward-Link Classifier is more focused on topics. Words such as "hotel", "air", "art" and "language" were some of the frequent features used by it.

The two classifiers are automatically created during the crawling process. Initially, the crawler starts with no link prioritization. After a specified number of crawled pages, a learning iteration

is performed by collecting the link neighborhood of the links that point to relevant and non-relevant pages in each set. The result of this process is used as training data for the Backlink and Forward-Link classifiers. Similar to previous focused crawling approaches (Chakrabarti et al., 2002; Barbosa and Freire, 2007), we use Naive Bayes algorithm for this purpose. As a final step, the relevance of the links in the frontier are updated based on the new classifiers.

3 Crawling Experiments

In this section, we assess our crawling strategy to locate bilingual sites and compare it with other crawling approaches.

3.1 Experimental Setup

Crawling Strategies. We executed the following crawling strategies to locate bilingual sites:

- Forward Crawler (FC): The forward crawler randomly follows the forward links without any restriction;
- Focused Crawler (FocC): although our strategy does not restrict its search to a particular domain, we set up a focused crawler (Chakrabarti et al., 2002) in the travel domain for comparison. The focused crawler is composed by a page classifier that restricts the crawl to pages in the travel domain and a link classifier that guides the crawler's link visitation to avoid unproductive Web regions (see (Chakrabarti et al., 2002) for more details);
- Out-of-site Back/Forward Crawler (OBFC): The out-of-site back/forward crawler uses the crawling strategy proposed in this paper without any prioritization to the links;
- Classifier-Based Out-of-site Back/Forward Crawler (COBFC): The classifier-based out-of-site back/forward is the OBFC along with the Backlink and Forward-link classifiers to prioritize the links in the frontier. Both classifiers are created after crawling 20,000 pages.

We set up the crawlers to locate bilingual sites in English and Spanish. Each configuration collected 100,000 pages and 1,000 links were provided as seeds. These were randomly selected from the URLs available on the Open Directory Project[1] related to Spanish speaking countries.

[1] http://www.dmoz.org/

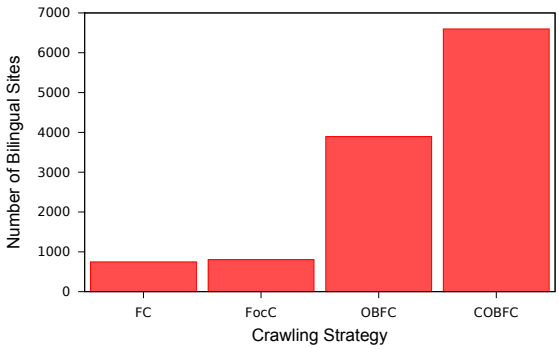

Figure 3: Total of bilingual sites collected by the crawling strategies in a crawl of 100,000 pages.

Effectiveness measure. The performance of the crawling strategies was measured by the total number of bilingual sites collected after the bilingual site detection during the crawl. The minimum likelihood used by BS Detector to consider a link as relevant was 0.8 since we are interested in obtain a high-quality collection of bilingual sites (see Section 2.1).

3.2 Assessing the Bilingual Site Crawler

In Figure 3, we present the total of bilingual sites collected by each crawling configuration after collecting 100,000 pages. Our crawling strategy, COBFC, collected the greatest number of bilingual sites (6598 sites). This result empirically confirms that our approach of restricting the crawler to the neighborhood of bilingual sites by using back and forward links, along with classifiers that prioritize these links is in fact effective for locating bilingual sites.

The comparison between the top two strategies, namely, COBFC (6598 bilingual sites) and OBFC (3894 bilingual sites) shows that: (1) the Backlink and Forward-link classifiers used to prioritize the links in the frontier improve the crawler's performance; and (2) even with no link prioritization, our strategy of restricting the search to the bipartite graph of backlink and forward pages is able to obtain good results. We can conclude from these numbers that bilingual sites are close to each other when one considers their backlinks. As we mentioned previously, this can be attributed to the fact that backlinks are typically hubs to bilingual sites.

From the experimental results, it is clear that our crawling is effective for locating bilingual sites on the Web. The main limitation, however, is that it relies on an external component (search engine) to provide backlinks. In the experiments presented

in this work, the use of a search engine slowed down the crawling execution since we did not want to submit many requests to the search engine and consequently have the backlink requests halted.

A final note regarding our crawling strategy is that even though we do not restrict it to any particular topic, as the crawling process evolves, it automatically focuses on topics where there is a higher concentration of parallel data, as travel, translator sites, etc. This is different from conventional approaches that explicitly constrain the crawl based on topics.

4 Machine Translation Experiments

In this section, we exploit the parallel text obtained through our crawling strategy as augmented data in machine translation. We use a phrase-based statistical machine translation system (Koehn et al., 2007) in all the experiments.

4.1 Experimental Setup

Web data. We focus on English and Spanish as the bilingual pair of languages. We used the crawling strategy presented in the previous section to obtain a set of 20186 bilingual sites. The parallel text from these sites was mined using the technique presented in (Rangarajan et al., 2011). A total of initial 4.84M bilingual sentence pairs were obtained from this process. We used length-based and word-based filters as well as a language model to filter these initial sentence pairs. After cleanup, a total of 2,039,272 bilingual sentence pairs was obtained from the crawling data.

Development and Test Data. In order to obtain a representative reference development and test set, we manually created bilingual sentences in the hospitality and tourism domain. A bilingual speaker was given instructions to create dialogs in a variety of travel scenarios such as *making a hotel reservation, booking a taxi, checking into a hotel, calling front desk and reporting problems*, etc. A total of 49 scenarios were created that resulted in 1019 sentences, 472 of which was used for development and 547 for testing. The dialogs were created in English and then translated to Spanish. The development and test sets are not very large, mainly because creating high quality bilingual data for a particular domain is expensive. We have given due consideration to create a test set that is highly similar to the domain of operation. We are working on evaluating the performance of the crawled data on different domains as part of future work (as we translate more data through human annotations).

MT Models. We performed machine translation experiments in both directions, English-Spanish and Spanish-English. Europarl data is the only source of parallel data (English/Spanish) that we have access to, and hence it serves as the data for our baseline translation model. Although the model can be considered to be out-of-domain with respect to our test domain, its language style is more similar to our test set (spoken dialogs) in comparison with the Web data. The Europarl data comprised 1.48M bilingual sentence pairs.

The Web data translation model was trained on the sentences resulting from the Web crawler. We also used a combination of the two models that we call as combined model. The combined model uses both the phrase tables during decoding. The reordering table was also concatenated from the two models.

4.2 Results

Table 2 presents the translation performance in terms of various metrics such as BLEU (Papineni et al., 2002), METEOR (Lavie and Denkowski, 2010) and Translation Edit Rate (TER) (Snover et al., 2006). The language model was a 5 gram language model optimized on the development set based on perplexity and the translation weights of the log-linear model were learned using Minimum Error Rate Training.

While the out-of-domain model trained using Europarl data achieves a BLEU score of 20.65 on the test set (tourism and hospitality domain) for English-Spanish, the model constructed by augmenting the web crawling data to europarl data achieves a relative improvement of 22%. Similar improvements hold for Spanish-English translation. The METEOR scores reported in Table 2 were computed only for exact match (synonyms and stemmed matches were not considered). For all three objective metrics, we achieve significant improvements in translation performance. The results demonstrate the efficacy of our bilingual crawling approach for harvesting parallel text for machine translation. The bilingual crawler can be initialized with a different policy based on the test domain of interest and hence our scheme is generalizable.

Regarding the results of Europarl versus Web data alone, the reason for the lower translation

Model	Training data	English-Spanish			Spanish-English		
		BLEU	METEOR	TER	BLEU	METEOR	TER
Baseline	Europarl	20.65	16.76	71.52	25.26	41.09	64.76
	Web	16.94	14.81	79.28	23.48	39.65	66.11
	Combined	23.00	17.90	68.86	28.86	44.18	61.24

Table 2: Automatic evaluation metric scores for translation models from out-of-domain data, Web data and combined models.

quality of the web crawled data on the test set considered in the experiments is mainly due to the style of the test set. Even though the domain of the crawler is travel and hospitality, the sentences in the test set are more conversational and better matched with Europarl in terms of BLEU metric. On the other hand, the METEOR metric that accounts for the overlapping unigrams is much closer for Europarl and Web data, i.e., the vocabulary coverage is comparable.

5 Related Work

There are basically two main types of approaches to locate parallel corpora: query-based (Resnik and Smith, 2003; Resnik, 1998; Chen and Nie, 2000; Tomás et al., 2005) and crawling-based (Ma and Liberman, 1999; Chen et al., 2004).

Query-based approaches typically try to explore common patterns that occur in this kind of data by using them as search queries. For instance, STRAND (Resnik and Smith, 2003; Resnik, 1998) tries to locate candidate parallel pages by issuing queries like: (anchor:“english” OR anchor:“anglais”) AND (anchor:“french” OR anchor:“francais”). Chen and Nie (Chen and Nie, 2000) used a similar principle to obtain two sets of candidate sites by issuing queries as anchor:“english version” to a search engine, and then taking the union. More recently, Hong et al. (Hong et al., 2010) proposed a method that discovers document pairs by first selecting the top words in a source language document, translating these words and issuing them as a query to a search engine. The main limitation of these previous approaches is that they only rely on the search engine results to obtain the parallel pages. And, since search engines restrict the total number of results per query and the number of requests, there is a limitation in terms of the total number of sites that can be collected. This is confirmed by the numbers presented in their experimental evaluation. For instance, Chen and Nie (Chen and Nie, 2000) reported a total of only 185 candidate sites for English-Chinese corpora.

With respect to crawling-based approaches for locating parallel text, there is not much prior work in this area. In fact, most of the research in this area is focused more on the problem of identifying the text pairs (Munteanu and Marcu, 2005; Zhang et al., 2006; Uszkoreit et al., 2010) than actually locating them. They typically use simple strategies to locate parallel text without exploring the Web link structure. For example, Ma and Liberman (Ma and Liberman, 1999) try to achieve this goal by simply restricting the crawler within in a particular internet domain whereby there might be a good chance of finding this kind of data.

6 Conclusions

This paper presents a novel focused crawling strategy to locate bilingual sites. It keeps its search in the bipartite graph composed by the backlink pages of bilingual sites (already discovered by the crawler) and the pages pointed by them. To focus on the most promising regions in this graph, the crawler explores the patterns presented in its links to guide its visitation policy. Another novelty proposed in this paper is our low-cost and high-precision strategy to detect a bilingual site. It performs this task in two steps. First, it relies on common patterns found in the internal links of these sites to compose a classifier that identifies link pages as entry points to parallel data in these sites. Second, it verifies whether these pages are in fact in the languages of interest. Our experiments showed that our crawling strategy is more effective in finding bilingual sites than the baseline approaches and that our bilingual site detection has high-precision while being efficient. We also demonstrated the efficacy of our crawling approach by performing machine translation experiments using the parallel text obtained from the bilingual sites identified by the crawler.

An interesting venue to pursue in a future work is to verify whether the crawling strategy proposed in this paper also works in other types of domains where regular focused crawling may have issues in finding the targeted Web sources.

Abstract

We present an efficient technique to incorporate a small number of cross-linguistic parameter settings defining default word orders to otherwise unsupervised grammar induction. A syntactic prototype, represented by the integrated model between Categorial Grammar and dependency structure, generated from the language parameters, is used to prune the search space. We also propose heuristics which prefer less complex syntactic categories to more complex ones in parse decoding. The system reduces errors generated by the state-of-the-art baselines for WSJ10 (1% error reduction of F1 score for the model trained on Sections 2–22 and tested on Section 23), Chinese10 (26% error reduction of F1), German10 (9% error reduction of F1), and Japanese10 (8% error reduction of F1), and is not significantly different from the baseline for Czech10.

1 Introduction

Unsupervised grammar induction has gained general interest for several decades, offering the possibility of building practical syntactic parsers by reducing the labor of constructing a treebank from scratch. One approach is to exploit the Inside/Outside Algorithm (Baker, 1979; Carroll and Charniak, 1992), a variation of EM algorithm for PCFG, to estimate the parameters of the parser's language models. More recent advances in this approach are the constituent-context model (CCM) (Klein and Manning, 2001; Klein and Manning, 2002), dependency model with valence (DMV) based on Collin's head dependency model (1999), and the CCM+DMV mixture (Klein and Manning, 2004; Klein, 2005). Several search techniques and models have been added to CCM+DMV for dealing with local optima and data sparsity (Smith, 2006; Cohen et al., 2008; Headden III et al., 2009). Spitkovsky et al. (2010) proposed a training strategy where the model fully trained on shorter sentences and roughly trained on longer sentences tend to outperform the model fully trained on the entire dataset. Recently, Gillenwater et al. (2010) proposed the use of posterior regularization in EM in which the posterior distribution of parent-child POS tags are regulated to an expected distribution.

However, purely unsupervised learning still does not perform well because the parameter estimation can be misled by unexpected frequent cooccurrence. A common example of it is the collocation of a verb (VBZ) and a determiner (DT) in a verb phrase. This collocation results in incorrect trees such as ((VBZ DT) NN).

To avoid this problem, the use of syntactic prototypes has been proposed. Instead of enumerating every possibility, syntactic structures are cautiously constructed regarding some syntactic constraints. Haghighi and Klein (2006) proposed the use of bracketing rules extracted from WSJ10 in CCM and considerably improved accuracy. Druck et al. (2009) used dependency formation rules handcrafted by linguists to improve the accuracy of DMV. Snyder et al. (2009) do semi-supervised grammar induction from bilingual text with the help of a supervised parser on one side and word alignment. However, bilingual corpora are not available for many language pairs. Naseem et al. (2010) proposed the use of cross-linguistic knowledge represented as a set of allowable head-dependent pairs. However, this method still requires provision of language-specific rules to boost accuracy. If language-specific rules are necessary to achieve accuracy, we need more efficient ways to encode this knowledge.

This paper proposes a method for inducing language-specific word order regularities captur-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 438–446,
Chiang Mai, Thailand, November 8 – 13, 2011.

ing cross-linguistically frequent constructions to constrain unsupervised grammar induction. We use the notion of syntactic prototype, a set of grammar rules automatically generated for such constructions. Categorial Dependency Grammar (CDG), which combines rules of constituency and dependency, is used to represent syntactic prototypes. We also propose a novel category penalty score for use in decoding, which defines the most probable parse according to a preference for less complex categories.

The paper is organized as follows. §2 details the method of encoding linguistic prior knowledge as a syntactic prototype. §3 explains an overview of our approach. §4 shows experiment results and discusses the errors. We conclude in §5.

2 Syntactic Prototypes

A *syntactic prototype* is a set of grammar rules representing default language parameters (such as word order for the most cross-linguistically frequent linguistic constructions, following Naseem et al. (2010)'s notion of cross-linguistic knowledge. This section shows how CDG rules are derived from a set of word order constraints.

2.1 Categorial Dependency Grammar

Categorial Dependency Grammar (CDG) is an extension of pure Categorial Grammar (CG) (Ajdukiewicz, 1935; Bar-Hillel, 1953) used for defining language-specific prototypes to be discovered. Its syntactic derivations define constituency and dependency in parallel. In CG, each constituent is assigned one or more syntactic categories, defined as an atomic category or a function category. For example, the proper name 'John' is assigned the atomic category np. If X and Y are categories of either kind, then X/Y and $X\backslash Y$ are function categories that map constituents of type Y respectively on the right and on the left into those of type X. For example, the intransitive verb 'walks' is assigned the function $S\backslash NP$.

We extended CG construct dependency structure alongside the syntactic derivation by encoding the direction of dependency in slashes. Using the head-outward notation for dependency of (Collins, 1999), the slash is subscripted $<$ ($>$) if the corresponding dependency is to be linked from the head on the right to its dependent on the left (the head on the left to its dependent on the right). For example, an English adjective (e.g. 'big') can be assigned the category $np/_{>}np$, while a transitive verb can be assigned $s\backslash_{>}np/_{<}np$. CDG differs from PF-CCG (Koller and Kuhlmann, 2009) in that dependency direction is specified independently from the order of function and argument, while theirs is determined by slash directionality. For them such an adjective has the implicit category $np/_{>}np$ and acts as the head of the noun phrase. The derivation rules for context-free CDG are listed below:

$$\begin{array}{llll} X/_{<}Y:d_1 & Y:d_2 & \Rightarrow & X:h(d_1)\rightarrow h(d_2) \\ X/_{>}Y:d_1 & Y:d_2 & \Rightarrow & X:h(d_1)\leftarrow h(d_2) \\ Y:d_1 & X\backslash_{<}Y:d_2 & \Rightarrow & X:h(d_1)\rightarrow h(d_2) \\ Y:d_1 & X\backslash_{>}Y:d_2 & \Rightarrow & X:h(d_1)\leftarrow h(d_2) \end{array} \quad (1)$$

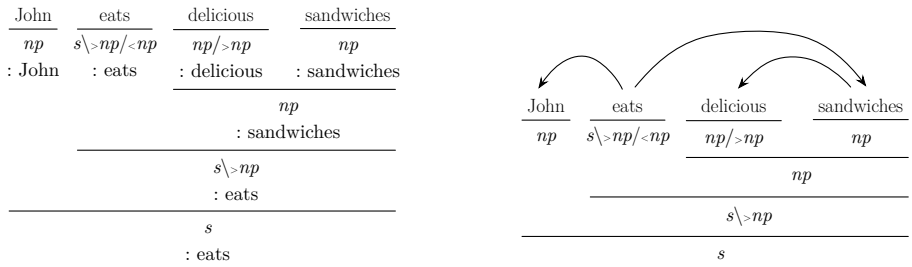
where the notations $h(d_1)\rightarrow h(d_2)$ and $h(d_1)\leftarrow h(d_2)$ mean a dependency linking from the head of the dependency structure d_1 to the head of d_2, and that linking from the head of d_2 to the head of d_1, respectively. Let us denote a constituent type with $C:w$, where C is a syntactic category and w is the head word of the constituent.

Given the CDG in (2), we obtain the syntactic derivation of the string 'John eats delicious sandwiches' in Figure 1.

$$\begin{array}{rcl} \text{John, sandwiches} & \vdash & np \\ \text{delicious} & \vdash & np/_{>}np \\ \text{eats} & \vdash & s\backslash_{>}np/_{<}np \end{array} \quad (2)$$

Figure 1(a) shows dependency-driven derivation, in which the heads of constituents are propagated. Figure 1(b) reflects the formation of the dependency structure corresponding to the dependency-driven derivation.

The attraction of using CDG for grammar induction is the integration of the constituent model and the dependency model. As shown in figure 1, the syntactic derivation defines the dependency structure, because we can directly construct a dependency structure from any head-driven syntactic derivations using the annotated directions. CDG can boost the accuracy of grammar induction by modeling rules of both constituent formation and dependency. However, the search space would become impossibly large if we had to enumerate all possible syntactic categories, including all possible arguments and dependency direction. This danger can be avoided by using small amounts of hand-crafted prior linguistic knowledge.



(a) Dependency-driven derivation.

(b) Equivalent dependency structure.

Figure 1: Syntactic derivation of 'John ate delicious sandwiches' based on CDG. Each constituent type is denoted by $C : w$, where C is a syntactic category and w is the head word, such as $s\backslash_{>}np/_{<}np$: eats.

However, a simple parametric syntactic prototype will give rise to parsing failures when faced with parametrically exceptional items, which occur in most if not all languages. We allow for such exceptions to be accommodated by defining an additional wildcard category $\star$ which combines with any syntactic category to yield the wildcard itself, according to the following additional combinatory rules:

$$\begin{aligned} \star : d_1 \quad X : d_2 \quad &\Rightarrow \quad \{\star : h(d_1) \leftarrow h(d_2), \\ &\qquad \star : h(d_1) \rightarrow h(d_2)\} \\ X : d_1 \quad \star : d_2 \quad &\Rightarrow \quad \{\star : h(d_1) \leftarrow h(d_2), \\ &\qquad \star : h(d_1) \rightarrow h(d_2)\} \end{aligned} \tag{3}$$

The wildcard is assigned to unknown words and large irreducible constituents so as to allow complete parses of otherwise unparsable sentences. As shown in (3), each wildcard derivation generates two possible dependency structures; i.e. d_1 and d_2 can be the head of a phrase. The wildcard will be revisited in §3.1.

2.2 Language Parameterization

We generate the CDG for each language automatically from language parameters. To facilitate this process, we have devised a questionnaire consisting of 30 questions concerning word orders for constructions that occur in most languages. Sorted by their importance, the questions can be grouped into the following categories:

1. The orders of subject, verb, direct object, and optional indirect object (1 question)
2. The argument orders of subject- and object-control verbs (2 questions)
3. The orders of adjectives, adverbs, and auxiliary verbs (4 questions)
4. The use of cardinal numbers and noun classifiers (2 questions)
5. The argument orders of adpositions, nominal modifiers, adverbials, possessive markers, relative pronouns, and subordinate conjunctions. (7 questions)
6. The orders of gerunds, infinitive markers, nominalizers, and sentential modifiers (6 questions)
7. The orders of particles, the existence of a copula, the usages of gerunds, the order of negative markers, the use of dative shifts, and the omission of discourse-given subject and object (8 questions)

These language parameters are used to automatically generate a CDG representing a syntactic prototype including language-specific types of cross-linguistically frequent categories[1] will be generated. For example, if a language has the word order SVIO, the syntactic category $s\backslash_{>}np$, $s\backslash_{>}np/_{<}np$, and $s\backslash_{>}np/_{<}np/_{<}np$ are generated and assigned by default to intransitive, transitive, and ditransitive verbs, respectively. Each slash in all syntactic categories is assigned with dependency directions according to Collins (1999)'s head percolation heuristics. All questions are optional; i.e. if any of the questions are left blank, all possible categories for that question will be generated.

Once the cross-linguistic category classes are generated, we then map them to the POS tags in a particular corpus. This part is an engineering task where the mapping should be best fitted to the

[1] E.g. intransitive verb, transitive verb, ditransitive verb, subject- and object-control verb, adjective, adverb, preposition, relative pronoun, gerund, copula, subordinate conjunction, noun classifier, infinitive marker, cardinal number, etc.

corpus. However, we will show in the experiment section that the preparation process for syntactic prototypes is quantifiable and reasonable in comparison to the improvement in accuracy attained.

3 Grammar Induction

3.1 Structure Enumeration

The first step in grammar induction is to enumerate all possible parses for each sentence. We use a table mapping from POS tags to language-specific categories to define the lexicon, and build a parse chart for each sentence with CKY Algorithm. A packed chart is used for both speed and space compactness. We apply a right-branching preference to eliminate spurious ambiguity caused by coordination and nominal compounding. In the event of a sentence yielding no parse using that lexicon, we assign the wildcard category '$\star$' to all unknown words and maximal irreducible constituents, and reparse the sentence.

3.2 Parsing Model

We extend the probabilistic context-free grammar with role-emission probabilities, defined as the product of the probability of each daughter category performing as a head or a dependent in a derivation. This model was motivated by Collins (1999)'s head-outward dependency model and Hockenmaier (2003)'s generative model for parsing CCG. Given a CDG G, we define the probability of a tree t having the constituent type $C : w$ by:

$$P(t|s,G) = \frac{1}{Z} \prod_{\substack{C:w\to\alpha \\ \in R(t)-L(t)}} \begin{array}{l} \pi_{\text{exp}}(\alpha|C:w,G) \\ \times \pi_{\text{head}}(H:w|G) \\ \times \pi_{\text{dep}}(D:w'|G) \end{array} \times \prod_{C:w\in N(t)} \pi_{\text{HE}}(w|C,G)^{\#_t(C:w)} \quad (4)$$

where Z is a normalization constant and each production α contains $H : w$ and $D : w'$, and $H : w$ and $D : w'$ are the head and the dependent, respectively. There are four types of parameters as follows.

1. $\pi_{\text{exp}}(\alpha|C : w, G)$: probability of the type $C : w$ generating a production α.

2. $\pi_{\text{head}}(C : w|G)$: probability of the type $C : w$ performing as a head.

$$\pi_{\text{head}}(C:w|G) = \frac{\sum_{C:w'} \#(C:w' \to \alpha_{\text{head}}^{C:w})}{\sum_{C':w'} \#(C':w' \to \alpha^{C:w})} \quad (5)$$

3. $\pi_{\text{dep}}(C : w|G)$: probability of the type $C : w$ performing as a dependent.

$$\pi_{\text{dep}}(C:w|G) = \frac{\sum_{C':w'} \#(C':w' \to \alpha_{\text{dep}}^{C:w})}{\sum_{C':w'} \#(C':w' \to \alpha^{C:w})} \quad (6)$$

4. $\pi_{\text{HE}}(w|C, G)$: probability of a category C generating the head w.

$$\pi_{\text{HE}}(w|C,G) = \frac{\sum_{t\in Q} \#_t(C:w)}{\sum_{t\in Q}\sum_{w'} \#_t(C:w')} \quad (7)$$

where $\alpha^{C:w}$ is a production that contains $C : w$, and $\alpha_{\text{head}}^{C:w}$ and $\alpha_{\text{dep}}^{C:w}$ have $C : w$ as the head and the dependent, respectively. $\#_t(C : w)$ is the frequency count of the category $C : w$ in the tree t. $N(t)$ is the set of all nonterminal nodes.

3.3 Parameter Estimation

Learning is achieved using the Variational Bayesian EM Algorithm (VB-EM) (Attias, 2000; Ghahramani and Beal, 2000) to estimate the parameters $\pi_{\text{exp}}, \pi_{\text{head}}, \pi_{\text{dep}}$, and π_{HE}. We followed the approach of Kurihara and Sato (2006) for training PCFGs with the VB-EM. This approach places Dirichlet priors over the multinomial grammar rule distributions. We set the Dirichlet hyperparameters to 1.0 for all rules containing the wildcard category and 5.0 for all others. In all other regards, we followed Kurihara and Sato (2006). The VB-EM algorithm iterates two processes of expectation calculation and parameter maximization. It is favored for the present purpose because it is less data-overfitting than the standard Inside/Outside Algorithm regarding its free-energy criteria for model selection. We calculate expected counts using Dynamic Programming (Baker, 1979; Lari and Young, 1990).

To further avoid the data over-fitting issue, we smoothed the probability of each substructure with the additive smoothing technique (Lidstone, 1920; Johnson, 1932; Jeffreys, 1948). An approximated parameter $\hat{\pi}(\tau)$ is calculated by

$$\hat{\pi}(\tau) = \frac{\pi(\tau)+\epsilon}{1+\epsilon} \quad (8)$$

where ϵ is a small constant value. In our experiments, we chose $\epsilon = 10^{-25}$.

3.4 Decoding with Category Penalty

By using prototypical syntactic categories in derivation, the system can be misled by complex

categories. A parse containing more complex categories is preferred to one containing less complex categories, because both simple and complex syntactic categories have the same chance of occurrence in parse enumeration. When learning the parameters, rules containing complex categories tend to have relatively excessive probability, as opposed to the Zipfian distribution of syntactic categories in which less complex categories are more frequently found in CCGbank. We therefore introduce a *category penalty* score.

The category penalty score is motivated by the observation that, in practical use of language, simpler categories tend to be used more frequently than the more complex ones. The penalty score $v(c)$ of the category c is defined as follows:

$$v(c) \quad = \quad k^{S(c)} \tag{9}$$

where $S(c)$ is the count of all forward and backward slashes in c and k is the penalty constant.

We weight each tree by the product of the penalty scores of the syntactic category on each node; i.e.

$$P(t|s,G) \quad = \quad \begin{cases} v(A) \cdot \pi(A \rightarrow w) & \text{lexicon} \\ v(A) \cdot \pi(A \rightarrow \alpha) & \text{branching} \\ \quad \cdot \prod_{i=1}^{|\alpha|} P(t_i|s,G) & \end{cases} \tag{10}$$

We use Viterbi decoding to find the most probable parse from a packed chart.

4 Experiments and Discussion

4.1 Datasets and Accuracy Metrics

In order to evaluate the method in comparison to the state of the art, we chose WSJ10, the standard collection of trees from WSJ part of PTB (Marcus et al., 1993) whose sentence length does not exceed ten words after taking out punctuation marks and empty elements. In stead of surface forms, we used a set of POS sequences taken from all WSJ10's trees to avoid the data sparsity issue. We converted the Penn Treebank into dependency structures with Collins (1999)'s head percolation heuristics. Following the literature, we trained the system with sections 2–22 and evaluated the resultant model on section 23.

For multilingual experiments, we made use of dependency corpora from the 2006 CoNLL X Shared Task (Buchholz and Marsi, 2006). Shown in Table 1, Chinese (Keh-Liann and Hsieh, 2004), Czech (Bohomovà et al., 2001), German (Brants et al., 2002), and Japanese (Kawata and Bartels, 2000) were chosen for the sake of language typology variety. We also chose sentences whose length does not exceed ten words after taking out punctuation marks. As a free-word-ordered, inflectional language, the Czech dataset was particularly prepared by augmenting the POS tags with inflectional information, resulting in significantly much more granularity. However, Czech's syntactic prototype does not make use of such syntactic information to restrain the search space.

Table 1: Sizes and granularity of POS of multilingual corpora

Languages	Sentences	POS Tags
WSJ10	7,422	36
Chinese10	52,424	28
Czech10	27,375	1,149
German10	13,473	51
Japanese10	12,884	77

We measured the capability of our system by two metrics: directed dependency accuracy, and undirected dependency accuracy (Klein, 2005). For directed dependency accuracy, we count a directed dependency of a word pair to be correct if it exists in the gold standard. For undirected dependency accuracy, we neglect the direction of the dependency. All accuracy numbers are reported in terms of precision, recall, and F1 scores.

4.2 Construction of Syntactic Prototypes

In order to construct syntactic prototypes for each language, we conduct an interview with a non-linguist native speaker. We ask him/her each question in the questionnaire mentioned in §2.2 by giving them a sample sentence and letting them build up the corresponding sentence in their language. We then ask questions to elicit word alignment and analyze the answers. Normally it takes up to two hours per previously unseen language to complete the questionnaire.

We then study the manual of the treebank's POS tags and mapped each to one or more language-specific category classes. Normally this process takes around four to six hours to thoroughly scrutinize the usage of each POS tag and assign them to appropriate classes. It therefore takes six to ten hours to build a syntactic prototype for each language.

4.3 Results

This section presents results of English and multilingual experiments using syntactic prototypes as a guide to grammar induction.

4.3.1 Experiments on English

Table 2 shows experiment results of English grammar induction on WSJ10. In the beginning, we compared the produced trees against the gold standard produced from Collins's parser. We trained the system with Sections 2–22 of WSJ10 and tested it on Section 23. In decoding, we set the category penalty constant to 10^{-15}. The F1 score outperforms the baseline set by (Naseem et al., 2010). To exhibit the stability of the approach, we also ran ten-fold cross validation on English; i.e. we divided WSJ10 into ten parts and, for each fold, we chose nine parts for as a training set and the other one as a test set. We attained higher F1 score, as expected for cross-validation, which effectively tests on the development set.

4.3.2 Effects of Numbers of Constraints and Category Penalties

Figure 2 shows the effects of numbers of constraints towards directed and undirected F1 scores. We varied the number of constraints in English syntactic prototypes. The category class 4 (the usages of cardinal numbers and noun classifiers) was neglected, because we can treat cardinal numbers as adjectives or nouns and there are no true noun classifiers in English. Therefore there are 28 constraints in total for English. We again trained on Sections 2–22 of WSJ10 and tested on Section 23. In decoding, we set the category penalty constant to 10^{-15}. We then evaluated the accuracy against the gold standard produced by Collins's parser.

As we increased the number of constraints in syntactic prototypes, we found that both directed and undirected F1 scores increase and start to saturate after the first 20 rules. In keeping with the Zipfian distribution, the first 20 rules cover frequent linguistic phenomena. When we pruned the search space with linguistic constraints, the directed accuracy starts to approach the undirected accuracy. We also note that errors generated by the system reflect the same attachment ambiguity errors as supervised parsing.

Figure 3 shows the effects of category penalty constants on accuracy. We again trained on Sections 2–22 of WSJ10 and tested on Section 23. We then evaluated the accuracy against the gold standard produced by Collins's parser. We notice that both accuracy scores saturate at the penalty constant of 10^{-15} and slightly decay afterwards.

	1	3	7	14	20	28
Directed	40.2	47.67	67.64	68.2	74.22	74.59
Undirected	54.02	59.59	73.74	73.58	78.55	79.11

Figure 3: Effects of category penalty on the directed and undirected dependency accuracy.

4.3.3 Multilingual Experiments

We also conducted multilingual experiments on Chinese, Czech, German, and Japanese to show the stability of the approach. We ran ten-fold cross validation on each language and calculated the average F1 scores. Our baseline systems are as follows: (Naseem et al., 2010) for English, (Snyder et al., 2009) for Chinese, and (Gillenwater et al., 2010) for Czech, German, and Japanese. In Table 3, our system significantly outperforms almost all the baselines, except in the Czech experiment. We believe that the under-performance of our system on Czech is caused by the data sparsity issue. Designed based on rather fixed word ordered languages, the syntactic prototype needs to generate almost all possible syntactic categories to capture Czech's free word orderedness. Although its POS

Table 2: Undirected and directed dependency accuracy of grammar induction on English Penn Treebank. The baseline for English is (Naseem et al., 2010).

	Undirected			Directed			Baseline
	Precision	**Recall**	**F1**	**Precision**	**Recall**	**F1**	**Directed F1**
WSJ10 (Sect. 23)	79.24	79.29	79.27	74.72	74.77	**74.75**	73.80
WSJ10 (10X)	79.59	79.65	79.62	75.44	75.50	75.47	—

tags are grouped to easily map to cross-linguistic category classes, each class still contains a lot of syntactic categories. Because we do not use inflectional information in restraining the search space, the data sparsity becomes significant in Czech and therefore deteriorates the accuracy.

4.4 Error Analysis

We counted erroneous dependency pairs generated in the English experiment (10X) in §4.3.1, and we classified errors into two types: over-generation and under-generation. From Table 4, we can notice that the majority of errors are caused by adverbial and prepositional attachment (e.g. RB > VB, CD < IN, and NN < IN), and NP structural ambiguity (e.g. NN > NNP, DT > NN, and NNP > NNP).[2] These errors are common in supervised parsing. There is also under-generation of adverbial preposition phrases. We believe that the category penalty score accounts for this issue, resulting in the NP-modifying preposition (such as $np\backslash_{<}np/_{>}np$) being preferred to the adverbial one (such as $s\backslash_{>}np\backslash_{<}(s\backslash_{>}np)/_{<}np$).

Table 4: Top-10 over-generation and under-generation in the English experiment (10X) when compared against Collins's gold standard

Over-generation		**Under-generation**	
Errors	**Counts**	**Errors**	**Counts**
RB > VB	402	VBD < IN	364
CD < IN	200	DT > NN	331
NN < IN	197	VBD < TO	283
RB > VBN	188	VBD < RB	275
NN < TO	181	VBZ < RB	244
NNP > CD	180	IN < NN	219
MD > VB	166	JJ > NN	203
NNS < IN	149	MD < RB	194
NNP > NN	145	MD < VB	185
NN > NNP	141	NNP > NNP	179

5 Conclusion

We have demonstrated an efficient approach to grammar induction using linguistic prior knowledge encoded as a prototype or lexical schema. This prior knowledge was used to capture frequent linguistic phenomena. To integrate the strength of constituent and dependency models, Categorial Dependency Grammar was used as the backbone formalism. We also proposed a category penalty score preferring less complex categories, based on the observation of the Zipfian distribution of category types in CCGbank.

Syntactic prototypes can capture the most frequent constructions and improve accuracy on almost all of the selected languages. We found that dependency accuracy correlates with the Zipfian distribution as the number of constraints increases, as the increase in accuracy saturates after the first 20 rules. Error analysis suggests that the main sources of error are in adverbial and prepositional attachment, and NP structural ambiguity, which are also problematic for supervised parsing.

Future work remains as follows. First, we are looking forward to improving the capability of our syntactic prototype to also handle free word ordered languages by generating syntactic categories with more flexible combination and restraining the search space with inflectional information. Second, we plan to experiment on grammar induction from untagged words by decomposing the model into tagging and parsing subproblems (Ganchev et al., 2009; Rush et al., 2010; Auli and Lopez, 2011). Third and finally, we will experiment on longer sentences to show the scalability of our approach in dealing with larger data.

Abstract

Various works have used word alignments in parallel corpora to transfer information like POS tags, syntactic trees and word senses from source to target sentences. In this paper, we work on the problem of projecting syntactic relations from English to morphologically rich Hindi parallel text. We show the effectiveness of Local Word Groups (LWGs) in simplifying alignments as well as in transferring syntactic dependencies by building an alignment model with LWGs as base units and training a dependency parser on the relations projected using these LWGs. The LWG alignment model using GIZA++ scores decreases the Alignment Error Rate by 1.16 points when compared to the best GIZA++ model trained on lemmas. We also show that a dependency parser trained on the syntactic relations projected using LWGs obtained statistical significant improvements over the relations projected using lemmas by a margin of 3.49%.

1 Introduction

Data driven dependency parsers rely on the availability of large amounts of annotated data and building them is a time consuming, labour intensive and expensive task. Recent efforts in treebank creation have looked at the concept of *annotation projection* from a resource-rich language to a resource-poor one in a parallel corpus (Yarowsky et al., 2001). The central idea is to transfer the relevant information from source to target text given the analysis on the source side and word-alignments in a parallel corpora. A projected dependency treebank is created by projecting source parse from an automatic parser on to a target sentence using word alignments between the source and target sentences (Hwa et al., 2005; Jiang and Liu, 2009; Spreyer and Kuhn, 2009; Spreyer et al., 2010).

Difficulties in transferring syntactic relations from the source to target sentences arise mainly due to (i) errors in the source parse, (ii) errors in word alignments and (iii) differences in the dependency annotation schemes of the two languages (Ganchev et al., 2009). The third one can be handled by systematically identifying the differences in the annotation schemes and applying relevant transformations (Hwa et al., 2005).

In this work, we minimize the scope of errors in (i) and (ii) and the effect they have on projection task by proposing a novel technique for projecting syntactic dependencies using alignments between local word groups instead of word forms. The aim is to make the projection task simpler by transferring the relations in source LWGs to the corresponding target LWGs first and then get the alignments and projections on the head words of these LWGs. We show how LWGs can effectively be used to handle the inflectional variations in Hindi and thereby improve the word alignment accuracy between English and Hindi. We also show that the projection of syntactic relations becomes easier and more effective when dealing with LWGs rather than word-forms. We present the experiments and report the improvements in results obtained by using LWGs in alignment accuracy and parsing accuracy for English-Hindi language pair. The approach described in the paper is not specific to the English-Hindi language pair and can be extended to other language pairs involving at least one morphologically rich language.

The rest of the paper is organized as follows: Section 2 gives the related work and section 3 introduces the concept of LWGs. Section 4 presents the alignment models used in this work and section 5 describes the dependency projection algorithm. Section 6 lists the experiments conducted

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 447–455,
Chiang Mai, Thailand, November 8 – 13, 2011.

and reports the results. Section 7 ends the paper with the concluding remarks and gives the scope of future work in this direction.

2 Related Work

Earlier works in projecting dependencies using word alignments have mainly concentrated on aligning word forms, projecting dependencies based on the aligned words and then improving the projections using post-projection transformations.

(Hwa et al., 2005) project the syntactic dependencies from one language to another using the notion of *direct correspondence*. If the syntactic tree is not fully connected, they used post-projection transformations to make it complete and reported significant improvements due to it. (Ganchev et al., 2009) used open source posterior alignment toolkit PostCAT (Graca et al., 2009) for word alignments to project the syntactic dependencies in a way similar to (Hwa et al., 2005). They use some soft-constriants for word alignments to prevent false transfer of information and also experiment with the projections by varying post-projection transformation rules.

For dependency projection, (Spreyer and Kuhn, 2009) also start with the notion of *direct correspondence* with additional constraints involving (i) only the bi-directional alignment links (alignment links marked from both source to target language and target to source language) and (ii) the completeness of the projected tree. This ensures the reduction of errors in the data. It is further extended to consider the uni-directional alignments based on the partial analyses built from the confident bi-directional links. They report no significant increase in accuracy with the above extension because of the increase in noise. To reduce this drawback and make use of non-fully connected trees, they stick to the use of bi-directional alignment links in conjunction with a fixed number of fragmented analyses in a sentence.

(Jiang and Liu, 2009) refer to an alignment matrix and a dynamic programming algorithm to search for a completed projected tree. To reduce the impact of word alignment errors, (Jiang and Liu, 2010) consider compact representation of multiple GIZA++ (Och and Ney, 2000) alignment results. For each pair of words in a target sentence, they calculate the score of an edge depending on the alignment scores and source parses information. During parsing, they treat each syntactic tree as a set of dependency edges without relying on the complete tree.

The above approaches either pick most confident alignments links for dependency projection or pick the alignments as it is and then reduce the noise in the data using post-projection transformation rules. In this work, we focus on reducing both alignment and dependency projection complexity using LWGs. The relations within LWGs are deterministically marked irrespective of the alignments and by using only the head word of each LWG during alignment we alleviate data sparseness arising due to the the presence of inflectional variations in Hindi.

3 Local Word Groups

We define *local word groups* as minimal contiguous sequence of words in a sentence with a fixed word order and deterministic (trivially predictable) syntactic structure among them. For example, `will be given` is a verb group with the syntactic structure `will`→`be`→`given` which can be determined deterministically given the POS tags. Each LWG has a head word which is the syntactic head of the group of words (`will` in the example). LWG is similar to chunk except that LWGs are always minimal and refer to the fixed order property of the components. The advantage of using LWGs over chunks is the accuracy of identifying LWGs is higher than the accuracy of identifying chunk boundaries in source and target language. Also, the dependency relations within a chunk are non-deterministic in few cases (if we consider noun chunks). Moreover they can be computed with minimum computational effort.

The advantages LWGs provide during word alignment and transfer of syntactic information from source language to target language are:

1. It transform certain kinds of many-to-one, one-to-many and many-to-many alignments between word forms as one-to-one alignments between the LWGs thereby reducing data sparsity during alignment.

2. Since the internal structure of a LWG is fixed, we can confidently mark the syntactic relations within a LWG leaving out scope for errors arising out of word alignment and source dependency parses.

3. Number of syntactic relations to be projected reduced from number of words in a sentence

to number of LWGs thereby reducing the scope of errors in projection.

In Figure 1(a), *administratively* is aligned to *prashaansanika roopa se*. Once these alignments are obtained, in order to get the dependency relations roopa→prashaansanika and roopa→se correct from the projection of dependencies, the source dependency parse should be correct and the word alignment to all the three target words should be correct. The word alignment complexity further increases in the case of aligning *does come* to *aathaa hai* correctly considering the presence of inflectional variations in Hindi. Unless all the four alignments are correct, the dependency projection will not be correct. The complexity is further increased due to the non-availability of large bilingual corpus. In such cases, LWGs play an important role in reducing the complexity as well as in reducing the scope of errors to certain extent. We consider three kinds

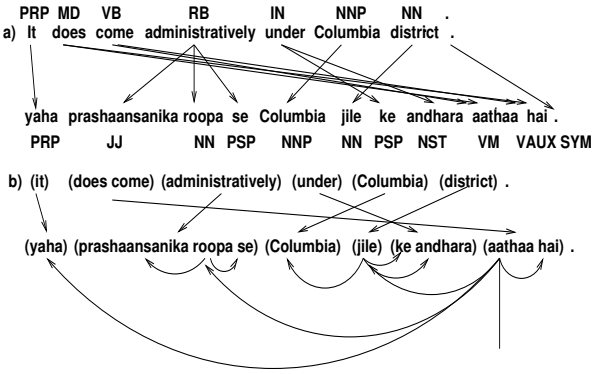

Figure 1: Alignments without and with LWGs

of LWGs verb groups (VG), preposition (postposition in case of Hindi) groups (PG) and adverb groups (ADVG). Noun groups are not considered since the internal syntactic structure is non-trivial to predict. For instance, in the example in figure 1(a), finding the syntactic structure for the words in the noun group Columbia←district is non-deterministic (non-trivial) given the POS tags. VM and VAUX are the two POS tags used to denote main verb and auxiliary verb in Hindi. Any occurrence of the pattern VM VAUX⋆ is considered a verb LWG eg. (kara rahaa hai [*doing*], karna chahtaa hu [*want to do*]). Any continuous sequence of auxiliary verbs and a main verb is taken as a LWG in English for eg. *are going*, *did not go*. Postpositions in Hindi are also grouped into LWG. This is done to make alignments easy between prepositions in English and multi-word postpositions in Hindi such as ke saatha [*with*], ke baahara [*outside*] etc. Adverbs in English often end up as roopa se [*+ly*] morpheme in Hindi. Combining the adjective/noun with roopa se into a LWG helps the alignment model. Similarly few other cases where forming LWGs help in making alignments easy were identified and are marked as LWGs.

In Figure 1, (aathaa hai [*does come*]) is a verb group, ke andhara [*under*], are post-positions and (prashaansanika roopa se [*administratively*]) is an adverb group. The syntactic relations aathaa→hai, roopa→prashaansanika and roopa→se are marked directly irrespective of the word alignments.

Table 1 lists the corpus stats of word forms and LWGs. Apart from the advantages of LWGs listed above in this section, the reduction in the sentence length also helps improve the alignment accuracy.

Metric	English	Hindi
No. of Words	224K	251K
Avg. sentence length with words	19.29	21.61
No. of LWGs	191K	226K
Avg sentence length with LWGs	16.45	19.49

Table 1: Statistics of the entire corpus used with respect to words and LWGs.

4 Word Alignment

4.1 Scoring Function

We use a slight variant of competitive linking algorithm (CL) described in (Melamed, 2000) as scoring function and is discussed below in section 4.2. We also generate mappings between source and target language word classes from a small bilingual corpus containing hand-aligned gold alignments and manually annotated word class information. For each source word class, the mappings are stored by decreasing order of target word class co-occurrences (Wcmap).

4.2 LWG model

Instead of computing scores between source and target word forms in a two-dimensional array as in (Melamed, 2000), we compute scores between source LWGs and target LWGs. For each source LWG, the candidate LWGs are restricted to the ones whose content word's POS tag are in the

mapping list of source LWG content word's POS. The alignment pair with the maximum score is chosen, the corresponding row and column are deleted for further processing. The process is repeated until it finishes. The differences here when compared to competitive linking algorithm (Melamed, 2000) are that we use LWGs instead of words and restricting the possible candidate LWGs by taking word class information into account. We refer to this model as CL-LWG in the rest of the paper.

Once the one-to-one alignments between source and target LWGs are computed, the word to word alignments have to be recovered from them in a postprocessing step. This is done by assigning alignments between all the words in a target LWG to all the words in the source LWG and vice versa. This postprocessing step makes the final set contain contain one-to-many, many-to-one and many-to-many alignments.

4.3 Case of Left Out *Units*

In the model described above, there is a possibility of source or target *units* being left out without any alignments. This is because the model only does one-to-one mapping and the number of *units* in the source and target sentence could be different. The left out *units* need not be a case of NULL alignments (such as determiners). The alignments for the left out *units* are assigned by using a greedy best first alignment strategy.

4.4 Weighted Model

The CL-LWG alignment model can be further extended to use alignment scores from GIZA++ model apart from the scoring function described in Section 4.1. A weighted score of the score from the scoring function and GIZA++ can be used to decode the model. Let s1 be the score of the scoring function described above and s2 be the score obtained from GIZA++ then the weighted score S is defined as

$$S = \lambda * s1 + (1 - \lambda) * s2; \quad (1)$$

whereas λ is varied from 0 to 1 and the best value of λ is chosen by tuning it on the development dataset.

5 Dependency Projection

Once the alignments are obtained, projection of dependencies from source to target sentences is undertaken. The input is a set of alignments between source and target language and the source dependency parse with the projected dependency parse of the target sentence as the output. Parses for English have been obtained using first order MST parser (McDonald et al., 2005) trained on 2-21 sections of Penn Treebank (Marcus et al., 1993).

5.1 Annotation Scheme Differences

When projecting relations from source to target text, the annotation scheme of source treebank is carried over to the target side. This projected target dependency treebank may not be consistent with the annotation scheme of the target language. The annotation scheme differences need to be handled to make the projected parses consistent for dependency parse evaluation. This also ensures that the projected treebank could be used for bootstrapping parsers (Steedman et al., 2003; Reichart and Rappoport, 2007).

Some of the major differences in the English and Hindi annotation schemes are

1. Head of a Verb Phrase (VP) is the main verb in Hindi whereas the head of a VP in an English sentence is the auxiliary verb.

2. Head of a Prepositional Phrase (PP) in Hindi is noun whereas it is the preposition in English.

3. In Hindi, conjunct is the head in case of both noun and verb co-ordination whereas in English it is not.

There are two possible ways of addressing this issue. The first one is to apply tranformations before dependency projection (pre-projection) i.e., to the source parse and the second one involves applying tranformations to the target parse once the dependency projection is made (post-projection). This assures that the projected treebank is consistent with the annotation scheme of the target language. It does not make any difference while choosing whether to apply pre-projection or post-projection. In our case, we choose to apply pre-projection i.e., to the source dependency parse just for our convenience. Appropriate pre-projection transformations shown in Figure 2 have been applied to the source parse to reflect the target language annotation scheme described in (Begum et al., 2008).

Figure 2(a) presents the tranformations applied in case of finite verbs (*going*) i.e., switch the dependencies between the current parent (*has*) and finite verb (*going*) then make the rest of them as dependents to the finite verb. In case of PP chunk, switch the dependencies of noun (*complaint*) and preposition (*on*) i.e., make parent of noun as parent of preposition and make the preposition (*on*) as dependent to the noun (*complaint*) as shown in Figure 2(b). In case of noun co-ordination shown in Figure 2(c), switch the dependencies between the rightmost conjunct (*officials*) and co-ordination word (*and*). Then the remaining words (*investors*, *managers* and ,) are made as dependents to the co-ordinated word (*and*). Same co-ordination transformations shown in Figure 2(d) are applied in case of verb co-ordination except that the switching of dependencies take place between the left most finite verb (*makes*) and co-ordination word (*and*) whereas it is rightmost conjunct in case of noun co-ordination (*officials*).

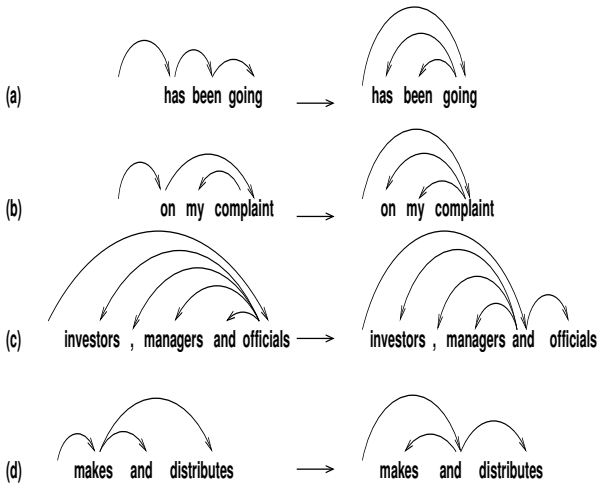

Figure 2: Transformations applied to the source parse.

5.2 Projection Algorithm

Let S(s_1,s_2,..,s_m), T(t_1,t_2,..,t_n) be the source and target language sentences of length m and n. For each dependency relation (s_i, s_j) where s_i is the head of s_j, the projection is done depending on the type of alignment s_i and s_j have with the words in the target sentence. The one-many, many-one and many-many alignments are transformed into one-one alignments by making the syntactic head word of the "many" words in the alignment as "one" representative word and the rest as the dependents of the head word.

1. If s_i is aligned to t_k (*one-one* alignment) and s_j is aligned to t_l (*one-one* alignment) then mark the dependency relation (t_k, t_l).

2. If s_i is aligned to t_a,...,tk (*one-many* alignment)and s_j is aligned to t_l (*one-one* alignment) then pick the head word t_h from t_a,...,tk target words and make the remaining as dependents to the head word and mark the dependency relation as (t_h, t_l).

3. if s_a,...,si are aligned to t_k (*many-one* alignment) and s_j is aligned to t_l then pick the head word s_h from s_a,...,si source words and repeat step 1.

4. The *many-many* alignments are also converted to *one-one* by first performing the *one-many* transformation in step 2 and then the transformation for *many-one* in step 3.

If there are any unaligned words in the target sentence then they are left as unconnected words in the projected target dependency tree. The head word from a list of words in the above transformations is obtained using word class information.

6 Experiments

Our experiments have been carried out on English-Hindi parallel text from EMILLE corpus. EMILLE is a 63 million word electronic corpus of South Asian languages, especially those spoken as minority languages in UK (Xiao et al., 2004). The dataset has 3341 training sentences and 90 manually aligned test sentences (with 1121 English words and 1323 Hindi words). It is a small corpus compared to corpora available for other language pairs.

We evaluate the word alignments as well as the projected target relations to measure the effectiveness of LWGs in alignment as well as in projection process. For evaluating the quality of projected target relations, a parser is trained on the dependency edges obtained using projections on alignments between LWGs and those obtained using projections on just word/lemma alignments.

6.1 Word Alignment Evaluation

The alignments are compared with those obtained by GIZA++ (Och and Ney, 2000) and PostCat (Graca et al., 2009). We train two GIZA++ models

for comparison with our model. The first model is trained with the word forms from the above dataset and second one with the lemmas (roots) of the words. For each of these models, the best among the grow-diag, grow-diag-final and grow-diag-final-and (gdfa) modes have been taken for comparison. Two models are trained using PostCAT, same as with GIZA++, one with the word forms and the other with the lemmas of the words. For each of these models, the best among the baseline, agreement and substochastic modes have been taken for comparison. The alignment models are evaluated using the standard alignment evaluation metrics precision, recall, F score and Alignment Error Rate (AER) as described in (Hua et al., 2005).

Id	Models	P	R	AER
WF-PC	PostCAT	59.49	46.73	47.65
WF-GZ	GIZA++	47.30	**52.55**	50.2
WF-LWG	CL-LWG	**60.94**	47.1	**46.88**

Table 2: Evaluation Results with Word Forms as *Units*. WF denotes word forms, PC is PostCAT, GZ is GIZA++ and LWG is our model.

Table 2 presents the Precision (P), Recall (R) and AER (1-F) for all the models. All the models in the table use the word forms given in the parallel sentences and do not consider the lemmas. Our LWG model (*WF-LWG*) performs better than the GIZA++ model (*WF-GZ*) and PostCAT model (*WF-PC*) by a margin of 3.32 and 1.23 points respectively . This shows that the LWGs are more effective than word forms when it comes to English-Hindi parallel data.

Since Hindi is a morphologically rich language and the bilingual corpus we use is small, data sparsity becomes a major problem for word alignment. This can be alleviated to some extent by learning from lemmas instead of the word forms themselves.

Id	Models	P	R	AER
LM-PC	PostCAT	51.07	42.25	53.75
LM-GZ	GIZA++	**62.14**	**49.78**	**44.72**
LM-LWG	CL-LWG	60.15	48.58	46.24

Table 3: Evaluation Results with Root Words as *Units*. LM denotes lemmas (roots) of the words.

Table 3 lists the performance of the PostCAT, GIZA++ and LWG model when trained with lemmas. In case of LWGs, the lemmas of the head words are used. GIZA++ trained on lemmas (*LM-GZ*) has a significant reduction in AER when compared to the one trained on word forms (*WF-GZ*). This is expected due to the above mentioned reason of Hindi being morphologically rich and lemmas reducing data sparseness. The lemmatized LWG model (*LM-LWG*) under performs when compared to GIZA++ trained on lemmas (*LM-GZ*) even though in the case of training on word forms, *WF-LWG* out performed *WF-GZ*. This is because LWGs with word forms reduce the problem of data sparseness when compared to just word forms being used in GIZA++ model *WF-GZ* but the gains in lemmatized model is not that significant to beat the gains achieved in lemmatized GIZA++ model. Moreover, the scoring function of GIZA++ is more sophisticated than the one we use.

To get the combined effects of using LWGs and GIZA++'s scoring function, two models using weighted scores of scores from LWG model and GIZA++ model for word forms (*WF-LWG-WGT*) and lemmas (*LM-LWG-WGT*) were built.

Id	Models	P	R	AER
WF-LWG-WGT	WM	61.86	47.94	45.98
LM-LWG-WGT	WM	**62.85**	51.21	**43.56**

Table 4: Evaluation Results for Weighted Models (WMs)

Table 4 lists the evaluation scores for the weighted models. The combined models beat the respective best word form and lemma models (i.e., *WF-LWG* and *LM-GZ*) by 0.9 and 1.16 respectively. The best alignment accuracy was achieved by the combined model trained on lemmas.

Experiments were conducted by combining words in each LWG using underscores and also by using only head word of each LWG as input to GIZA++. Using a post-processing step, the word alignments were recovered from the resulting alignments. The alignment accuracies decreased significantly using this approach.

6.2 Evaluation of projected parses

Projections from English dependency trees using alignments produced by various models described above have been obtained and trained separately. We used a modified version of bidirectional parser (Shen and Joshi, 2008) described in (Mannem and Dara, 2011) to train the projected dependencies. The parsers evaluation was done on manually an-

Alignment	Word forms (WF)			Lemmas (LM)		
	EMILLE	*EILMT*	*BOTH*	*EMILLE*	*EILMT*	*BOTH*
PC	72.76	72.31	74.26	72.15	72.23	72.48
GZ	74.93	77.71	77.17	75.87	77.33	77.08
LWG-WGT	**78.06**	**79.50**	**79.79**	**78.76**	**80.52**	**80.57**

Table 5: Parsing accuracy corresponding to the parsers trained on projections from alignment models when evaluated with gold POS tags. The six respective parsers are referred by prefixing WF- and LM- to the three alignment models (PC, GZ and LWG-WGT).

Alignment	Word forms (WF)			Lemmas (LM)		
	EMILLE	*EILMT*	*BOTH*	*EMILLE*	*EILMT*	*BOTH*
PC	61.06	61.60	62.50	61.98	61.90	61.51
GZ	63.40	65.85	65.71	64.51	65.50	65.50
LWG-WGT	**66.86**	**67.88**	**68.37**	**67.50**	**68.22**	**68.75**

Table 6: Parsing accuracy corresponding to the parsers trained on projections from alignment models when evaluated with automatic POS tags. The six respective parsers are referred by prefixing WF- and LM- to the three alignment models (PC, GZ and LWG-WGT).

notated test data with gold POS tags released as part of ICON-2010 NLP Tools Contest (ICON, 2010). We also presented the results on the manually annotated test data with the automatic POS tags.

We use an additional English-Hindi parallel corpus containing 8169 sentences developed as part of a consortium project (Venkatapathy, 2008) [1]. This dataset wasn't used for evaluating word alignments due to the lack of manually annotated alignments. This sentence aligned corpus was developed to aid building translation systems for the tourism domain and doesn't have any human annotated word alignments. The corpus is a collection of articles about various tourist and pilgrimage places. It has a high occurrence of proper nouns as a result of this. The corpus is also noisy with typographical errors, mismatched sentences and unfaithful translations.

The parser is trained on the projected data extracted using alignments from all the three different alignment models using word forms and LWGs. Table 5 gives the Unlabeled Attached Score (UAS) of the parser on the test data. The parsers corresponding to *WF-LWG-WGT* and *LM-LWG-WGT* alignments obtained siginificant improvements of 2.62 points and 3.49 points in parsing accuracy over the ones using GIZA++ alignments on words and lemmas when both the datasets are used for training. The results obtained are statistically significant (McNemar's and $p < 0.05$). The parser trained on the projected data obtained using *LM-LWG-WGT* alignments achieved an improvement of over 0.78 points over the one trained using *WF-LWG-WGT* alignments and it is expected.

Table 6 gives the parsing accuracies on test data with automatic POS tags. The parsing accuracy corresponding to *LM-LWG-WGT* alignment model has dropped from 80.57 to 68.75 due to the difference in usage of POS tags. For all the datasets, the parser trained on the projected data obtained using word alignments from the weighted models (*WF-LWG-WGT*, *LM-LWG-WGT*) performed the best and the results are statistically significant (McNemar's and $p < 0.05$) over the models using alignments from GIZA++ and PostCAT in terms of both word forms and lemmas. (Ambati et al., 2010) achieved an accuracy of 85.5% UAS by training on Hyderabad Dependency Treebank (Bhatt et al., 2009) and evaluating with automatic POS tags. This would be an upper-bound for approaches like ours which do not use any annotated data to build the parser.

The Hindi dependency treebank has chunks marked for every sentence and the dependencies are marked between chunk head words. Following the tradition in Hindi dependency parsing, we

[1]The original training and test sets in this corpus contained 11,300 and 500 sentences respectively. But, both the datasets had a large number of sentence repetitions. The sizes reported in this paper are after removing all duplicate sentences. http://ltrc.iiit.ac.in/icon2008/nlptools.php

evaluate and compare the two parsing models on their inter-chunk and intra-chunk dependencies. A total of 6454 dependency relations are present in the test data out of which 3401 are intra-chunk dependencies and the rest 3053 are inter-chunk dependencies. The models which achieved best accuracy (*LM-LWG-WGT*, *WF-GZ* and *WF-PC*) are taken into comparison when both the datasets are used for training.

Table 7 gives the accuracies w.r.t few POS tags achieved by various parsing models tested with gold POS tags in the test data. These POS tags are the most frequent tags of chunk head words and the accuracies denote the inter-chunk accuracies of the models. The analysis on intra-chunk dependencies hasn't been shown since there isn't much difference in the accuracies between the two parsing models. This is because, though *WF-PC* and *WF-GZ* don't use any LWGs, the intra-chunk relations are corrected and are made similar to those produced using *LM-LWG-WGT* by using transformation rules during projection as described in section 3. As seen in Table 7 for inter-chunk dependencies, *LM-LWG-WGT* alignment based parsing model performs better than the model using *WF-GZ* and *WF-PC* alignments for most POS tags (except CC tag) when compared to *WF-GZ*. This is because of better alignments achieved by *LM-LWG-WGT* using LWGs over *WF-GZ*, *WF-PC* and thereby better dependency projections to learn from.

POS	Total	WF-PC	WF-GZ	LM-LWG-WGT
NN	1257	57.28	58.15	**66.35**
VM	710	33.10	44.65	**55.91**
NNP	444	38.29	45.27	**50.00**
CC	213	39.90	**52.58**	46.95
PRP	209	35.41	47.85	**51.67**
JJ	129	72.10	74.42	**88.37**
RB	33	24.24	45.45	**51.51**

Table 7: Parsing Accuracies on inter-chunk dependencies when both the datasets are combined. Total represent the total number of inter-chunk dependencies with each POS tag occurred in the test data. Third, fourth and fifth columns represent the percentage of correct inter-chunk dependencies for each POS tag obtained using the respective alignment models.

7 Conclusions and Future Work

In this work, we presented a novel approach for syntactic transfer of relations from source to target sentences by using alignments between LWGs instead of word forms. We also showed the effectiveness of LWGs while handling one-to-many, many-to-one and many-to-many alignments during both word alignment and dependency projection. The LWG weighted alignment model decreased the AER by 1.16 points over GIZA++ trained on lemmas and a bidirectional dependency parser trained on the syntactic relations projected using LWGs outperforms the relations projected using lemmas by a statistically significant margin of 3.49 points. We also presented evaluation of parsers in terms of inter chunk and intra chunk dependencies. Extending this work to other resource-poor Indian language pairs will be the starting point of our future work.

Generative Modeling of Coordination by Factoring Parallelism and Selectional Preferences

Daisuke Kawahara and **Sadao Kurohashi**

Yoshida-Honmachi, Sakyo-ku, Kyoto, 606-8501, Japan
{dk, kuro}@i.kyoto-u.ac.jp

Abstract

We present a unified generative model of coordination that considers parallelism of conjuncts and selectional preferences. Parallelism of conjuncts, which frequently characterizes coordinate structures, is modeled as a synchronized generation process in the generative parser. Selectional preferences learned from a large web corpus provide an important clue for resolving the ambiguities of coordinate structures. Our experiments of Japanese dependency parsing indicate the effectiveness of our approach, particularly in the domains of newspapers and patents.

1 Introduction

Coordinate structures are a potential source of syntactic ambiguity in natural language. Although many methods have been proposed to resolve the ambiguities of coordinate structures, coordination disambiguation still remains a difficult problem for state-of-the-art parsers. Previous studies on coordination disambiguation used two kinds of clues:

- parallelism of conjuncts, and
- selectional preferences.

Syntactic, lexical and semantic parallelism of conjuncts is frequently observed in coordinate structures. For example, Dubey et al. (2005) empirically confirmed syntactic parallelism in coordinate structures. This clue was modeled by string matching, part-of-speech matching, number agreement, semantic similarities, and so forth (Agarwal and Boggess, 1992; Kurohashi and Nagao, 1994; Resnik, 1999; Chantree et al., 2005; Buyko and Hahn, 2008). For instance, consider the following example:

(1) eat Caesar salad and Italian pasta

We can observe lexical or semantic parallelism between *salad* and *pasta*, which can be automatically detected via a thesaurus or distributional similarity. In addition, syntactic parallelism can be observed; each conjunct has a modifier *Caesar* and *Italian*, respectively. These types of parallelism contribute to identifying the coordinate structure that conjoins *Caesar salad* and *Italian pasta*.

The other clue is selectional preferences, such as *eat* in the above example. Since *eat* is likely to have *salad* and *pasta* as its objects, it is plausible that *salad* and *pasta* are coordinated. Such selectional preferences of predicates are thought to support the construction of coordinate structures, and were used in Japanese dependency parsing by Kawahara and Kurohashi (2008). Selectional preferences of nouns (noun-noun modifications) were used by Resnik (1999), Nakov and Hearst (2005) and Kawahara and Kurohashi (2008). For example, let us see the following examples:

(2) a. mail and securities fraud
b. corn and peanut butter

In (2a), the coordination of *mail* and *securities* is guided by the estimation that *mail fraud* is a salient compound nominal phrase. In (2b), on the contrary, the coordinate structure that conjoins *corn* and *peanut butter* is led because *corn butter* is not a familiar concept.

Each clue has been empirically proven to be effective for coordination disambiguation. However, a unified approach that combines both clues has not been explored comprehensively. In this paper, we propose a unified framework for coordi-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 456–464,
Chiang Mai, Thailand, November 8 – 13, 2011.

nation disambiguation by incorporating both the clues into a generative parser. To capture syntactic parallelism of conjuncts, we formulate the generative process of pre-modifiers of conjuncts in a synchronized manner. In the above example, the generation process of *Caesar* from *salad* is synchronized with that of *Italian* from *pasta*. An interpretation of an unbalanced coordinate structure without synchronization (e.g., "Caesar salad and Italian") is penalized. Lexical parallelism, which is a tendency that some words, such as *salad* and *pasta*, are likely to be coordinated, is also modeled within the generative model.

In this paper, we focus on the Japanese language. A synchronization-based model of coordination disambiguation is integrated into a fully-lexicalized Japanese generative parser (Kawahara and Kurohashi, 2008). For the selectional preferences, we use case frames and statistics of noun-noun modifications that are automatically extracted from large raw corpora. Our method can resolve coordinate structures with parallelism on the basis of the synchronized generative model, and can also handle unlike coordinate structures using selectional preferences.

The remainder of this paper is organized as follows. Section 2 summarizes previous work related mainly to parsing models with coordination disambiguation. Section 3 briefly overviews the Japanese language and coordination ambiguity in Japanese. Section 4 illustrates our idea and describes our model in detail. Section 5 is devoted to our experiments. Finally, section 6 gives the conclusions.

2 Related Work

Resnik (1999) and van Noord (2007) incorporated parallelism and selectional preferences into coordination disambiguation or parsing. Resnik (1999) integrated semantic similarities and noun-noun modifications into voting or decision trees to disambiguate the scope ambiguities of nominal compounds "n1 and n2 n3." He did not integrate this method into parsing, but applied it to an independent task. Van Noord (2007) proposed a MaxEnt model of Dutch parsing that incorporated selectional preferences learned from a large corpus. He used various features in the MaxEnt model including some features that capture parallelism. This indirect treatment of parallelism is different from our generative model that explicitly factors parallelism.

Several other studies have considered parallelism in parsing models. Charniak and Johnson (2005) incorporated some features of syntactic parallelism in coordinate structures into their MaxEnt reranking parser. Kübler et al. (2009) used a reranking parser with automatically detected scope possibilities to improve German parsing. As for a generative parser, Dubey et al. (2006) proposed an unlexicalized PCFG parser that modified PCFG probabilities to condition the existence of a coordinate structure. Hogan (2007) proposed a generative lexicalized parser that considered the symmetry of part-of-speech tags and phrase categories of conjuncts, which is more shallow information than our synchronization model. She also used cooccurrence statistics of conjunct heads, which are similar to our modeling of lexical parallelism, but her model did not use selectional preferences.

Kurohashi and Nagao (1994) proposed a rule-based method of Japanese dependency parsing that included coordination disambiguation. Their method first detects coordinate structures in a sentence using dynamic programming, and then determines the dependency structure of the sentence under the constraints of the detected coordinate structures. Shimbo and Hara (2007) and Hara et al. (2009) considered many features for coordination disambiguation and automatically optimized their weights, which were heuristically determined in Kurohashi and Nagao (1994), by using a discriminative learning model.

3 Japanese Grammar and Coordinate Structure

3.1 Japanese Grammar

Let us first briefly introduce Japanese grammar. The structure of a Japanese sentence can be described well by the dependency relation between *bunsetsu*s. A *bunsetsu* is a basic unit of dependency, consisting of one or more content words and the following zero or more function words. A *bunsetsu* corresponds to a base phrase in English and *eojeol* in Korean. The Japanese language is head-final, that is, a *bunsetsu* depends on another *bunsetsu* to its right (but not necessarily the adjacent *bunsetsu*).

For example, consider the following sentence:[1]

[1]In this paper, we use the following abbreviations: NOM (nominative), ACC (accusative), DAT (dative), ALL (alla-

(3) *ane-to gakkou-ni itta*
sister-CMI school-ALL went

(went to school with (my) sister)

This sentence consists of three *bunsetsu*s. The final *bunsetsu*, *itta*, is a predicate, and the other *bunsetsu*s, *ane-to* and *gakkou-ni*, are its arguments. Their endings, *to* and *ni*, are postpositions that function as case markers.

3.2 Coordinate Structure in Japanese

Coordinate structures in Japanese are roughly classified into two types. The first type is the nominal coordinate structure.

(4) *nagai enpitsu-**to** keshigomu-wo katta*
long pencil-CNJ eraser-ACC bought

(bought a long pencil and an eraser)

The other type is the predicative coordinate structure, in which two or more predicates form a coordinate structure.

(5) *kanojo-to kekkon-**shi** ie-wo katta*
she-CMI married-CNJ house-ACC bought

(married her and bought a house)

For both of these types, we can detect the possibility of a coordinate structure by looking for a *coordination key bunsetsu* that contains *to*, *-shi*, comma and so forth. That is to say, the left and right sides of a coordination key bunsetsu constitute possible pre- and post-conjuncts, and the key bunsetsu is located at the end of the pre-conjunct.

For the evaluation of our method, which is described in section 5, we use analyzed corpora that are annotated on the basis of the annotation criteria of the Kyoto University Text Corpus (Kurohashi and Nagao, 1998).[2] Under this annotation criteria, the last *bunsetsu* in a pre-conjunct depends on the last *bunsetsu* in a post-conjunct, as shown in the dependency trees of Figure 1.

4 Our Method

4.1 Idea

Consider, for example, the following sentence.

(6) *houou-no kenkou-**to** tibet-no heiwa-wo*
pope-GEN health-CNJ tibet-GEN peace-ACC

inotta
prayed

(prayed (for) health of pope and peace of Tibet)

In this sentence, the coordination key "*to*" is a coordinate conjunction.[3] The coordinate structure in example (6) has four possible scopes. Among these, two structures are illustrated in Figure 1. In this figure, our parser generates the constituent words according to the arrows.

First, let us describe the effect of selectional preferences and lexical parallelism. In (a), two coordinated arguments, *kenkou* (health) and *heiwa* (peace), are generated from the verb *inotta* (prayed), and are eligible as accusative words of the verb *inotta* (prayed). *Kenkou* (health) is also generated from its coordinated head *heiwa* (peace). This generation is plausible because people often say this coordinated pair. In (b), the heads of conjuncts, *kenkou* (health) and *tibet*, are generated from the noun *heiwa* (peace). This is not appropriate because we are not referring to the nominal compound "*kenkou-no heiwa*" (peace of health). *Kenkou* (health) is also generated from its coordinated head *tibet*, but this generation has a low probability because this coordination is meaningless and rare.

These judgments are determined based on selectional preferences of predicates including nouns and lexical parallelism. As resources for considering these factors, we use automatically compiled case frames, and cooccurrences of noun-noun modifications and coordinated nouns.

Second, syntactic parallelism of conjuncts is also effective for coordination disambiguation. In (a), after the conjunct heads, *kenkou* (health) and *heiwa* (peace), are generated, the modifier in the pre-conjunct, *houou* (pope), is generated. In this generation, the generative probability of a genitive case from *kenkou* (health), $P(A(\text{GEN}) = \text{Y}|health)$, is considered. Note that $A(CASE)$=$\{\text{Y}, \text{N}\}$ is a binary function that returns Y if a case slot $CASE$ is filled with an ar-

tive), GEN (genitive), CMI (comitative), CNJ (conjunction) and TOP (topic marker).

[2] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?Kyoto%20University%20Text%20Corpus

[3] Note that the coordination key "*to*" can be used as a coordinate conjunction and also as a comitative case marker. The tasks of coordination disambiguation include the detection of coordinate conjunctions as well as the identification of coordination scopes. Both of these tasks are simultaneously carried out in our method.

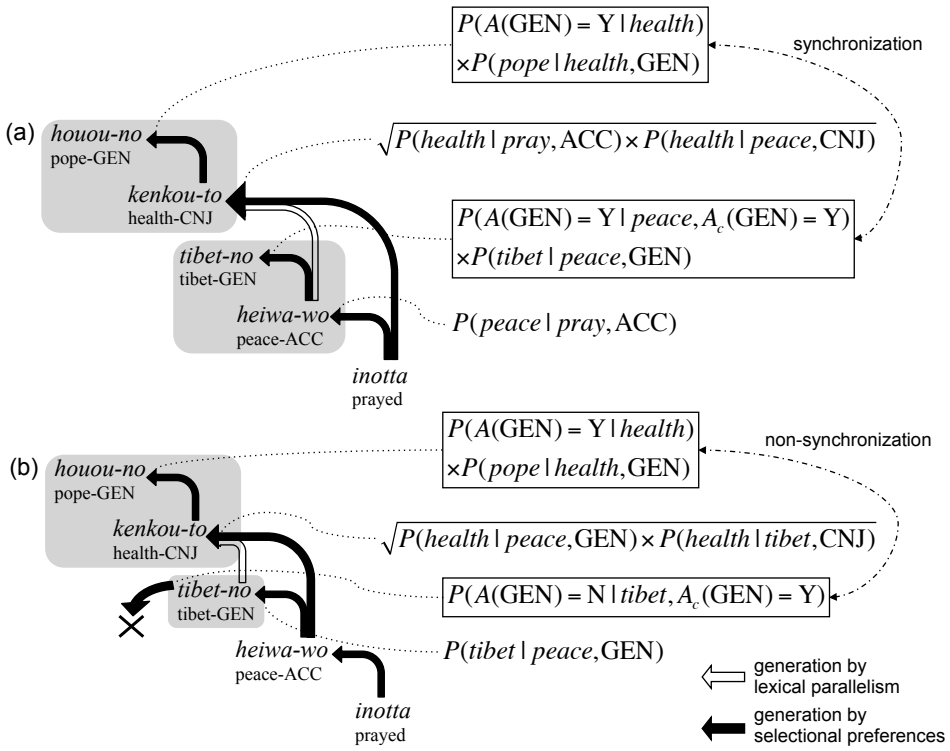

Figure 1: Two possible dependency and coordinate structures with some generative probabilities. The rounded rectangles represent conjuncts of coordinate structures.

gument; otherwise, it returns N. Subsequently, the modifier in the post-conjunct, *tibet*, is generated. This generation includes the synchronous generation of a genitive case from *heiwa* (peace) with the probability $P(A(\text{GEN})=\text{Y}|peace, A_c(\text{GEN})=\text{Y})$, which is conditioned on the previously generated genitive case of the pre-conjunct. Since syntactic parallelism is preferred in coordinate structures, this probability has a larger value than other probabilities $P(A(\text{GEN})=\text{Y}|peace)$ without coordination and $P(A(\text{GEN})=\text{Y}|peace, A_c(\text{GEN})=\text{N})$ without synchronization.

In (b), $P(A(\text{GEN}=\text{N})|tibet, A_c(\text{GEN})=\text{Y})$ means that nothing is generated from *tibet*, whereas the head of the pre-conjunct has a genitive case. This probability has a small value because of non-synchronization (unbalanced coordinate structure).

4.2 Resources

As the resources of selectional preferences to support coordinate structures, we use automatically constructed case frames and cooccurrences of noun-noun modifications. As a parser for extracting these resources, we use the Japanese dependency parser, KNP,[4] which is also used as a base model in the following sections.

	CS	examples
yaku (1) (bake)	*ga*	I:18, person:15, craftsman:10, ···
	wo	bread:2484, meat:1521, cake:1283, ···
	de	oven:1630, frying pan:1311, ···
yaku (2) (have difficulty)	*ga*	teacher:3, government:3, person:3, ···
	wo	fingers:2950
	ni	attack:18, action:15, son:15, ···
yaku (3) (burn)	*ga*	maker:1, distributor:1
	wo	data:178, file:107, copy:9, ···
	ni	R:1583, CD:664, CDR:3, ···
⋮	⋮	⋮

Table 1: Acquired case frames of *yaku*. "CS" indicates case slots, such as *ga* (NOM), *wo* (ACC), *ni* (DAT) and *de* (LOC). Example words are expressed only in English due to space limitation. The number following each word denotes its frequency.

4.2.1 Automatically Constructed Case Frames

We employ automatically constructed case frames (Kawahara and Kurohashi, 2006). This section outlines the method for constructing the case frames.

A large corpus is automatically parsed, and case

[4] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP

frames are constructed from predicate-argument examples in the resulting parses. The problems of automatic case frame construction are syntactic and semantic ambiguities. That is to say, the parsing results inevitably contain errors, and verb senses are intrinsically ambiguous. To cope with these problems, case frames are gradually constructed from reliable predicate-argument examples.

First, predicate-argument examples that have no syntactic ambiguity are extracted, and they are disambiguated by a pair consisting of a verb and its closest case component. Such pairs are explicitly expressed on the surface of text, and are thought to play an important role in sentence meanings. For instance, examples are distinguished not by verbs (e.g., *yaku* (bake/broil/have difficulty)), but by pairs (e.g., *pan-wo yaku* (bake bread), *niku-wo yaku* (broil meat), and *te-wo yaku* (have difficulty)). Predicate-argument examples are aggregated in this way, and yield basic case frames.

Thereafter, the basic case frames are clustered to merge similar case frames. For example, since *pan-wo yaku* (bake bread) and *niku-wo yaku* (broil meat) are similar, they are clustered. The similarity is measured by using a distributional thesaurus based on the study described in Lin (1998).

By using this gradual procedure, we constructed case frames from a web corpus. The case frames were obtained from approximately 1.6 billion sentences extracted from the web. They consisted of 43,000 predicates, and the average number of case frames for a verb was 22.2. In Table 1, some examples of the resulting case frames of the verb *yaku* are listed.

4.2.2 Cooccurrences of Noun-noun Modifications

Adnominal nouns have selectional preferences to nouns, and thus this characteristic is useful for coordination disambiguation. We collect dependency relations between nouns, which have the form of "N_1-*no* N_2" (N_2 of N_1), from automatic parses of a large corpus. We performed this extraction using the web corpus of 1.6 billion sentences, and obtained 55.5 million unique dependency relations. We keep a cooccurrence frequency for each relation.

4.2.3 Cooccurrences of Coordinated Nouns

Some nouns are likely to be coordinated. We use this characteristic as lexical parallelism. We collect cooccurrences of coordinated nouns from automatic parses of a large corpus. We extracted 54.1 million unique noun pairs from the web corpus of 1.6 billion sentences.

4.3 Our Model

We employ the probabilistic generative model of dependency and case structure analysis (Kawahara and Kurohashi, 2008) as a base model. This base model resolves coordination ambiguities only on the basis of selectional preferences of predicates and nouns on which conjuncts depend. To capture syntactic parallelism, we integrate the synchronized generation process into the base model. Lexical parallelism is also factored within the generation of pre-conjuncts of coordinate structures.

Our model assigns a probability to each possible dependency structure, T, and case structure, L, of the input sentence, S, and outputs the dependency and case structure that have the highest probability. In other words, the model selects the dependency structure T_{best} and the case structure L_{best} that maximize the probability $P(T, L|S)$ or its equivalent, $P(T, L, S)$, as follows:

$$\begin{aligned}(T_{best}, L_{best}) &= \mathrm{argmax}_{(T,L)} P(T, L|S) \\ &= \mathrm{argmax}_{(T,L)} \frac{P(T, L, S)}{P(S)} \\ &= \mathrm{argmax}_{(T,L)} P(T, L, S). \quad (1)\end{aligned}$$

The last equation follows from the fact that $P(S)$ is constant.

In the model, a clause (or predicate-argument structure) is considered as a generation unit and the input sentence is generated from the root of the sentence. The probability $P(T, L, S)$ is defined as the product of the probabilities of generating clauses C_i as follows:

$$P(T, L, S) = \prod_{C_i \in S} P(C_i|C_h), \quad (2)$$

where C_h is the modifying clause of C_i. Since the Japanese language is head final, the main clause at the end of a sentence does not have a modifying head; we account for this by assuming $C_h = \mathrm{EOS}$ (End Of Sentence).

The probability $P(C_i|C_h)$ is defined in a manner similar to that in Kawahara and Kurohashi (2008). This probability is calculated as the product of generative probabilities of a case frame, its case slots and governed argument nouns. The differences between the probability in the above

study and that in our study are the generative probability of case slots and the generative probability of argument nouns. We describe these two probabilities in the following sections.

4.3.1 Generative Probability of Case Slot

In the base model, the generative probability of case slots is defined as follows:

$$P(A(s_j)=\{\mathrm{Y},\mathrm{N}\}|CF_l), \quad (3)$$

where CF_l is a case frame; s_j is a case slot of the case frame CF_l; and $A(s_j)$ is a binary function that returns Y if a case slot s_j is filled with an argument; otherwise, N.

In our model, if the target predicate or noun does not constitute a coordinate structure, we use the probability (3) for the case slot generation. If the target predicate or noun constitutes a coordinate structure and has a pre-conjunct, we use the following modified probability that depends on whether the same case slot of a pre-conjunct is filled.

$$P(A(s_j)=\{\mathrm{Y},\mathrm{N}\}|CF_l, A_c(s_j)=\{\mathrm{Y},\mathrm{N}\}), \quad (4)$$

where $A_c(s_j)$ represents the situation of the same case slot of the pre-conjunct.

In practice, to avoid the data sparseness problem, we interpolate this probability, which is conditioned on case frames, with the probability conditioned on predicates in the same manner as in Collins (1999).

4.3.2 Generative Probability of Argument Nouns

In the base model, the generative probability of argument nouns in a clause is defined as the product of the generative probability of an argument noun $P_{n_{jk}}$:

$$\prod_{s_j:A(s_j)=Y} \prod_{n_{jk}\in N_{s_j}} P_{n_{jk}}, \quad (5)$$

where N_{s_j} is a set of nouns including a noun filled in the case slot s_j and its coordinated nouns. The generative probability of an argument noun is given as follows:

$$P_{n_{jk}} = P(n_{jk}|CF_l, s_j). \quad (6)$$

In our model, the direct argument noun filled in the case slot s_j is generated with the above probability. The coordinated nouns, which have no direct dependency relation to the predicate, are generated with the following probability:

$$P'_{n_{jk}} = \sqrt{P(n_{jk}|CF_l, s_j) \times P(n_{jk}|n_{jh}, \mathsf{CNJ})}, \quad (7)$$

	# of sents.	# of coord.	# of words in coord.
newspaper	1,000	630	14.7
patent	1,000	1,264	14.8
web	759	453	11.4

Table 2: Statistics of three test sets: the number of sentences, the number of coordinate structures and the average number of words that constitute a coordinate structure. Since a sentence can contain more than one coordinate structure, the number of coordinate structures in the patent set is larger than the number of sentences.

where n_{jh} is a head of n_{jk}, which constitutes a coordinate structure (designated as CNJ) with n_{jh}.

For instance, in Figure 1, the probability of generating *kenkou* (health) and *heiwa* (peace) from the verb *inoru* (pray) is written as follows:[5] [6]

$$P(\text{peace}|CF_{pray}, \mathsf{ACC}) \times \sqrt{P(\text{health}|CF_{pray}, \mathsf{ACC}) \times P(\text{health}|\text{peace}, \mathsf{CNJ})}.$$

This probability is estimated on the basis of the cooccurrence data of coordinated nouns described in section 4.2.3.

4.4 Practical Issue

The proposed model considers all the possible dependency structures including coordination ambiguities. To reduce this high computational cost, we introduced the CKY framework to the search (Eisner, 1996).

5 Experiments

5.1 Experimental Settings

We evaluated the dependency structures that were output by our proposed model. The necessary lexical resources for this parser, which include case frames, statistics of noun-noun modifications and coordinated nouns, and lexical parameters of our model, were acquired from automatic parses of 1.6 billion Japanese sentences crawled from the web (Kawahara and Kurohashi, 2006).

[5] In the probabilities in Figure 1, "pray" is used instead of "CF_{pray}" for simplicity.

[6] This probability can be intuitively understood from the approximation: $P(\text{peace}, \text{health}|\text{pray}) = P(\text{peace}|\text{pray}) \times \sqrt{P(\text{health}|\text{pray}, \text{peace})^2} \approx P(\text{peace}|\text{pray}) \times \sqrt{P(\text{health}|\text{pray}) \times P(\text{health}|\text{peace})}$.

		pref (baseline)	pref+parallelism	improve
newspaper	all	7,356/8,248 (89.2%)	7,398/8,248 (89.7%)	0.5%**
	coordination key	1,226/1,592 (77.0%)	1,251/1,592 (78.6%)	1.6%**
	coordination scope	2,291/2,631 (87.1%)	2,320/2,631 (88.2%)	1.1%**
patent	all	9,758/11,318 (86.2%)	9,852/11,318 (87.0%)	0.8%**
	coordination key	1,839/2,528 (72.7%)	1,887/2,528 (74.6%)	1.9%**
	coordination scope	3,776/4,573 (82.6%)	3,839/4,573 (83.9%)	1.3%**
web	all	4,563/5,114 (89.2%)	4,584/5,114 (89.6%)	0.4%**
	coordination key	893/1,125 (79.4%)	906/1,125 (80.5%)	1.1%*
	coordination scope	1,242/1,462 (85.0%)	1,257/1,462 (86.0%)	1.0%*

Table 3: Dependency accuracies of "pref" (baseline) and "pref+parallelism" (proposed) in the domains of newspapers, patents and web. ** and * represent statistically significant with $p < 0.01$ and with $p < 0.05$, respectively.

The parameters related to unlexical types were calculated from a training part of the Kyoto University Text Corpus. The Kyoto University Text Corpus is syntactically annotated in dependency formalism, and consists of 40K Japanese newspaper sentences. The training part is the remaining part excluding the test 1,000 sentences that are described below.

To evaluate the effectiveness of our model, our experiments were conducted using three test sets: newspaper set, patent set and web set. Table 2 lists some statistics of these test sets. As the newspaper set, we randomly extracted 1,000 sentences from the Kyoto University Text Corpus. The patent set consists of 1,000 sentences drawn from 2004's patent filings of the domain of "*Microbe/Ferment*." The web set consists of 759 sentences from the web, which are not included in the raw corpus of 1.6 billion sentences. This web set is the same as the test set used in previous studies. All the test sets follow the annotation criteria of the Kyoto University Text Corpus. As the input of our experiments, all the test sets were automatically segmented and tagged using the JUMAN morphological analyzer.[7]

We used the probabilistic generative model of dependency and case structure analysis (Kawahara and Kurohashi, 2008) as a baseline system for the purpose of comparison. This parser resolves coordination ambiguities based only on selectional preferences. We use the above-mentioned case frames in the baseline parser, which also requires automatically constructed case frames.

[7]http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN

5.2 Evaluation

We evaluated the dependency structures analyzed by the proposed model and the baseline model. The dependency structures obtained were evaluated with regard to unlabeled dependency accuracy — the proportion of correct dependencies out of all dependencies.

Table 3 lists the dependency accuracies. In this table, "pref" represents the baseline model, which is the probabilistic parser of dependency and case structure with only selectional preferences, and "pref+parallelism" represents our proposed model. "all" represents the overall dependency accuracies. The proposed model significantly outperformed the baseline system in all the sets (McNemar's test; $p < 0.01$).

In Table 3, the dependency accuracies are further classified into *coordination key* and *coordination scope*. Coordination key means the dependency accuracy of coordination key *bunsetsus*, which possibly lead coordinate structures. Coordination scope means the dependency accuracy of *bunsetsus* inside coordinate structures of the manual annotation.

5.3 Discussions

In the newspaper and patent sets, in particular, the accuracies of both coordination key and coordination scope were improved by 1.1% to 1.9%. These improvements were conduced by the consideration of syntactic and lexical parallelism. In the web set, the accuracies of coordination related dependencies were less improved than those of the newspaper and patent sets.

Figure 2 shows improved analyses; here, the dotted lines represent the analysis performed using the baseline "pref," and the solid lines rep-

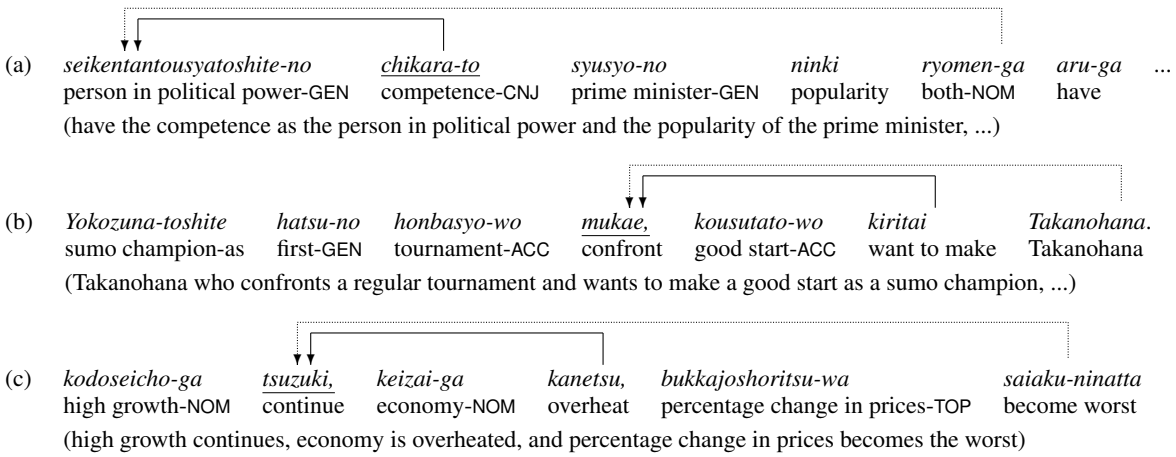

Figure 2: Improved examples. The dotted lines represent the results of "pref," and the solid lines, which are correct dependencies, represent the analysis of "pref+parallelism." The underlined *bunsetsu*s represent coordination key *bunsetsu*s.

resent the analysis performed using the proposed method, "pref+parallelism." These sentences are incorrectly analyzed by the baseline but correctly analyzed by the proposed method. For example, in sentence (a), the head of *seikentantousyatoshite-no* (person in political power-GEN) was correctly judged as *chikara-to* (competence-CNJ). This is because the two genitive (GEN) *bunsetsu*s were synchronously generated to prefer syntactic parallelism.

The proposed model did not largely outperform the baseline in the web set. One of the reasons of this result was due to weak parallelism in the web set. We found that coordinate structures in the newspaper and patent sets tend to have greater syntactic parallelism than those in the web set. The average number of words that constitute a coordinate structure in the newspaper set was 14.7 and that in the patent set was 14.8, whereas that in the web set was 11.4, as shown in Table 2. Therefore, it was hard to show substantial improvement by considering such weak parallelism of coordinate structures in the web set.

In order to compare our results with a discriminative dependency parser, we input the patent set and the web set into an SVM-based Japanese dependency parser, CaboCha (Kudo and Matsumoto, 2002),[8] which was trained using the Kyoto University Text Corpus.[9] Its dependency accuracies were 86.3% (9,770/11,320) for the patent set and 88.7% (4,534/5,114) for the web set, which are lower than those of our proposed model. This low performance can be attributed to the lack of sufficient consideration of both parallelism and selectional preferences, as mentioned in Sassano (2004). Another cause of the low performance is the out-of-domain training corpus. This SVM-based parser was trained on a newspaper corpus, while the test sets were obtained from patent filings and the web because tagged corpora of these domains that are large enough to train a supervised parser are not available. In other words, our proposed model achieved a good performance on the patent set without using in-domain corpora.

6 Conclusion

In this paper, we have proposed a unified generative model of coordination that simultaneously considers parallelism and selectional preferences. Syntactic parallelism is modeled by the synchronized generation process of pre-modifiers of conjuncts, and lexical parallelism was factored within the generation of pre-conjuncts. Selectional preferences are acquired from large raw corpora as case frames and statistics of noun-noun modifications. The experimental results indicate the effectiveness of our model, particularly in the domains of newspapers and patents. The acquired case frames can be obtained from a non-profit organization and our analysis system will be freely available at our web site. Our future research involves incorporating ellipsis resolution to develop an integrated model for syntactic, case, and ellipsis analyses.

[8] http://chasen.org/~taku/software/cabocha/

[9] We did not input the newspaper set into CaboCha, because it is included in the training corpus used in CaboCha.

Abstract

Recent research efforts have led to the development of a state-of-the-art supervised coreference model, the cluster-ranking model. However, it is not clear whether the features that have been shown to be useful when employed in traditional coreference models will fare similarly when used in combination with this new model. Rather than merely re-evaluate them using the cluster-ranking model, we examine two interesting types of features derived from syntactic parses, tree-based features and path-based features, and discuss the challenges involved in employing them in the cluster-ranking model. Results on a set of Switchboard dialogues show their effectiveness in improving the cluster-ranking model: using them to augment a baseline coreference feature set yields a 8.6–11.7% reduction in relative error.

1 Introduction

Coreference resolution is the task of determining which noun phrases (NPs) in a text or dialogue refer to the same real-world entity. According to Webber (1979), coreference resolution can be decomposed into two complementary subtasks: "(1) identifying what a text potentially makes available for anaphoric reference and (2) constraining the candidate set of a given anaphoric expression down to one possible choice". These two subtasks are commonly known as *anaphoricity determination* and *anaphora resolution*, both of which have recently been tackled using machine learning techniques. More specifically, anaphoricity determination is typically tackled by training an *anaphoricity classifier*, which determines whether an NP is anaphoric or not (e.g., Poesio et al. (2004), Zhou and Kong (2009)). If so, the NP is passed to the second component, the resolution system, which identifies an antecedent for the NP. This resolver is typically implemented by training a *mention-pair* (MP) model, which is a binary classifier that determines whether a pair of NPs are co-referring or not (e.g., Soon et al. (2001), Ng and Cardie (2002b)).

While this architecture is popularly adopted by coreference researchers and was implemented even within recently developed coreference resolvers (e.g., Bengtson and Roth (2008), Stoyanov et al. (2009)), neither the architecture itself nor its aforementioned implementation is satisfactory for at least two reasons. First, in this pipeline architecture, anaphoricity determination is performed prior to coreference resolution, so errors in anaphoricity determination can propagate to the downstream coreference component and adversely affect its performance (Ng and Cardie, 2002a). Second, the MP coreference model is fundamentally weak in that (1) the information extracted from two NPs may not be sufficient for making an informed coreference decision and (2) since the model is trained to compare the NP to be resolved (henceforth the *active NP*) against a candidate antecedent, it only determines how good the candidate is relative to the active NP, not how good the candidate is relative to other candidates.

In light of the aforementioned problems, researchers have proposed a number of solutions:

- To address the *error propagation* problem, researchers have proposed *joint inference* (Denis and Baldridge, 2007) and *joint learning* (Rahman and Ng, 2009) for anaphoricity determination and coreference resolution.
- To address the *expressiveness* problem resulting from making a coreference decision based on only two NPs, researchers have proposed the *entity-mention* model, where coreference decisions are made by determining whether an NP belongs to a preceding coreference *cluster* (e.g., Luo et al. (2004), Yang

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 465–473,
Chiang Mai, Thailand, November 8 – 13, 2011.

et al. (2008)).

- To address the failure to directly compare candidate antecedents and determine the best one, researchers have proposed the *mention-ranking* model, which imposes a ranking on the candidate antecedents and therefore captures the competition among them (e.g., Denis and Baldridge (2008), Iida et al. (2009)).

Recent research efforts have led to the development of a state-of-the-art supervised coreference model that can address *all* of the aforementioned problems, namely the *joint cluster-ranking* (CR) model (Rahman and Ng, 2009). However, other than its superior empirical performance to competing coreference models (such as the MP model), little is known about the joint CR model. In particular, most of the linguistic features for coreference resolution were developed and evaluated in the context of the MP model, and thus it is not clear whether these features would fare similarly when used in combination with the joint CR model.

Motivated by this observation, our goal in this paper is to examine the value of features derived from syntactic parses for the joint CR model. Note that parse-based features have been investigated extensively for the MP model. For example, they have been used to implement Binding Constraints (e.g., Luo and Zitouni (2005)) and encode syntactic salience (e.g., Haghighi and Klein (2009)). Rather than re-evaluate them for the CR model, we investigate two types of parse-based features that we believe are particularly interesting.

First, we employ parse trees directly as *structured* features for the joint CR model. The main advantage of employing tree-based structured features is simplicity: we no longer need to design heuristics to extract the desired features (e.g., salience, Binding Constraints) from the parse trees, as designing heuristics can be time-consuming and sometimes difficult for certain tasks. Note, however, that previous attempts have employed structured features to train an MP model for anaphora resolution (Yang et al., 2006; Versley et al., 2008) and an anaphoricity classifier in the aforementioned pipeline architecture (Zhou and Kong, 2009). In both cases, the structured features are combined with their non-structured (i.e., *flat*) counterparts via a composite kernel and used to train a classification model. What is interesting for us to investigate in this paper, however, is the question of how to combine flat and structured features in a *ranking* model that employs *joint* learning. With the increasingly important role structured features and ranking models play in natural language learning, we believe that a method for combining flat and structured features for training a ranker would be of particular interest to natural language processing (NLP) researchers.[1]

Second, motivated in part by lexical semantics research (Lin and Pantel, 2001), we investigate *path-based* features, which encode the contextual relationship between an active NP and a candidate antecedent as the shortest path between the corresponding nodes in the parse tree. As with other NLP tasks, the effectiveness of a given type of features for coreference resolution depends in part on how the linguistic information it intends to capture is represented. We seek to investigate the extent to which a joint CR model can benefit from this path-based representation of context.

Unlike the vast majority of English coreference resolvers, which were evaluated using the MUC and ACE corpora, our resolver was evaluated on a set of Switchboard dialogues. To our knowledge, we are among the first to report results for the full coreference task on this dataset. As a result, our work contributes to the establishment of a baseline using a state-of-the-art supervised coreference model against which future work can be compared. Our experimental results indicate that while both the tree-based and path-based features improve coreference performance when applied to a Baseline feature set in isolation, the best performance is achieved when they are applied in combination. In particular, these two types of features yield an improvement of 2.2–3.7% in F-measure over the Baseline joint CR model, which corresponds to a 8.6–11.7% reduction in relative error.

The rest of the paper is organized as follows. Section 2 discusses our implementation of the joint CR model. Section 3 describes tree-based and path-based features and how they can be integrated into the CR model. We present evaluation results in Section 4 and conclude in Section 5.

2 The Baseline Coreference Model

This section describes the Baseline CR model. Since the CR model is a natural extension of the

[1] The dual form of Collins and Duffy's (2002) ranking algorithm can also combine flat and structured features. Note that their algorithm employs online learning, whereas ours employs batch learning in a maximum-margin fashion.

MP model, in order to understand the CR model, it helps to first understand the MP model.

2.1 The Mention-Pair Model

As noted before, the MP model is a classifier that determines whether two NPs are co-referring or not. Each instance $\boldsymbol{i}(\text{NP}_j, \text{NP}_k)$ corresponds to two NPs, NP_j and NP_k, and is represented by 39 features (see Table 1 of Rahman and Ng (2009) for a description of these features). Linguistically, these features can be divided into four groups: string-matching, grammatical, semantic, and positional. However, they can also be categorized based on whether they are *relational* or *non-relational*: relational features capture the relationship between NP_j and NP_k, whereas non-relational features capture the linguistic properties of one of them.

We follow Soon et al.'s (2001) method for creating training instances. Specifically, we create (1) a positive instance for each anaphoric NP NP_k and its closest antecedent NP_j; and (2) a negative instance for NP_k paired with each of the intervening NPs, NP_{j+1}, NP_{j+2}, ..., NP_{k-1}. The classification associated with a training instance is either positive or negative, depending on whether the two NPs are coreferent. To train the MP model, we use the SVM learner from SVM^{light} (Joachims, 1999).[2]

After training, the classifier is used to identify an antecedent for an NP in a test text. Each NP, NP_k, is compared in turn to each preceding NP, NP_j, from right to left, and NP_j is selected as its antecedent if the pair is classified as coreferent. The process ends as soon as an antecedent is found for NP_k or the beginning of the text is reached.

2.2 The Cluster-Ranking Model

The CR model addresses two weaknesses of the MP model, one concerning expressiveness and the other concerning its failure to compare candidate antecedents directly and capture the competition among them. It does so by combining the strengths of the entity-mention model and the mention-ranking model. As discussed before, the mention-ranking model addresses the failure to compare candidate antecedents by training a ranker to impose a ranking on the candidate antecedents for an active NP. On the other hand, the entity-mention model addresses the expressiveness problem by determining whether an active NP belongs to a preceding, possibly partially-formed, coreference cluster. Its increased expressiveness stems from its ability to employ *cluster-level* features (i.e., features that are defined over any subset of NPs in a preceding cluster). Combining the entity-mention model and the mention-ranking model yields the CR model, which ranks the preceding clusters for an active NP so that the highest-ranked preceding cluster is the one to which the active NP should be linked.

Since the CR model ranks preceding clusters, a training instance $\boldsymbol{i}(c_j, \text{NP}_k)$ represents a preceding cluster c_j and an anaphoric NP NP_k. Each instance consists of two types of features: (1) features that are computed based solely on NP_k, and (2) cluster-level features, which describe the relationship between c_j and NP_k. Motivated in part by Culotta et al. (2007), we create cluster-level features from the *relational* features in our 39-feature set using four logical predicates: NONE, MOST-FALSE, MOST-TRUE, and ALL. Specifically, for each relational feature X, we first convert X into an equivalent set of binary-valued features if it is multi-valued. Then, for each resulting binary-valued feature X_b, we create four binary-valued cluster-level features: (1) NONE-X_b is true when X_b is false between NP_k and each NP in c_j; (2) MOST-FALSE-X_b is true when X_b is true between NP_k and less than half (but at least one) of the NPs in c_j; (3) MOST-TRUE-X_b is true when X_b is true between NP_k and at least half (but not all) of the NPs in c_j; and (4) ALL-X_b is true when X_b is true between NP_k and each NP in c_j.

We follow Rahman and Ng's (2009) method for creating training instances. Specifically, for each NP, NP_k, we create a training instance between NP_k and *each* preceding cluster c_j using the features described above. Since we are training a model for jointly learning anaphoricity determination and coreference resolution, we need to provide the ranker with the option to start a new cluster by creating an additional training instance that contains features that solely describe NP_k. The rank value of a training instance $\boldsymbol{i}(c_j, \text{NP}_k)$ created for NP_k is the rank of c_j among the competing clusters. If NP_k is anaphoric, the rank of $\boldsymbol{i}(c_j, \text{NP}_k)$ is HIGH if NP_k belongs to c_j, and LOW otherwise. However, if NP_k is non-anaphoric, the rank of $\boldsymbol{i}(c_j, \text{NP}_k)$ is LOW unless c_j corresponds to the NULL cluster, in which case its rank is HIGH. Given these training instances, we can train a ranker using SVM^{light}'s

[2] For this and subsequent uses of the SVM learner in our experiments, we set all parameters to their default values.

ranker-learning algorithm.

After training, the cluster ranker processes the NPs in a test text in a left-to-right manner. For each active NP, NP_k, we create test instances for it by pairing it with each of its preceding clusters. To allow for the possibility that NP_k is non-anaphoric, we create an additional test instance containing features that solely describe the active NP (as during training). All these test instances are then presented to the ranker. If the additional test instance is assigned the highest rank value by the ranker, then NP_k is classified as non-anaphoric and will not be resolved. Otherwise, NP_k is linked to the cluster that has the highest rank.

3 Tree-Based and Path-Based Features

In this section, we describe the tree-based and path-based features in detail and show how they can be exploited by the joint CR model.

3.1 Path-Based Features

As mentioned before, a path-based feature encodes the contextual relationship between an active NP and a candidate antecedent as the shortest path between the corresponding nodes in the parse tree. More formally, a *path* between an active NP, NP_k, and a candidate antecedent, NP_j, in a parse tree is defined as the shortest sequence of nodes in the tree that need to be traversed in order to reach NP_j from NP_k, and is represented as a sequence of non-terminal symbols, $s_1 s_2 \ldots s_m$, where s_i ($1 \leq i \leq m$) is the non-terminal symbol associated with the ith node being traversed in the path, with s_1 and s_m being the non-terminal symbol associated with the nodes spanning NP_k and NP_j, respectively. Given this representation, a path captures the shallow syntactic context in which two NPs appear.

There is a caveat, however. If the active NP and a candidate antecedent appear in different sentences, there will be no path between them. To enable the application of path-based features to these NPs, we create an additional "root" node with a random label (e.g., R) that connects the root nodes of the two trees containing these NPs. This allows a path to be established even if the two NPs appear in different sentences.

Now, to employ these paths for coreference resolution, two questions need to be answered. First, which paths should be used? In our implementation, we collect from each training text a path between each NP and each of its preceding NPs. This yields approximately 512K paths. For efficiency reasons, we reduce the number of paths being considered by removing those paths that occur less than seven times in the training set. After this filtering process, only approximately 22K paths remain. Each resulting path is represented as a binary-valued feature for coreference resolution.

Second, how can we compute the value of a path-based feature? If we were to train an MP model, its value is 1 if the path between the two NPs under consideration is the same as the path represented by the feature. Otherwise, its value is 0. Since we are training a joint CR model, where each instance corresponds to an NP, NP_k, and a preceding cluster, c_j, rather than two NPs, we compute its feature value as follows: its value is 1 if the path between NP_k and one of the NPs in c_j is the same as the path represented by the feature; otherwise, its value is 0.

We hypothesize that by capturing shallow syntactic context, path-based features can improve the performance of a coreference system. The reason is that through these features, a learner can potentially learn to distinguish between *good* paths (i.e., paths that are likely to connect coreferent NPs) and *bad* paths (i.e., paths that are likely to connect non-coreferent NPs), thus improving the resulting model's ability to identify the correct antecedent or preceding cluster for an active NP.

3.2 Tree-Based Features

Not only can parse trees be exploited to identify coreference relations via the extraction of paths, but they can be used to determine the anaphoricity of an NP. Specifically, we aim to identify *non-anaphoric* NPs by employing parse trees as structured features. While previous work has employed parse trees as structured features (Zhou and Kong, 2009), it does so in a pipeline architecture where anaphoricity determination is performed prior to coreference resolution. In contrast, we are faced with the challenge of integrating tree-based structured features with flat features in a model that involves both *joint learning* and *ranking*.

To understand how this can be done, recall that in the joint CR model, joint learning for anaphoricity determination and coreference resolution is achieved by introducing an additional training instance, $\boldsymbol{i}(\text{NULL}, \text{NP}_k)$, which is formed between an active NP, NP_k, and a NULL preceding cluster, effectively providing NP_k with an option to start a

new cluster. Since we aim to use tree-based features to identify non-anaphoric NPs, we augment the set of features for $\boldsymbol{i}(\text{NULL}, \text{NP}_k)$, which currently contains the flat features derived from NP_k, with these (structured) tree-based features.

Of course, having an SVM learner learn a ranking model from both the flat and tree-based features requires more than just adding the tree-based features to the feature set. In particular, we need to implement the three steps below.

Step 1: Specifying the Parse Substructure

While we want to use a parse tree directly as a feature, we do *not* want to use the *entire* tree as a feature. The reason is that a complex tree may make it difficult for the SVM learner to make generalizations: the more complex the tree is, the less likely it is to find similar trees in other instances.

To strike a better balance between having a rich representation of context and improving the learner's ability to generalize, we extract a substructure from a parse tree and use it as the value of the structured feature of an instance. This substructure was previously shown to be useful when used as a structured feature for training a classifier for determining the information status of an NP (Rahman and Ng, 2011). Given an instance $\boldsymbol{i}(\text{NULL}, \text{NP}_k)$, we extract the substructure from the parse tree containing NP_k as follows. Let $n(\text{NP}_k)$ be the root of the subtree that spans all and only the words in NP_k, and let $Parent(n(\text{NP}_k))$ be its immediate parent node. We (1) take the subtree rooted at $Parent(n(\text{NP}_k))$, (2) replace each leaf node in this subtree with a node labeled X, (3) replace the child nodes of $n(\text{NP}_k)$ with a leaf node labeled Y, and (4) use the subtree rooted at $Parent(n(\text{NP}_k))$ as the structured feature for $\boldsymbol{i}(\text{NULL}, \text{NP}_k)$. Figure 1 illustrates this substructure extraction procedure via an example.

Intuitively, the first three steps aim to provide generalizations by simplifying the tree. For example, step (1) allows us to focus on using a small window surrounding NP_k as its context. Steps (2) and (3) help generalization by ignoring the words within NP_k and its context. Note that using two labels, X and Y, helps distinguish the active NP from its context within this substructure. Also note that we simply use one node (Y) to represent the active NP, since NP-internal information (e.g., gender) has been captured by the flat features.

While this parse substructure ignores the words in NP_k, these unigrams could be useful for determining its anaphoricity, as a learner may learn from coreference-annotated data that "it" only has a moderate probability of being anaphoric, and that "the contrary" from the phrase "on the contrary" is never anaphoric. As a result, we augment the set of flat features in $\boldsymbol{i}(\text{NULL}, \text{NP}_k)$ with the unigrams extracted from NP_k.

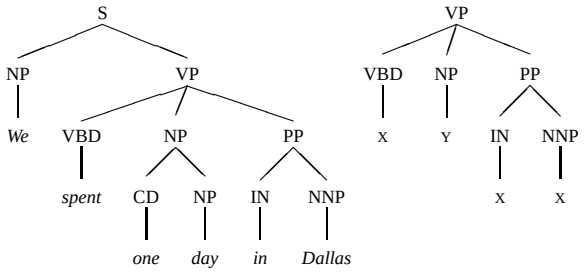

Figure 1: A parse tree (left) and the parse substructure extracted for the NP "one day" (right).

Step 2: Recasting Ranking as Classification

Existing implementations of SVMs, such as SVM^{light}-TK (Moschitti, 2004), allow us to combine flat and (structured) tree-based features to train a classifier by designing appropriate kernels. Hence, if we were to train an SVM classifier, all we need to do is to design a kernel. However, we are given a ranking problem, and it is not immediately clear how an SVM can learn a ranking model in the presence of tree-based features.

Our approach to this problem is to reduce the given ranking problem to an equivalent classification problem. Once we have a classification problem, all we need to do is to design a kernel for training a classifier, as mentioned above. To reduce a ranking problem to an equivalent classification problem, we need to convert the training set for the joint CR model to an equivalent training set that can be used to train a classifier.

Before describing the conversion process, let us first recall how the training set for a joint CR model is created. Given a training text D, we create from D a set of training instances T for a joint CR model by taking the union of $T_1, T_2, \ldots, T_n$, where T_k $(1 \leq k \leq n)$ is the set of training instances generated from NP_k in D. If NP_k has $|C|$ preceding clusters, T_k will contain exactly $|C|+1$ training instances, since one training instance is generated from NP_k and each of its $|C|$ preceding clusters, and one training instance is formed between NP_k and the NULL antecedent. Each instance is associated with a rank value, which is either HIGH or LOW. Given T, the SVM ranker-

learning algorithm aims to learn how to rank preceding clusters for an active NP by learning how to rank the instances within each T_k.

As noted before, to facilitate learning a ranker from both flat and tree-based features, we reformulate the given ranking problem as a set of pairwise ranking problems. The reason is that a pairwise ranking problem is essentially a *binary classification* problem, since pairwise ranking merely involves ranking two objects. Not surprisingly, this reformulation requires that we convert T into an equivalent training set T', which consists of pairwise ranking problems and can therefore be used to train a classifier (i.e., a pairwise ranker). Below we describe how to convert T to T'.

For each T_k in T, we create a training instance $inst$ for T' from each pair of training instances in T_k that have different rank values. For example, if $\boldsymbol{i}(c_i, \text{NP}_k)$ and $\boldsymbol{i}(c_j, \text{NP}_k)$ in T_k have ranks r_1 and r_2 respectively where $r_1 \neq r_2$, we create a training instance for T' whose feature vector is obtained by subtracting $\boldsymbol{i}(c_j, \text{NP}_k)$ from $\boldsymbol{i}(c_i, \text{NP}_k)$. If both feature vectors contain only flat features, the subtraction is straightforward, since each flat feature is real-valued. However, if one of the feature vectors has a tree-based feature[3] (which happens when c_i or c_j is NULL), we handle the flat features and the tree-based feature separately. Specifically, we first perform subtraction for the flat features as described above, and then append the tree-based feature to the feature set of $inst$. If $r_1 > r_2$, the class value of $inst$ is 1; otherwise, it is -1.

In sum, each T_k in T constitutes a ranking problem, and we described how to convert this ranking problem into a set of pairwise ranking problems in T'. As noted before, a pairwise ranking problem is a binary classification problem. Hence, the resulting training set, T', can be used to train a (binary) SVM classifier that minimizes the number of violations of pairwise rankings in T'.

Step 3: Designing the Composite Kernel

To train an SVM classifier on T', we need to define a kernel function for computing the similarity between a pair of instances. If both instances contain only flat features, we simply employ a normalized linear kernel, which computes similarity as the cosine of their feature vectors. However, if one or both of them has a tree-based feature, a linear kernel is not directly applicable. In this case, we need to (1) compute the similarity of their flat features and the similarity of their tree-based features separately, and then (2) employ a composite kernel, K_c, to combine the two similarity values. Specifically, we define K_c as follows:

$$K_c(F_1, F_2) = K_1(F_1, F_2) + \alpha K_2(F_1, F_2),$$

where F_1 and F_2 are the full set of features (containing both flat and structured features) that represent the two instances under consideration. K_1 is a linear kernel, which operates on the flat features. K_2 is a convolution tree kernel (Collins and Duffy, 2001), which operates on the tree-based features. Specifically, K_2 computes the similarity of two parse trees by efficiently enumerating the number of common substructures in them. To prevent the kernel value returned by K_c from being consistently dominated by one of the component kernels (i.e., K_1 and K_2), we normalize the kernel values returned by K_1 and K_2 so that they fall between 0 and 1. α is as a weight parameter that allows the two kernel values to be combined linearly, providing the flexibility to vary the relative importance of the component kernels. We will determine α empirically on the development set.

3.3 Applying the Pairwise Ranker

So far, we have described a method for training a (pairwise) ranker when the feature set contains both flat and tree-based features, which involves converting training set T to training set T'. A natural question, then, is: do we have to similarly perform this conversion on the test set so that the pairwise ranker can be applied to it?

It turns out that the answer is no. Given a set of test instances T_k to be ranked, all we need to do is to apply the pairwise ranker to each instance in T_k. The ranker produces one real value for each instance. According to the values provided by the ranker, these test instances can be ranked: the most positive value corresponds to the highest rank.

It may not be immediately clear why it makes sense to apply the pairwise ranker in the aforementioned manner to rank the test instances. Space limitations preclude a rigorous mathematical explanation. Here, we will provide a sketch of the explanation. Recall that each instance in T' was created by subtracting the feature vectors of two instances. In addition, when SVM^{light} was applied to train the pairwise ranker on T', it attempted to minimize the number of violations of

[3]Note that at most one of these two feature vectors has a tree-based feature. The reason is that exactly one of the instances in T_k has a tree-based feature, namely the one corresponding to the NULL cluster.

pairwise rankings. To do so, SVM^{light} needs to position the hyperplane so that an instance with a higher rank in T is assigned a more positive value by the hyperplane than one with a lower rank in T. Consequently, we can apply the pairwise ranker to each test instance to be ranked, and use the value returned by the ranker for each instance to impose a ranking on the test instances.

4 Evaluation

In this section, we examine the effectiveness of the tree-based and path-based features in improving the joint CR model.

4.1 Experimental Setup

Corpus. We employ in our evaluation a dataset comprising 147 coreference-annotated Switchboard dialogues, which contain a total of 68,992 NPs.[4] We partition the dialogues into a training set (117 dialogues) and a test set (30 dialogues). We extract the NPs and the parse trees directly from the gold-standard annotations, but the coreference features are computed entirely automatically.

Scoring programs. We employ two commonly-used coreference scoring programs, B^3 (Bagga and Baldwin, 1998) and ϕ_3-CEAF (Luo, 2005), both of which report results in terms of recall (R), precision (P), and F-measure (F).

4.2 Results and Discussion

The baseline mention-pair model. We employ as our first baseline the MP model, which is trained using the procedure described in Section 2.1. Given that our goal is to examine the effectiveness of the tree-based and path-based features for the joint CR model, one may wonder why the results of the MP model are relevant to our investigation. Recall from the introduction that we chose to improve the joint CR model with the two types of features derived from syntactic parses because the joint CR model has been shown to achieve state-of-the-art performance on the ACE corpus. To ensure that the joint CR model also outperforms the MP model on our Switchboard corpus (and is therefore the strongest baseline we can use), we show the results of the MP model in row 1 of Table 1. As we can see, it achieves F-measure scores of 69.1 (B^3) and 62.8 (CEAF).[5]

[4]This dataset is released by the LDC as part of the NXT corpus (Calhoun et al., 2010).

[5]Since gold-standard NPs are used in our coreference experiments, CEAF recall, precision, and F-measure will all be the same. See Luo (2005) for details.

The baseline joint cluster-ranking model. Our second baseline is the joint CR model, which is trained using the method described in Section 2.2. In particular, this baseline model does not employ any tree-based or path-based features. Results are shown in row 2 of Table 1. In comparison to the MP model in row 1, we can see that B^3 F-measure rises from 69.1 to 74.5 and CEAF F-measure rises from 62.8 and 68.5. These results are consistent with our hypothesis that the joint CR model is indeed a stronger baseline than the MP model.

Incorporating path-based features. Next, we incorporate the path-based features into the Baseline joint CR model. Results are shown in row 3 of Table 1. In comparison to the results of the Baseline joint CR model in row 2, we can see that adding the path-based features into the feature set improves the joint CR model according to both scorers. In particular, B^3 and CEAF F-measure scores rise by 1.3% and 2.1%, respectively, suggesting the usefulness of the path-based features.

In addition to the R, P and F columns, Table 1 has two columns labeled "% err. red.", which show the error reduction of a system relative to the Baseline joint CR model. Here, we compute the error of a system by subtracting its F-measure score from the perfect F-measure (i.e., 100). With the addition of path-based features, we can see that relative error is reduced by 5.1 and 6.7 according to B^3 and CEAF, respectively.

Incorporating tree-based features. Next, we incorporate the tree-based features into the Baseline joint CR model. Recall that from a tree, we extract both flat features (i.e., unigrams) and structured features (i.e., parse substructures), so both types of features are used to augment the Baseline feature set. Because both types of features are involved, we need to tune α in the composite kernel. To ensure a fair comparison among different systems, we do *not* employ additional labeled data for tuning α. Rather, we use 75% of the available training data for training the joint CR model and reserve the remaining 25% for parameter tuning.

Results are shown in row 4 of Table 1. In comparison to the results of the Baseline joint CR model in row 2, we can see that adding the trees and the unigrams into the feature set improves the joint CR model according to both scorers. In particular, B^3 and CEAF F-measure scores rise by 1.0% and 1.9%, respectively.

		B^3				CEAF			
	System	R	P	F	% err. red.	R	P	F	% err. red.
1	Baseline MP model	78.1	61.6	69.1	—	62.8	62.8	62.8	—
2	Baseline CR model	71.1	78.2	74.5	—	68.5	68.5	68.5	—

Table 1: Coreference results on the test set obtained using B^3 and CEAF.

Incorporating tree- and path-based features. Next, we incorporate both tree-based (i.e., unigrams and parse substructures) and path-based features into the Baseline joint CR model. As in the previous experiment, we reserve 25% of the available training data for tuning α. Results are shown in row 5 of Table 1. In comparison to the results of the Baseline joint CR model in row 2, we can see that adding both types of features improves F-measure by 2.2% (B^3) and 3.7% (CEAF), which is equivalent to a relative error reduction of 8.6% (B^3) and 11.7% (CEAF).

In comparison to the results in rows 3 and 4, we can see that better results can be obtained by applying the two types of features in combination than in isolation to the Baseline joint CR model. This suggests that although both types of features are derived from parse trees, they provide complementary information for the CR model.

Understanding the value of parse substructures. So far, we have always applied the unigrams and the parse substructures in combination in our experiments. To better understand the value of the parse substructures, we perform an ablation experiment in which we repeat the previous experiment *without* using the parse substructures.

Results are shown in row 6 of Table 1. In comparison to the results in row 5, we can see that F-measure drops by 0.9% (B^3) and 0.7% (CEAF). Since the difference in results between the two rows can be attributed entirely to the presence/absence of the parse substructures, the drop in F-measure suggests that the parse substructures are indeed useful features for the joint CR model.

Pipeline vs. joint modeling. One challenge we addressed here involves enabling the integration of structured and flat features in a ranker that performs joint learning. A natural question is: is this joint learning architecture indeed better than the traditional pipeline architecture in which anaphoricity determination is performed prior to coreference resolution? To answer this question, we show in row 7 of Table 1 the results obtained using the pipeline architecture, where (1) an anaphoricity classifier is trained with all the features used to represent an instance involving the NULL antecedent in the joint CR model in row 5 and (2) the joint CR model is trained using the Baseline and path-based features. This setup would therefore allow us to determine whether the joint architecture or the pipeline architecture can better exploit the structured features. In comparison to the results in row 5, we see that F-measure drops by 0.6–0.8%. These results suggest that joint learning is indeed better than pipeline learning in terms of exploiting structured features.

5 Conclusions

We have examined the effectiveness of tree-based and path-based features in improving a state-of-the-art supervised coreference model, the cluster-ranking model. Results on 147 Switchboard dialogues, show that both types of features are effective at improving the performance of the cluster-ranking model. In particular, when they are applied in combination, we see a reduction in relative error by 8.6–11.7%. One challenge that we addressed during the course of this investigation involves enabling flat and structured features to be employed simultaneously in a ranking model that employs joint learning. With the increasingly important role structured features and ranking models play in natural language learning, we believe that our method for combining flat and structured features for training a ranker would appeal to researchers working in different areas of NLP.

Abstract

We propose a statistical sentence simplification system with log-linear models. In contrast to state-of-the-art methods that drive sentence simplification process by hand-written linguistic rules, our method used a margin-based discriminative learning algorithm operates on a feature set. The feature set is defined on statistics of surface form as well as syntactic and dependency structures of the sentences. A stack decoding algorithm is used which allows us to efficiently generate and search simplification hypotheses. Experimental results show that the simplified text produced by the proposed system reduces 1.7 Flesch-Kincaid grade level when compared with the original text. We will show that a comparison of a state-of-the-art rule-based system (Heilman and Smith, 2010) to the proposed system demonstrates an improvement of 0.2, 0.6, and 4.5 points in ROUGE-2, ROUGE-4, and $AveF_{10}$, respectively.

1 Introduction

Complicated sentences impose difficulties on reading comprehension. For instance, a person in 5th grade can comprehend a comic book easily but will struggle to understand New York Times articles which require at least 12th grade average reading level (Flesch, 1981). Complicated sentences also challenge natural language processing applications including, but not limited to, text summarization, question answering, information extraction, and machine translation (Chandrasekar et al., 1996). An example of this is syntactic parsing in which long and complicated sentences will generate a large number of hypotheses and usually fail in disambiguating the attachments. Therefore, it is desirable to pre-process complicated sentences and generate simpler counter parts. There are direct applications of sentence simplification. Dalemans et al. (2004) applied sentence simplification so that the automatically generated closed caption can fit into limited display area. The Facilita system generates accessible content from Brazilian Portuguese web pages for low literacy readers using both summarization and simplification technologies (Watanabe et al., 2009).
