Query suggestion aims to suggest related refined query words to users, and is employed by most modern search engines. Many research efforts have been devoted to query suggestion (Ma et al., 2010; Chirita et al., 2007a) and other, similar tasks such as query expansion (Chirita et al., 2007b; Cui et al., 2003; Theobald et al., 2005; Xu and Croft, 1996) and query refinement (Kraft and Zien, 2004). Applying query suggestion to K2Q is problematic for two reasons: 1) Query suggestion makes heavy use of the query log information such as click sessions. However, less than 1% of queries are questions, and even less of those repeat more than twice. The sparsity of questions renders query suggestion algorithms ineffective when applied to K2Q. 2) To propose new query suggestions, keyword-level editing operations such as *add, delete or change* are used (Jones et al., 2006). These operations do not take grammar into consideration, and are too simple to be applied to whole, complete sentences.

Question recommendation suggests questions which are related to the initial question (Cao et al., 2008; Wu et al., 2008). By treating the initial keywords as a question, question recommendation algorithms can also be used to suggest questions for K2Q. However, question recommendation focuses on proposing existing questions, which fails at the first challenge of generating unseen questions.

Researchers have worked on solving individual challenges posed by K2Q. For question generation, Lin (2008) proposed an "automatic question generation from queries" task in 2008, but no technical approaches were discussed. Kotov and Zhai (2010) proposed to organize search results by corresponding questions. They employed some manually created templates to transform normal sentences into questions. Their work was to generate questions from a paragraph or a sentence, but not according to keywords. In addition, since producing templates requires human effort, it is difficult to achieve high coverage. In IR field, some researchers automatically generate query templates (Agarwal et al., 2010; Szpektor et al., 2011). Inspired by their work, we try to generate templates automatically.

For question ranking, Wu et al. (2008) calculated user-to-question similarity and question-to-question similarity by employing the PLSA model, then ranked candidate questions by combining the two similarity scores. However, it is dif-

ficult to model users in K2Q, so this algorithm is not suitable for our purpose. Cao et al. (2008) proposed an "MDL-based Tree Cut Model" to rank candidate questions. They organized the candidate questions in a tree, then defined question similarity based on both *specificity* and *generality*. They ranked the candidate questions by combining the two similarity scores. Their work aimed to suggest interesting questions to the user, but K2Q proposes to recommend questions with high popularity in order to make correct predictions. Sun et al. (2009) ranked questions with several CQA specific features. However, since the candidate questions in K2Q come from different CQA sites, and some candidates are even unseen questions, it is difficult to apply these features in K2Q. In this paper, we rank questions according to their popularity, which is measured by including an adaptive language model in UII model.

For the generation of refinement words, the most relevant task is query suggestion. Diversity is an important factor in query suggestion, and most of the related works exploited the information of query logs in order to diversify the query suggestion results. Wang et al. (2009) extracted subtopics of a query by mining query reformulations in user session logs. Ma et al. (2010) proposed a method based on Markov random walks and hitting time analysis on a query-URL bipartite graph. Sadikov et al. (2010) clustered query refinements by performing multiple random walks on a Markov graph that approximates user search behavior. However, in K2Q, we cannot get sufficient click information between keywords and questions due to its sparsity in the query logs. In this paper, we use click information to evaluate our methods, but not for training since the total amount is small.

3 User Inquiry Intent Model

When a user inputs a query or posts a question, she wants to get some information. We will refer to the information need as user intent. Both the query and the question are generated from the user intent. We will use an example to illustrate the generative process. A user wants to know what the hot research topics in natural language processing are. If she employs search engines, she might create a query *hot research topics NLP* from her intent. If she wants to post a question in the community, she might choose a way to express her intent. She may choose *What are hot research topics in [subject_areas]*, or *Which research topics are hot in [subject_areas]*. Different ways of posting her intent generate different questions. In this example, let the corresponding final questions be *What are hot research topics in NLP* and *Which research topics are hot in NLP*. The replaceable part (such as *[subject_areas]*) can be considered as slots for concrete words. Generally, a slot can be interpreted as a word or a word cluster. A word cluster is a set of words which can be used in similar contexts. For example, *Beijing* and *Paris* are in the same cluster since they are both suitable to be used in the context *in [cities]*. We obtain the word clusters by using k-means as was shown in (Lin and Wu, 2009).

Here, we propose a User Inquiry Intent model to describe the process of generating queries and questions from the user intent.

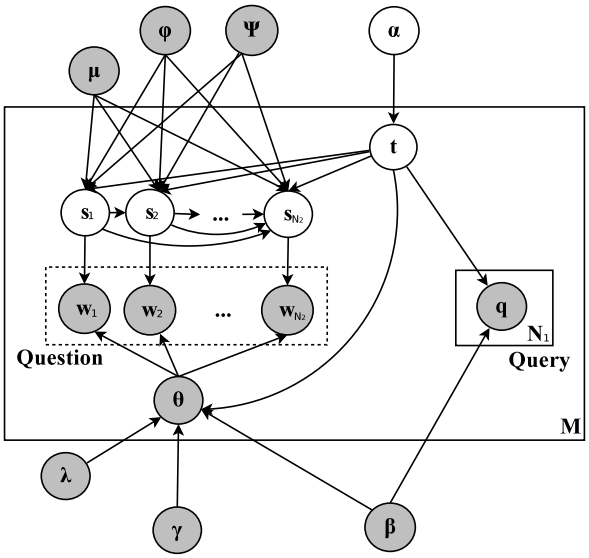

Figure 1: The plate representation of the UII model. (as in Probabilistic Graphical Models)

The plate representation of UII model is shown in Figure 1. In the model:

is the index of user intents, ranging from to (is the number of different user intents). A user intent not only corresponds to a distribution over all words but also corresponds to a distribution over the slots .

and are both indices of words, ranging from to (is the number of different words). In Figure 1, the left group of is the question which is able to express the user intent . The right group of is the query which is also able to express .

is the index of slots, ranging from to

. Besides the slots which are reserved for exact words, there are an additional more slots for word clusters.

is the prior parameter of the distribution of user intents. is a vector of length : , .

is the prior parameter of the word distribution on each user intent . is a matrix of size : , , .

is the prior parameter of the slot transition. is a matrix. Denote the preceding slots of as . Since there are too many possible values of , in practice we only reserve the frequent N-grams as possible values of . The size of is then , where is the size of frequent N-grams. , , .

is the prior parameter of the word distribution on each slot . is a matrix of size . , , .

is the prior parameter of the slot distribution on each user intent . is a matrix of size . , , .

is a matrix. Each row of is the word distribution on a slot under a particular user intent.

and are two mixture weights of prior distributions. Under user intent , , follow the Dirichlet distribution with parameters . Under user intent , the slot transition probability is calculated by Eq. 1, which is an adaptive language model (Kneser et al., 1997).

——— (1)

—

We refer the generative process as Algorithm 1. The process is illustrated with the same example as in the beginning of this section. The user intent has high probabilty on the words *hot*, *research*, *topic*, *NLP*, and hence generates the set of query words *hot research topic NLP*. Assuming that the probability of seeing a slot is determined by two preceding slots, then by considering both the slot distribution on the user intent and the slot transition probability, the user intent first generates *What* from a *START* slot; then *are* from *START What*; *hot* from *What are*; *research* from *are hot*; *topics* from *hot research*; *in* from *research topics*; *[subject_areas]* from *topics in*; and finally an *END* slot from *in [subject_areas]*. Under the user intent, we generate question words from the slots in the slot sequence *What are hot research topics in [subject_areas]*, and form the question word sequence *What are hot research topics in NLP*.

Algorithm 1: The algorithm for UII model

3.1 Inference

Given prior parameters (for convenience, we denote all prior parameters as , and all other variables as), the joint distribution is calculated as:

We integrate out to calculate :

The right side of the equation is separated into four parts: (1) ; (2) ; (3) , is calculated by Eq. 1; (4) The integration is solved by:

Here, is a matrix, is the count of slot generating words in the question. Function is the gamma function.

3.2 Parameter Estimation

As the complexity of the UII model is non-trivial, in this work we choose to estimate the parameters of different components separately instead of performing a global joint optimization.

and are weight parameters for combining different distributions. We set them empirically.

We estimate the other prior parameters with a given question set (we refer to these questions as known questions). is the prior word distribution of slots. There are two kinds of slots, one can be filled with exactly one word, and the other can be filled with any words from the corresponding word cluster. Hence, we estimate as:

Here is the probability of the -th word in the -th word cluster. We set the history to be the preceding slots, which allows the slot sequence to be an -order Markov chain. We obtain from statistics on the known questions.

In order to estimate , and , we cluster the known questions, where the questions in the same cluster contain the same bag of words (We only exclude the stopwords). Suppose we obtain question clusters such that each cluster contains questions, then we estimate as: . According to the statistics of word distributions on each question cluster, we estimate and as: , .

3.3 Question Generation

In order to reduce the computational complexity of the model, we do not actually generate all possible questions that the UII model is capable of. Instead, we use a template based method to generate the candidate questions, which are subsequently ranked by the UII model.

Question Templates Generation

To generate unseen questions, we generate question templates from known questions. A question template is a sequence of slots, where each slot is a word or a word cluster. If there are cluster slots in a template, we refer to it as a -variable template. Given a set of questions, we initialize a set of -variable templates. By replacing one word of a -variable template with a corresponding cluster, we obtain a -variable template. By merging all the same -variable templates, we get a set of -variable templates with their support numbers (the support number is the number of -variable templates employed to generate the -variable template). By increasing the threshold of the minimum support number (denoted as), we filter out those templates with low quality.

Question Generation from Initial Keywords

Firstly, we search for known questions that contain all the keywords and use them as suggestion candidates (We search for at most questions). For popular keywords such as *New York steakhouse*, we have enough known questions covering all aspects of the inquiry intents. However, for rare keywords such as *Tangshan*[1] *steakhouse*, performing a search in the known questions might yield only a few or no candidates.

Secondly, we generate unseen questions by the use of question templates. By replacing one of the initial keywords with its cluster, we search for -variable templates that contain both the cluster and the rest keywords (We search for at most -variable templates). Then, we replace the cluster slot in the templates with the actual initial keyword, creating a new question.

Both known and generated questions are added into the final candidate question set.

3.4 Question Ranking

With the candidate question set, we use the UII model to rank the candidates by , the probablity of the question was generated given the keywords. The probability is calculated as:

(2)

We could perform exact computation (i.e. Dynamic Programming) to compute the sum over all possible , however, since each suggestion should be finished in a timely fashion, the complexity of exact computation is not acceptable. Recall the process where we generated candidate questions, we only consider all the question templates that we obtained as all possible slot permutations. Then we only need to sum up all these to calculate the probability, which makes it possible to finish in real-time.

3.5 Refinement Word Generation

The goal of refinement words is to reduce the number of interactions required to reach the desired

[1] A city in China.

question. With the UII model, we use an information theory based approach to select refinement words. We define the entropy on the distribution of the user intents given the initial keywords as:

Here, ————, and is calculated as:

Then, if the user selects a refinement word , the resulted entropy gain is:

Entropy gain measures the reduced uncertainty that results by adding . As we aim to reduce the number of interaction steps in K2Q, we select those refinement words that maximize the expected entropy gain in each step. The expected entropy gain of a refinement words set R is:

———

Here is the probability that a user will choose from when a set of refinement words is given to query . is calculated as:

If the user does not select any refinement words from R, then the expectation of entropy gain on R is meaningless. Hence we define our optimization function as Eq. 3:

——— (3)

Here ———, where is the number of candidate questions when giving query , and is the number of the candidate questions which contain at least one refinement word in R.

The optimization problem is an NP-complete problem, hence in practice, we use a greedy strategy described by Algorithm 2.

Initialize , = true;
while *and* **do**
  Select =
  ;
  if
    then
      ;
      = true;
  else
    = false;
  end
end

Algorithm 2: Greedy strategy algorithm of refinement words generation

4 Experiments

In the section, we use real world questions and Web queries to evaluate the performance of candidate question generation, question ranking and refinement word generation.

4.1 Data Sets

We use a large set of English questions as the training set to generate question templates and estimate the prior parameters in the UII model. There are questions in the question set, which are obtained from popular CQA sites such as Yahoo! Answers. Notice that questions from WikiAnswers[2] are intentionally excluded from the training set, as we want to use WikiAnswers' questions as samples of unseen questions to evaluate the performance of question ranking when faced with unseen questions.

To evaluate the performance of K2Q, we need to know the mapping relationship between query and question. To this end, we use Web query logs to create the data set. After the user inputs a query, she will click a result if she thinks it is satisfactory. By only considering the clicked results that are from CQA sites, we collect pairs of queries and their target questions. We employ a one week query log from Google. To avoid data noise, we collect only those query-question pairs which occur at least times in the query log. Under these conditions, we get approximate query-question pairs.

4.2 Evaluation of Candidate Question Generation

First, we show the number of templates under different support numbers ( ) in Figure 2. As the figure shows, the number of 1-variable templates drops significantly when we need more supports. According to our observation, suffices as a good balance point between quantity and quality.

[2]http://wiki.answers.com

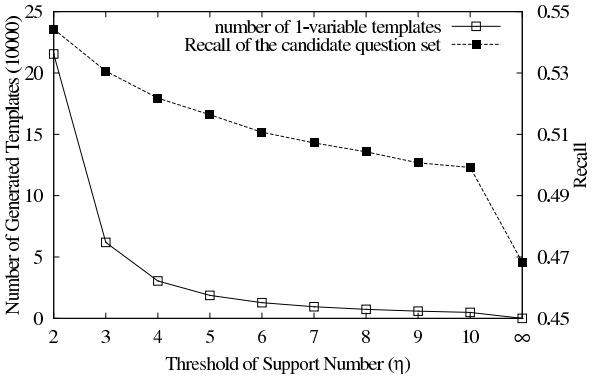

Figure 2: Number of -variable templates and recall of candidate questions with different . The templates help improve the recall (Note: means no template is used)

Second, we set up an experiment to evaluate the coverage of candidate questions generated by K2Q. We select the top most frequent query-question pairs as the test set. For each query-question pair, we generate candidate questions for the query. We define the query-question pair to be *recalled* in a candidate question set if the set contains the target question in the query-question pair. We use recall to measure the performance of our candidate question generation algorithm, which is defined as:

$$\frac{\textit{recalled query-question pair}}{\textit{query-question pairs}} \quad (4)$$

Recall measures the coverage of the candidate question set. The higher the recall, the more target questions are included in the candidate question sets. Figure 2 also shows the results under different (means no 1-variable template is used). Compared to the case when 1-variable templates are not used, our candidate question generation algorithm improved the recall by % %.

4.3 Evaluation of Question Ranking

The baseline method that we compare our approach to is the language model (denoted as LM). The language model ranks the candidate questions according to the probability that it would generate the question. Since a popular question tends to contains popular N-grams, the language model also measures the popularity of the question. Specifically, we use the same question set as that in Section 4.1 to train a -gram language model.

To construct the test set, we select query-question pairs that satisfy the following conditions: 1) the target question in the query-question pair is generated as a candidate question; 2) the target question comes from WikiAnswers, as we are more concerned with the ranking performance on unseen questions. The results in Table 1 show that the UII model provides a better ranking of the candidate questions when compared to the language model. We argue this improvement results from two aspects of the UII model: 1) The UII model introduces word clusters, which smooths the probability of rare N-grams. This is important in ranking since the generated unseen questions always contain several rare N-grams. 2) The UII model generates slot sequences via an adaptive langugage model, which helps adjust slot transition probabilities under different user intents.

We select two examples (shown in Table 2) to illustrate the aforementioned aspects of our UII model's superiority to the conventional language model. The target question of the first query is *what is the meaning of advocacy*. Since the 3-gram *meaning of advocacy* never occurs in the training set, LM does not rank the target question as the top 1 best candidate. However, the 3-gram *meaning of WordCluster* occurs frequently in the training set, so the UII model ranks the target question as the top 1 best candidate. The target question of the second query is *what are the different types of Google*. In the training set, the phrases *how many* occurs more frequently than the phrase *what are the different*, so LM does not rank the target question as its number 1 candidate. However, the corresponding user intent has high probability to generate the slot *different*, so the target question is ranked as the best candidate by the UII model.

Recall at	**LM**	**UII model**	Improvement
top 1	37.5%	43.5%	+16.0%
top 2	54.2%	58.0%	+7.0%
top 3	64.1%	66.6%	+4.1%

Table 1: The UII model performs better on the most frequent query-question pairs set

4.4 Evaluation of Refinement Word Generation

We use the query-question pairs to evaluate the performance of the generation of refinement words. We compare the UII model with an intuitive method which selects the most frequent words in the candidate questions as refinements (denoted as MF). The goal of refinement words is to interact with the user in those cases

Query	Question at top 3	
	UII model	**LM**
advocacy meaning	**What is the meaning of advocacy?** The meaning of advocacy? What is meaning of advocacy?	What is the meaning advocacy? **What is the meaning of advocacy?** What is the meaning of the advocacy?
Google types	**What are the different types of Google?** What are the types of Google? How many types of Google?	How many types of Google? Different types of Google? **What are the different types of Google?**

Table 2: Two examples of top 3 suggestions by UII model and LM (The target questions of the queries are shown in bold)

when the initial keywords are too simple to express the user intent. Since one word queries are often too simiple to express the user intent, we use one word queries as the test set. These query-question pairs also satisfy the following two conditions: 1) the target question in the query-question pair is generated as a candidate question; 2) the UII model ranks the target question not to be among the top ten.

We use such query-question pairs as the test set. For each method, we generate a list of refinement words. We use each of the refinement words to refine the query, and then subsequently re-rank the candidate questions and create a new set of 10 refinement words. By exploring all possible choices of refinement words among the list of 10 in each interaction, we find the minimal number of interaction steps that lead to the target questions. We search for at most steps. If K2Q ranks the target question among the top 10 within these interactions, then set the query cost to be the minimal interaction number in which this occured; otherwise, let the query cost be . We consider two metrics: 1) the number of query-question pairs where K2Q ranks the target question among the top ten within interactions (denoted as RN); 2) the reciprocal average query cost (denoted as RAQC). The larger RAQC is, the fewer the number of interactions K2Q requires to successfully rank the target question.

	MF	**UII model**	Improvement
RN	363	409	+12.7%
RAQC	0.258	0.265	+2.63%

Table 3: UII model performs better than the baseline method on refinement words generation

From the results in Table 3, we find that: 1) With refinement words, K2Q is more effective of suggesting the target questions. 2) With refinement words generated by the UII model, K2Q gets more efficient feedback, which leads to better performance when compared to the intuitive method. MF only considers the frequency of the words, not the diversity. In contrast, the UII model is effective in suggesting those refinement words that maximally reduce the entropy of the distribution of user intents. It is clear that the UII model suggests a better list of refinement words than the intuitive method.

5 Conclusion

In this paper, we propose the UII model to solve the K2Q problem. The UII model exhibits a simultaneous process of generating both questions and queries based on the user intents. UII model utilizes existing questions on the Web, and leverages templates to generate and rank unseen questions. This model is also equipped with the ability to suggest refinement words that maximize the entropy gain of inferred intent distribution. Experiments show that: 1) using templates improves the coverage of suggestions by % %; 2) the UII model improves the ranking of suggestions over conventional language models with recall at top ranked questions increased over ; 3) the UII model suggests better refinement words when compared to a baseline method of suggesting words based on frequency. By interacting via these refinement words, K2Q is able to rank target questions within top ten, higher than the baseline method. These results show that our proposed UII model yields better suggestions than separated methods in K2Q.

The UII model is a generative model. In this paper, we estimate all the prior parameters without using query-question pairs. Since there are mountains of query-question pairs from query logs, we plan to better estimate the prior parameters with these pairs in future work. Another important direction is to use real-world feedback to evaluate the model, as our current evaluation does not consider real users.

Abstract

This paper regards social Q&A collections, such as Yahoo! Answer as a knowledge repository and investigates techniques to mine knowledge from them for improving a sentence-based complex question answering (QA) system. In particular, we present a question-type-specific method (QTSM) that studies at extracting question-type-dependent cue expressions from the social Q&A pairs in which question types are the same as the submitted question. The QTSM is also compared with question-specific and monolingual translation-based methods presented in previous work. Thereinto, the question-specific method (QSM) aims at extracting question-dependent answer words from social Q&A pairs in which questions are similar to the submitted question. The monolingual translation-based method (MTM) learns word-to-word translation probabilities from all social Q&A pairs without consideration of question and question type. Experiments on extension of the NTCIR 2008 Chinese test data set verify the performance ranking of these methods as: QTSM $>$ {QSM, MTM}. The largest F_3 improvements of the proposed QTSM over the QSM and MTM reach 6.0% and 5.8%, respectively.

1 Introduction

Research on the topic of QA systems has mainly concentrated on answering factoid, definitional, reason and opinion questions. Among the approaches proposed for answering these questions, machine learning techniques have been found more effective in constructing QA components from scratch. Yet these supervised techniques require a certain scale of question and answer (Q&A) pairs as training data. For example, Echihabi et al. (2003) and Sasaki (2005) respectively constructed 90,000 English and 2,000 Japanese Q&A pairs for their factoid QA systems. Cui et al. (2004) collected 76 term-definition pairs for their definitional QA system. Higashinaka and Isozaki (2008) used 4,849 positive and 521,177 negative examples in their reason QA system. Stoyanov et al. (2005) required a known subjective vocabulary for their opinion QA system. This paper is concerned with answering complex questions which answers generally consists of a list of nuggets (Voorhees, 2003; Mitamura et al., 2008). Apart from definitional and opinion (TAC, 2008) complex questions, many other types of complex questions have not yet to be thoroughly studied[1]. To answer these complex questions via supervised techniques, we need to collect training Q&A pairs for each type of complex question, though this is an extremely expensive and labor-intensive task.

This paper is to explore the possibility of automatic learning of training Q&A pairs and mining needed knowledge from social Q&A collections such as Yahoo! Answer[2]. That is to say, we are interested in whether or not millions of, possible noisy, user-generated Q&A pairs can be exploited for automatic QA system. This is a very important question because a positive answer can indicate that a plethora of training Q&A data is readily available to QA researchers.

Many studies, such as (Riezler et al., 2007; Surdeanu et al., 2008; Duan et al., 2008; Wang, 2010a) have addressed retrieving of similar Q&A pairs from social QA websites as answers to test questions; thus answers cannot be generated for questions that have not been answered on such

[1]Most complex questions have generally been called what-questions in previous studies. This paper argues that it is helpful to treat them discriminatively.

[2]http://answers.yahoo.com/

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 956–964,
Chiang Mai, Thailand, November 8 – 13, 2011.

sites. Our study, however, regards social Q&A websites as a knowledge repository and aims at exploiting knowledge from them for synthesizing answers to questions, which have not been answered on these sites. Even for questions that have been answered, it is necessary to perform answer summarization as (Liu et al., 2008) indicated. Our approach can also be used for this purpose. To the best of our knowledge, there appears to be very little literature on this aspect.

Various kinds of knowledge can be mined from social Q&A collections for supporting complex QA system. In this paper, we present a question-type-specific method (QTSM) to mine question-type-specific knowledge and compare it with question-specific and monolingual translation-based methods proposed in related work. Given a question Q, the three methods can be summarized as follows: (1) The proposed QTSM studies at recognizing question type Q_t from the Q; collecting Q&A pair in which question types are the same as Q_t; extracting salient cue expressions that are indicative of answers to the question type Q_t; and using the expressions and Q&A pairs to train a binary classifier for removing noise candidate answers. (2) The question-specific method (QSM) tries to collect Q&A pairs that are similar to Q from social Q&A collection, and extract question-dependent (Q-specific in this case) answer words to improve complex QA system. (3) The monolingual translation-based method (MTM) employs all social Q&A pairs and learns word-to-word translation probabilities from them without consideration of question Q and question type Q_t to solve the lexical gap problem in complex QA system. The three methods are evaluated in terms of the extension of the NTCIR 2008 test data set. The Pourpre v.0c evaluation tool (Lin and Demner-Fushman, 2006) is employed, which is also adopted to evaluate TREC QA systems. The experiments show that the proposed QTSM is most effective, for instance, the largest F_3/NR improvements of QTSM over the baseline, QSM, and MTM models reach 8.6%/12.6%, 6.0%/6.7%, and 5.8%/7.1%, respectively. The ranking of the methods was: QTSM $>$ {QSM, MTM}.

2 Social Q&A Collection

Social QA websites such as Yahoo! Answer and Baidu Zhidao[3] provide an interactive platform for users to post questions and answers. After questions are answered by users, the best answer can be chosen by the asker or nominated by the community. Table 1 demonstrates an example of these Q&A pairs, the number of which has risen dramatically on such sites. The pairs could collectively form a source of training data needed in supervised machine-learning-based QA systems.

Question	What do you think is the main cause of global warming?
Best Answer	The primary cause of global warming is the emission of green house gases like carbon dioxide, methane, nitrous oxide...
Other Answer	...What is NOT at all clear is whether human-activity is causing for the current warming trend...
Other Answer	First of all, it is damaging outcome of man-made faults...

Table 1: Example of social Q&A pairs

This paper aims at exploiting such user-generated Q&A collections for improving complex QA systems via automatic learning of Q&A training pairs and mining needed knowledge from them. Social collections, however, have two salient characteristics: textual mismatch between questions and answers (i.e., question words are not necessarily used in answers), and user-generated spam or flippant answers, which are unfavorable factors in our study. We only crawl questions and their best answers to form Q&A pairs, wherein the best answers are longer than the empirical threshold (20 words). Finally, about 40 million Q&A pairs were crawled from Chinese social QA websites and will be used as a source of training data.

3 Complex QA System

The typical complex QA system architecture is a cascade of three modules. The Question Analyzer analyzes test question and identifies type of question. The Document Retriever & Answer Candidate Extractor retrieves documents related to questions from the given collection (*Xinhua* and *Lianhe Zaobao* newspapers from 1998-2001 were used in this study) for consideration, and segments them into sentences as answer candidates. The Answer Ranker applies state-of-the-art IR formulas (e.g., KL-divergence language model) to estimate "similarities" between sentences (we used 1,024 sentences) and question and ranks sentences according to their similarities. Finally, the top N sentences are deemed the final answers.

Given question Q_1 = "What are the hazards of global warming?" and its three answer candidates, a_1 = "Solutions to global warming range from changing a light bulb to engineering giant reflec-

[3] http://zhidao.baidu.com/

tors in space ...," a_2 = "Global warming will bring bigger storms and hurricanes that hold more water ...," and a_3 = "nuclear power has relatively low emission of carbon dioxide (CO_2), one of the major causes of global warming", it is hard for the above architecture to correctly select a_2 as answer, because the three candidates contain the same keywords in question Q_1. To improve this architecture, external knowledge must be incorporated. As introduced in section 2, social Q&A collection is a good choice for mining needed knowledge. In this paper, we propose a question-type-specific technique of exploiting social Q&A collection (as introduced in section 4) to mine the knowledge, and compare it with question-specific (section 5.1) and monolingual translation-based (section 5.2) methods in experiments.

4 QTSM

Based on our observation, that is, answers to a type of complex question usually contain question-type-dependent cue expressions that are helpful in answering complex questions, we propose the QTSM that aims to learn these cue expressions for each type of question and utilize them to improve complex QA systems.

For each test question, the QTSM performs the following steps: (1) Recognizing the type of test question by identifying the *question focus* of question. (2) Collecting positive and negative training Q&A pairs of the type of question from the social Q&A collection. (3) Extracting question-type-specific salient cue expressions from the Q&A pairs. (4) Utilizing the cue expressions and Q&A pairs to build a binary classifier of the type of the test question. (5) Employing the classifier to remove noise from candidate answers before using the Answer Ranker to select final answers to the question.

4.1 Question Type

Earlier work on factoid QA systems tried to recognize question types via classification techniques (Li, et al., 2002), which require taxonomy of question types such as location, organization, person and training instances for each type. This algorithm may be inappropriate to complex QA systems due to there are hundreds of question types and we have little prior knowledge about defining complex QA-oriented taxonomy. This paper recognizes type of complex question by identifying its question focus. Question focus is defined as a short subsequence of tokens (typically 1-3 words) in a question that are adequate for indicating its question type. Take Q_1 = "What are the hazards of global warming?" and Q_2 = "What disasters are caused due to global warming?" as examples, *hazard* and *disaster* are their corresponding question focuses.

To recognize question type, we simply assume that type of complex question is only determined by its question focus; that is to say, question-type and question focus can be used interchangeably in this paper. Based on this assumption, question Q_1 and Q_2 belong to the hazard-type and disaster-type questions, respectively. Krishnan (2005) has showed that (a) the accuracy of recognizing question types reached 92.2% by using only question focuses and (b) the accuracy of recognizing question focuses was 84.6%. This indicates that most questions contain question focuses and it is practicable to represent question types by question focuses. Thereby, the task of recognizing question types shifts to recognizing question focuses from questions.

We regard question focus recognition as a sequence-tagging problem and employ conditional random fields (CRFs) because many studies have proven a consistent advantage of CRFs in sequence tagging. We manually annotate 4,770 questions with question focuses to train a CRF model, which classifies each question word into a set of tags $O = \{I_B, I_I, I_O\}$: I_B for a word that begins a focus, I_I for a word occuring in the middle of a focus and I_O for a word outside of a focus. In the following feature templates used in the CRF model, w_n and t_n refer to word and part-of-speech (PoS), respectively, and n refers to the relative position from the current word n=0. The feature templates contain four types: unigrams of w_n and t_n, where $n = -2, -1, 0, 1, 2$; bigrams of $w_n w_{n+1}$ and $t_n t_{n+1}$, where n=$-1, 0$; trigrams of $w_n w_{n+1} w_{n+2}$ and $t_n t_{n+1} t_{n+2}$, where $n = -2, -1, 0$; and bigrams of $O_n O_{n+1}$, where n=$-1, 0$.

Among 4,770 questions, 1,500 are held out as test set, the others are used for training. The experiment shows that precision of the CRF model on the test set is 89.5%. At offline, the CRF model is used to recognize question focuses from questions of social Q&A pairs. Finally, we recognize 103 question focuses for which frequencies are larger

than 10,000. Moreover, the numbers of question focuses for which frequencies are larger than 100, 1,000, and 5,000 are 4,714, 807, and 194, respectively. Among 4,714 recognized question focuses, 87% are not included in the question focus training questions. At online phrase, the CRF model is used to identify question focus of test question.

4.2 Q&A Pairs

It is necessary to manually annotate question focuses for identifying question types, however, training Q&A pairs for the question types can be automatically leant as follows once question types are determined.

4.2.1 Basic Positive Q&A Pairs

For question-type X, social Q&A pairs for which question focuses are the same as X are regarded as basic positive Q&A pairs QA_{basic} of X-type questions. Formally, $QA_{basic} = \{QA_i | AT_i = X\}$, where QA_i denotes a Q&A pair, and AT_i denotes question focus of QA_i. Table 2[4] reports the number of Q&A pairs for each type of question in the extension of the NTCIR 2008 test set (discussed in the experimental section). For example, 10,362 Q&A pairs are leant for answering hazard-type questions. Table 3 lists questions which, together with their best answers, are utilized as basic positive training pairs of the corresponding type of complex questions.

Qtype	#	Qtype	#
Hazard-type	10,362	Function-type	41,005
Impact-type	35,097	Significance-type	14,615
Attitude-type	1,801	Measure-type	3,643
Reason-type	50,241	Casualty-type	102
Event-type	5,871	Scale-type	642

Table 2: Numbers of basic positive Q&A pairs learned (#)

4.2.2 Bootstrapping Positive Q&A Pairs

For question types like casualty(伤亡)-type for which only a few basic positive Q&A pairs are learnt, Q&A pairs for similar question types like fatality(死伤)-type can be used. Hownet (Dong, 1999), a lexical knowledge base with rich semantic information and which serves as a powerful tool for meaning computation, is adopted for bootstrapping the basic positive Q&A pairs. In Hownet, a word may represent multiple concepts, and each concept consists of a group of sememes. For example, the Chinese word for "伤亡(casualty)" is described as: "phenomena|现象, wounded|受伤, die|死, undesired|莠". The similarity between two words can be estimated by,

$$sim(w_1, w_2) = \max_{1 \le i \le |w_1|; 1 \le j \le |w_2|} sim(c_i, c_j)$$

$$sim(c_i, c_j) = \frac{\sum_{1 \le k \le |c_i|} \max_{1 \le z \le |c_j|} sim(se_{i,k}, se_{j,z})}{|c_i|}$$

where c_i and c_j represent the i-th and j-th concept of word w_1 and w_2, respectively, $|w_1|$ is the number of concepts that w_1 represents, $se_{i,k}$ denotes the k-th sememe of concept c_i, $|c_i|$ is the number of sememes of concept c_i, and $sim(se_{i,k}, se_{j,z})$ is 1 if they are same, otherwise the value is set to 0.

Accordingly, the bootstrapping positive Q&A pairs QA_{boot} of X-type questions is composed of the Q&A pairs in which question focuses are similar to X. Formally, $QA_{boot} = \{QA_j | sim(AT_j, X) > \theta_1\}$, where, AT_j is question focus of QA_j, θ_1 is the similarity threshold.

Qtype	Questions of Q&A pairs
Hazard -type	What are the **hazards** of the trojan.psw.misc.kah virus? List the **hazards** of smoking. What are the **hazards** of contact lenses?
Casualty -type	What were the **casualties** of the Sino-French War? What were the **casualties** of the Sichuan earthquake? What were the **casualties** of the Indonesian Tsunami?
Reason -type	What are the main **reasons** for China's water shortage? What are the **reasons** for asthma? What are the **reasons** for air pollution?

Table 3: Questions (translated from Chinese) of Q&A pairs (words in bold are question focuses).

4.2.3 Negative Pairs & Preprocessing

For each type of question, we also randomly select some Q&A pairs that do not contain question focuses and their similar words in questions as negative training Q&A pairs.

Preprocessing of the training data, including word segmentation, PoS tagging, named entity (NE) recognization (Wu et al., 2005), and dependency parsing (Chen, 2009), is conducted. We also replace each NE with its tag type.

4.3 Extracting Cue Expressions and Building Classifiers

In this paper, we extract two kinds of cue expressions: n-grams at the sequential level and depen-

[4]Function-type: What are the **functions** of the United Nations? Impact-type: List the **impact** of the 911 attacks on the United States. Significance-type: List the **significance** of China's accession to the WTO. Attitude-type: List the **attitudes** of other countries toward the Israel-Palestine conflict. Measure-type: What **measures** have been taken for energy-saving in Japan? Event-type: List the **events** in the Northern Ireland peace process. Scale-type: Give information about the **scale** of the Kunming World Horticulture Exposition. Refer to Table 3 for other types of questions.

dency patterns at the syntactic level. The purpose of cue expression mining is to extract a set of frequent lexical and PoS-based subsequences that are indicative of answers to a type of question.

The n-gram cue expressions include (1) 3,000 lexical unigrams selected using the formula: $score_w = tf_w \times log(\frac{N}{df_w})$, where tf_w denotes the frequency of word w, df_w denotes the frequency of Q&A pairs in which w appears, and N is the total number of the Q&A pairs; (2) lexical bigrams and trigrams that contain the selected unigrams and their frequencies are larger than the empirical thresholds; (3) PoS-based unigrams; and (4) PoS-based bigrams with frequencies larger than the threshold. The dependency pattern is defined as relation between words of a dependency tree. Figure 1 shows an example. Both lexical and PoS patterns with frequencies larger than the threshold are selected.

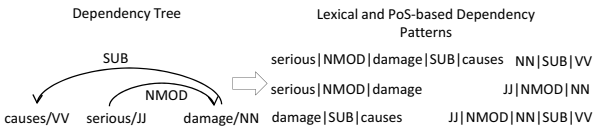

Figure 1: Example of dependency patterns

We also assign each extracted cue expression ce_i a weight calculated using the equation $weight_{ce_i} = c_1^{ce_i}/(c_1^{ce_i} + c_2^{ce_i})$, where, $c_1^{ce_i}$ and $c_2^{ce_i}$ denote its frequencies in positive and negative training Q&A pairs, respectively. The weights are used as values of features in SVM classifier.

The extracted cue expressions and collected Q&A pairs are used to build a question-type-specific classifier for each type of question, which is then used to remove noise sentences from answer candidates. For classifiers, we employ multivariate classification SVMs (Thorsten Joachims, 2005) that can directly optimize a large class of performance measures like F_1-Score, prec@k (precision of a classifier that predicts exactly k = 100 examples to be positive) and error-rate (percentage of errors in predictions).

5 Comparison Models

5.1 QSM

The QSM (question-specific method) first learns potential answer words to the question, and then re-ranks candidates by incorporating their "similarities" to the answer words. For each submitted question, the following four steps are performed. (1) An IR algorithm is used to retrieve the most similar Q&A pairs (top 50 in our experiments) to the question from the social Q&A collection. (2) All non-stop words from the retrieved Q&A pairs are weighted using a TFIDF score and the top M words are selected to form an answer profile Ap. (3) Answer candidates are re-ranked according to the similarity formula $sim(a_i) = \gamma sim(Q, a_i) + (1-\gamma)sim(a_i, Ap)$, where $sim(Q, a_i)$ denotes the similarity between question Q and candidates a_i, $sim(a_i, Ap)$ means the similarity between candidates and the answer profile Ap, γ is the weight. Both $sim(Q, a_i)$ and $sim(a_i, Ap)$ are estimated using cosine similarity in this paper. (4) Finally, the top N candidates are selected as answers to Q.

QSM is also widely used in answering definitional questions and TREC QA "other" questions (Kaisser et al., 2006; Chen, et al., 2006), which, however, learn answer words from the most relevant snippets returned by a Web search engine. Section 6 compares QSM based on 50 most relevant social Q&A pairs and that based on 50 most relevant snippets returned by Yahoo!.

5.2 MTM

The MTM learns word-to-word translation probability from all social Q&A pairs without consideration of the question and question type to improve complex QA system. The monolingual translation-based method treats Q&A pairs as the parallel corpus, with questions corresponding to the "source" language and answers to the "target" language. Monolingual translation models have recently been introduced to solve the lexical gap problem in IR and QA systems (Berger et al., 1999; Riezler et al., 2007; Xue, et al., 2008; Bernhard et al., 2009). A monolingual translation-based method for our complex QA system can be expressed by:

$$P(Q|a_i) = \prod_{w \in Q} ((1-\gamma)P_{mx}(w|a_i) + \gamma P_{ml}(w|C))$$
$$P_{mx}(w|a_i) = (1-\zeta)P_{ml}(w|a_i) + \zeta \sum_{t \in S} P(w|t)P_{ml}(t|a_i) \quad (1)$$

where Q is the question, a_i the candidate answer, γ the smoothing parameter for the whole Q&A collection, $P(w|t)$ the probability of translating an answer term t to a question term w, which is obtained by using the GIZA++ (Och and Ney, 2003),

the impact of the translation probabilities is controlled by ζ (=0.6 in this paper).

As in the common practice in translation-based retrieval, we utilize IBM model 1 for obtaining word-to-word probability $P(w|t)$ from 6.0 million social Q&A pairs. Preprocessing of the Q&A pairs only involves word segmentation (Wu et al., 2005) and stop word removal.

6 Experiments

As Section 4.1 shows, there exist hundreds of types of complex questions, it is hard to evaluate our approach on all of them. In this paper, question types contained in the NTCIR 2008 test set (Mitamura et al., 2008) are used. The NTCIR 2008 test data set contains 30 complex questions[5] that we discuss here. However, a small number of test questions are included for certain question types; e.g., it contains only one hazard-type, one scale-type, and three significance-type questions. To form a more complete test set, we create another 57 test questions to be released with this paper. The test data used in this paper therefore includes 87 questions and is called an extension of the NTCIR 2008 test data set. For each test question we also provide a list of weighted answer nuggets, which are used as the gold standard answers for evaluation. The evaluation is conducted by employing Pourpre v1.0c tool that uses the standard scoring methodology for TREC "other" questions (Voorhees, 2003). Each question is scored using nugget recall NR, nugget precision NP, and a combination score F_3 of NR and NP. Refer to (Lin and Demner-Fushman, 2006) for the detailed computation. The final score of a system run is the mean of the scores across all test questions.

6.1 Overall Results

Table 4 summarizes the evaluation results of the systems. The baseline refers to the conventional method in which the similarity is the same as $sim(Q, a_i)$ in section 5.1. QSM$_{web}$ and QSM$_{qa}$ indicate QSM that learns answer words from the Web and the social Q&A pairs, respectively. QTSM$_{prec}$ denotes QTSM based on the classifier optimizing performance prec@k.

This table indicates that the complex QA performance can be clearly improved by exploiting social Q&A collection. In particular, we observe that: 1) QTSM obtains the best performance; e.g., the F_3 improvements of QTSM$_{prec}$ over MTM and QSM$_{qa}$ in terms of N=10 are 5.8% and 6.0%, respectively. 2) QSM$_{qa}$ outperforms QSM$_{web}$ by 2.0% when N=10. Further analysis shows that the average number of the gold standard answer words learned in QSM$_{web}$ (42.9%) are fewer than that learned in QSM$_{qa}$ (58.1%). The reason may lie in: Q&A pairs are more complete and complementary than snippets that only contain length-limited contexts of question words. This proves that learning answer words from social Q&A pairs is superior to that from the snippets returned by a Web search engine. 3) The performance ranking of these models is: QTSM$_{prec}$ > {MTM, QSM$_{qa}$} > QSM$_{web}$. QSM$_{qa}$ depends on very specific knowledge, i.e. answer words to each question, which may fail when social Q&A collection does not contain similar Q&A pairs, or similar Q&A pairs do not contain answer words to the question. MTM learns very general knowledge from social Q&A collection, i.e., word-to-word translation probability, which is not apt to any question, any type of question, or any domain question. QTSM$_{prec}$, however, learns question-type-specific salient expressions, which granularity is between QSM$_{qa}$ and MTM. This may be the reason that QTSM$_{prec}$ achieves better performance.

Figure 2 displays how well QTSM$_{prec}$ performs for each type of question when N=10 for further comparison. This figure indicates that our method improves QSM$_{qa}$ on most types of test questions; e.g., the F_3 improvements on function-type and hazard-type questions are 20.0% and 14%, respectively. It is noted that QSM$_{qa}$ achieves better performance than QTSM$_{prec}$ on event-type questions. We interpret this to mean that the extracted salient cue expressions may not characterize answers to event-type questions. More complex features such as templates used in MUC-3 (MUC, 1991) may be needed. Figure 3 shows NR recall curves of the three models, which characterize the amount of relevant information contained within a fixed-length text segment (Lin, 2007). We observe that QTSM$_{prec}$ can greatly improve MTM and QSM$_{qa}$ at every answer length. For example, the improvement of QTSM$_{prec}$ over MTM is about 10.0% when the answer length is 400 words. Yet there is no distinct difference between MTM and QSM$_{qa}$.

[5]Because definitional, biography, and relationship questions in the NTCIR 2008 test set are not discussed here.

	F_3 (%)		NR (%)		NP (%)	
	$N = 5$	$N = 10$	$N = 5$	$N = 10$	$N = 5$	$N = 10$
Baseline	18.18	21.95	19.85	27.64	25.32	18.96
QSM$_{web}$	20.36	22.57	23.47	29.63	22.30	13.57
QSM$_{qa}$	21.28†	24.63†	24.60	33.49	22.99	15.47

Significance tests are conducted on the F_3 scores. †: significantly better than Baseline at the $p = 0.1$ level using two-sided t-tests; $^{\flat}$: significantly better than QSM$_{qa}$ at the 0.005 level.

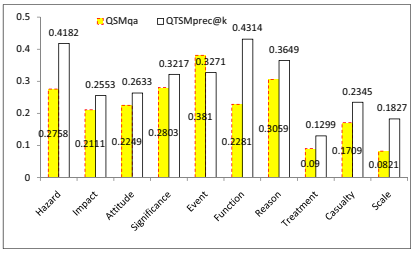

Figure 2: F_3 performance by type of question

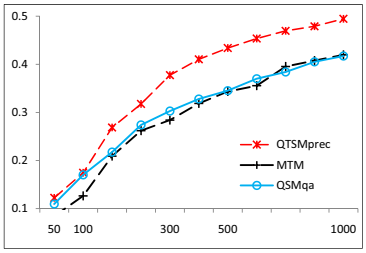

Figure 3: Recall over various answer lengths

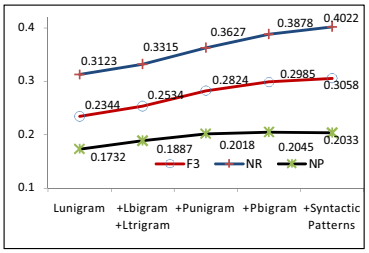

Figure 4: Impact of features on QTSM$_{prec}$

6.2 Impact of Features

To evaluate the contributions of individual features to the QTSM, this experiment gradually adds them. Figure 4 shows the performance of QTSM$_{prec}$ on different sets of features, L and P represent lexical and PoS-based n-gram cue expressions, respectively. This table demonstrates that all the lexical and PoS features can positively impact QTSM$_{prec}$. The contribution from dependency patterns is, however, not significant, which may be due to the limited number of dependency patterns learned.

6.3 Subjective evaluation

Pourpre v1.0c evaluation is based on n-gram overlap between the automatically produced answers and human-generated reference answers. Thus, it is not able to measure the conceptual equivalent. In subjective evaluation, the answer sentences returned by QA systems are labeled by two native Chinese assessors. Given a pair of answers for each question, the assessors are asked to determine which summary has better content for the question, or whether both are equally responsive. If their judgements are different, they will discuss a final judgement. This kind of evaluation is also used in (Biadsy et al., 2008; Liu et al., 2008).

Table 6 indicates that QTSM$_{prec}$ is much better than MTM and QSM$_{qa}$. For example, 56.3% of these judgements preferred the answers produced by QTSM$_{prec}$ over those produced by MTM. Table 5 compares the top 3 answers to question Q_1 answered by MTM and QTSM$_{prec}$.

QTSM$_{prec}$	Better	Equal	Worse
QTSM$_{prec}$ vs. MTM	56.3%	12.6%	31.1%
QTSM$_{prec}$ vs. QSM$_{qa}$	55.2%	13.8%	31.0%

Table 6: Results of subjective evaluation

7 Related Work

Some pioneering studies on social Q&A collection have recently been conducted. Much of the research aims at retrieving answers to queried questions from social Q&A collection. For example, Surdeanu et al. (2008) proposed an answer-ranking engine for non-factoid questions by incorporating textual features into a machine learning approach. Duan et al. (2008) retrieved questions semantically equivalent or close to the queried question for a question recommendation system. Agichtein et al. (2008) investigated techniques for finding high-quality content in social Q&A collection, and indicated that 94% of answers to questions have high quality. Xue, et al. (2008) proposed a retrieval model that combines a translation-based language model for the question part with a query likelihood approach for the

MTM	...非洲将是最易受全球气候变暖危害冲击的大陆.../...Africa will be most vulnerable to the impacts of global warming...
	...全球气候变暖将会对全球不同地区气候变化产生更为严重的影响。/...global warming will more seriously impact climate change in different regions of the world...
	...气候变暖对非洲造成的严重负面影响.../...global warming had a serious negative impact on Africa...
QTSM$_{prec}$	...全球气候变暖将给生态环境带来严重破坏, 致使自然灾害频繁发生, 而受其影响最为严重的当属非洲大陆。/...global warming will bring serious damage to the ecological environment, and result in frequent occurrences of natural disasters. There is no doubt that Africa is the most seriously impacted continent.
	全球气候变暖将会使非洲大陆的干旱地区, 特别是非洲中部和南部的干旱、半干旱地区更加缺水, 耕地退化和荒漠化现象越来越严重。/Global warming will cause more serious water shortages in the arid areas of the African continent, especially in central and southern arid and semi-arid areas. Land degradation and desertification will become increasingly serious.
	此外, 全球变暖还会导致极端气候现象频繁发生, 如寒潮、热浪、暴雨、龙卷风等, 对人类社会构成极大威胁。/Global warming will also lead to frequent extreme weather phenomena such as cold waves, heat waves, storms, and tornados, which poses a great threat to human beings.

Table 5: Top 3 answers to question, "What are the hazards of global warming?" returned by MTM and QTSM$_{prec}$

answer part. Wang (2010a) proposed an effective question retrieval in social Q&A collections.

Another category of study regards social Q&A collection as a kind of knowledge repository and aims to mine knowledge from it for generating answers to questions. To the best of our knowledge, there appears to be very limited work addressing this aspect. Mori et al. (2008) proposed a QSM method for improving complex Japanese QA systems, which collect Q&A pairs using 7-grams for which centers are interrogatives.

This paper is also related to query-based summarization of DUC (Dang, 2006; Harabagiu et al., 2006), which aims at synthesizing a fluent, well-organized 250-word summary for a given topic description and a collection of relevant documents generated manually. The topic descriptions usually consist of several complex questions such as "*Describe theories on the causes and effects of global warming and arguments against them.*" Thus, many approaches such as LexRank (Erkan and Radev, 2004) focus on compressing the relevant documents. We implement a LexRank method for our task, for which performance is even worse than the baseline. Our observation is that a query-based summarization task is given a set of manually generated relevant documents, but our QA systems need to retrieve relevant documents automatically, and there exist a great deal of noise.

8 Conclusion

This paper investigated techniques for mining knowledge from social Q&A websites for improving a sentence-based complex QA system. The proposed QTSM (question-type-specific method) explored social Q&A collection to automatically learn question-type-specific training Q&A pairs and cue expressions, and create a question-type-specific classifier for each type of question to filter out noise sentences before answer selection. Experiments on the extension of NTCIR 2008 test questions indicate that QTSM is more effective than QSM (question-specific method) and MTM (monolingual translation-based method) methods; e.g., the largest improvements in F_3 over QSM and MTM reaches 6.0% and 5.8%, respectively.

In the future, we will endeavor to: (1) reduce noise in the training Q&A pairs, and design more characteristic cue expressions to various types of questions such as event-templates for event-type question (MUC, 1991); (2) adapt QTSM to summarize answers in social QA sites (Liu et al., 2008); (3) learn paraphrases to recognize types of questions that do not contain question focuses such as "What causes global warming?"; (4) adapt the QA system to a topic-based summarization system, which will, for instance, summarize accidents according to "casualty" and"reason", and events according to "reason", "measure" and "impact".

Abstract

This paper describes efforts of NLP researchers to create a system to aid the relief efforts during the 2011 East Japan Earthquake. Specifically, we created a system to mine information regarding the safety of people in the disaster-stricken area from Twitter, a massive yet highly unorganized information source. We describe the large scale collaborative effort to rapidly create robust and effective systems for word segmentation, named entity recognition, and tweet classification. As a result of our efforts, we were able to effectively deliver new information about the safety of over 100 people in the disaster-stricken area to a central repository for safety information.

1 Introduction

On March 11, 2011 at 14:46[1], a massive earthquake of Magnitude 9.0 struck off the coast of Japan. The earthquake and the ensuing Tsunami caused damage across the entire eastern coast of the country, with homes destroyed, roads impassible, and large swaths of the disaster-stricken area losing electricity and the ability to communicate.

Figure 1 shows the death toll and the number of missing people from tsunami and earthquake, presented by the Japanese National Police Agency. The number of missing people reached its peak on March 25th, indicating that the government took 2 weeks to fully grasp the total number of victims, although they began gathering information about the whereabouts of victims and survivors as soon as the earthquake hit. One of the main reasons for this delay was that prefectures could not effectively collect the information from municipal governments or police stations because many of them

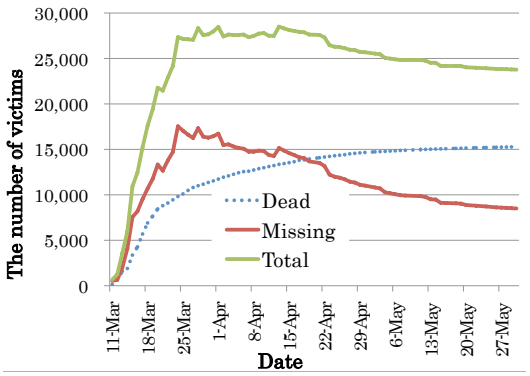

Figure 1: Change of overall death toll and missing people

were extensively damaged or destroyed by the disaster (Anonymous, 2011)[2]. Furthermore, damage to communication equipment, power outages, and inundation of the air waves prevented the use of mobile phones, which are generally the most important tool for communication during a disaster.

As a result, Twitter or social network services (SNS) such as mixi[3] played an important role for propagating safety information among people. However, with SNSs flooded with information about the disaster, it was difficult to ensure that people would be properly connected with the information they were seeking. Soon after the disaster struck, many NLP researchers, engineers, and students from all over Japan (including the authors), spontaneously created a working group called "ANPI_NLP"[4] to try to organize this information into a form that would be useful. In particular, we focused on mining and organizing information on Twitter regarding safety of individuals in the disaster-stricken area, as people are initially more concerned about the safety of their family or

[4] The word "ANPI" means "safety" in Japanese.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 965–973,
Chiang Mai, Thailand, November 8 – 13, 2011.

friends than anything else.

There were three major elements to this process:

- Separating the tweets that contained safety information from the huge number of irrelevant tweets.
- Extracting important information, such as person names and locations from highly domain-specific text included in the tweets.
- Verifying and delivering this information to the people that need it.

The working group tackled these issues in safety information extraction from Twitter, preparing resources, building tools, and connecting the extracted information with Google Person Finder (GPF)[5], a central location for safety information that was widely publicized through the Japanese news media. Our priorities were not only the accuracy, but also the speed with which we could provide the information.

In this paper, we report the process of building an information extraction system in a disaster-response situation within a matter of days. The challenges involved included organizing volunteers (§2), building resources for out-of-domain, noisy internet data (§3), and applying these volunteers and resources to the construction of NLP tools (§4 and §5). We also describe the final results of the project, the provision of new information about missing persons to GPF (§6), and summarize related work (§7). Finally in §8 we discuss what went right and what went wrong with the project, and provide some insight into what can be done to prepare for similar situations in the future.

2 Organization and Communication

The project began with a single Twitter post soon after the earthquake hit, imploring NLP researchers and engineers to think about what they could do to help in the time of need. In particular, the creation of resources and tools that could be used to process information about the earthquake was cited as one example. In under an hour, the first responders to this call had started creating the language resources described in §3.

Given the public nature of Twitter, word of the efforts spread, and the number of participants quickly increased. With the large number of weakly connected participants, there was no clear power structure in place to delegate authority. Instead, several leaders spontaneously emerged, centered around people who joined the project early, had large Twitter followings, or were experts in a specific area (such as the creation of data or domain adaptation of tools). In addition to the discourse on Twitter, a publicly available Wiki page was created to gather information about the project in a single place[6]. Overall, we believe that the existing online communication framework proved quite effective in rallying and organizing members for the project.

On the other hand, the largest challenge in the project organization was the initial underestimation of the outpouring of support that the project would see. In the end, over 65 volunteers joined the project, and it was often difficult for the few main organizers to rapidly design and delegate tasks to such a large number of volunteers. This resulted in an over-concentration of effort in some areas, and lack of effort in others. We hope that this paper will help provide a road-map for the type of tasks that may be necessary in rapid-response NLP situations, and prompt discussion on what other tasks may be taken on in a disaster.

3 Language Resources and Tweet Corpus

The earliest stage of the project focused on sharing linguistic resources. These included dictionaries, which were used to improve various text analyzers and classifiers. At the same time, we also made efforts towards building a labeled corpus of tweets containing safety information, with the final goal of extracting information from unlabeled tweets.

3.1 Text Analysis Resources

Among the earliest contributions to the project were dictionaries, especially those containing person and place names specific to the Tohoku region. These were generally contributed by people directly familiar with the resources, the creators or maintainers of the dictionaries themselves.

As time was critical, the linguistic analysis tools actually used in the project were based on widely available general domain resources, as well as domain-specific resources gathered within the very early stages of the project. The general domain language resources consisted of the Balanced Corpus of Contemporary Written Japanese

[5] http://japan.person-finder.appspot.com/

[6] http://trans-aid.jp/ANPI_NLP (in Japanese).

(BCCWJ) (Maekawa, 2008) and the UniDic dictionary (Den et al., 2008), which are high quality and annotated with a variety of tags.

The domain-specific resources gathered specifically for the project and used in the analysis tools described in §4 included:

- The dictionary used in the open source Mozc Japanese Input method, which contained 50,848 first names and 26,519 last names and was provided by the maintainer of the project.
- A name list that contains last names specific to northeast Japan[7]. These resources were publicly available on the web.
- A location name list of Iwate, Miyagi, Fukushima, and Ibaraki prefectures created by downloading a database of postal code information and manually checking the data.

A number of other resources were created by volunteers, including a list of all the station names in Japan, station location information, landmark names in Kanto and Tohoku extracted from Wikipedia, a list of geopolitical entities, and a list of abbreviated school names and places. While these resources were certainly significant, it was the resources that were prepared early on in the process that provided the most aid to the project as a whole. This indicates that for similar situations in the future, it is essential to have as many resources as possible immediately available, and preferably familiar to the people in the project to facilitate rapid processing and dispersal.

3.2 Tweet Corpus Construction

As Twitter contained a wide variety of earthquake-related posts including information about the safety of people in the disaster-affected area, we decided to create a corpus of disaster-related tweets to aid our information extraction efforts. The first tweet corpus shared was the collection of 469,504 tweets containing the word "地震" (earthquake) from March 11th 16:09 to March 13th 8:59. We also collected tweets with the hash tags "#anpi" (safety information) such as "#hinan" (evacuation), "#j_j_helpme" (help request), and "#save_"+ location names. Tweets containing RT (re-tweets) and QT (quote tweets) were removed to eliminate duplication. As a result, 61,376 tweets were collected from March 13th 1:37am until March 14th 16:45pm.

A typical tweet containing safety information looked like the following [8]:

> 気仙沼市の田中太郎・花子さんと連絡が取れません！どなたか消息をご存知ありませんでしょうか？
> TANAKA Taro and Hanako who lived in Kesennuma City can't be reached. Does anybody know where they are?

From the large corpus of tweets, we hope to discover two pieces of information. First, we must recognize the *topic* of the tweet, in this case that the tweet is asking for information about missing people (tweet classification). Second, we need to recognize that the people in question are "TANAKA, Taro" and "Hanako," both of whom live in "Kesennuma City" (NE recognition).

In order to create data to train tools to perform both tweet classification and NE recognition, volunteers began to perform tagging as soon as the tweet collection was finished. First, we defined nine kinds of tweet labels specifying the tweet topics, which are listed in Table 1. The distinction among S/O/U was sometimes unclear and went under extensive discussion among volunteers. In practice, the distinction of I/L/P/M from others (S/O/U) is of the highest importance.

One example is shown below:

```
<person type="M">TANAKA Taro</person> and
<person type="M">Hanako</person> living in
<location>Kesennuma city</location> can't
be reached.
```

Safety information is optionally added to every person tag, specifying the object of the safety information, as shown in the above example. Also multiple tags are permitted when multiple types of safety information are contained in a single tweet.

Utilizing Twitter, word was spread about the tagging task force, gathering a large number of volunteers, most of whom were NLP researchers, engineers, or students. In order to facilitate the task-force, several people with annotation experience responded to questions in real-time, and various tools were created and shared among the annotators. Over 65 volunteers gathered to tag the corpus with class and NE tags over the course of two days, resulting in a total of 33,242 tweet annotated.

[8] The actual person and place names have been replaced with pseudonyms to preserve anonymity.

Label	Definition	Example	Count
I	Him/Herself is alive	I'm XXX in YYY City. I'm all right.	405
L	Alive	Mr./Ms. XXX in YYY City is at ZZZ Shelter. He/She is alive.	1,154
P	Passed away	—	93
M	Missing	The safety of Mr./Ms. XXX living in YYY City is unknown.	4,438
H	Help Request	Mr./Ms. XXX is left in YYY and needs help!	280
		My relatives/parents/... staying in South XXX City are missing.	
S	Information request	Refugees at XXX School are provided enough daily supplies? (Safety information of unspecific individual, region, etc.)	1,903
O	Not safety information	You can post safety information on this site!	24,035
R	External link	Survivor list of XXX City: http://...	773
U	Unknown	(Non-Japanese or nonsense postings)	1,235

Table 1: Safety information tags on tweets

While the annotators were generally more skilled and motivated than those in previous attempts to create language resources using crowdsourcing (Callison-Burch and Dredze, 2010; Finin et al., 2010), given the rapid nature by which the project developed, annotation started before tagging standards were put in place, leading to some inconsistency in the tagged corpus. In retrospect, despite the speed of the project, it would have been helpful to spend some more time thinking about what information was really necessary for the task, and have more experienced annotators do a quick test run before opening annotation to the broader volunteer base. In addition, as many of the annotators were less experienced, explicitly allowing the annotators to "pass" on difficult instances would have reduced the amount of time wasted on difficult or ambiguous cases.

4 Text Analysis

Before mining the tweets for useful information, it was necessary to create text analysis tools that were capable of handling this very specialized data set. The main objective of text analysis was named entity recognition (NER), which would allow for the identification of names and locations.

4.1 Morphological Analysis and NER

The first step in Japanese text processing is morphological analysis (MA), which splits raw Japanese text into words and assigns POS tags to each word. While previous research in tagging for Twitter has profited by building a custom NLP pipelines over the course of several months (Gimpel et al., 2011; Ritter et al., 2011) or by building semi-supervised learning systems (Liu et al., 2011), it was necessary to create a morphological analyzer in the course of several hours. This is due to the fact that all other components of the system depend on MA, and cannot be developed until MA is in place. Thus, we utilized existing general domain resources, and added new resources as they were collected in a domain-adaptation framework.

For this task we used KyTea[9], an open source morphological analysis tool notable for being relatively robust to out-of-domain data, and being able to flexibly incorporate a variety of language resources (Neubig et al., 2011).

We trained a word segmentation (WS) and POS tagging model for KyTea using the BCCWJ and UniDic as a base. We trained the POS tagging model, but in order to facilitate NE recognition farther down the pipeline, we replaced all proper nouns with their subcategory tag ("first name," "place name," etc.). We also added a corpus of conversational and news text (CN Corpus) that was only annotated with word boundaries, and a large list of Japanese first and last names. We indicate the model trained with all of these resources as ORIG.

While the POS tagger works on a word-by-word basis, most named entities consist of multiple words. Previous work has developed linguistic resources for English NE tagging on Twitter (Finin et al., 2010), but again considering the short time frame, we developed a simple rule-based system to connect multiple words into single named entities. Rules scanned the corpus in order, finding the first of three POS tags: "first name (FNAME)," "last name (LNAME)," or "place name (PNAME)." These words are labeled with PERSON, PERSON, or LOCATION NE tags respectively. Continuing in the order of the corpus, all words directly following a marked NE are merged if marked with one of the three previously mentioned POS tags, or as a "suffix (SUF)[10]". An example of the three step

[9] Available at `http://www.phontron.com/kytea`.

[10] A small set of suffixes that are used in conjunction with person names such as "*-san*" or "*-kun*" were omitted.

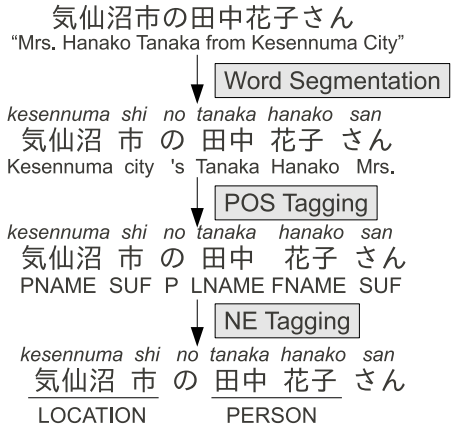

Figure 2: An example of the three steps of named entity recognition. Pronunciations and English translations are also provided for reference.

Name	Words	WS	POS	Group
BCCWJ	997k	○	○	ORIG
CN Text	503k	○		ORIG
UniDic	217k	○	○	ORIG
Names	144k	○	○	ORIG
Address	73.4k	○	○	+DICT
+Names	29.4k	○	○	+DICT
Active	10.2k	○		+ACTIVE

Table 2: Resources used in building the model with names, word counts, whether each corpus is annotated with WS and POS information, and which group the resource was added in.

NE tagging process is shown in Figure 2.

4.2 Domain Adaptation

While this classifier worked well on general domain data, it is known that accuracy greatly decreases for text in different domains or styles than the training data (Finin et al., 2010; Neubig et al., 2011; Ritter et al., 2011). In the tweet data there were a large number of place and person names specific to the disaster-stricken region, as well as a large number of linguistic phenomena specific to tweets, and thus it was necessary to add a number of language resources (summarized in Table 2) to adapt the text processing tools to the new domain.

To improve the accuracy on person and place names, we added the language resources previously described in section 3. The combination of these dictionaries is indicated by “+Names” in Table 2, and a model trained adding these resources is indicated with +DICT.

Finally, to handle the the large number of Twitter-related linguistic phenomena such as the word “tweet” or hash tags, we annotated word boundaries using the active-learning/partial-annotation method described by Neubig et al. (2011). For each round of active learning, we chose the 100 words for which the morphological analyzer was least confident, and had a single human annotator correct the word boundaries for these words. This was repeated for 4 rounds (400 words), which took approximately 1.5 hours total. The model trained by adding this data to +DICT is indicated as +ACTIVE.

		ORIG	+DICT	+ACTIVE
WS	F	97.3%	97.3%	97.7%
Lab. NE	P	53.9%	69.6%	69.2%
	R	55.6%	71.7%	72.7%
Unlab. NE	P	70.6%	80.4%	80.8%
	R	72.7%	82.8%	84.9%

Table 3: Word segmentation F-measure and NE precision (P) and recall (R) for both labeled and unlabeled evaluation.

4.3 Result Analysis

In order to demonstrate the necessity and effectiveness of domain adaptation, we present results of a quantitative and qualitative analysis of WS and NER for ORIG, +DICT, and +ACTIVE.

Table 3 shows results for a quantitative analysis of WS and NE tagging results on a manually annotated corpus of 50 tweets. Labeled NE accuracy indicates that the NE is only considered correct if both its span and its label (PERSON/LOCATION) are correct, and unlabeled NE accuracy indicates that the NE is considered correct if the span is matched, regardless of the label. It can be seen that the addition of dictionaries for the target domain greatly increased the NE accuracy, up to 16% for labeled tagging. The active-learning-based annotation further improved the WS accuracy by 0.42%, resulting in gains of NE recall of 1-2%.

The main reason for the improvement between the ORIG and +DICT was the proper handling of place names in the disaster-stricken area. ORIG would split long addresses into several NEs, some of which were mistakenly recognized as as person names. For example, “気仙沼_市” (Kesennuma city) was mistakenly split into “気仙_沼_市” (Kesen swamp city) and “気仙” was recognized as a person name. Further, the active learning for WS fixed segmentation errors such as correcting the improperly segmented “平浄_水場” to the properly segmenting “平_浄水_場” (Taira water purify-

ing plant). This, in turn, allowed for "平" (Taira) to be properly recognized as a location name.

The largest remaining challenge for the fully adapted system was the distinction between last names and place names, which are highly ambiguous in Japanese. The use of the address information corpus greatly improved the NE tagging results, but also biased the classifier heavily towards place names. In a rapid-response situation it is necessary to use any and all of the resources available, even if they are known to be biased. This sample-bias problem can likely be ameliorated by recent progress in machine learning techniques (Huang et al., 2007).

5 Safety Information Classifier

Next, we describe the classifier that we built to find tweets containing safety information out of all the tweets in the corpus.

5.1 Model 1

Our first classifier, which we will call Model 1, was developed in several hours by over-simplifying the classification problem and using a very limited feature set.

While, as explained in §3.2, a single tweet could be assigned multiple labels, for Model 1 we simply took the first label that each annotator assigned to be true, and trained a one-vs.-rest classifier on this data. We used two types of features for the classification, bag-of-character-n-gram features, and NE features. The bag-of-character-n-gram features created a separate feature for each character n-gram from unigram to trigrams. As most Japanese words are relatively short, this is able to capture the most important words while not requiring word segmentation and thus being relatively robust. Second, we used the counts of each type of named entity tag, which are generally larger in tweets that contained useful information.

We trained all models using the default SVM solver of LIBLINEAR (Fan et al., 2008). 10-fold cross validation on the test set showed that the classifier achieved a tag accuracy of 86.13%.

5.2 Model 2

After few days, we created Model 2 as an extension of Model 1. Model 2 used a multi-class and multi-label classifier which output all the labels each of whose score exceeds a threshold t.

We extended the feature set for Model 2. Model 2 includes the same features as Model 1, but for n-grams, Model 2 does not count duplicated sequences. As NE features, co-occurrence information of PERSON and LOCATION in a single tweet was added as tweets for safety confirmation should generally include both of them. Combination of character 3-grams and the appearance of a PERSON was also added to capture a tweet's intention for that person. We also used existence of the hash tag "#anpi" and the total number of appearance of hash tags except for "#anpi" as clues for dividing tweets not related to safety confirmation (label O, U, S) from the others. Finally, we used the existence of the string "http(s)" and combination of existence of "http(s)" and NE as clues for the label R (external lists).

5.3 Evaluation

We evaluated the Model 2 classifier in detail using the corpus from the 17th of March, which contained 9,812 tweets. We divided the corpus into three sets: 80% for training, 10% for development, and the other 10% for test. For comparison, we also developed Model $1'$ which is a multi-label model using the same feature set as Model 1.

Table 4 shows the results of the two models. The performance is not significantly different in terms of accuracy, but Model 2 obtained higher recall than Model $1'$. The thresholds here were empirically determined to the one that maximize the F1-scores on the development set.

We described the result for each label with Model 2 in Table 5. Good performance was obtained for the O and M that comparatively have a larger number of instances. However, the recalls for the labels having few instances were lower. Especially, most of the label L were still missing. The most frequent mis-prediction was occurred between U, S and O. This is not a big problem since all these three labels are unrelated to safety confirmation. However, by analyzing errors, we found that there are a significant number of inconsistencies for these three labels depending on the annotators due to the inconsistent annotation standards mentioned in Section 2. A promising solution for situations like these is the recent development of methods and publicly available tools for extremely efficient active learning for text classification (Tong and Koller, 2002; Settles, 2011). These would allow for similar final results to be

		Dev				Test			
Model	t	P	R	F	Acc.	P	R	F	Acc.
Model 1′	0.55	87.8%	84.3%	86.0%	96.8%	87.9%	84.9%	86.4%	96.9%
Model 2	0.45	86.1%	85.7%	85.9%	96.7%	87.1%	86.4%	86.8%	97.0%

Table 4: Micro-averaged precision (P), recall (R), F-score (F), and accuracy (Acc.) achieved by Model 1′ and Model 2. For the evaluation, we transformed the gold and predicted data from multi-labeled instances to nine sets of binary-labeled instances.

Label	#samples	P	R	F
O	719	88.4%	98.3%	93.1%
M	134	91.2%	93.3%	92.3%

Table 6: Label sequences where the errors occurred with Model 2 ($t = 0.45$).

achieved by a fewer number of annotators, reducing inconsistency issues.

6 Application of the System

The final step was verifying that the information was in fact reliable, and then matching PERSON and LOCATION tokens from tweets, which were classified as "L" (the person is alive) to the information of Google Person Finder (GPF). We chose to verify and match the information by hand to prevent the provision of misinformation on a sensitive topic such as safety of earthquake victims.

GPF contained several columns, such as the first name and last name of the person, home neighborhood, home city and home prefecture. The manually corrected NE information was matched with GPF data, and we were able to update the personal information of more than a hundred individuals that were confirmed to be alive in tweets.

However, many tokens extracted from tweets had problems, including:

- **Incomplete** LOCATION **information:** The tokens lacked a couple of information such as city, or neighborhood. "I was able to contact Taro Tanaka, who lives in Miyagi prefecture! [宮城県の田中太郎と無事に連絡が取れました！]". In this case, there may be many Taro Tanakas living in the prefecture, so a single individual cannot be identified.
- **Incomplete** PERSON **names:** a) Last or first names were be omitted when describing people of the same family. "I found Taro, Jiro, and Hanako Tanaka of Sendai at an evacuation shelter. [仙台市に住む田中太郎、次郎、花子が避難所にいました。]" or "The Tanaka family who live in Sendai has been reached! [仙台市に住む田中一家の安否が確認できました。]" b) Many person names that are likely written in logographic *kanji* in normal text were instead written phonetically (using *katakana* or *hiragana*).

While we focused mainly on extracting information about missing people, it has also been noted that Twitter is a source of other information in disaster situations (Corvey et al., 2010; Vieweg et al., 2010). For example, "50 people in Kesennuma city have evacuated to a hill behind the city hall. [気仙沼で被災し、市民会館の裏山に 50 人避難しています]" includes the number of people (50) and a concrete location (a hill behind the city hall), and could be a good indicator of where to concentrate rescue efforts. This could be an area of very practical application for recent research in verifying reliability of information on Twitter (Kawahara et al., 2008; Qazvinian et al., 2011).

7 Related Work

Besides the safety information mining task which we described in the previous sections, we observed many other efforts to help the earthquake

victims via NLP technologies as sub-projects of ANPI_NLP. Prominent ones include:

- **Association of tweets to evacuation shelter locations:** This includes geo-coding location names extracted from tweets and associating them with the evaluation shelter lists, which are also geo-coded.
- **Visualization of tweets on a map:** This includes mapping geo-tagged tweets on a map so that they can be searched easily.
- **Translation of information to foreign languages:** This includes compilation and sharing of technical term multilingual dictionaries, automatic translation of earthquake information, and provision of the translated information in four major languages spoken by foreigners in Japan.

We are definitely not the first to focus on the disaster-related natural language processing. Lewis (2010) reports the development project of Haitian Creole translation system in rapid response to the Haiti earthquake in 2010. While their motivations have a lot in common with ours, such as the necessity to set up a deployable system in a very short time span. Corvey et al. (2010) describe the annotation of a corpus about the Oklahoma wildfires, aiming at provision of broad-scale information as opposed to safety information mining about individuals. There have also been a number of works on detecting general trends from twitter, including work by Sakaki et al. (2010), who detect earthquakes based on Twitter postings. There are many other systems designed for information sharing in emergency, including the one described in (Hasegawa et al., 2005).

8 Conclusion

In this paper we presented a description of the efforts of a group of volunteers to create a useful NLP system in a short time frame in response to a natural disaster.

On the whole, we believe the project was a success. In an extremely short time-frame, we were able to design, implement, and run a system for extracting useful information from a highly unorganized and difficult-to-process information source. In the short term, this allowed us to provide information about the safety of over 100 people. In addition, this allowed us to clarify the framework required, and develop tools that can be used to allow for provision of information on an even larger scale in future disaster situations. On a more abstract level, we were able to show that NLP has the potential to make a contribution in a disaster-response situation, which we hope will provide an impetus for similar future projects.

However, a number of challenges remain, and we conclude by summarizing the major lessons learned in the project.

- **Speed is everything:** Gathering data, making analysis tools, creating a classifier, and providing information to the public all needed to be performed on a limited time frame. As each of these steps must be completed in order, a delay in any part would result in delays for the overall process. Thus, it was necessary to create working tools as fast as possible, even if this meant making sacrifices in accuracy and refining later.
- **A better annotation framework is needed:** To resolve the challenges posed by annotation in such a short time frame, we must focus on create of better standards considering only the necessary information, do test annotation runs to work out the kinks, and allow annotators to "pass" on difficult annotations.
- **Human resources must be used effectively:** The project summoned an outpouring of support much larger than originally expected. To harness all of the people that are willing to help, it is important to have an overall project vision, and be able to quickly identify new projects for volunteers to work on.

Disasters such as earthquakes are tragic, overwhelming times, with too much information coming in for any individual to handle. We hope that our work has demonstrated that there is a need and a means for processing of this information, and will motivate similar projects in the future.

Acknowledgments

While too numerous to list here, the authors would like to sincerely thank all of the over 65 participants in the project. Without their generous contributions of time, resources, and expertise, the work described here would have never been possible. Finally, we thank Taiichi Hashimoto, Atsushi Fujita, Shinsuke Mori, and anonymous reviewers for their helpful comments on this manuscript.

Abstract

This paper describes a two-phase method for expanding abbreviations found in informal text (*e.g.*, email, text messages, chat room conversations) using a machine translation system trained at the character level during the first phase. In this way, the system learns mappings between character-level "phrases" and is much more robust to new abbreviations than a word-level system. We generate translation models that are independent of the way in which the abbreviations are formed and show that the results show little degradation compared to when type-dependent models are trained. Our experiments on a large data set show our proposed system performs well when tested both on isolated abbreviations and, with the incorporation of a second phase utilizing an in-domain language model, in the context of neighboring words.

1 Introduction

Text messaging (SMS) is a rapidly growing form of alternative communication for cell phones. This popularity has caused safety concerns leading many US states to pass laws prohibiting texting while driving. The technology is also difficult for users with visual impairments or physical handicaps to use. We believe a text-to-speech (TTS) system for cell phones can decrease these problems to promote safe travel and ease of use for all.

Text normalization is the usual first step for TTS. Text message lingo is also similar to the chatspeak that is prolific on forums, blogs and chatrooms. Screen readers will thus benefit from such technology, enabling visually impaired users to take part in internet culture. In addition, normalizing informal text is important for various language processing tasks, such as information retrieval, summarization, and keyword, topic, sentiment and emotion detection, which are currently receiving a lot of attention for informal domains.

Normalization of informal text is complicated by the large number of abbreviations used. Some previous work on this problem used phrase-based machine translation (MT) for SMS normalization; however, a large annotated corpus is required for such a supervised learning method since the learning is performed at the word level. By definition, this method cannot make a hypothesis for an abbreviation it did not see in training. This is a serious limitation in a domain where new words are created frequently and irregularly.

We propose a two-phase approach. In the first phase, an MT model is trained at the character-level rather than the word- or phrase-level, allowing recognition of common abbreviation patterns regardless of the words in which they appear. We decode the hypotheses in the second phase using a language model for the final prediction.

2 Related Work

Text normalization is an important first step for any text-to-speech (TTS) system and has been widely studied in many formal domains. Sproat et al. (2001) provides a good resource for text normalization and its associated problems. Spell-checking algorithms are mostly ineffective on this type of data because they do not account for the phenomena in informal text. Some prior work instead focused on single typographic errors using edit distance (Kukich, 1992), perhaps combined with pronunciation modeling, such as (Toutanova and Moore, 2002).

One line of research views normalization as a noisy channel problem. Choudhury et al. (2007) describe a supervised noisy channel model using HMMs for SMS normalization. Cook and Stevenson (2009) extend this work to create an unsuper-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 974–982,
Chiang Mai, Thailand, November 8 – 13, 2011.

vised noisy channel approach using probabilistic models for common abbreviation types and choosing the English word with the highest probability after combining the models. Deletion-based abbreviations were addressed in our past work using statistical models (maximum entropy and conditional random fields) combined with an in-domain language model (LM) (Pennell and Liu, 2010; Pennell and Liu, 2011). Liu et al. (2011) extend the statistical model to be independent of abbreviation type with good results.

Whitelaw et al. (2009) used a noisy channel model based on orthographic edit distance using the web to generate a large set of automatically generated (noisy) pairs to be used for training and for spelling suggestions. Although they use the web for collection, they do not focus on informal text but rather on unintentional spelling mistakes. Beaufort et al. (2010) combine a noisy channel model with a rule-based finite-state transducer and got reasonable results on French SMS, but have not tried their method on English text. Han and Baldwin (2011) first determine whether a given out-of-vocabulary (OOV) word needs to be expanded or is some other type of properly-formed OOV. For those predicted to be ill-formed, a confusion set of possible candidate words is generated based on a combination of lexical and phonetic edit distance and the top word is chosen in context using LM and dependency parse information.

Machine translation (MT) techniques trained at the word- or phrase-level are also common. Translation of SMS from one language to another led Bangalore et al. (2002) to use consensus translations to bootstrap a translation system for instant messages and chat rooms where abbreviations are common. Aw et al. (2006) view SMS lingo as if it were another language with its own words and grammar to produce grammatically correct English sentences using MT. Q. and H. (2009) trained an MT system using three on-line SMS dictionaries for normalizing chat-like messages on Twitter. Kobus et al. (2008) incorporate a second phase in the translation model that maps characters in the texting abbreviation to phonemes, which are viewed as the output of an automatic speech recognition (ASR) system. They use a non-deterministic phonemic transducer to decode the phonemes into English words. The technical paper of Raghunathan and Krawczyk (2009) details an explicit study varying language model orders, distortion limit and maximum phrase length allowed by the MT system during decoding. Contractor et al. (2010) also uses an SMT model; however, in an attempt to get around the problem of collecting and annotating a large parallel corpus, they automatically create a noisy list of word-abbreviation pairs for training using some heuristics. As far as we know, we are the first to use an MT system at the character-level for this task.

3 Data

Due to the lack of a large parallel corpus suitable for our study, we are building a corpus using status updates from twitter.com. Twitter allows users to update status messages by sending an SMS message to a number designated for the Twitter service. To ensure that our corpus is representative of the domain we are modeling, we use Twitter's meta-data to collect only messages sent via SMS. Some examples of highly abbreviated messages from our corpus are shown below.

(a) `Aye.oops,dat was spose to be a txt`

(b) `Rndm fct bout wife:  n the past 10 yrs I can cnt on one hand the num Xs she's 4gotn to unlock my car door`

(c) `OMG I LOVE YOU GUYS. You pwn :)  !!!`

(d) `i need to qo to bedd qotta wakee up at 7am for school....`

(e) `heard it again!  xD 3 TIMES.a sng i nvr hear!`

3.1 Choosing Messages for Annotation

An annotator's time is wasted if he is presented with many messages containing no abbreviations, or with sentences all containing the same, very common abbreviations. A scoring system was thus devised using the following metrics:

1. **Word Count Index.** A low word count index indicates that a message is close to the mean message length. Messages with fewer than five words are removed from consideration. We calculate the index as $|N-E(N)|/\sigma(N)$, where N is the number of words in the message and mean and standard deviation are calculated over the entire corpus.

2. **Perplexity Scores.** Two perplexity scores are calculated against character-level language

models. A low perplexity of the message compared to standard English text indicates that the message is less likely to be in a foreign language or jibberish. Similarly, a low perplexity of the message compared to our corpus indicates that the message is more representative of the domain. A sentence is removed if in either case the perplexity value is greater than a threshold (1000 in our study).

3. **OOV Count.** This is a simple count of the number of out of vocabulary (OOV) words in the message compared to an English dictionary, which we denote N_{OOV}. This metric helps guarantee that we select messages containing many OOV words. We remove the sentence completely when $N_{OOV} = 0$.
4. **OOV Percentages.** This metric consists of two scores: the first is N_{OOV}/N; the second is a non-duplicate OOV percentage, where we remove all repeated words and then recalculate the percentage. If the first score is greater than 0.5 but the second is not, we remove the message from consideration.
5. **OOV Frequency Scores.** For each OOV token (including emoticons) we find the frequency of the token across the entire corpus. This ensures that we annotate those abbreviations that are commonly used.

A sorted list is generated for each metric. The final score for each sentence is a weighted average of its position in each list, with more weight given to the non-duplicate OOV percentage and less weight given to the OOV frequency scores. The sentences are ranked in a penultimate list based on this final score. Finally, a post processing step iterates through the list to remove sentences introducing no new OOV words compared to higher-ranked sentences. Messages were annotated in the order of rank.

3.2 Annotation

Five undergraduate students were hired for the annotation task. In total, 4661 twitter status messages were annotated. Of these, 74 were given to multiple annotators so that we can calculate inter-annotator agreement. All 74 of these messages were also annotated by the first author as a standard for comparison. There were 7769 tokens annotated as an abbreviation by at least one annotator with 3761 (48%) unique to a single annotator.

We calculate pairwise agreement for whether or not a token is an abbreviation for all tokens given to each pair, including those that both agreed were not abbreviations. The Fleiss' Kappa $\kappa = 0.891$ for these pairwise values is quite high so the number of annotators can be reduced without negative effects to the project as long as they are familiar with the domain.

4 Normalization Approach

We describe a two-phase approach for SMS normalization. The first phase uses a character-level MT system to generate possible hypotheses for each abbreviation. The second uses a language model (LM) to choose a hypothesis in context.

Typically, an SMT system translates a sentence from one language to another. An alignment step learns a mapping of words and phrases between the two languages using a training corpus of parallel sentences. During testing, this mapping is used along with LMs to translate a sentence from one language to another. While researchers have used this method to normalize abbreviations (Bangalore et al., 2002; Aw et al., 2006; Kobus et al., 2008; Q. and H., 2009; Contractor et al., 2010), it is not robust to new words and leads to poor accuracy in this domain where new terms are used frequently and inconsistently.

Our system differs in that we train the MT model at the character-level during the first phase; that is, rather than learning mappings between words and phrases we instead map characters to other characters in what can be a many-to-many mapping. For example, the ending "-er" (as in "teacher" or "brother") is often abbreviated with the single character 'a'. Characters may also be mapped to symbols ("@" for "at"), numbers ("8" for "ate") or nothing at all (deletions).

Formally, for an abbreviation a : $c_1(a), c_2(a), ..., c_m(a)$ (where $c_i(a)$ is the i^{th} character in the abbreviation), we use an MT system to find the proper word hypothesis:

$$\begin{aligned} \hat{w} &= \arg\max p(w|a) \\ &= \arg\max p(w)p(a|w) \\ &= \arg\max p(c_1(w), ...c_n(w)) \\ &\quad \times p(c_1(a), ..., c_m(a)|c_1(w), ...c_n(w)) \end{aligned} \tag{1}$$

where $c_i(w)$ is a character in the English word w, $p(c_1(w), ...c_n(w))$ is obtained using a character LM, and $p(c_1(a), ..., c_m(a)|c_1(w), ...c_n(w))$ is based on the learned phrase translation table.

Pairs of words from our annotated data are used for training: the original token (which may or may not be an abbreviation) and its corresponding English word. We removed tokens which the annotators were unable to translate and those marked as sound effects (*e.g.*, ahhhhh, zzzzz, blech, hrmpf, etc.). Punctuation was removed from the remaining data, excluding that found in emoticons (which we treat as words) and apostrophes in common contractions and possessive forms. To facilitate character-level training, we insert a space between each character and replace any spaces with the underscore character.

Because training is done at the character-level, each hypothesis (w) for an abbreviation (a) is a sequence of characters, which may or may not be a valid word. To see why, examine the partial phrase-table shown in Figure 1[1]; using this table, "hab" could be translated to "hib", "habulary" or "habou" as well as the word "have". It is also very likely that a hypothesis will appear many times in the hypothesis list due to different segmentation (two characters may be generated by a single phrase mapping or by two different mappings, one for each character). We generate 20 *distinct* hypotheses for each token and then eliminate hypotheses that do not occur in the CMU Lexicon.

Until this point, we have only normalized a single abbreviation without context. In a realistic setting contextual information is available to help with translation. We thus introduce a second phase using a word-level LM to disambiguate hypotheses when context is available. This is the typical noisy channel model used for speech recognition or MT decoding and is comparable to equation 1.

Determining the standard English sentence, $W = w_1 w_2 ... w_n$, from a given informal sentence, $A = a_1 a_2 ... a_n$, can be formally described as:

$$\begin{aligned} \widehat{W} &= \arg\max P(W|A) \\ &= \arg\max P(W)P(A|W) \\ &\approx \arg\max \prod P(w_i|w_{i-n+1}...w_{i-1}) \\ &\quad \times \prod P(a_i|w_i) \\ &= \arg\max(\sum \log P(w_i|w_{i-n+1}...w_{i-1}) \\ &\quad + \sum \log P(a_i|w_i)) \end{aligned} \tag{2}$$

where the approximation is based on the assumption that each abbreviation depends only on the corresponding word (we are not considering one-to-many mappings in this study), and a word is dependent on its previous $(n-1)$ words. In other words, this probability is represented by a traditional *n*-gram LM.

The abbreviation score in Equation 2, $P(a_i|w_i)$, represents the likelihood that abbreviation a_i is derived from word w_i, and can be obtained from:

$$p(a_i|w_i) \propto \frac{p(w_i|a_i)}{p(w_i)} \tag{3}$$

where $p(w_i|a_i)$ is the abbreviation model (AM) score from the character-level MT system, and $p(w_i)$ is from the character LM we used in MT decoding. In this study, we just use the score from the MT system as the likelihood score, without dividing by the character-level LM contribution. This is equivalent to using both character- and a word-level LMs during decoding.

Equation 2 assumes that the AM and LM should be weighted equally, but in actuality one model may prove to be more helpful than the other. For this reason, we allow the terms from equation 2 to be weighted differently, yielding the final equation

$$\begin{aligned} \widehat{W} &= \arg\max(\alpha \sum \log P(w_i|w_{i-n+1}...w_{i-1}) \\ &\quad + \beta \sum \log P(a_i|w_i)) \end{aligned} \tag{4}$$

where α and β are determined empirically.

5 Experiment 1: Evaluation on Isolated Abbreviations

We use the Moses MT system (Koehn et al., 2007) in all our experiments, including Giza++ for alignment. The score assigned to a translation is derived from four models: the phrase translation table, the language model, the reordering model,

[1]Aside from the possible translations, the phrase table also shows five values for each word. They correspond to the inverse phrase translation probability $\phi(f|e)$, the inverse lexical weighting $lex(f|e)$, the direct phrase translation probability $\phi(e|f)$, the direct lexical weighting $lex(e|f)$ and the phrase penalty (always $exp(1) = 2.718$), where e and f are the English and foreign phrases, respectively. We do not currently make use of these values.

Figure 1: An excerpt from a phrase table showing possible translations when the character sequence "ab" is found in a message.

and a word length penalty. We use Moses' default weights for these models, but plan to adjust the weights in the future to determine each model's contribution to a good translation. For each abbreviation we generate 20 distinct hypotheses. We finally remove non-word hypotheses using the CMU lexicon. Note that occasionally Moses generates a positive score (impossible for a real log-probability). When this occurs, we use the value -0.1 instead, indicating that this pair is very likely.

Note that our accuracy is bounded from above by the percentage of pairs in testing that appear in the 20-best hypotheses generated by Moses. For this reason, we first wish to find a setup to maximize the upper bound on our performance.

5.1 Experimental Variations

There are different factors that may affect the performance of our system for individual words: the character-level LM used for decoding, the way the models are trained, and the data used to train those models. We thus evaluate different experimental variations, described below.

Training/Testing Configuration

To test the effect of using more specific versus more general data when training the MT system, we used the following training sets:

1. **General Setup:** Training and testing are both done using all of the annotated data, including words that are already in standard form in the message.
2. **Single-word Abbreviation Setup:** In training, we remove those abbreviations corresponding to multiple words (for example, "brb" representing "be right back") and those words already in standard form. Again we test the system using all of the annotated data.
3. **Type-dependent Setup:** We train a separate model for each major abbreviation type (see Table 1) except insertions. The type of each abbreviation in the test set has been annotated so we use its respective model for testing. We assumed that knowledge about the abbreviation formation method would increase the model's ability to translate the abbreviation. Currently there is no known procedure for automatically determining the abbreviation type without having prior knowledge of its translation, so this setup is just for comparison purpose to evaluate how well the more general methods are performing.

Formation Method	Example
Deletions	ppl (people)
Substitutions	2nite (tonight)
Repetitions	yeeeeesssss (yes)
Swaps	tounge (tongue)
Insertions	borded (bored)

Table 1: Examples of major abbreviation types.

Language Model (LM) Order

We wanted to determine how the order of the character-level LM used by Moses affected performance. A smaller order model may not capture larger phrases or long distance dependencies, but the smaller model may generalize better due to the sparseness of many high-order phrases.

We explore different character LMs used in decoding to generate word hypotheses, including character-based 3-, 5-, and 7-gram LMs. These are trained on a subset of 16,543,813 messages from the Edinburgh Twitter corpus (Petrovic et al., 2010) containing no OOV words compared to an English dictionary. Each model is used in the above training/testing configurations.

	Order 3		Order 5		Order 7

5.2 Results

The results from different training/testing configurations and LM orders are shown in Tables 2, 3 and 4. We use a cross-validation setup where we train the MT system using the annotations from four annotators and test on the data from the fifth. The mean score from the five runs is reported here. In all three tables, we show top-1 and top-20 accuracy. For top-1 accuracy, the system is considered correct if and only if the top hypothesis given by Moses exactly matches the standard English form. If the correct standard English form is listed anywhere in the 20 hypotheses generated by Moses, we count it correct in top-20 accuracy. The top 20-accuracy represents the possible gain we can achieve by re-ranking the lists using context.

We break down the results by abbreviation type to determine any performance difference. The top portion of Tables 2 and 3 shows results for all 14611 unique pairs in the annotated data, including words already in standard form and abbreviations corresponding to multiple words. The following two rows show results on abbreviations of single words and words already in standard form, respectively. The lower portion breaks down the results by abbreviation type. The rows listing specific types include those abbreviations using *only* that abbreviation method. The final row lists results for those abbreviations formed using multiple methods. The type-dependent setup (Table 4) reports results for each type when using the model trained for that specific type.[2]

Removing multi-word abbreviations and words already in standard form from training generally increases accuracy. The type-dependent model usually outperforms the single-word model, as expected. Comparing Tables 3 and 4 shows that performance decrease using the type-independent single-word model is usually small, helping avoid costly human annotation of types in the future. Contrary to expectations, the type-independent

[2]We do not train a separate model for the insertions due to the small number of abbreviations of that type in our data. Looking at those marked as insertions, most of them appear to be typographical errors caused by "fat fingering" a keypad (*e.g.* "jusyt" for "just"), although a few appear stylistic in nature, *e.g.*,"confrused" for "confused".

Swaps (106)	35.85	97.17	77.36	97.17	77.36	97.17

Table 4: Accuracy using the type-dependent training and testing (%).

model outperformed the type-dependent model for the deletion type. Examining the abbreviations formed by combining at least two methods helps explain why this occurs. Of the 140 abbreviations combining abbreviation types, 102 contain at least one deletion. Adding these abbreviations in training yields additional examples for the model to learn from.

There is a large increase in accuracy between using a 3-gram versus a 5-gram model. However, the jump from 5-gram to 7-gram is much smaller, and in some cases it even decreases performance. We thus recommend using a 5-gram character model and training using only single-word abbreviations.

6 Experiment 2: Incorporation of Contextual Information

In many cases, there are many word hypotheses for a given abbreviation. Without contextual information the top hypothesis is static. In some cases the system can use contextual information to suggest the correct word even when it may not be the most likely choice using the AM alone. To evaluate the effect of context on normalization, we create a test set containing trigrams using one word of context on either side of each abbreviation. If an abbreviation falls at the beginning or end of a message we use <s> and </s> for the left or right context, respectively. We replace OOV context words with their annotated standard forms.

The top performing setup from Section 5 is used to build the AM, which is then combined with a bigram LM for decoding using equation 2. The LM uses Kneser-Ney smoothing and was trained on the same portion of the Edinburgh corpus as used for the character-level models. We do not include the <unk> token in the LM because its probability is quite high and preliminary tests (not included here) show a degradation in performance when it is utilized. Instead, we use a log probability of -99 for all unknown terms seen in testing.

LM-only	**Full**	**Partial**	**Section 5.2**[3]
13.5	69.7	69.3	36.45

Table 5: Accuracy on tests using context (%).

We performed three types of tests in order to determine the best setup for decoding using context.

1. **LM-only.** This system serves as a baseline for comparison. We eliminate the abbreviation model completely and use only the LM for decoding. In this case, all unigrams in the LM are considered to be possible candidates for each abbreviation.

2. **Full.** We use the LM in combination with the abbreviation model using equation 2 with $\alpha = 1.0$ and $\beta = 0.1$ (found empirically).

3. **Partial.** Due to the small weight found for the abbreviation model in the previous setup, we wish to show that the abbreviation score is helpful for decoding. We use the abbreviation model to generate the candidate words for each abbreviation, but we do not use the abbreviation score in decoding.[4]

We again performed cross validation by first training an AM using the data from four of the annotators and then testing on the trigrams formed from the final annotator's data. In total there were 4415 context trigrams used in testing. This is larger than the 2842 abbreviations shown in the previous section because the previous tests used unique abbreviations, which may in reality correspond to multiple words and unique contexts. Table 5 shows the normalization results. As a basis of comparison, the state-of-the-art Jazzy spell-

[3]Using single-word training and 5-gram character LM.

[4]We eliminate the AM term from equation 4, yielding $\widehat{W} = \arg\max_{w_i \in S}(\sum \log P(w_i|w_{i-n+1}...w_{i-1})$ where the candidate set S is generated by the MT system. Equivalently, we set $\beta = 0$.

	Top-1	Top-3	Top-10	Top-20
Jazzy (Idzelis, 2005)	49.86	53.13	54.78	55.44
(Choudhury et al., 2007)	59.9	–	84.3	88.7
(Cook and Stevenson, 2009)	59.4	–	83.8	87.8
(Liu et al., 2011)[a]	58.09	70.96	–	–
(Liu et al., 2011)[b]	62.05	75.91	–	–
This Work	60.39	74.58	75.57	75.57

Table 6: System comparison on the 303-term test set from (Choudhury et al., 2007).

[a] LetterTran.
[b] LetterTran + Jazzy.

checker (Idzelis, 2005) achieves 38% accuracy on this dataset.

It is clear that the LM-only setup is not sufficient for this task and that our AM is necessary. The **Full** and **Partial** setups perform similarly; while the **Full** model consistently performs slightly better for all annotators, it is probably not a significant difference. We hope that by optimizing Moses' parameters we can obtain higher performance from the AM.

Compared to the 1-best results from Section 5.2 we see that incorporating contextual information yields significant gain. Our performance is bounded from above by the percentage of correct solutions that appear in our candidate lists. For the contextual task, 77.2% of the correct words appear in the lookup lists after the AM is applied, showing that we can still improve the decoding process. Fully 91.7% of the correct words appear in the LM, meaning that the AM is still eliminating many correct answers from consideration. We are investigating methods to address these shortcomings for our future work.

7 Comparison to Past Work

Although there has been very little work on this task until quite recently, multiple studies have been done using the small 303-term dataset first used by (Choudhury et al., 2007). For this reason, we run our system on this small data set. We also use the state-of-the-art Jazzy spell-checker (Idzelis, 2005) as a baseline.

System comparisons are shown in Table 6. The results shown for other systems (except Jazzy) are those reported in their respective papers; we did not re-implement their systems. Our system performs comparably to the work of (Liu et al., 2011) on this dataset. Although we outperform both (Choudhury et al., 2007) and (Cook and Stevenson, 2009) in top-1, they outperform our system at top-10 and top-20. With better re-ranking, their systems have the potential to outperform ours. One of our goals is thus to obtain better coverage.

8 Conclusions and Future Work

In this paper we presented a two-phase approach using character-level machine translation for informal text normalization. When combined with contextual information at the word level, our results are state-of-the art, but there is still some room for improvement.

Although they are far more common, abbreviations formed by deletion and substitution method have worse performance compared to those formed by repetition or swap. It may be useful to create systems specific to those formation types, such as the deletion system from (Pennell and Liu, 2010). Provided that these systems are not trained using the MT approach, it is likely that they contain complementary (rather than redundant) information. Combining hypotheses from multiple sources may increase performance on these abbreviation types.

Although we incorporate contextual information in Section 6, the setup is not entirely realistic. We test only on abbreviations, assuming that we know which words are abbreviations and which are not. A simple heuristic of only applying our system to OOV words (compared to a dictionary) may not perform well. Proper nouns are often OOV and should not be expanded, but we *would* like to expand "off" ("office") or "cat" ("category"), which are also dictionary words. We also assume there are not other abbreviations to be expanded in the context. In reality, many users write highly abbreviated messages, posing greater difficulties for sentence-level decoding. We will address sentence-level decoding in future work.

Abstract

In this paper we address the problem of obtaining structured information about products in the form of attribute-value pairs by leveraging a combination of enterprise internal product descriptions and external data. Product descriptions are short text strings used internally within enterprises to describe a product. These strings usually comprise of the Brand name, name of the product, and its attributes like size, color, etc. Existing product data quality solutions provide us the capability to standardize and segment these descriptions into their composing attributes using domain specific rulesets. We provide techniques that can leverage the supervision provided by these existing rulesets for extracting missing values from other external text data sources accurately. We use a large real life data collection to demonstrate the effectiveness of our approach.

1 Introduction

Enterprises usually store information of its products in the form of unstructured text strings. Such product descriptions contain the name of the product and its specific attributes. These product descriptions are usually written by multiple people and could contain overlapping information or even the same information written differently. For example, a superstore may source the same product from many different vendors and each vendor may give varying descriptions of the same product. Information could be scattered through various departments and held by certain employees or systems instead of being available centrally. This results into varying standards and vocabulary.

Consider the following product descriptions obtained from an enterprise selling cameras. They are provided by different vendors supplying the cameras to the enterprise:
Nikon D90 4288×2848 703 g Digicam F/1.8
Nikon Digital 90 Cam 12.3MP 1.8 F-Len(1.55lb)
Nikon D-90 Camera with Nikkor 50mm 1.8D
Expert knowledge specific to the domain (that D90, D-90 and Digital 90, 4288 × 2848 and 12.3 MP, F-number 1.8 and 1.8 D focal length, and 703 g and 1.55lbs are same) is required to conclude that the entries above are the same product. Coupled with data entry errors, the problem of identifying a standard representation of the product becomes even harder.

The problem of obtaining a structured representation of such product descriptions is similar to the 'Attribute-Value pair' mining problem. Attribute represents an aspect of the product. It could be anything from a manufacturing detail like model number to information like color, size and weight.

Due to its practical applications, the problem has drawn interest from the research community as well as the industry. There are many products which provide solutions for standardizing, matching, merging and validating such descriptions. Popular ones include Oracle middleware, Silvercreek, Ethoscontent product-copy, Trilliumsoftware and IBM Data Stage-Quality Stage. Since rules are easy to understand, manage and give good accuracies in practice, they are widely used by these solutions. Overall, the product data cleansing solution is achieved by a collection of rule sets, each tackling a given product vertical. A ruleset scales to descriptions within its vertical.

Often, the product descriptions are very brief and do not convey the entire information about the product. Critical information about the product could be missing. Because of this, an enterprise does not have a complete view of its products and services. Suppose an enterprise wants to have manufacturer wise information about its products for making important demand-supply decisions. If

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 983–991,
Chiang Mai, Thailand, November 8 – 13, 2011.

the manufacturer information is erroneously captured or missing, it wouldn't be possible. This lack of information makes it difficult for a potential customer to compare products and make an informed decision about it. At the same time, low data quality impedes business. An enterprise may loose its competitive edge due to poor customer service and advertising resulting from incorrect reporting and incomplete view of its products and services. Having a standard and complete structured representation of a product can help in consolidation and is useful in various business intelligence applications. Given the purchasing history of its customers, a better view of enterprise products would result into a host of benefits like better targeted advertising, better recommender systems and reduced maintenance effort.

At the same time, as more and more people are beginning to write reviews, blogs and opinions about their experiences in using products, it is possible to obtain a lot of information about the products on the web. Popular merchant sites like Ebay and Amazon contain a large number of product reviews from its customers. These reviews not only contain reviewer sentiments but also contain key information which can be used to create an enriched view of the products. Our goal is to obtain a complete view of the products by extracting attribute values from such sources.

Here we note that existing rulesets used by data cleansing solutions can give us critically important supervision to drive the attribute-value extraction. This would not only help us in achieving greater accuracy but also allow us to extract true product values. Infact, a key differentiator that puts this work apart from its peers is that the supervision provided by the rules allows us to extract attribute 'values' in the real sense and not merely sentiment words as in most previous works.

Overall, the task of creating a complete view of the products comprises of standardization of appropriate features present in the product descriptions along with enrichment using web data. We carry out product description segmentation by writing handcrafted rules on top of a domain specific dictionary. Then, we show that the same rules can be reused on web data to fill-in missing values for many of the product attributes. Our paper is organized as follows. Section 2 gives us the necessary background and describes related work. Then, Section 3 describes our approach in detail. In Section 4, we report experimental results on real datasets. Finally, Section 5 concludes.

2 Related Work and Background

There has been significant work in information extraction from text data for products. In particular the extraction of product attributes and user sentiments has received wide attention. One of the methods (Hu and Liu, 2004) is to use frequent item sets of nouns along with the opinion words to mine infrequent product attributes. This method is further improved (Zhuang et al., 2006) by using domain knowledge along with noun phrases for attribute extraction. Another refinement (Qiu et al., 2009) uses extraction rules based on different relations existing between opinion words and attribute words. These relations are syntactic and are propagated in an iterative manner.

Some approaches detect product attributes along with opinion extraction. (Liu et al., 2005) first detects attributes by using a rule miner to find noun phrases. Further, it finds polarity descriptors for these noun phrases. (Popescu and Etzioni, 2005) computes the point wise mutual information between noun phrases and product class specific discriminators to determine whether a noun phrase is a product attribute. It finds part-whole patterns by querying the web and uses a part-whole pattern for attribute mining. It further finds the sentiments of these attributes. In contrast, our work finds actual values for the attributes and not merely sentiments expressed by users.

An approach to finding attributes and sentiments jointly is to mine patterns of aspects-evaluation (Kobayashi et al., 2007) using statistical and contextual cues. Here aspects are attributes for a particular product and evaluations are the opinions expressed. The significance of discovered patterns are computed based on their statistical strength. (Wang and Wang, 2008) uses iterative boot strapping to find opinion words from attributes and then finding attributes from opinion words in an alternating fashion. It uses mutual information to measure association between them and linguistic rules to identify infrequent attributes and opinion words. In one of the most interesting works of its kind, (Zhai et al., 2010) groups domain synonyms to form feature groups using a naive Bayesian EM formulation iteratively on the labeled and unlabeled data. It leads to each unlabeled example being assigned a posterior proba-

Table 1: Sample Segmented Product Descriptions

Description	BrandName	ProductName	Product	Lens	Resolution	Price
Fujifilm Quick Snap Single Use Camera	Fujifilm	Quick Snap	Camera	NULL	NULL	NULL
$25 cannon EF f/2.8 USM Lens	Canon	EF	Lens	f/2.8 USM	NULL	$ 25
Sony DSCP 8 3.2 MP Camra	Sony	DSCP 8	Camera	NULL	3.2 MP	NULL

bility of belonging to a group giving it the ability to find multigram attribute terms. However, these methods concentrate on detecting product attributes and do not find associated values.

Among machine learning approaches CRF (Peng and McCallum, 2006) (Stoyanov and Cardie, 2008) has been effective if we have training data and want to extract template attributes and values. However, we do not always have a predefined list of explicit attributes and values which have to be extracted and populated. The method in (Ghani et al., 2006) finds attributes and values together using a naive bayes algorithm combined with EM. This method requires labeled training data which is often difficult and expensive to produce. Also, since both the attribute and value extraction is automatic, the accuracy is low and hence, not useful for most business applications. Our method differs from it as we propose an automatic approach to detect potential attributes and a combination of rules and semi-supervised learning to extract values. Our method also has the flexibility to detect values of pre-defined attributes.

3 Our Approach

We pose the problem of Product Entity Completion as two sub-problems: Product description segmentation and Enrichment. The segmentation problem simulates the product data standardization done in the industry. It constructs a standard attribute value representation using product descriptions found in the enterprise database. A set of attributes $\{A_1 \ldots A_n\}$ is decided by applying some initial domain knowledge. We are given a set of product descriptions comprising of values for one or more attributes. Our task is to segment these descriptions and put each segment into one of the n attribute bins. Since the descriptions are incomplete, large number of attribute values are null after the segmentation step. Enrichment task leverages the supervision provided by the rules to extract unknown or missing values from external web data.

3.1 Product Description Segmentation

Enterprise descriptions of products are short strings containing information about one or more attributes like “Brand Name”, “Product Name”, “Model Number”, “Manufacturer” and few other product specific attributes. To attain a standard view of products and to conform to organization-wide specifications, product data cleansing solutions are used to segment the descriptions into these product attributes. Non-standard representations are converted to standard forms and misspellings, etc are corrected. Some typical examples of product descriptions and their corresponding standardized forms are shown in Table 1.

To begin with, the enterprise or a domain expert ascertains the attributes comprising the descriptions. To perform the task of moving free-form descriptions into these pre-determined fixed attribute columns, a dictionary classification for generic tokens like involved brand names and product names is maintained from various intellectual property organizations like UNSPSC[1] and WIPO[2], and common metric units and currency symbols from common knowledge. This dictionary of standards is often stored in the form of rich taxonomies and is fixed. Each token is assigned a classification symbol depending on its type. To account for all misspellings (“Camera”, “Camcorder” and “Camrecorder”), difference in vocabularies(“Oz” and “Ounces”), classifications, synonyms and abbreviations, and other non-standard representations, the native forms(like Camrecorder) are mapped to a standard form (Camcorder) using signature clustering techniques as described in (Prasad et al., 2011). This is conveniently achieved by popular string similarity measures and by looking at context of these native forms in the input descriptions. Such data driven context mining approaches to find various ways in which similar words (which often have the same classification entry) like “Camera”, “Camcorder” and “Camrecorder”, and “LCD”, “CFD” and “TFT” help reduce the manual effort in rule writing and dictio-

[1] http://www.unspsc.org/

[2] http://www.wipo.int/portal/index.html.en

nary building. Despite this, suitable additions to these dictionaries are sometimes needed from domain experts. Example classification for our running example is given in Table 2.

Table 2: Classification Entries

NativeForm	StandardForm	Classification	Symbol
Canon	CANON	Brand	B
Cannon	CANON	Brand	B
Sony	SONY	Brand	B
Fujifilm	FUJIFILM	Brand	B
Quick Snap	QUICK SNAP	Product Name	N
Camera	CAMERA	Product	P
Camra	CAMERA	Product	P
USM	USM	Lens Property	L
$	$	Currency	C
MP	MEGAPIXEL	Metric	M
F	F	Alphabet	A

Also, we generate symbols for each number or unknown word to help us make use of the context to write rules. The classifications lead to a pattern of symbols for every product description entry.

For the following product description,
"Canon Powershot SD1200IS 10 MPIXEL Digital Cam $f/3.5 - 6.3\ 8''$ LCD Screen $123"
the corresponding pattern would be:
"$B + @\#M + PA/\# - \#\#M + +C\#$"
Here, B is a brand name and P is a product name recognized from one of the catalogues lying with the enterprise or some intellectual property database. M is a metric unit and C is a currency symbol lying in the dictionary of metric standards and currencies, respectively. Other symbols include $+$ for an unknown word, $\#$ for a number and $@$ for an alphanumeric. Finally, a domain expert writes rules to move entries into appropriate database columns and complete the standardization. Rules are written to process important subpatterns from the left or the right and capture attribute values in one pass. Table 3 lists some hand crafted segmentation rules to capture Resolution, Focal Length and Price. People invest a great amount of time, effort and money in building and maintaining these rules for extracting information from product descriptions. The output of these rules are used to populate Data Warehouses and Product Information Management (PIM) systems. However, these rules are applied only to short product descriptions which do not lead to a complete view of the product. In the subsequent step, we provides techniques that employ these rules to discover missing values of existing attributes. Doing so reuses the time and effort spent in building the rules on external content which otherwise is very expensive and time consuming to build.

Table 3: Rules for Segmentation Process

Subpattern	Rule[a]
# | M="MP"	COPY [1][2] "Resolution";
A="F" | / | # | - | #	COPY [1][2][3][4][5] "FocalLength";
C | #	COPY [1] "Currency"; COPY [2] "Price";

[a] [N] represents the N^{th} token in the subpattern
"Resolution", "FocalLength" and "Price" are Attribute columns
| represents a token separator

3.2 Missing Value Filling

We observe that the product descriptions after standardization have missing values for many predefined attributes (Nambiar et al., 2011). Next, to obtaining a complete view of the product we extract these values from the product reviews available on the web. Our approach is general and can be extended to other data sources like Sales and Marketing data, Product Catalogs, Website Product Listings and so on. Unlike many previous attempts, we extract meaningful 'values' of interesting attributes such as the shape, size and manufacturer's name and not merely use sentiments. We make use of the supervision provided by already existing rulesets frequently used for standardization to get a handle of such values. However as the reviews are verbose and noisy, these values too contain a lot of noise. Hence some text processing heuristics are used to choose most appropriate values.

However, we should note that the rules are meant for short product descriptions and not the user reviews. Due to high degree of verbosity and possibility of competing product talk in the reviews, direct rule application on the reviews yields many candidate values for each attribute. Hence, we devise a strategy to prune inappropriate candidates. Our approach to prune out unimportant candidates assesses the affinity of all the candidate values with their corresponding product descriptions and calculates a confidence level for each of them. Confidence level intuitively measures the likelihood that the candidate is a true value of the attribute and product in question. For each product and each of its attributes, the enterprise can then choose the value with the highest confidence (if its confidence is above a certain threshold).

Table 4: Sample Standardized Product Descriptions

Brand Name	Product Name	Product	Focal Length	Lens Diameter	Price	Weight
Canon	EF	Lens	2.8D	70-200mm	-	-

Table 5: Sample Product Reviews

... I bought a *Canon 2.8D lens*...certainly worth each of the **1369 bucks**.....**2.9 pounds** is a bit heavier...
... new *Nikon AF f/3.5-5.6G* ... fair price deal of **$ 685** ...

We compute the affinity for a candidate by looking at the appearances of known attribute values(values obtained by segmentation of the product description strings) of the product in its context. The 'known attribute values' are assigned certain weights and the confidence score for the candidate is computed using the weights carried by the 'known attribute values' in its context. Assuming all weights to be equal, the following example explains the idea in detail:
Consider the product description "Canon EF 70-200mm f/2.8D Lens" and its corresponding segmented output in table 4. Here - represents the missing values to be filled using the reviews. Consider the two reviews given in table 5. Out of the candidates "1369 bucks " and "$ 685" for the price attribute, "1369 bucks" is chosen as it contains more known attribute values (Canon, 2.8D, lens) in its context in review 1. On the other hand as "$ 685" has many competing attribute values (which do not match the known values) in its context (Nikon, AF, f/3.5-5.6G), it is rejected. Similarly, "2.9 pounds" being the only candidate for the weight attribute is accepted due to the presence of many matching known values in its context.

In the above example, we simply counted the number of known attribute values in each candidate's context to compute its confidence score. All the known values carried equal weights.

However, certain values occur much more rarely than others in free text. Hence, matching a rarer value in a candidate's context should give us more confidence that the review author is talking about the same product (as in the product description string) than one which occurs more frequently. For example, matching a value Focal length '18-55 mm' (which occurs rarely) instills more confidence than if the value color 'black' (a value which should occurs very frequently) is matched. We quantify this idea by assigning an 'importance' measure to all known values. The importance $I(v)$ of a known value v can be decided by the proportion of distinct product entities in the database(output of the standardization phase) that contain the value v. Since we wish to weigh rarer values more as they signify more importance, we use the inverse document frequency(IDF) formulation popularly used in previous text mining works to define:

$$I(v) = \begin{cases} log(\frac{N}{n(v)}) & \text{if n(v) } >0 \\ 0 & \text{otherwise} \end{cases}$$

where, N is the total number of distinct entities for the attribute in the database, and $n(v)$ is the number of distinct product entities that contain the value v.

We also note that matching the value for a certain attribute can signify greater confidence than others. For instance, if the "Product:Camera" or "Brand:Nikon" matches we still cannot be very sure because the author can be comparing two different cameras or two Nikon products. However if a value mentioning weight or lens of the camera matches, we can be more certain as it is unlikely to have two cameras with exactly the same weight or the same lens.

With this intuition in mind, we also give different weights to each 'attribute' in the standardization schema for matching. These weights intuitively signify our confidence on a value of the given attribute towards matching. In our running example, intuitively we should give more weight to 'Weight' or 'Lens' attributes than 'Product' and'Brand'. Weight of the attributes can be expressed by the domain expert during the schema decision process. Please note that this schema decision and weight assignment needs to be done only once per product vertical. For the matching to be effective, all real numbers were morphed to a common representation '#' and misspellings were corrected for terms known in the dictionary.

Finally, these weights and importance measures are tied together to estimate the confidence for each candidate value. We introduce a distance metric to quantify the distance between two words in a review. The effect of a value on the confi-

dence of a candidate dies off with its distance from the candidate. A formal description of the idea is given below.

Given: Attribute schema A=$\{A_1 \dots A_N\}$, set of products P and set of reviews R_p for each $p \in P$,

$$R = \bigcup_{p \in P} R_p$$

Let $A_i(p)$ be the value of attribute A_i for the product $p \in P$ from the segmentation step. Let $I_p(A_i, r)$ be the set of index positions at which $A_i(p)$ occurs in the review $r \in R_p$. Define:

$$B_p(A_i) = \begin{cases} 1 & \text{if } A_i(p) \text{ is known} \\ 0 & \text{otherwise} \end{cases}$$

Let attribute value A_j be missing for some product p after the segmentation step i.e. $B_p(A_j) = 0$ for some $j \in \{1 \dots n\}$. Given a set of candidates $C_p(A_j, r)$ (obtained by applying rules on a product review $r \in R_p$) for attribute A_j and product p, we define:

$$Q_p(c, r) = \sum_{x=1}^{n} \left(B_p\left(A_x\right) W(A_x) \sum_{i \in I_p(A_x, r)} I(i) d_r(i, c) \right)$$

$$\forall c \in C_p(A_j, r)$$

where d_r is a distance metric defined over every pair of words in a given review r.

In similar lines to the idea presented so far, occurrence of a value that contests a value already known from the standardization stage(segmentation output of the product description) can be used as an indicator that the author is talking of some other product or attribute. Hence, we have a case to reject candidates in its vicinity. Also, often people compare two products or brands while writing a review. Use of comparative adjective forms or coordinating conjunctions like "but, whereas, while, although, etc." that express a contrast mark such cases. To incorporate both of the above ideas, we can easily extend the objective function Q_p to account for these contingencies by adding terms to the summation that reduce the score of a candidate if conflicting attribute values and active comparison is found in its vicinity. Consider the following review:

I love the Point and Shoot mode in my new camera X. I was bored of using the same auto mode in my old cam Y. Though it lacks the auto-program feature, still it's worth its price in gold. While auto mode in Camera Y was a sham, night mode was a cool addition. A f/1.8 lens , preferably brand Z would just be the icing on the cake.

Here the author compares his old camera with the one he just purchased and finally talks about buying a different product (a lens). A naive extraction scheme will extract features for each of cameras X and Y, and lens Z. The problem could be further compounded if the author swings back and forth comparing two products leading us to the deep waters of Pronoun Resolution and Attribute Coreference Resolution. However, we easily find a way around them with the assumption that the switch will not happen too frequently in most reviews.

Finally, as the descriptions are often sparse, we do not have all representative values for an attribute. A better 'importance' measure for a value ($I(v)$) can be obtained from the reviews. Also, in the above description, Q_p values can be arbitrarily large or small. Hence, we translate this idea in the probabilistic sense to a scale between 0 and 1. In an informal manner, the affinity of each candidate with the product can be treated as a confidence measure (represented by $P(c)$ instead of discrete Q_p values) in a scale of 0 to 1.

We also give a linear time algorithm based on the above idea. The algorithm iterates over all the candidates, modifying their affinity and dispersing the change to all other candidates in the review.

Given:- A set of products P and a set of reviews R_p for every product $p \in P$. Let $C_{p,r}$ be the set of candidates for product p in review r. Let A be the set of attributes. $W_{sim}(A_k)$ and $W_{diff}(A_k)$ are the weights of the attribute A_k for a matching value and a competing value, respectively. Weight W_{comp} penalizes a comparative sentence in the affinity calculation. $d_r(c, c')$ is some distance metric defined on all candidate pairs in a review r. We set the distance between two candidates as the number of words between their occurrence in the review in our simulations.

for each $p \in P$:
  for each $r \in R_p$:
    for $c \in C_{p,r}$:
      Compute: $I(c)$
      Initialize: $P(c) = \frac{1}{2}$
      Init_value=P(c)
      for $k \in 1 \dots n$:
        if $c = A_k(p)$:
          $P(c) := W_{sim}(A_k) * P(c) + (1 - W_{sim}(A_k))$

end if
else if $c = A_k(p'), p' \in P, p'! = p$:
$P(c) := W_{diff}(A(k)) * P(c)$
end elseif
end for
if c lies in a comparative sentence:
$P(c) := W_{comp} * P(c)$
end if
Change(c)=$P(c)$-Init_value
for $c' \in C_{p,r}, c'! = c$:
$P(c) += Change(c') \times I(c') \times e^{-d_r(c',c)}$
end for
Normalize P
end for
end for
end for

Selection:- Finally for each product p and attribute A_j that misses a value for p, we choose the candidate with maximum affinity($P(c)$) i.e. choose c^*_{p,A_j} such that,

$$c^*_{p,A_j} = \underset{c' \in C_p(A_j,r), r \in R_p}{\text{argmax}} P(c', r).$$

Finally, c^*_{p,A_j} is filled in as a value for A_j if $P(c^*_{p,A_j}, r))$(r is the review containing c_{p,A_j}) is above a certain threshold. The algorithm runs with a complexity of $O(N + C^2)$ where N is the size of the reviews(number of words) and C is the number of candidates generated by applying rules on them. Since C is generally small, this is effectively linear with respect to size.

4 Evaluation

4.1 Dataset

The algorithms were tested on a real life dataset crawled from 'Amazon'. It contains reviews and short descriptions of 996 products in the Camera and Accessories space (Cameras, lenses, filters, etc). The total number of reviews was 23,337 leading to reviews per product ratio of about 24. Average number of words per review was around 40. Each product has a minimum of 20 reviews.

4.2 Experimental Setup

4.2.1 Product Description Segmentation

The experiments were carried out by first identifying the appropriate schema and 12 attributes were identified for description segmentation. They are given in Table 6. Rules (as described in Section 4.1) were used to standardize the descriptions into the composing attributes. The dictionary augmentation and rule writing together took nine man-hours. This is much lower than usual since we used Intellectual Property datasets on Brands and Products and clustering used to detect misspellings and varying vocabulary.

Table 6: Attributes guessed by the Rule Writer

Attribute	**Value**		**Attribute**	**Value**
Brand	Nikon		Product Type	Digital
Zoom	True		Color	Black
Lens	F/2.8 D		Retail Price	$ 250
Model	D 90		Product	Camera
Filter	UV		Size	Compact
Resolution	12MP		Features	Point&Shoot

4.2.2 Missing Value Filling

It was observed that around 60% of the attributes after the segmentation stage were null. So we used the reviews to fill in these missing values. Reusing the rules on the reviews led to a whopping 8434 candidates for the 12 attribute places in 969 products, which on using the confidence score based pruning scheme reduced to 5321. We set 0.5 as the weights for Brand Name, Product Name, Product Type and Color; and 1 for the remaining attributes. Recall that this is in-line with our arguments that there can be many products with the same Brand name, Product name, type and color but it is less likely for two products to have the same value for other attributes (say Retail Price or Weight). This choice of weights is done once and can be done at the time of the initial schema selection. Finally to select or reject candidates, we use a threshold. We used 0.4 times the mean(of the candidate confidence values) as the threshold for selection in our experiments. The threshold can be chosen based on the general confidence that the enterprise has on the correctness of the reviews. As the threshold is decreased, the number of values filled in increases but the precision-recall (and thereby F-Score) decreases.

4.3 Results

To evaluate our work, we also compute the entire attribute values view manually. Using this as ground truth, we calculate the Precision, Recall and F-Score of the overlap it has with our proposed techniques. Sometimes the values extracted are only partially correct for example, if the measurement unit is missing for the weight attribute.

Table 7: Evaluation Metrics for each Stage

Evaluation Stages	**100 Cameras**			**100 Lenses**		
Partially Correct	**Precision**	**Recall**	**F-Score**	**Precision**	**Recall**	**F-Score**
1.Standardization	1.000	0.909	0.952	1.000	0.925	0.961
2.Missing Value Extraction	0.888	0.705	0.786	0.837	0.700	0.762
Baseline 1	0.728	0.682	0.704	0.706	0.676	0.691
Baseline 2	0.771	0.709	0.739	0.741	0.703	0.712
Completely Correct	**Precision**	**Recall**	**F-Score**	**Precision**	**Recall**	**F-Score**
1.Standardization	0.998	0.901	0.947	1.000	0.917	0.957
2.Missing Value Filling	0.773	0.613	0.683	0.721	0.632	0.674
Baseline 1	0.644	0.607	0.625	0.618	0.596	0.607
Baseline 2	0.613	0.534	0.571	0.578	0.527	0.551

Hence, we evaluate results for both cases (when the values match perfectly or only partially).

4.3.1 Product Description Segmentation

As the Standardization stage is rule based, with time, close to perfect precision and recall can be achieved. In nine man-hours of effort, we achieved very high precision and recall as shown in Table 7.

4.3.2 Missing Value Filling

In Table 7, we give the precision and recall for the Enrichment phase. Here, we also draw two baseline comparisons for our work.

Baseline 1 is drawn by using the values extracted by the standardization stage from a training set (remaining 886 cameras) as seeds to train a CRF. The value extraction task is treated as a multi-class classification problem where each word is to be classified as a value to one of the attributes ($A_1 \dots A_n$) or as a "not a value" class. To generate a training set, every word is represented as a feature vector of $n + 20$ features. First n features are boolean entries and represent if the word matches an already known attribute value of the product. If the word matches with a value for A_j, then j^{th} feature is set to true and the rest to false. 10 words in the context of that word and their POS tags are remaining 20 features. The seeds are used to assign class labels to the training set. State of the art CRF is used for value extraction in a 10-fold setting. Please note that drawing the seeds from the standardization stage (which was rule based) gives this baseline the supervision provided by the rules. This is done to make a comparison with our approach fair. Recall that our technique for missing value Assignment leverages the supervision of existing rules to come up with meaningful values for the attributes.

(Ghani et al., 2006) laid down an ingenious technique to automatically extract candidate attribute-value seeds. They considered all pair of consecutive words (w_i, w_{i+1}) where w_i is a candidate value for the attribute w_{i+1}. Next, they computed the mutual information between all such candidate attribute-value pairs to prune down to fewer but cleaner seeds. Baseline 2 generates seeds by their technique and filters them for the attributes $\{A_1 \dots A_n\}$. Again, CRF is trained with the same feature space.

It can further be observed that due to rule based cues, our techniques do well even when completely correct values are expected. However, Baseline 2 (projection of (Ghani et al., 2006) on the attribute set) falls apart as most extracted values are incomplete and partial.

The entire experiment is also carried out on a similar dataset of 100 lenses to prove the generalization ability of our technique within the product domain(Photography). Results on the lens dataset (shown in Table 7) are very close to the camera dataset, and occasionally better.

5 Conclusion

In this work, we tackle the problem of creating the complete view of an enterprise's products and services. We utilize the rulesets developed by existing product data cleansing solutions for value extraction from unstructured text media. Hereby, we escaped the laborious process of writing annotators. Supervision provided by the rules helped us uncover values which can give us a better view of the product and not merely sentiments.

Mining bilingual topic hierarchies from unaligned text

Sumit Negi

Abstract

Recent years have seen an exponential growth in the amount of multilingual text available on the web. This situation raises the need for novel applications for organizing and accessing multilingual content. Common examples of such applications include Multilingual Topic Tracking, Cross-Language Information retrieval systems etc. Most of these applications rely on the availability of multilingual lexical resources which require significant effort to create. In this paper we present an unsupervised method for building *bilingual topic hierarchies*. In a *bilingual topic hierarchy*, topics (where a topic is a distribution over words) are arranged in a hierarchical fashion with abstract topics appearing near the root of the hierarchy and more concrete topics near the leaves. Such bilingual topic hierarchies can be useful for organizing bilingual corpus based on common topics, cross-lingual information retrieval and cross-lingual text classification. Our method builds upon the prior work done on Bayesian non-parametric inferencing of topic hierarchies and multilingual topic modeling to extract bilingual topic hierarchies from unaligned text. We demonstrate the effectiveness of our algorithm in extracting such topic hierarchies from a collection of bilingual text passages and FAQs.

1 Introduction

The last few decades have seen an explosive growth in Internet accessibility in developing regions of the world. A significant part of this growth has been in countries that use languages other than English as their primary language (Chinese, Spanish, Arabic, Hindi etc). The increasing number of multilingual Internet users has resulted in a tremendous increase in the amount multilingual content that is available on the Web. This situation raises the need for novel ways of organizing and accessing multilingual content. Work done on Cross Language Information Retrieval (CLIR) (Xu et al., 2001) i.e. retrieving information written in a language different from the language of the user's query is one key attempt in this very direction. Similarly, there has been increased interest in multilingual text mining applications such as sentiment detection (Boiy and Moens, 2008), mining multilingual news feeds, cross lingual text categorization (Bel et al., 2003) etc. Most of these applications use bilingual dictionaries or lexical databases to perform such tasks. For instance, (Pouliquen et al., 2004) use the *Eurovoc* multilingual thesaurus for cross-lingual news topic tracking. (Mihalcea et al., 2007) use a bilingual dictionary to generate subjectivity analysis resources for a given language. Similarly, CINDOR (Ruiz et al., 2000) uses interlingua resources to address the cross language information retrieval problem.

Considering the importance of multilingual lexical resources efforts to (semi) automatically build/populate such resources from Web or other large text collections have gained prominence. For example, (Nagata et al., 2001) build a bilingual dictionary of English-Japanese technical term by collecting and scoring translation candidates from the Web. (Widdows et al., 2002; Nerima et al., 2003) describe similar initiatives related to building multilingual lexical resources from large text corpora.

The work presented in this paper is similar in spirit i.e. it presents an automated way of building and populating a lexical resource given a text corpus. In this paper we propose an unsupervised method of building *bilingual topic hierarchies* using Topic models (Blei et al., 2003). In a topic hierarchy, topics (where a topic is a distribution over

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 992–1000,
Chiang Mai, Thailand, November 8 – 13, 2011.

words) are arranged in a hierarchical fashion with abstract topics appearing near the root of the hierarchy and more concrete topics near the leaves. Figure 1 is an example of a bilingual topic hierarchy. Such topic hierarchies can be useful for organizing/navigating bilingual corpus based on common topics, cross-lingual information retrieval and multilingual text categorization.

Motivating Example: Consider a corpus containing medical documents from two different languages on a common set of topics (e.g. genetics, pharmacology, toxicology etc). The documents in this corpus are not aligned in anyway i.e. there is no document or sentence level alignment between documents of the two languages in the corpus. Let us assume that the goal is to organize this bilingual corpus in such a way that it is easy to locate documents of a certain topic/sub-topic irrespective of the language in which the document was authored. One way of achieving this would be to arrange the document from the corpus in some sort of a hierarchy where (a) documents pertaining to different topics appear in different subtrees of the hierarchy and (b) within a given subtree documents belonging to abstract topics appear at higher levels of the subtree than documents belonging to concrete subtopics.

Organizing documents in such a fashion could be aided by the availability of a bilingual topic hierarchy as shown in Figure 1 in which topics (where a topic is a collection of words) are arranged in a hierarchical fashion with abstract topics appearing near the root of the hierarchy and more concrete topics near the leaves. Moreover, using a data-driven approach (as proposed by our method) for building such a bilingual topic hierarchy ensures that the hierarchy is representative of the structure present in the data. Note, that the hierarchy shown in Figure 1 was generated by our proposed method from a corpus containing English and Hindi medical documents on topics such as Behavior (MeSH [1]Category F01.145), Alcohol Drinking (MeSH Category F01.145.317.269) etc.

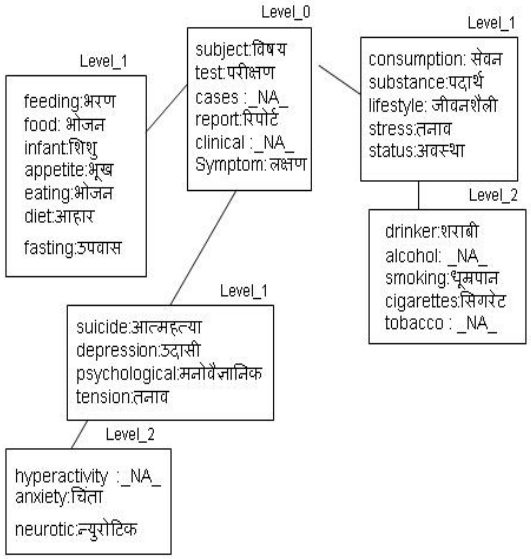

Figure 1: Bilingual Topic Hierarchy

2 Prior Work

Topic models have been used for analyzing topic trends in research literature, inferring captions for images, social network analysis in email, and expanding queries with topically related words in information retrieval. Most of the topic modeling work on text has occurred in the monolingual context. *Multilingual topic models* (MTM) is a relatively new area of research as compared to Topic modeling on monolingual corpus. In their work (Jagarlamudi and Daum III, 2010) (Boyd-Graber and Blei, 2009) demonstrate how a monolingual topic model, which groups together semantically similar words based on similar context, cannot be used directly on a multilingual corpus. This is because of the fact that almost all documents are written in a single language hence similar meaning words from different languages will never share similar context. Consequently, even though a topic model applied on a bilingual corpus will find coherent topics (for each language independently) it will bifurcate the topic space between the two languages.

In Figure 2 we show a few topics discovered by Latent Dirichlet Allocation (Blei et al., 2003) on a bilingual corpus containing Hindi and English documents. The outcome is similar to what was demonstrated by (Jagarlamudi and Daum III, 2010) on the Europarl[2] parallel corpus i.e. LDA bifurcates the topics between the two languages despite their being striking similarity between topics in the two languages. For instance, Topic *C1* and *C3* should be merged together as they form one coherent topic cluster (both these clusters have

[1]Medical Subject Headings

[2]http://www.statmt.org/europarl/

words relevant to *'crop-disease'*). Similarly, Topic *C2* and *C5* should be merged together as they form one coherent topic cluster (both these clusters have words relevant to *'agriculture'*).

In order to discover coherent topics across languages, most multilingual topic models take the document's language into consideration. Previous work on Multilingual Topic Modeling connects the languages by assuming parallelism at either the sentence level or document level. (Zhao and Xing, 2006) propose BiTAM (Bilingual topic admixture models) and HM-BiTAM (Hidden Markov Bilingual topic admixture model), bilingual topic model for Statistical Machine Translation that assume sentence level alignment. Work done by (Kim and Khudanpur, 2004; Tam and Schultz, 2007; Ni et al., 2009) relax the sentence level alignment but require document level alignment. These requirements, namely sentence/document level alignment are too restrictive as finding parallel corpus for all possible domains and languages is difficult. Recent work by (Jagarlamudi and Daum III, 2010) and (Boyd-Graber and Blei, 2009) relax these restrictions by proposing multilingual topic models that work on unaligned text in multiple languages. MuTo (Multilingual Topic Model) (Boyd-Graber and Blei, 2009) does away with the alignment requirement by assuming that similar themes and ideas appear in both languages. The JointLDA model (Jagarlamudi and Daum III, 2010) , which can be seen as a generalization of MuTo, uses a bilingual dictionary to mine bilingual topics from an unaligned corpus. As JointLDA requires only a bilingual dictionary, which is easy to obtain for most pair of languages, we use this model for extracting bilingual topic hierarchies. Please note that the JointLDA model cannot be used directly to infer topic hierarchies. This is because like LDA, JointLDA treats topics as a flat set of probability distributions, with not direct relationship between topics. To discover relationships between topics the Hierarchical Latent Dirichlet Allocation (Blei et al., 2010) is used.

To the best of our knowledge our work of discovering bilingual topic hierarchies using Topic models is a first. Our generative model uses the JointLDA (a multilingual topic modeling approach) and hLDA (a hierarchial topic modeling approach) models to discover bilingual topic hierarchies from an unaligned bilingual corpus. Combining these two models gives us an unsupervised mechanism of discovering bilingual topic hierarchies. Moreover, in this setup no assumption about the topics or hierarchy structure (there are no limitation such as maximum depth or maximum branching factor) needs to be made.

The paper is organized as follows. In Section 3 we provide a short overview of the Hierarchical Latent Dirichlet Allocation and JointLDA. Section 4 provides details of the proposed generative model for extracting bilingual topic hierarchies from an unaligned bilingual corpus. Experiments and conclusion are provided in Section 5 and Section 6 respectively.

3 Hierarchical Latent Dirichlet Allocation and JoinLDA models

For ease of exposition, we first describe the basics of the Hierarchical Latent Dirichlet Allocation and JoinLDA models. Topic models such as Latent Dirichlet Allocation (LDA) treat topics as a flat set of probability distributions, with no direct relationship between topics. While such models can be used to discover set of topics from a corpus they fail to detect the level of abstraction of a topic, or how topics are related. Blei et al. propose a *hierarchical topic model* hLDA (Blei et al., 2010) that learns such relations between topics. Given a collection of documents each of which contains a set of words, hLDA discovers topics in the documents and organizes these topics into a hierarchy. More general topics appear near the root whereas more specialized topics appear near the leaf of the hierarchy. In the hierarchy each node is associated with a topic, where topic is distribution over words. Under this generative model a document is generated by choosing a path from the root to a leaf, repeatedly sampling topics along the path, and sampling the words from the selected topics. Blei et al. define a *nested Chinese restaurant process* which is used as a prior distribution over the possible hierarchies (a hierarchy can be thought of as a infinitely-deep and infinitely-branching tree).

In hLDA each document is assigned a single path in the hierarchy. The first level, which is directly below the root, induces a coarse partition on the documents. Topics at this level place high probability on words that are useful within the corresponding subset/partition. The nested partitions of documents become finer as one moves down the hierarchy. Consequently, the corresponding topics (and the words associated with those topics) be-

C1	C2	C3	C4	C5	C6	C7	C8
pesticide	soil	बीमारी	कीटनाशक	फसल	market	disease	मंडी
pest	harvest	टीका	छिड़कना	गेहूँ	wholesale	vaccine	थोक
blight	grain	परजीवी	बिमारी	चावल	storage	viral	वितरण

parasite	rice	खाल	परजीवी	मौसम	price	symptoms	दाम
	wheat			खेती		influenza	

Figure 2: Topics extracted by LDA from a bilingual Hindi-English corpus

come more specialized to the particular documents in those paths. As mentioned in (Blei et al., 2010) the goal of finding a topic hierarchy at different levels of abstraction is distinct from the problem of hierarchical clustering. Hierarchical clustering treats each data point as a leaf in a tree, and merges similar data points up the tree until all are merged into a root node. Thus, the internal nodes formed during the hierarchical clustering process shares words with their children. In contrast, in the hierarchical topic model the internal nodes are not summaries of their children. Rather, the internal nodes reflect the shared terminology of the documents assigned to the paths that contains them.

We extend the hLDA model to extract *bilingual topic hierarchies* from unaligned bilingual corpus. Even though there has been some attempts to extract topics (not topic hierarchies) from cross-lingual corpus, these approaches assume either explicit or indirect clues about document alignment. In order to overcome such restrictions, namely sentence/document alignment, we use the JointLDA model proposed by (Jagarlamudi and Daum III, 2010). The JointLDA model is an extension of the LDA model which uses bilingual dictionaries to generate documents in different languages. The JointLDA model, like LDA, models a document as a mixture over T topics, where the mixture weight (θ_d) is drawn from a Dirichlet distribution. JointLDA introduces an additional hidden variable called *concepts*, in defining a topic distribution. Each topic is now a distribution over concepts rather than words, where the topic distribution is also drawn from a Dirichlet distribution. Finally, a *concept* can be realized in different ways depending on the choice of the document's language (l_d). This additional layer of language independent abstraction over the words allows the model to capture common topics in different languages effectively. JointLDA use bilingual dictionary entries as substitute for these concepts. Out-of-dictionary words are handled by adding artificial dictionary entries to the dictionary. For more details on the JointLDA model readers should see (Jagarlamudi and Daum III, 2010).

In the next section we describe in detail our proposed bilingual-topic hierarchy generative model.

4 Generative Process

In the bilingual-topic hierarchy model for a given document d a path $\mathbf{c}_d$ (where a path denotes a collection of topics) is drawn from a nested Chinese Restaurant Process (nCRP). Given a choice of a path, or in other words a collection of topics, the GEM (Pitman, 2002) distribution is used to define a probability distribution on the topics along that path. Given a draw from a GEM distribution, a document for language l_d is generated by first repeatedly selecting topics according to the probabilities defined by that draw, followed by selecting a *concept* from a multinomial distribution, and then selecting a word given the *concept* and language of the document. The generative process can thus be summarized as

1. For each table $k \in T$ in the infinite tree
   (a) draw a topic $\beta_k \sim \mathrm{Dir}(\eta)$
2. For each doc $d \in \{1,2....D\}$
   (a) draw $\mathbf{c}_d \sim \mathrm{nCRP}(\gamma)$
   (b) draw a distribution over levels in the tree, $\theta_d|\{\mathrm{m},\pi\} \sim \mathrm{GEM}(\mathrm{m},\pi)$
   (c) for each word in the document
      i. choose level $z_{d,n}|\theta \sim \mathrm{Mult}(\theta_d)$
      ii. select a concept (dictionary entry) $v_{d,n} \sim \mathrm{Mult}(\beta_{\mathbf{c}_d}[z_{d,n}])\Psi(v_{d,n},\mathrm{l}_d)$
      iii. select a word from $\mathrm{p}(w_{d,n}|\ v_{d,n},\mathrm{l}_d)$

Where the function $\Psi(v_{d,n},\mathrm{l}_d)$ is 1 if the dictionary entry $v_{d,n}$ can generate a word from language l_d

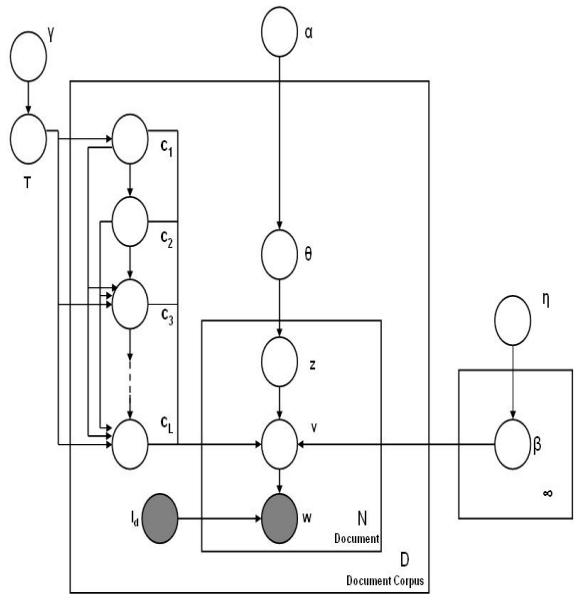

Figure 3: bilingual-topic hierarchy model

and otherwise 0. Given a dictionary entry and language there is only one possibility for a word and hence p($w_{d,n}$| $v_{d,n}$,l_d) = 1 (Jagarlamudi and Daum III, 2010). Figure 3 illustrates the bilingual-topic hierarchy generative process using the plate model notation.

4.1 Approximate Inference

Given the bilingual-topic hierarchy model the goal is to perform *posterior inference* i.e. to invert the generative process of documents for estimating the hidden topical structure of a bilingual document collection. The posterior distribution gives us the distribution of the underlying topic structure that might have generated an observed collection of bilingual documents. Finding this posterior distribution is a key problem in Bayesian statistics. Since the posterior distribution does not have a closed form we employ an approximate inferencing technique namely a variant of Markov Chain Monte Carlo (MCMC) technique called *collapsed Gibbs sampling* (Liu, 1994). In a Gibbs sampler each latent variable is iteratively sampled conditioned on the observations and all other latent variables. To speed up convergence the collapsed Gibbs sampler marginalize out some of the latent variables. Collapsed Gibbs sampling for topic models has been widely used in topic modeling applications (McCallum et al., 2004; Mimno and McCallum, 2007; Rosen-Zvi et al., 2004).

The variables needed by the sampling algorithm are: $w_{d,n}$: the *n*th word in document *d* (observed), l_d : document *d*'s language (observed), $c_{d,l}$: the *l*th topic in document *d*, $v_{d,n}$: the *concept* (dictionary entry) associated with the *n*th word in document *d* and $z_{d,n}$: the assignment of the *n*th word in document *d* to one of the L available topics. The Gibbs sampler integrates out all the other variables in the model to assess the values of $z_{d,n}$, $c_{d,l}$ and $v_{d,n}$.

We approximate the posterior
p($\mathbf{c}_{1:D}$, $\mathbf{z}_{1:D}$, $\mathbf{v}_{1:D}$ | η, γ, m, π, $\mathbf{w}_{1:D}$, $\mathbf{l}_{1:D}$)
where hyper-parameter γ reflects the likelihood that documents will choose new paths when traversing the nested CRP, η reflects the expected variance of the underlying topics ($\eta \ll 1$ will tend to choose topics with fewer high probability words), and m and π reflect our expectation about the allocation of words to levels within a document. Bold fonts $\mathbf{c}_{1:D}$, $\mathbf{z}_{1:D}$, $\mathbf{v}_{1:D}$ denote vector of level allocations, topic allocations and concept allocation respectively. The variable $\mathbf{c}_d$ denotes the per-document path, $z_{d,n}$ denotes per-word level allocation to topics in those paths (as mentioned in Section 3, a path in a tree picks out a collection of topics) and $v_{d,n}$ denotes *concept* for the *n*th word in document *d*. Next, we describe in detail how level allocations, concepts and paths are sampled.

4.1.1 Sampling

In this section Equation (1), (2), (3) detail how the level allocation variable $z_{d,n}$ is sampled. Given the current path assignments, we sample the level allocation variable $z_{d,n}$ for word *n* in document *d* from its distribution given the current value of all other variables

$$p(z_{d,n}|\mathbf{z}_{-(d,n)}, \mathbf{c}, \mathbf{v}, m, \pi, \eta) \propto p(z_{d,n}|\mathbf{z}_{d,-n}, m, \pi).p(v_{d,n}|\mathbf{z}, \mathbf{c}, \mathbf{v}_{-(d,n)}, \eta) \quad (1)$$

Where $\mathbf{z}_{-(d,n)}$ and $\mathbf{v}_{-(d,n)}$ are vectors of level allocations and concepts leaving out $z_{d,n}$ and $v_{d,n}$ respectively. The first term in (1) is a distribution over levels.

$$p(z_{d,n} = k \mid \mathbf{z}_{d,-n}, m, \pi) = \frac{(1-m)\pi + \#[\mathbf{z}_{-(d,n)} = k]}{\pi + \#[\mathbf{z}_{-(d,n)} \geq k]} \prod_{j=1}^{k-1} \frac{m\pi + \#[\mathbf{z}_{d,-n} > j]}{\pi + \#[\mathbf{z}_{d,-n} \geq j]} \quad (2)$$

Where #[..] counts the elements of an array satisfying a given condition. Interested readers are requested to refer to (Blei et al., 2010) for detailed

derivation. The second term in (1) is the probability of a given concept based on possible assignment. From the assumption that the topic parameter β_i are generated from a dirchilet distribution with hyper-parameter η we obtain

$$p(v_{d,n} = j \mid \mathbf{z}, \mathbf{c}, \mathbf{v}_{-(d,n)}, \eta) \propto \#[\mathbf{z}_{-(d,n)} = z_{d,n}, \mathbf{c}_{z_{d,n}} = c_{(d,z_{d,n})}, \mathbf{v}_{-(d,n)} = j] + \eta \quad (3)$$

Where (3) gives the smoothed frequency of the number of times concept *j* is allocated to topic at level $z_{d,n}$ of the path c_d.

Given level allocation, in order to sample the path associated with each document conditioned on all other paths and concept assignments (4), (5) is used. Where

$$p(\mathbf{c}_d \mid \mathbf{c}_{-d}, \mathbf{v}, \mathbf{z}, \eta, \gamma) \propto p(\mathbf{c}_d \mid \mathbf{c}_{-d}, \gamma).p(\mathbf{v}_d \mid \mathbf{c}, \mathbf{z}, \mathbf{v}_{-d}, \eta). \quad (4)$$

The probability of *concept* is obtained by integrating over the multinomial parameters.

$$p(\mathbf{v}_d \mid \mathbf{c}, \mathbf{z}, \mathbf{v}_{-d}, \eta) = \prod_{l=1}^{max(z_d)} \frac{\Gamma(\sum_v \#[\mathbf{z}_{-d} = l, \mathbf{c}_{-d,l} = c_{d,l}, \mathbf{v}_{-d} = v] + V\eta)}{\prod_v \Gamma(\#[\mathbf{z}_{-d} = l, \mathbf{c}_{-d,l} = c_{d,l}, \mathbf{v}_{-d} = v] + \eta)} \times \frac{\prod_v \Gamma(\#[\mathbf{z} = l, \mathbf{c}_l = c_{d,l}, \mathbf{v} = v] + \eta)}{\Gamma(\Sigma_v \#[\mathbf{z} = l, \mathbf{c}_l = c_{d,l}, \mathbf{v} = v] + V\eta)} \quad (5)$$

For each document *d* the topic and concept assignments for each word i.e. ($z_{d,n}$,$v_{d,n}$) is sampled from the probability distribution given by

$$p(z_{d,n} = k, v_{d,n} = j \mid \mathbf{z}_{-(d,n)}, \mathbf{v}_{-(d,n)}, \mathbf{w}, \mathbf{l}) \propto \frac{n^d_{-(d,n),k} + \gamma}{n^d_{-(d,n),(.)} + L\gamma} \cdot \frac{n^j_{-(d,n),k} + \eta}{n^{(.)}_{-(d,n),k} + V\eta} \quad (6)$$

In (6) $n^j_{-(d,n),k}$ ($n^{(.)}_{-(d,n),k}$) is the number of times the dictionary entry *j* (any dictionary entry) is used along with topic *k* for sampling any word excluding the word $w_{d,n}$. Similarly, $n^d_{-(d,n),k}$ ($n^d_{-(d,n),(.)}$) is the number of words in document *d* that are assigned to topic *k* (any topic) excluding the word $w_{d,n}$. Note, L is the number of topics (levels in the hierarchy) and V the vocabulary size. Figure 4 provides an overview of the sampling algorithm.

Given the current state of the sampler [$\mathbf{c}_{1:D}$, $\mathbf{z}_{1:D}$, $\mathbf{v}_{1:D}$]
Begin
  For each document *d* ∈ {1,.....,D}
    Draw $\mathbf{c}_d$ using (4)
    For each word in document *d* draw $z_{d,n}$ using (1)
    For each word in document *d* draw $v_{d,n}$ using (6)
End

Figure 4: Gibbs Sampling Algorithm

5 Experiments

To demonstrate that the bilingual-topic hierarchy model extracts meaningful topic hierarchies the model was applied on two real world data-sets. The first data-set is a collection of 2000 questions on the following three topics: *health insurance*, *auto insurance* and *passport/visa* queries. This data set was built by crawling government and insurance company web sites. The average length of a question in this corpus is eleven words. The question corpus contains 1200 questions in Hindi and 800 question in English. Further details of this data-set, henceforth referred to as *Data-Set A*, is provided in Table 1. The extracted bilingual topic hierarchy is shown in Figure 5. For our experiments we used *Shabdanjali*[1] as our bilingual (Hindi-English) dictionary. Since the coverage of a bilingual dictionary will be limited we add artificial entries ($\_NA\_$) for out-of-dictionary words. This is similar to the approach adopted by (Jagarlamudi and Daum III, 2010) in their JointLDA work.

Language	Health	Auto	Passport/Visa	Total
Hindi	440	330	430	1200
English	280	350	170	800

Table 1: Data-Set A.

We apply our algorithm on a second data set which is a collection of text passages on *agricultural* and *animal rearing*. This data-set, henceforth referred to as *Data-Set B*, is a collection of 1100 passages, 700 of which are in Hindi and the rest 400 in English. The average length of a passage in this data-set is 221 words. The extracted bilingual topic hierarchy is shown in Figure 6.

In order to facilitate the visualization of extracted topic hierarchies we restrict the number of levels to three. As is evident from Figure 5, Figure 6 the model was able to successfully extract the underlying bilingual-hierarchical struc-

[1] http://www.shabdkosh.com/content/category/downloads/

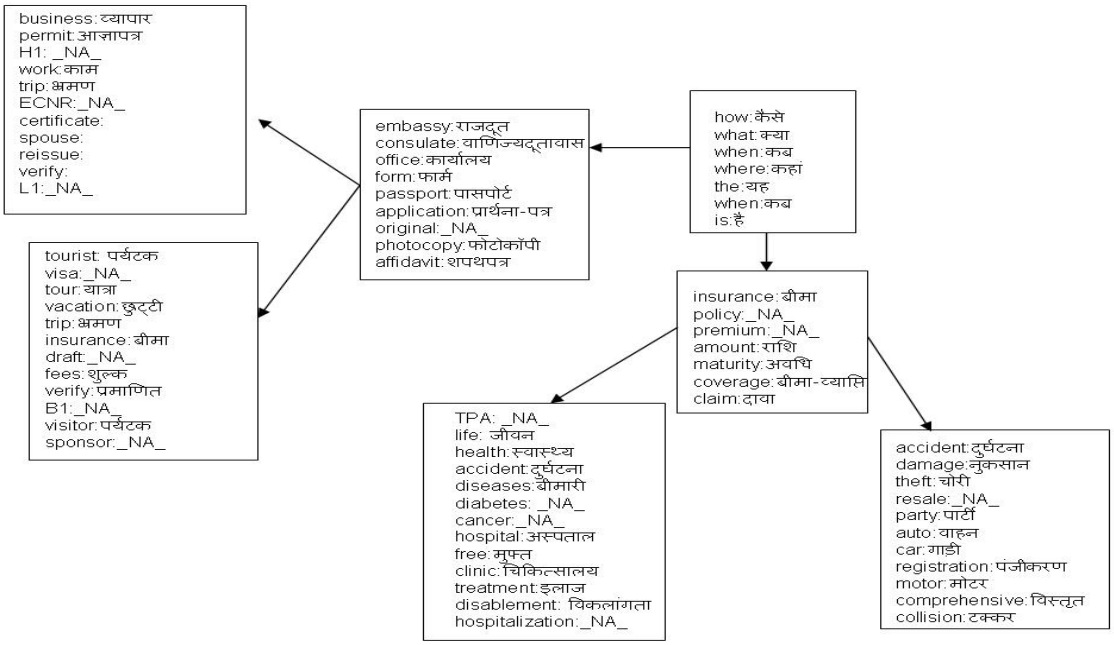

Figure 5: Bilingual Topic Hierarchy: Data-Set A

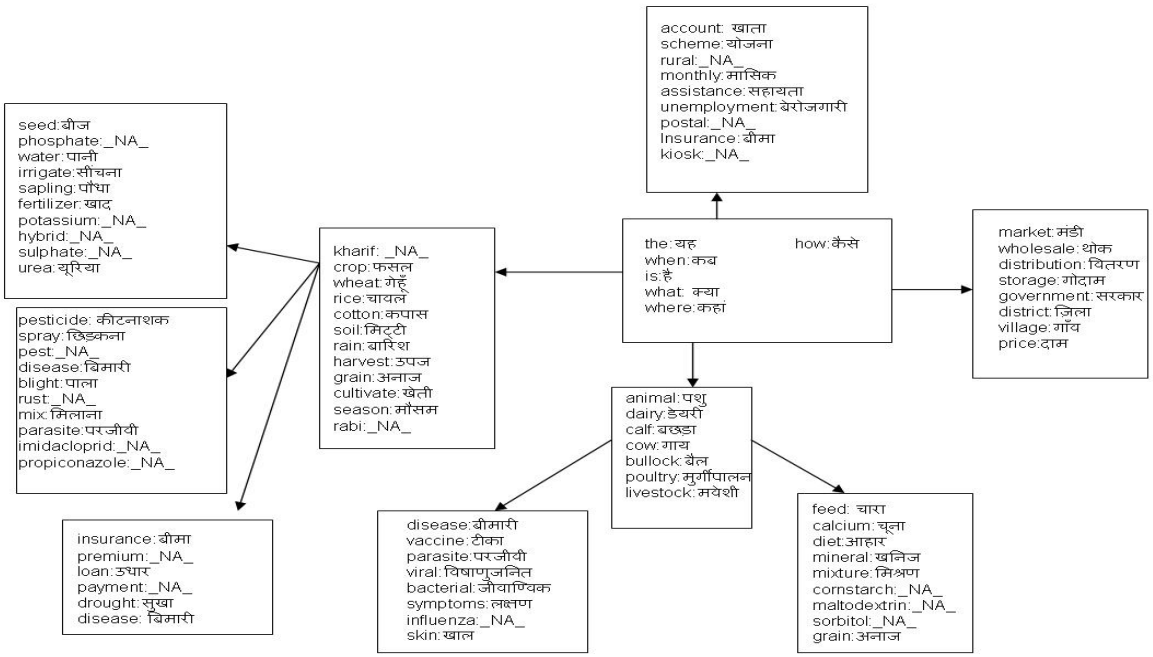

Figure 6: Bilingual Topic Hierarchy: Data-Set B

ture from the two document collections. For example for *Data-Set B* (Figure 6) the second level of the hierarchy captures the two prominent topics (where a topic is a distribution over words) present in the document collection namely that related to agriculture and animal rearing. The third level of this hierarchy further refines these topics. The *agriculture* topic is further split into subtopics related to crop-disease, crop-cultivation and crop-insurance. Similarly, the *animal-rearing* topic cluster is split into subtopic related to animal-disease and animal-feed. For a quantitative evaluation of our method we use predictive held-out likelihood as a measure of performance. Fig-

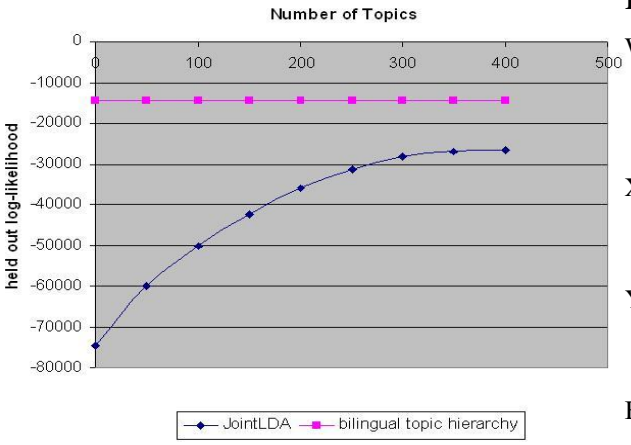

Figure 7: Held out log-likelihood vs Number of topics

ure 7 illustrates the five-fold cross-validated held-out likelihood for JointLDA and bilingual topic hierarchy on the test corpus. It is evident from this experiment that for topic cardinalities in the range 0 to 400, bilingual topic hierarchy provides significantly better predictive performance than JointLDA.

6 Conclusion

In this paper we presented an unsupervised method for building *bilingual topic hierarchies*. In a topic hierarchy, topics (where a topic is a distribution over words) are arranged in a hierarchical fashion with abstract topics appearing near the root of the hierarchy and more concrete topics near the leaves. Such bilingual topic hierarchies can be useful for organizing bilingual corpus based on common topics, cross-lingual information retrieval and cross-lingual text classification. We propose a generative model that employs Bayesian non-parametric inferencing of topic hierarchies and multilingual topic modeling to extract such bilingual topic hierarchies from unaligned text. The effectiveness of the algorithm in extracting bilingual topic hierarchies is demonstrated on a collection of bilingual text passages and FAQs. As part of future work we plan to use the extracted bilingual topic hierarchies for cross-lingual text classification and information retrieval tasks.

Efficient Near-Duplicate Detection for Q&A Forum

Yan Wu, Qi Zhang, Xuanjing Huang

School of Computer Science
{10210240075,qz,xjhuang}@fudan.edu.cn

Abstract

This paper addresses the issue of redundant data in large-scale collections of Q&A forums. We propose and evaluate a novel algorithm for automatically detecting the near-duplicate Q&A threads. The main idea is to use the distributed index and Map-Reduce framework to calculate pairwise similarity and identify redundant data fast and scalably. The proposed method was evaluated on a real-world data collection crawled from a popular Q&A forum. Experimental results show that our proposed method can effectively and efficiently detect near-duplicate content in large web collections.

1 INTRODUCTION

There is a rise in popularity of Question and Answering forums in recent years. The forums allow users to post, browse, search and answer questions. Q&A forum acts not only as a medium for knowledge sharing , but also as a place in which one can seek advice, and satisfy others' curiosity about a countless number of things (Adamic et al., 2008). However, because of the ever-increasing growth of it, and the fact that users are not always experts in the areas they post threads on, duplicate content becomes a serious issue. And, most of the current Q&A forums haven't had a efficient mechanism to identify threads with near-duplicate content. As a consequence, users have to go through different versions of duplicate or near-duplicate content, and are often frustrated by it. Baidu Zhidao[1] is one of the largest Q&A forums in China. It contains more than 100 million question and answer pairs. Because of the increasing popularity and the number of users, it also encounters the long-standing problem – content duplication. For example, there are more than four hundred question-answer pairs which contain the same content "When is the birthday of Jay?" Other Q&A forums are facing the similar problem.

Along with the increasing requirements and the limitations of manual methods, there have been growing research activities in duplicate detection, during the past few years. Common automatical methods to detect duplicates are copy detection or near-duplicate detection (Gionis et al., 1999; Muthmann et al., 2009; Shivakumar and Garcia-Molina, 1995; Shivakumar and Garcia-Molina, 1999; Theobald et al., 2008; Zhang et al., 2010). Most of the current near-duplication detection approaches usually focus on the document level to figure out the web pages with different framing, navigation bar, and advertisements, but duplicate content. However, unlike duplicated web-pages, forum threads have the following differences:

1. Forum threads contain additional structured meta information, e.g. title, tags, external/internal links, etc. So, the method used to detect near-duplicate of the forum thread is to the web-page.

2. The average length of threads is usually less than the news articles. Adamic et al. reported that most of the thread lengths are less than 400 words in Yahoo! Answers(Adamic et al., 2008).

3. The number of threads grows in a significant pace compare to other media. Thus a more efficient method need to be used to handle millions of content.

[1] http://zhidao.baidu.com

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1001–1009,
Chiang Mai, Thailand, November 8 – 13, 2011.

In this paper we propose a novel algorithm for detecting near-duplicate threads in the Q&A forums. Threads with similar content can be identified. The proposed algorithm completes the pairwise similarity comparisons in two steps: inverted index building and then similarity computations with it. Thread content and other meta information can be represented by signature/feature sets. As the Web collections contain hundreds of millions pages, this algorithm is done through MapReduce (Dean and Ghemawat, 2004), which is a framework for large-scale distributed computing. We implement our method and compare it with the state-of-the-art approaches on a real-world data crawled from a Q&A web forum and one manually labeled evaluation corpus. From the experimental results, we can observe that both effectiveness and efficiency are significantly improved. The major contributions of this work are as follows:

- We analyze the common structure of threads in Q&A forums, and give a definition of near-duplicate thread.
- We propose efficient solutions, which use distributed inverted index and are implemented under Map-Reduce framework, for calculating pairwise similarity and identifying redundant data fast and scalably.
- We describe a number of signatures for unstructured content and other meta information, and experimentally evaluate them.
- A tight upper bound of Jaccard coefficient is given and used in the to speed up the similarity calculation.
- We evaluate our method on a real-world corpus crawled from Baidu Zhidao. Experimental results showed that our algorithm can achieve better result than the state-of-the-art algorithms for detecting near-duplicate web pages on forum content.

The rest of the paper is structured as follows: In Section 2, a number of related work and the state-of-the-art approaches in related research areas are briefly described. Section 3 defines the problem we try to deal with and gives the introduction of MapReduce framework. In Section 4, we present the proposed methods. Experimental results in testing collections and performance evaluation are shown in Section 5. Finally, Section 6 concludes this paper.

2 RELATED WORK

Near-duplicate detection has been widely studied over the past several years. Previous works on duplicate and near-duplicate detection can be roughly divided into two research ares: document representation and efficiency. The first one focuses on how to represent a document with or without linguistic knowledge. The second area, which focuses on how to handle hundreds of millions of documents, has also received lots of attentions. The technique of estimating similarity among pairs of documents was presented by Broder et al. (Broder, 1997). They used *shingles*, which does not rely on any linguistic knowledge, to represent documents and Jaccard overlap to calculate the similarity. I-Match (Chowdhury et al., 2002) divided the duplicate detection into two tasks: 1) filtering the input document based on collection statistics; 2) calculating a single hash value for the remainder text. The documents with same hash value are considered as duplicates. SpotSigs was proposed in 2008 by Theobald et al. (Theobald et al., 2008), which combines stopword antecedents with short chains of adjacent content terms. Hajishirzi et al. (Hajishirzi et al., 2010) presented an adaptive near-duplicate detection method, which can achieve high accuracy across different target domains. Besides the approaches focused on Web pages or documents, Muthmann et al. (Muthmann et al., 2009) proposed their work to identify threads with near-duplicate content and to group these threads in the search results.

3 PRELIMINARIES

Although there are several different websites which provide the Q&A service, their question-answer thread structure are very similar. Usually, each thread includes a question (Title), none or several sentences used to describe the question (*Description*), a best an-

swer, and a number of other answers. Based on the common structure of Q&A forum threads, we will use the following definition to capture near-duplicate threads:

Definition 1 *Near-Duplicate Thread – Two threads are near-duplicate with each other in Q&A forum: (1) if both of their question and answer parts are the same with each other, or (2) if their question parts are same and one of the answers contains additional information compare to another answer.*

Consider the following examples:

Example 1
Question: *When is the birthday of Jay?*
Description: The birthday of Jay.
Best Answer: January 18th, 1979

Example 2
Question: *Who can tell me what's the Jay's birthday?*
Description: Jay "male, top R&B singer", I want to know when he was born.
Best Answer: 18/1/1979

Since the question part of example 1 and example 2 have the same meaning and answer parts are also the same, they are near-duplicate threads according to our definition, although the two threads use different words and expressions in the question parts and different date formats in the answer parts.

4 OUR APPROACH

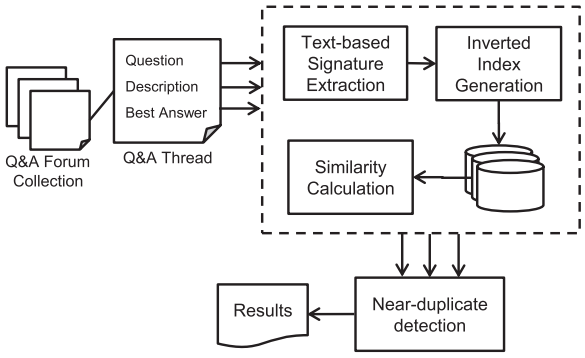

Figure 1: Process for detecting near-duplicate threads

Figure 1 shows the process for identifying near-duplicate threads in Q&A forums. The process consists of four stages:

Stage 1. Text-based Signature extraction produces signatures for each thread. Signatures for different parts are separately extracted. We only consider three parts including "Question", "Description", and "Best Answer" in this paper.

Stage 2. Inverted index generation treats signatures as terms and builds distributed inverted indexes for collections.

Stage 3. Similarity Calculation solves the pairwise similarity comparison problem with the generated distributed inverted indexes.

Stage 4. Near-duplicate detection identifies near-duplicate threads based on the calculated similarities among Q&A threads in different parts.

In Stage 1, we try to use several types of signatures extracted from different meta-information to partially overcome the problem of word-overlap limitation. The efficient pairwise similarity comparison problem is captured in Stage 2 and 3. This section describes two algorithms for solving the similarity calculation problem with two kinds of distributed inverted index: *Term-based Index* and *Doc-based Index*. These two algorithms are described in turn. Both term-based and doc-based algorithms follow the unified framework. Based on the similarities among different parts, the near-duplicate detection is done in Stage 4.

4.1 Upper Bound of Jaccard Similarity

Jaccard coefficient is widely used to measure the similarities among sets. In this work, we use it to measure the similarities among forum threads, which are represented by a group of signatures. $J(A,B) = \frac{|A \bigcap B|}{|A \bigcup B|}$ is the default Jaccard similarity defined for two sets. Theobald et al. described the bounds of it (Theobald et al., 2008), which is

$$\begin{aligned} J(A,B) &= \frac{|A \bigcap B|}{|A \bigcup B|} = \frac{|A \bigcap B|}{|A| + |B| - |A \bigcap B|} \\ &\leq \frac{\min(|A|,|B|)}{\max(|A|,|B|)} \end{aligned} \quad (1)$$

For $|A| \leq |B|$, we can get:

$$J(A,B) \leq \frac{|A|}{|B|} \quad (2)$$

With the upper bound and vector representation of threads, we observe that near-duplicated threads have the similar length. If

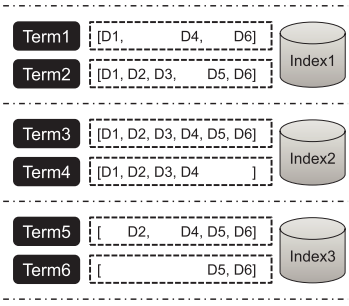

Figure 2: Example of term-based distributed index

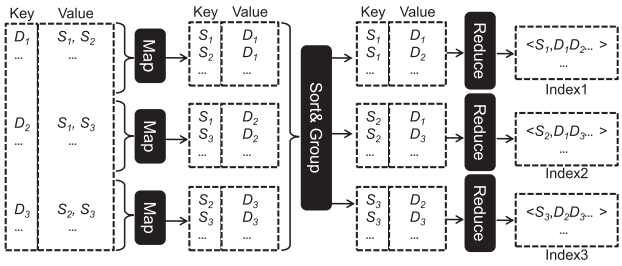

Figure 3: Data flow of term-based distributed index generation

we set the threshold to τ, thread pairs where $\frac{|A|}{|B|} \leq \tau$ can be safely removed.

Inspired by Eq.2, we further propose a more tightly upper bound of Jaccard similarity as follows:

$$J(A,B) = \frac{|A \bigcap B|}{|A \bigcup B|} = \frac{|A| - |A-B|}{|B| + |A-B|} \leq \frac{|A| - |C|}{|B| + |C|}, C \subseteq A - B \quad (3)$$

It can be easily proofed that this bound 3 is tighter than the upper bound of Eq. 2. If the set C can be detected, more calculation can be reduced with it. In this work, both of the upper bounds are used to reduce the size of intermediate data. In algorithm 1, the Eq.2 is used. While the more tightly bound Eq.3 is used in the algorithm 2.

4.2 Term-based approach

Inverted index is an index data structure storing a mapping from terms (signatures in this work) to its documents. In order to distributedly calculate the pairwise similarity, the inverted index should be split into multiple parts, which can be parallelly processed in the further steps. The term-based distributed index splits the inverted index according to the rows. Each partition of the distributed index only contains a number of terms and their corresponding posting list. Figure 2 shows an example of it. In the figure, "Index 1" contains posting lists of "Term 1" and "Term 2". Other terms are separately stored in "Index 2" and "Index 3".

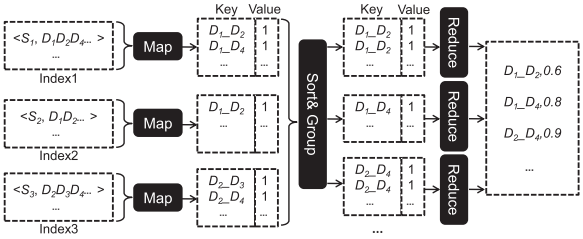

Figure 4: Data flow of similarity calculation based on term-based distributed index

Algorithm 1 Pseudo-code of term-based algorithm

MAP$(S_i, [D_1, D_2, ...])$

1: **for all** $D_i \in [D_1, D_2, ...]$ **do**
2: **for all** $D_j \in [D_1, D_2, ...]$ **do**
3: **if** ($|D_i| \geq |D_j|$ **and** $\frac{|D_j|}{|D_i|} \geq \tau$) **or** ($|D_i| \leq |D_j|$ **and** $\frac{|D_i|}{|D_j|} \geq \tau$) **then**
4: EMIT$(\langle D_i, D_j \rangle, S_i)$
5: **end if**
6: **end for**
7: **end for**

REDUCE$(\langle D_i, D_j \rangle, [S_1, S_2, ...])$

1: **if** $\frac{|D_i \bigcap D_j|}{|D_i \bigcup D_j|} \geq \tau$ **then**
2: EMIT$(\langle D_i, D_j \rangle)$
3: **end if**

The data flow of term-based distributed index generation using MapReduce is shown in Figure 3. Input to the distributed indexer consists of thread ids as key and extracted signatures as terms. In each mapper operation, all signatures are iteratedly processed. For each signature, a pair consisting of the signature id as key and the thread id as value is created. The mapper emits those key-value pairs as intermediate data. After grouping and sorting, thread ids which contain the same signature are grouped together. The reducer gets a part of key-value pairs (term and associate posting

list) as input and emits them as a partition of the distributed index.

Based on the term-based distributed index, the data flow of near-duplicate detection algorithm is shown in Figure 4. The input of the procedure *map* is the signature id (S_i) and associated postings list ($[D_1, D_2, ...]$, where D_i represents thread id). Inside each mapper, all candidate thread pairs which fit the the Eq. 2 , the upper bound of the Jaccard similarity, are emitted to the key-value pair ($\langle D_i, D_j \rangle, S_i$). After grouping and sorting, all signature ids belonging to the same thread pair are brought together. With the list, Jaccard similarity can be easily calculated. The procedure *reduce* takes the thread pair and corresponding list as input and emits the Jaccard similarity (the predefined threshold τ is used to reduce the size of output). The pseudo-code of this algorithm is shown in Algorithm 1. The line 4 in the algorithm is based on the upper bound of Jaccard similarity and used to reduce the size of intermediate data.

However, in practical terms, the term-based method can not be directly used to process the collection which contains more than one million threads. Too many intermediate outputs will cause problem. In this work, we limit the maximum number of intermediate output as the approximation method, which is proposed by Lin (Lin, 2009). This approximation can improve the efficiency of the term-base algorithm, based on which the term-based method can process large collections. However the calculated similarities may not reflect the real similarities with this approximation method.

4.3 Doc-based approach

Different to the term-based distributed index, doc-based distributed index splits the inverted index according to the columns. Each partition of doc-based distributed index only contains a number of threads and their corresponding terms. Figure 6 shows an example of it. In the figure, "Index 1" contains terms which are contained in the "D_1" and "D_2"and their corresponding posting lists.

Figure 5 shows two kinds of doc-based distributed index generation data flows using MapReduce. Input to both of the distributed indexers is the same as the term-based one, which consists of thread ids as key and extracted signatures as terms. Figure 5(a) shows a standard inverted index generation procedure using MapReduce. Different with the standard one, only a partition of forum threads collection are input to the MapReduce job at each time. And the procedure is iterated over the entire collection. An alternative method is shown in Figure 5(b). The entire collection is processed with a MapReduce job. In each mapper operation, a partition of doc-based distributed index is generated and is written to the disk. No reducers are required in the job. Although the second approach is simple and no iteration is required, the size of the input collection is much smaller compare to the first one, because of the memory limitation.

Algorithm 2 Pseudo-code of doc-based algorithm

MAP$(S_i, [D_1, D_2, ...])$

1: **for all** $D_i \in InitializedIndex$ **do**
2: **for all** $D'_i \in InputIndex$ **do**
3: **if** ($|D_i| \geq |D'_i|$ **and** $\frac{|D'_i|}{|D_i|} \leq \tau$) **or** ($|D_i| \leq |D'_i|$ **and** $\frac{|D_i|}{|D'_i|} \leq \tau$) **then**
4: **continue**
5: **end if**
6: $C \leftarrow \emptyset$
7: $\delta \leftarrow 0$
8: **for all** $S_{ij} \in D_i$ **do**
9: **if** $S_{ij} \in D'_i$ **then**
10: $\delta \leftarrow \delta + 1$
11: **else**
12: $C \leftarrow C \bigcup S_{ij}$
13: **if** $\frac{|D_i|-|C|}{|D'_i|+|C|} \leq \tau$ **then**
14: **continue**
15: **end if**
16: **end if**
17: **end for**
18: $sim(D_i, D'_i) \leftarrow \frac{\delta}{|D_i|+|D'_i|-\delta}$
19: EMIT$(\langle D_i, D'_i \rangle, sim(D_i, D'_i))$
20: **end for**
21: **end for**

REDUCE$(\langle D_i, D'_i \rangle, sim(D_i, D'_i))$

1: EMIT$(\langle D_i, D'_i \rangle)$

The data flow of similarity calculation algorithm based on the doc-based distributed

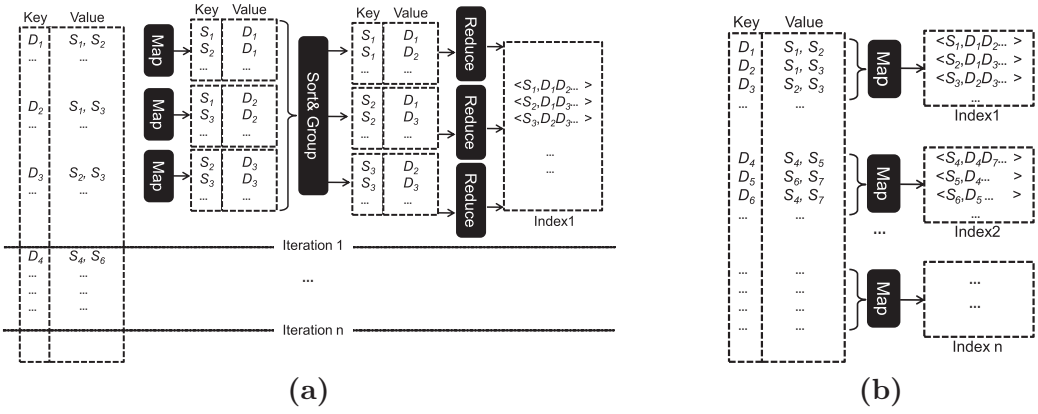

Figure 5: Data flow of doc-based distributed index generation

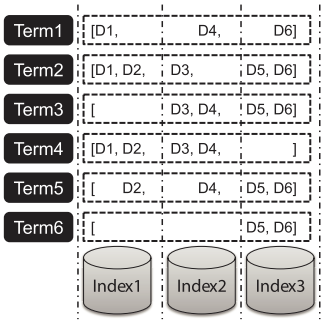

Figure 6: Example of doc-based distributed index

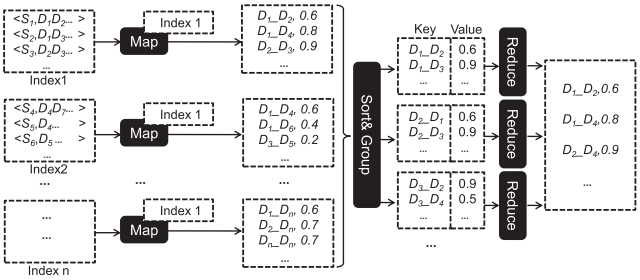

Figure 7: Data flow of one iteration of the similarity calculation based on doc-based distributed index

index is shown in Figure 7. The whole procedure should be iterated until all partitions of the distributed index have been processed. At the each iteration, all mappers are initialized with a same partition of distributed index (E.g. "Index 1" in the figure). The input of the procedure *map* is the signature id (S_i) and associated postings list ($[D_1, D_2, ...]$, where D_i represents thread id). Different mappers will get different partitions of the index as input. Inside each mapper, a inverted-index based algorithm is used to calculate the similarities between the initialized index and the input index. The pseudo-code of this algorithm is shown in Algorithm 2.

4.4 Near-Duplicate Detection

Based on the definition of near-duplicate thread, the final stage, near-duplicate detection, tries to combine the similarities calculated through the previous steps and other information extracted from threads to determine whether threads are near-duplicate or not. Obviously, most of the popular machine learning methods (e.g. Support Vector Machines, Maximum Entropy, AdaBoost, and so on) can be used to solve the problem with the calculated similarities and extracted information as feature sets. However, for simplification, in this paper we use linear combination of different parts' similarities and a predefined threshold τ to do that. If the similarities $S(T_i, T_j)$ calculated through the Eq. 4 are bigger than τ, those Q&A pairs are emitted as near-duplicates.

$$S(T_i, T_j) = \theta_t S_T(T_i, T_j) + \theta_d S_D(T_i, T_j) + \theta_a S_A(T_i, T_j), \quad \text{where } \theta_t + \theta_d + \theta_a = 1, and\ \theta_t, \theta_d, \theta_a \geq 0 \tag{4}$$

S_T,S_D, and S_A respectively represent similarities calculated through different parts. θ_t, θ_d, and θ_a represent the weights of similarities between different parts, and are roughly tuned based on a small number of manually labeled corpus.

Table 1: Summarization of F_1 scores of different signatures in different parts

Signature	Question	Description	Answer
2-Shingles	59.33%	**99.54%**	90.74%
3-Shingles	**60.29%**	**99.54%**	**95.05%**
4-Shingles	58.33%	**99.54%**	91.58%
Winnowing($k = 3, w = 3$)	52.06%	97.24%	85.30%
Winnowing($k = 5, w = 3$)	52.62%	97.16%	87.69%
I-Match([0.10, 0.90])	53.59%	95.31%	44.16%
I-Match([0.20, 0.80])	51.82%	93.95%	44.95%
SpotSigs(# Antecedent=50)	20.77%	13.70%	74.56%
SpotSigs(# Antecedent=100)	34.06%	18.75%	75.54%

5 EXPERIMENTS

In this section, we detail experimental evaluations of the proposed method on both effectiveness and efficiency. We crawled a portion of the Baidu Zhidao, resulting in a local archive of about 28.6 million questions, all of which have user-labeled "best answers". The corpus covers more than 100 categories. From this set we manually selected 2000 question-answer threads as "Gold-Standard". Four individuals were asked to label the duplications among question-answer threads. Meanwhile, the duplications between threads in different parts have also been manually judged. The average kappa statistic among them is around 73.2%, which shows good agreement.

We ran experiments on a 15-node cluster. Each node contains two Intel Xeon processor E5430 2.66GHz with four cores, 32GB RAM, and 128GB hard disk. We used an extra node for running the master daemons to manage the Hadoop job and distributed file system. Software stack of the experiments used Java 1.6 and Hadoop version 0.20.2. All the MapReduce jobs were implemented in Java for Hadoop framework. HDFS was used to provide the distributed storage.

5.1 Comparison of Signatures

In order to compare the performance of different signatures in the Q&A domain, the "Gold-Standard" serves in the following experiments, since these near-duplicates have been manually judged by humans. Performance comparison of different signatures with various parameters in question, description, and answer parts is shown in this section.

Table 1 summarizes the best result of different signatures in question, description and answer parts (the main parameters are shown in the bracket). We observe that 3-Shingles achieve the best result in all three parts. However, the performances of 2-Shingles, 4-Shingles are comparable. I-Match and SpotSigs achieve worse result than other methods. The possible reasons are given in the previous of the section. We also observe that although all signature extraction methods are highly tunable, the results are stable with a large range of parameters' values. With all different signatures, the performance of question part is not very satisfactory. After carefully examining the results, we observe that questions with same meaning often differ significantly in syntax and language. In (Jeon et al., 2005; Muthmann et al., 2009), it is also mentioned that two threads that have the same meaning may use different wording. Most of the signatures used for near-duplicate detection can not process this kind of issue very well. We think that it is also the main reason of the low performance of I-Match. The best F_1 score of question part is only 60.29%, however, the precision can achieve 96.46%. It indicates that although not all the duplications can be detected, most of the duplications we extracted are right. For answer part, since the average length is more than 200 characters, the performance of it is satisfactory.

5.2 Performance of Near-Duplicate Detection Stage

To investigate the parameters used in the Eq.3 and the threshold τ, hill climbing algorithm is used for tuning the four parameters. We randomly selected 100 initial seeds. Table 2 shows a number of F_1 score with different parameters. The best F_1 score of the near-duplicate thread detection is 66.22% (P=94.98%, R=50.83%) in this domain with parameters $\theta_t = 0.4$, $\theta_t = 0.2$, $\theta_t = 0.4$, and $\tau = 0.5$. Based on the definition of near-duplicate threads, question parts should have the same intuition. Because of this, the final detection performance is highly impacted by the performance of question part. More natural language processing techniques would improve the detection recall. While it may also consume much more computational time.

5.3 Term-based V.S. Doc-based

To judge and compare the efficiency and scalability of doc-based and term-based distributed

Table 2: Performance of near-duplicate detection stage with different parameters

θ_t	θ_d	θ_a	τ	P	R	F_1-Score
0.2	0	0.8	0.1	10.73%	**96.90%**	19.32%
0.3	0.6	0.1	0.1	17.30%	69.01%	27.66%
0.5	0.3	0.2	0.2	24.82%	62.40%	35.51%
0.4	0.5	0.1	0.2	35.88%	54.34%	43.22%
0.7	0.1	0.2	0.3	46.49%	57.44%	51.39%
0.6	0.2	0.2	0.3	65.01%	56.82%	60.64%
0.5	0.3	0.2	0.3	77.26%	54.75%	64.09%
0.4	0.2	0.4	0.5	**94.98%**	50.82%	**66.22%**
0.4	0.3	0.3	0.4	89.93%	51.65%	65.62%
0.4	0.4	0.2	0.3	40.50%	53.31%	46.03%
0.6	0	0.4	0.5	80.24%	54.55%	64.94%

index, it is best to evaluate them in a real-world data set. Figure 8 summaries the efficiency comparison between the two distributed indexing methods. 3-Shingles method is used to extract signatures from all three parts of the input corpus. In near-duplicate detection stage, parameters is set as follows: $\theta_t = 0.4$, $\theta_t = 0.2$, $\theta_t = 0.4$, and $\tau = 0.5$. The x-axis represents the size of the corpus, the total number of processing time is represented in y-axis. The doc-based method is much efficient than the term-based method when the size of the corpus is smaller than 2 million. Because of the approximation used in the term-based method, the slope of the term-based method's curve is lower than doc-based method ones when the size of the corpus is bigger than 2 million. However, the approximation also made the impact on the number of near-duplicates extracted by term-based method to be much lower than the doc-based method.

Figure 9 shows the number of detected near-duplicate threads through term-based method versus doc-based method. The total number of threads which are near-duplicate with one or more threads is shown in the figure. We observe that there are about 0.473 million (15.78%) threads which can be found one or more near-duplications in the corpus. We observe that although the corpus we used in this experiment only contain 3 million threads, 4.25 million of near-duplicate threads pairs are

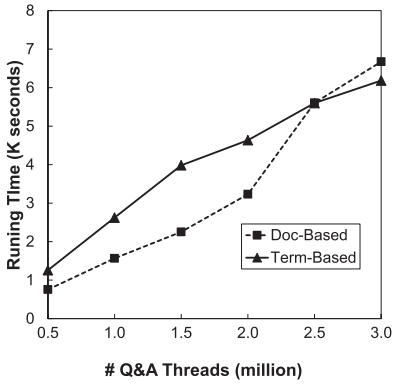

Figure 8: Term-based V.S. Doc-based in Efficiency

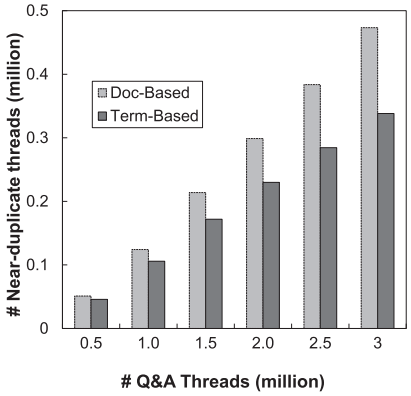

Figure 9: Number of detected Near-duplicated threads

extracted from it. It means that some popular questions have a huge number of near-duplicated ones.

6 CONCLUSION AND FUTURE WORK

In this paper we studied the problem of near-duplicate detection for Q&A forums. We proposed two distributed inverted index methods to calculate similarities in parallel using MapReduce framework. We defined the near-duplicate Q&A thread and used the evaluated signatures, parallel similarity calculating and a liner combination method to extract near-duplications. Experimental results in the real-world collection show that the proposed method can be effectively and efficiently used to detect near-duplicates. About 15.78% of Q&A threads contain more than one near-duplicates in the collection.

Abstract

In this paper, we formalize the task of finding a knowledge base entry that a given named entity mention refers to, namely entity linking, by identifying the most "important" node among the graph nodes representing the candidate entries. With the aim of ranking these entities by their "importance", we introduce three degree-based measures of graph connectivity. Experimental results on the TAC-KBP benchmark data sets show that our graph-based method performs comparably with the state-of-the-art methods. We also show that using the name phrase feature outperforms the commonly used bag-of-word feature for entity linking.

1 Introduction

Entity linking is the task of computationally mapping a named entity mention in given context to the intended entry in a referential knowledge base. Large-scale knowledge bases have been proved to be valuable for many natural language processing applications such as question answering (MacKinnon and Vechtomova, 2008), information extraction (Paşca, 2009), information retrieval (Santamaría et al., 2010), coreference resolution (Ponzetto and Strube, 2007) and word sense disambiguation (Fogarolli, 2009). And entity linking is a natural way to access these knowledge bases.

Mention ambiguity is prevalent in language use. For example, in the following two sentences

- "Mount Bromo is one of Java's most popular tourist attractions."
- "Candidates must have technical skills in JSP, ASP, Java, HTML."

the named entity mention *Java* refers to *an island in Indonesia* and *a programming language* respectively.

In this paper, we focus on the named entity disambiguation in entity linking and approach this problem from a graphical perspective. We begin by building a graph in which nodes correspond to the context around the target mention and the candidate entries from the knowledge base, whereas directed edges represent the reference dependency between nodes. Then we calculate the "importance" score for each candidate node and assign the most "important" candidate to the target mention. Here we compare three degree-based measures of graph connectivity that assess the node importance. Through experiments performed on benchmark data sets, we show that the graph-based method achieves comparable performance to the state-of-the-art in the entity linking task. The result also indicates that to build linkage between nodes, name phrase (i.e. n-gram of name words) performs better than the traditional bag-of-word feature. Our contributions are threefold: introducing an entity linking method under the graph-based framework, a novel in-degree graph connectivity measure for entity disambiguation, and an empirical comparison of the bag-of-word and the name phrase feature.

This paper is organized as follows. Section 2 gives a brief overview of the related work. Section 3 introduces the Wikipedia encyclopedia and our graph-based method. Section 4 describes each components of our entity linking system, especially the disambiguation algorithm. Experimental settings, results and analysis are presented in

2 Related Work

Linking name mentions to knowledge base entries has attracted more and more attentions in these years. As an open available resource, Wikipedia is a natural choice of knowledge source for its large scale and good quality. Early work mainly focused on the usage of the structure information in Wikipedia. Bunescu and Pasca (2006) trained a taxonomy kernel on Wikipedia data to disambiguate named entities in open domain. Cucerzan (2007) integrated Wikipedia's category information in their vector space model for named entity disambiguation. Mihalcea and Csomai (2007) extracted sentences from Wikipedia, regarding the linking information as sense annotation, and used supervised machine learning models to train a classifier for disambiguation. Similarly, Milne and Witten (2008) adopted a learning approach for the disambiguation in Wikipedia. Their method is to balance the prior probability of a sense with its relatedness to the surrounding context.

Recently, an Entity Linking task in the Knowledge Base Population (KBP) track evaluation (McNamee and Dang, 2009) provided a benchmark data set. The first KBP track was held at the Text Analysis Conference (TAC)[1], aiming to explore information about entities for Question Answering and Information Extraction. The knowledge base in the evaluation data is also based on Wikipedia. Many information retrieval based models have been proposed on this data set. For example, Dredze et al. (2010) presented a maximum margin approach to rank the candidates. They combined rich features including Wikipedia structure and entity's popularity. Zheng et al. (2010) proposed learning to rank models for the entity linking problem and obtained high accuracy.

One of the most important component of entity linking is to compute the relatedness between entities. Some of the previous works use vector space model and calculate the cosine similarity over the bag-of-word feature vectors (Mihalcea and Csomai, 2007) or the category feature vectors (Cucerzan, 2007). Others take into account citation overlap of the relevant Wikipedia entry (Milne and Witten, 2008; Kulkarni et al., 2009; Radford et al., 2010), which implies the co-occurrence of the entities. These methods work when significant overlap can be observed between the entities or their features. For example, the co-occurrent frequency of *Java (programming language)* and *HTML* is higher than *Java (island)* and *HTML* in the Wikipedia articles. Hence the *Java* probably means the programming language rather than the island when its context contains *HTML*. However, entities like *human* and *homo* are seldom cited in the same article. Although they are highly related. In fact, their relatedness can be easily captured through their mutual citations. In this paper, we compute the entity relatedness by using the direct citation in the Wikipedia.

Graph-based approaches are proved useful in the research of word sense disambiguation. Sinha and Mihalcea (2007) compared several measures of word semantic similarity and algorithms for graph centrality for word sense disambiguation. They found that the performances of their graph-based algorithms are competitive to the unsupervised state-of-the-art ones. Navigli and Lapata (2009) investigated several graph connectivity measures for word sense disambiguation. They found the best measures are degree and PageRank (Brin and Page, 1998). In this paper, we approach entity linking by leveraging graph-based methods.

3 Graph-based Entity Linking

As defined in the TAC-KBP track, the input of the entity linking task includes:

- a Knowledge Base $KB \subseteq \mathcal{E}$, where $KB = \{e_i | 1 \leq i \leq n\}$, e_i is the ith entity in *KB* and $\mathcal{E}$ is the set of all entities around the world, and
- a query that consists of a mention string $m \in \mathcal{L}$ and the background document $D \in \mathbb{D}$ it appears in, where $\mathcal{L}$ is a lexicon which is composed of words and phrases, and $\mathbb{D}$ is a collection of documents.

The output is

- the entity e_i that m refers to in the context of D, where $e_i \in KB$, and
- `NIL` if such an entity is absent from the *KB*.

We formalize the task as a function:

$$\textsc{Link}(m, D) = \begin{cases} e_i & \text{if } 1 \leq i \leq n \\ \texttt{NIL} & \text{otherwise} \end{cases}$$

[1] http://www.nist.gov/tac

where $e_i = \text{ENTITY}(m, D)$ and

$$\text{ENTITY} : \mathcal{L} \times \mathbb{D} \rightarrow \mathcal{E}$$

is the function to find the corresponding entity for a query.

In our experiments we use Wikipedia as the knowledge base. In the following, we first briefly introduce the structure of Wikipedia. Next we describe our entity linking method. Note that although we use the Wikipedia in the experiments, our method is not limited to this knowledge source.

3.1 Wikipedia

Wikipedia is an online encyclopedia written by volunteers around the world. Its English version contains more than 3,400,000 articles [2]. Each article in the Wikipedia consists of a unique title and a main body which includes descriptions of the concerned entity. Articles are usually titled by the formal name of the entities, which sometimes are suffixed with a discriminative string on condition that another entity also share the same name. In the latter situation, the namesakes will be listed in a **Disambiguation Page**[3]. As an example, consider two entities of the same name *Java*, "the most populous island in Indonesia,", and "an object-oriented high-level programming language." In the page of *Java (disambiguation)*, the corresponding titles are represented as:

1. *Java (island)*,
2. *Java (programming language)*.

The main body of an article consists of descriptive words for the entity. In this text, many related entities are mentioned and some of the entities' titles are further wrapped with brackets to link to the corresponding articles with the aim of facilitating the access to those articles. For instance, in the following fragment of the article *Java (programming language)*,

> "Sun relicensed most of its Java technologies under the [[GNU General Public License]].[4]"

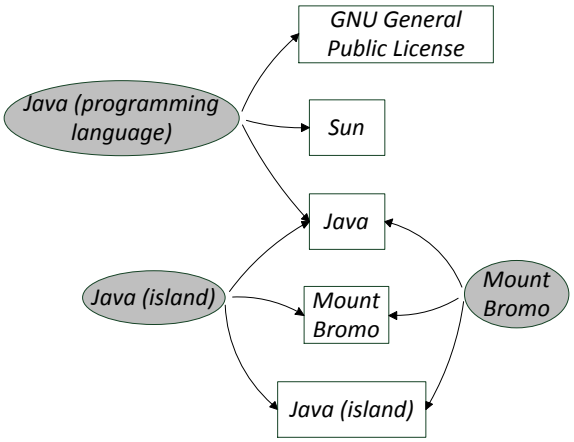

Figure 1: An example of the Wikipedia graph.

The entities: *Sun*, *Java*, and *GNU General Public License* are mentioned, where the square brackets "[[]]" will generate a cross reference link to the article of *GNU General Public License*.

We can view the Wikipedia as a graph with two types of nodes: the article nodes and the name nodes. A directed edge from an article node to a name node represents that the name appears in the article.

Figure 1 shows a partition of the Wikipedia graph. In this graph, the dark gray ellipse nodes correspond to articles which we tag with their titles and the white square nodes correspond to name strings. *Sun*, *Java*, and *GNU General Public License* are mentioned in the article of *Java (programming language)*, and hence we draw directed edges from the article to them.

3.2 The Disambiguation Method

In this paper, we approach to the entity linking task in two stages. The first stage is to find the candidate entities to the target name string. And the second stage is to estimate the "importance" of each candidate according to the context of the mention and select the most "important" one. Here we focus on the second stage. The steps of our candidate extraction will be described in section 4. In this section, we will introduce a disambiguation method based on out-degree and in-degree measures of graph connectivity .

We build a graph $G = (V, E)$ corresponding to the context where the target name appears in. For the out-degree connectivity measure, the node set in the graph consists of the names that are mentioned in the context and the articles of the corre-

[2] Throughout our experiment, we will use the English version of Wikipedia snapshotted in January, 2010.

[3] See: http://en.wikipedia.org/wiki/Wikipedia:Disambiguation for detail

[4] In our experiment the main body text we use is the source of the article, which is encoded in the wiki markup language. See: http://en.wikipedia.org/wiki/Wiki_markup

Figure 2: An example of the graph-based named entity disambiguation method.

sponding candidates (i.e. context: name nodes and candidate: article nodes). There exists a directed edge from an article node to a name node when the name is mentioned in the article. The article node of the highest out-degree is considered as the most "important" one in this graph and the corresponding entity to this article node is then selected for the queried mention. For the in-degree measure, the node set consists of the names of the candidate entities and the articles of the context entities that mentioned in the context (i.e. context: article nodes and candidate: name nodes). There is an edge that linked to a candidate name node when a context article contains that name. This time name node with the highest in-degree is considered most "important" and we assign the corresponding entity of this name node to the queried mention.

Here we give a simplified example. Consider of a context fragment:

> "Mount Bromo is one of Java's most popular tourist attractions."

and candidates of a query name *Java*:

1. *Java (island)*,
2. *Java (programming language)*.

The graphs for the out-degree and the in-degree measures are illustrated in Figure 2. In Figure 2(a) we can see the article nodes are *Java (island)* and *Java (programming language)*, and the name nodes are *Mount Bromo*[5] and *Java*. The node of *Java (island)* has 2 outer links which is higher than any other nodes and therefore *Java (island)* is assigned to the query *Java*. In Figure 2(b) *Java (island)* will also be selected because its in-degree is the highest.

[5] Anchor text *Bromo* appears in the Wikipedia page of *Java (island)*. In the source of the article, we can find the target *Mount Bromo*

Formally, the above method can be represented as to find the node:

$$u^* = \arg\max_u imp(u). \quad (1)$$

For the out-degree measure,

$$imp(u) = deg_{out}(u) = |(u, v) \in E : v \in V|.$$

And for the in-degree measure,

$$imp(u) = deg_{in}(u) = |(v, u) \in E : v \in V|.$$

We can combine the out-degree and in-degree measures and get:

$$imp(u) = (1-\lambda)ndeg_{out}(u) + \lambda ndeg_{in}(u), \quad (2)$$

where

$$ndeg_{out}(u) = \frac{deg_{out}(u)}{\sum_{u \in V} deg_{out}(u)}$$

and

$$ndeg_{in}(u) = \frac{deg_{in}(u)}{\sum_{u \in V} deg_{in}(u)}$$

are normalized degree scores. In our experiment, when there are two tied candidates, we choose a random one.

4 An Entity Linking System

In this section, we will introduce an entity linking system. This system includes 2 components: candidate selection and disambiguation, in which the disambiguation part is based on the graphical method we described in section 3.2.

4.1 Candidate Selection

As described in (Dredze et al., 2010), usually an entity has three kinds of name variations, including acronyms (e.g. *American Broadcasting Company* vs. *ABC*), aliases (e.g. *Robert Gates* vs. *Bob Gates*), and alternate spellings (e.g. *Air Macau* vs. *Air Macao*) etc.

1) For an acronym, we try to find its full form in the context through the following rules:

- If the acronym is bracketed, we extract the name phrase immediately before the capitalized letter nearby (e.g. *"... The Mexican Football Federation (FMF) on Monday ..."*).
- If the acronym is followed by a bracket, we extract the phrase in the bracket (e.g. *"... From the PRC (People's Republic of China) we get much benefit. ..."*).
- Or else, we just find the phrase in the context with the same capitalized letter as the acronym (e.g. *"... he told the Australian Broadcasting Corporation. ..."* vs. *ABC*).

When the full form of the acronym is found, we substitute the target mention string with its full form.

2) The Wikipedia provides the most common alias names for entities through the **Redirect Pages**[6], which maps an alias to the corresponding article titled with the formal name. By this mechanism we can access the candidate with the formal name from an alias name (e.g. *Bob Gates* $\rightarrow$ *Robert Gates*), or find several candidates listed in a disambiguation page (e.g. *Gates* $\rightarrow$ *Gates (disambiguation)*).

3) However, name variations which are not included in the Wikipedia's redirect pages (e.g. *Air Macao*) could not be found by the above function. We invoke web search engines to find the most relevant term of the name string in the Wikipedia using the "within a site" search function. We construct and submit a search query like "*Air Macao site:en.wikipedia.org*" and extract the first returned entity (i.e. *Air Macau*) as a candidate.

4.2 Disambiguation

To build a graph for the disambiguation, we need to extract names from the context of the query (either as the name node or the article node). We use a segmentation technique which is inspired from a Chinese word segmentation algorithm, the forward maximum matching algorithm (Guo, 1997) on the context to find all the names which are included in the Wikipedia title list (i.e. all the name phrases in our Wikipedia graph are the Wikipedia article titles). This algorithm prefers to find the longest names that match with the string. Here we refer the context name as neighboring name and the corresponding entity as neighboring entity of the target name string.

For the out-degree measure (as described in Section 3.2), we search for each neighboring name in the article of each candidate. If there is a match, we draw a directed edge from the candidate node to the neighboring name node. This procedure can be represented as Algorithm 1, where C_a is the article node set of the candidate entities, N_n is the node set of the neighboring names, and $Article(a)$ is the main body text of an article node a.

Algorithm 1 Out-degree measure based graph construction

Require: C_a and N_n
Ensure: Graph $G = (V, E)$

$V := C_a \cup N_n$
$E := \emptyset$
for all $c \in C_a$ **do**
  for all $n \in N_n$ **do**
    if $n \in Article(c)$ **then**
      $E := E \cup (c, n)$
    end if
  end for
end for
return (V, E)

Similarly, for the in-degree measure we build the graph in Algorithm 2, where C_n is the name node set of the candidate entities and N_a is the article node set of the neighboring entities.

Algorithm 2 In-degree measure based graph construction

Require: C_n and N_a
Ensure: Graph $G = (V, E)$

$V := C_n \cup N_a$
$E := \emptyset$
for all $c \in C_n$ **do**
  for all $n \in N_a$ **do**
    if $c \in Article(n)$ **then**
      $E := E \cup (n, c)$
    end if
  end for
end for
return (V, E)

For the combined measure we build both of the above graphs. And then we normalize the measures and combine them with a λ parameter (see

[6]See http://en.wikipedia.org/wiki/Wikipedia:Redirect for detailed instructions

Equation 2) for each candidate node.

When the graph is constructed, we then select the candidate node with the maximum out-degree or in-degree or the combined degree based measure. In our method, if the maximum out-degree or in-degree of the candidate nodes is zero, which means for all the candidate nodes there is no edges out or in, then the system will return `NIL` to assert the corresponding entity is not included in the knowledge base.

5 Experiment

5.1 Data set

We evaluated our disambiguation method on two benchmark data sets. Specifically, we use the entity linking data from TAC-KBP track in 2009 (McNamee and Dang, 2009) and the same track in 2010 (Ji et al., 2010).

The TAC-KBP 2009 data set includes 3,904 queries for 560 distinct entities and a track knowledge base (TKB) which contains 818,741 entities. The knowledge base were derived from a snapshot of English Wikipedia in October, 2008. Each query is comprised of a target name mention and a context document where the name occurs. These documents are mainly newswire documents. Over a half (2229) of the queries could not be linked to any entity in the TKB and should be tagged with `NIL`.

The TAC-KBP track in 2010 inherit the knowledge base used in the TAC-KBP 2009 and its test data set contains 2,250 queries. Similar to the track in 2009, Over a half (1230) of the entities are absent from the knowledge base. In this data set, a third (750) of the context documents are from weblog texts and the rest are from newswire documents.

In our system, we use Wikipedia as the knowledge base (KB). The result of our system can be easily mapped to the TKB entries because the KB is a superset of the TKB. In the entity linking, if the selected entity in the Wikipedia KB is not included in the TKB, our system will return `NIL`. We used the snapshot of English Wikipedia in January, 2010 and employed a Java based application programming interface (Zesch et al., 2008) to access this archive. The Wikipedia dump is open available in the web site: http://dumps.wikimedia.org/enwiki/.

TAC-KBP track	2009	2010
candidates/query	6.36	4.55
coverage	0.8083	0.7862

Table 1: Data sets and the result of the candidate selection.

# sentence	1	3	5	7	9	all
# neighbor	6	10	14	16	18	36

Table 2: The average number of the neighboring names for each query with different context window sizes in the TAC-KBP 2009 data set.

5.2 Candidate Coverage

As a result of the candidate selection (see Section 4.1), we obtained 6.36 candidates for each query on average from TAC-KBP track 2009 and 4.55 from TAC-KBP track 2010. In order to isolate the impact of the disambiguation method, we evaluated the coverage of the candidate set, which is the percentage of the intended queries that fall into the candidate set. Formally,

$$coverage = \frac{\sum_{q \in Q} |\{e_q \in C_q \cap \textit{TKB}\}|}{\sum_{q \in Q} |\{e_q \in \textit{TKB}\}|},$$

where Q is the set of the queries, e_q is the corresponding entity for the query q, C_q is the candidate entity set of q, and *TKB* is the track knowledge base, which is a set of entities here. In Table 1, we show the result of the candidate selection for the two data sets.

5.3 Entity Linking

We segment the context document into word or name phrase fragments and filter out stop words (e.g. *about*, *have*, *the*, etc.). In order to evaluate our graph-based method in different scales, we select nodes of neighboring entities from these fragments in several context window sizes around the target mention name: the sentence where the target name appears in, plus the immediately adjacent sentence before and after the sentence containing the target name, and plus the adjacent two sentences before and after, etc. From Table 2 we can see that in the data set of TAC-KBP 2009, the average number of the neighbor nodes per query we extracted increases as the context range increases.

Figure 3 shows the micro-averaged accuracies of our graph-based method on the TAC-KBP 2009

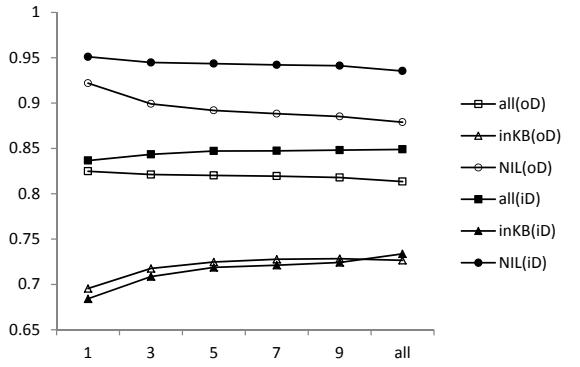

Figure 3: Accuracies for the out-degree based algorithm (oD) and the in-degree based algorithm (iD) on TAC-KBP 2009 data with different number of sentences around the target name mention as context.

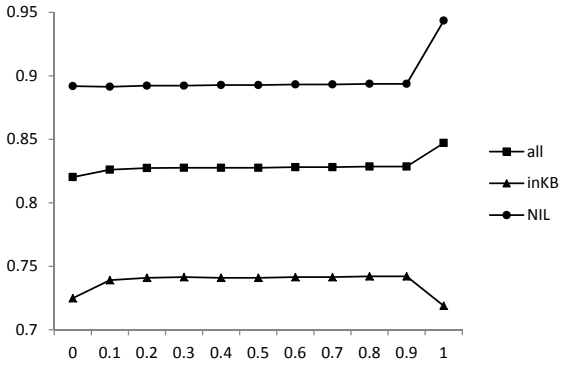

Figure 4: Accuracies for the combined measure with the λ parameter.

data set. Our evaluation metric includes the accuracy of all queries (all), the accuracy of the queries that are in KB (inKB), and the accuracy of identifying the out-of-KB entities (NIL). The horizontal axis is the number of the sentences around the target mention name (i.e. context window size), where "all" means that all the sentences in the document are included. From this figure, we can see that the inKB accuracies of the out-degree measure and the in-degree measure increase and portray a similar trend as more neighbor nodes imported. On the contrary, the NIL accuracies decrease and the overall accuracies have no obvious changes. The accuracies of the two measures for the inKB queries are very close, but for the NIL queries the in-degree measure outperforms the out-degree significantly (z test with p=0.01). This results in that for all queries the accuracies of the in-degree measure (i.e. all(iD)) are higher than the out-degree measure (i.e. all(oD)) in all the context ranges. We find that among the candidate nodes for each query, more than 2 nodes have non-zero out-degree on average, whereas less than 0.5 node has non-zero in-degree, which means that the in-degree measure returns more NIL entities, resulting in higher precision on NIL queries in this data set.

We combine the out-degree measure and the in-degree measure through Equation 2. The system performance with the λ parameter is illustrated in Figure 4. Here we set the context window size as 5. Note that when $\lambda = 0$ or $\lambda = 1$, the method reduces to the pure out-degree measure or in-degree based measure. In Figure 4 we can see that for the non-trivial combination (i.e. $\lambda \neq 0$ and 1) the accuracies have no obvious changes with the λ parameter. The NIL accuracies of the combined method are nearly the same as the out-degree ones and significantly lower than the in-degree measure. For the inKB queries, the combined method performs better than the other two methods. For all queries, the accuracy of the combined method is lower than the in-degree but higher than the out-degree ones. The reason for the higher accuracy of the in-degree measure than the combined measure is that in the combined measure the candidates of zero score are fewer than that in the in-degree measure even if λ is near to 1. So that the accuracy for NIL queries of the combined measure is lower than the in-degree measure.

In Table 3 we show the results of our graph based method on TAC-KBP 2009 and TAC-KBP 2010 data set. A number of the state-of-the-art system results are compared. According to our experiment on TAC-KBP 2009 data set, here we set the context window size as 1 for the out-degree measure (oD), as "all" for the in-degree measure (iD) and as 5 for the linear combined measure (Comb.), and set $\lambda = 0.5$.

We list the results of the top 3 systems in the TAC-KBP track 2009 and 2010. Most of them used sophisticated feature or labeled data for training. On the contrary, our graph-based methods need no feature other than the named phrases. Besides, our system has few parameters to tune. Among these system results, our graph-based method with in-degree measure outperform-

	TAC-KBP 2009			TAC-KBP 2010		
Acc.	all	inKB	NIL	all	inKB	NIL
Rank 1	0.8217	0.7654	0.8641	0.8680	0.8059	0.9195
Rank 2	0.8033	0.7725	0.8264	0.8373	0.7520	0.9081
Rank 3	0.7984	0.7063	0.8677	0.8191	0.7373	0.8870
sLesk	0.8066	0.7075	0.8811	0.7938	0.7059	0.8667
oD	0.8248	0.6955	0.9219	0.8169	0.7059	0.9089
iD	0.8489	0.7337	0.9354	0.8240	0.7127	0.9163
Comb.	0.8276	0.7409	0.8928	0.8160	0.7402	0.8789

Table 3: System accuracies on TAC-KBP 2009 and 2010 data sets. Rank 1-3 are top 3 systems in the TAC-KBP track 2009 and 2010, sLesk is the simplified Lesk algorithm based system, oD and iD are the out-degree based and the in-degree based systems and Comb. is the system that combined the out-degree and in-degree measure.

s the best system in TAC-KBP 2009 significantly (z test, p=0.01) and can outperform the third rank system in TAC-KBP 2010.

Simplified Lesk algorithm (sLesk) (Lesk, 1986; Banerjee and Pedersen, 2002; Agirre and Edmonds, 2006) is a well-known disambiguation algorithm which is similar to our graph-based method with in-degree measure. This algorithm is usually used as the baseline for word sense disambiguation. The main idea of this algorithm is to find the sense, the glossary of which has the most overlap with the context of the target multi-meaning word. The difference between these two algorithms is that our method uses name phrases as the feature other than the bag-of-word feature used in sLesk. Here we set the context window size of sLesk the same as the out-degree measure. The result shows that on both data sets our method with out-degree measure outperforms the simplified Lesk algorithm by a significant margin (z test, p=0.05).

From the last three rows in Table 3 we can see that in our graph based methods, the in-degree measure performs best among the three measures for all queries. The combined measure has a higher accuracy in inKB queries. The high NIL accuracy of the in-degree measure makes it to be suitable for the task of identifying novel concepts such as knowledge base population.

6 Conclusion

In this paper, we presented a preliminary study of graph based method for entity linking. We evaluated three degree-based measures to find the most suitable entity node for the target name mention. Our experimental results on two benchmark data sets show that our simple but effective method performs comparably to the sophisticated state-of-the-art methods and the in-degree measure outperforms the other two measures.

Based on the comparison between the simplified Lesk algorithm and our out-degree based method, we also conclude that the name phrase feature is better than the common used bag-of-words.

Abstract

This paper addresses the problem of related entity extraction and focuses on extracting related persons as a case study. The proposed method builds on a search engine. Specifically, we mine candidate related persons for a query person q using q's search results and the query logs containing q. The acquired candidates are then automatically rated and ranked using a SVM regression model that investigates multiple features. Experimental results on a set of 200 randomly sampled query persons show that the precision of the extracted top-1, 5, and 10 related persons exceeds 91%, 90%, and 84%, respectively, which significantly outperforms a state-of-the-art baseline.

1 Introduction

Facilitating efficient navigation in the knowledge space is essential to satisfying the current Web search demands. Named entities are vital building blocks of such a space, and retrieving related entities provides an efficient way of navigation. Related entity extraction refers to mining from text resources named entities with certain relationships between them, e.g. *person-affiliation* and *organization-location*. To this end, great efforts have been made recently in both academic (Banko et al., 2007; Wu and Weld, 2010) and industry (Zhu et al., 2009; Shi et al., 2010) circles.

A wide range of NLP applications could benefit from the high-quality repository of related entities. For query suggestion in Web search and e-business, given a query concerning some entity e, one can suggest entities related to e, in which users may also have interest. This could be regarded as a remarkable complement to the current techniques suggesting queries that merely contain the entity e or are similar in wording with e (Boldi et al., 2009). In online encyclopedia (e.g. Wikipedia) construction, linking together related entities can facilitate the users for effective navigation. Additionally, related entity extraction also allows us to automatically construct social networks.

In this paper, we focus on related person extraction, though our proposed techniques can be extended to other types of entities. Here, we provide a comprehensive definition of related persons, which fall into the following four categories.

- **Persons with definite relationships.** The relationships in this category can be explicitly represented with definite concepts, e.g. *parent*, *friend*, *colleague*, etc. Most previous literature focuses on such definite relationships between persons (Brin,1998; Etzioni et al.,2005; Banko et al.,2007; Zhu et al.,2009).

- **Persons related in certain events.** In the second category, the related persons interact with the query person in certain events, such as *co-starring* in the same movie or *co-authoring* in the same scientific paper.

- **Persons with similar identities** may also be of interest. In the case of query recommendation, for instance, when users query some particular type of persons, such as *actors* or *singers*, it is highly informative to recommend other similar persons of the same type.

- **Persons having other relationships** with the query person that do not fall into the three main categories above. For instance, given a person q, characters played by q (an actor) in a movie or created by q (an author) in her fiction belong to this category.

Chiang Mai, Thailand, November 8 – 13, 2011.

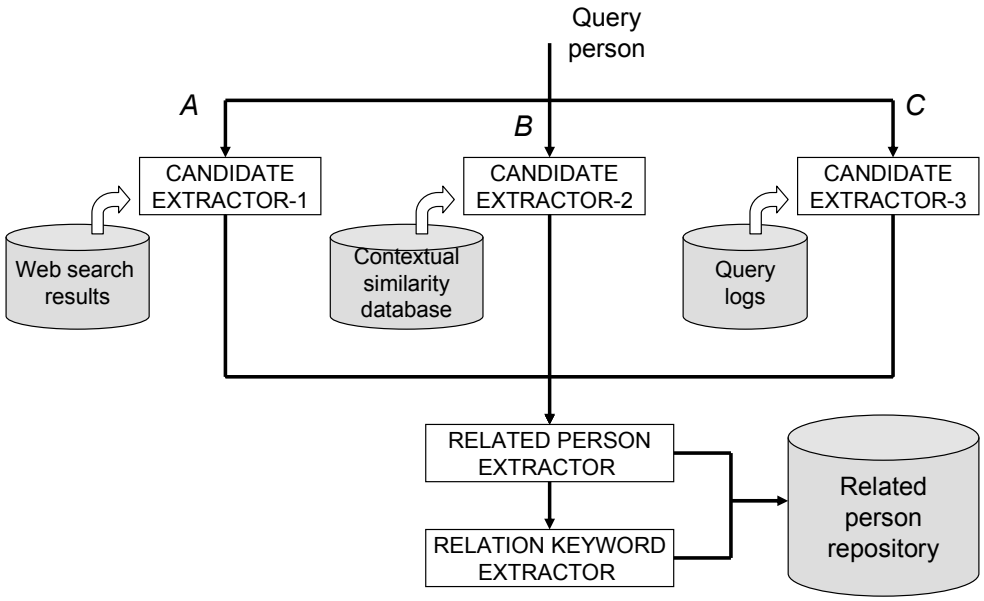

Figure 1: Overview of the proposed method.

Figure 1 illustrates the overview of our method. Our work is motivated by related entry suggestion in online encyclopedia construction and query suggestion in Web search. Thus, we are interested in finding related persons given a query person q. We employ a search engine SE to facilitate the extraction of related persons. In particular:

- We directly extract related persons from q's context in its search results returned by SE (flow A);
- Guided by distributional hypothesis (Harris, 1985), we mine q's related persons appearing in similar contexts (also collected from search results) with q (flow B);
- In addition, we exploit the query logs of SE, and extract q's related persons that co-occur with q in the same queries (flow C).

Extracting related persons aided by search engines has the following advantages. First, it can easily pinpoint web documents containing the query person, so that we can efficiently extract co-occurring persons and collect context information. Second, search results provided by search engines always contain the latest information, from which we can identify the newly emergent related persons. Third, the tremendous amount of search engines' indexed Web pages dramatically broadens the scope of the query person's context. Fourth, by exploiting search engine query logs, we can capture the related persons that the Web users are most interested in.

Using each of the three resources above, we aggregate up to 10 candidate related persons for each query person, and re-rank them with a Support Vector Machine (SVM) regression model that exploits multiple features, which finally outputs the top 10 related persons for each query person.

We evaluated our method with a set of 200 query persons randomly selected from Baidu[1] query logs, and compare it with Renlifang[2], a well known system developed for related person extraction. Experiment results show that our approach consistently outperforms Renlifang with a gap of 8%-13% in terms of averaged $Precision@K$. Specifically, 8.28% (0.915 vs. 0.845), 12.9% (0.9 vs. 0.797), and 9.73% (0.846 vs. 0.771) improvement has been achieved at rank 1, 5, and 10 respectively.

2 Related Work

Our work has its roots in both relation extraction and thesaurus construction. For relation extraction, the main approaches focus on binary relations between entities. These works use classifiers (Jiang and Zhai, 2007; Wang, 2008), extraction templates (Brin, 1998; Etzioni et al., 2005) or formulae (Agichtein and Gravano, 2000) to iden-

[1]http://www.baidu.com. Baidu is the largest commercial Chinese search engine in China.

[2]http://renlifang.msra.cn/

tify whether certain relations exist between pairs of entities. Supervised approaches view relation extraction as a classification problem, using either prior-designed feature sets (Jiang and Zhai, 2007) or kernel-based similarities (Wang, 2008) in classification. On the other hand, semi-supervised approaches avoid the heavy human labor in providing training examples by using bootstrapping techniques. For instance, DIPRE (Brin, 1998), Snowball (Agichtein and Gravano, 2000), and KNOWITALL (Etzioni et al., 2005) all adopt seed-pattern iterations to aggregate related entities.

Besides the works on traditional relation extraction, studies on open information extraction (Open IE) have emerged recently, which avoid pre-defining types of relations, and enjoy the capability of mining arbitrary types of semantic relations from both document collections (Shinyama and Sekine, 2006) and Web environment (Banko et al., 2007). Banko et al. (2007) build an Open IE system, TEXTRUNNER, that trains a Naïve Bayes classifier under the supervision of dependency rules. WOE (Wu and Weld, 2010) improves the precision and recall of TEXTRUNNER by mining clues from semi-structured texts in online encyclopedia and adopting different learning algorithms. Another descendent of TEXTRUNNER is the work of Mintz et al. (2009), which uses Freebase tuples as initial supervising information for training extractors. It is worth noting that building the learners is not mandatory. For example, Eichler et al. (2008) directly use syntactic patterns to perform Open IE.

There are also approaches that combine traditional relation extraction and Open IE together. Banko and Etzioni (2008) present H-CRF combining the two types of systems' output. StatSnowBall (Zhu et al., 2009) also performs both relation-specific extraction and Open IE. Like the technique proposed in (Banko and Etzioni, 2008), it formalizes the extraction problem as sequence labeling, but uses Markov Logic Networks (MLN) instead of Conditional Random Field (CRF).

In thesaurus construction, mainstream efforts related to our work consist of synonym / comparable entities clustering (Lin, 1998; Pantel, 2003; Wang and Cohen, 2007). Lin (1998) popularized the automatic clustering of similar words using distributional similarity. Pantel (2003) presents a more sophisticated clustering algorithm that first collects a small set of representative elements for each concept and then assigns words to their most-similar concept. Wang and Cohen (2007) alternatively investigate set expansion problem, that is, how to retrieve similar entities given a small number of seeds. With flexible matching patterns and random walk based ranking algorithm, their system outperforms Google Sets^{TM} in terms of Mean Average Precision (MAP). There are also researches forcusing on the relationship between verbs or adjectives, such as (Turney et al., 2003) and (Chklovski and Pantel, 2004).

In comparison to previous works on relation extraction, our work does not restrict itself to identifying pairs of entities whose relation is explicitly described by "infix"-like patterns, such as "Louis XVI *was born in* 1754". Alternatively, we mine related entities from context similarity and co-occurrence points of views. Moreover, through empirical studies, we find that query log is an effective data source in the extraction of related entities. On the other hand, different from synonym / comparable entities mining, our work retrieves a more extensive scope of results. In addition to entities similar or comparable to the query, we also extract those having more complicated relationships with the query, such as entities that interact with each other in certain events. Our work is also different from social network construction (Kautz et al., 1997), in that the evidences we use are also applicable to other types of named entities besides person.

3 Proposed Method

Our method for extracting related persons consists of two main stages. First, we generate candidate related persons in three fashions, based on context co-occurrence, contextual similarity, and query text co-occurrence, respectively. We collect up to 10 candidates from each source and combine them together. Second, we apply a SVM regression model to rate and rank the candidates and retain top 10 related persons for each query person. Five features are investigated, three of which are corresponding to the candidate extraction methods noted above, while the other two are based on joint-search of the query and each candidate.

3.1 Candidate Extraction

3.1.1 Context Co-occurrence

Co-occurrence is a traditional knowledge source for relation extraction (Church and Hanks, 1990).

In comparison to previous studies, we utilize a search engine to efficiently traverse the enormous Web corpus. In detail, we submit each query person q to a search engine and collect top 200 search results. We recognize co-occurred persons of q in the content of the search results within a window of limited length centered at each occurrence of q. The NER tool we used is based on a large NE table and a set of specific rules. In our experiments, the search engine we used is Baidu, and the length of the window is 5 words on both sides of the query. As a filtering step, we weed out persons that co-occur with the query for less than 3 times. Finally, we rank the co-occurred persons in descending order by their frequency, and keep up to top 10 as candidates.

3.1.2 Contextual Similarity

The distributional hypothesis presumes that words occurring in similar contexts tend to have similar meanings (Harris, 1985). In the scenario of related entity extraction, entities share similar contexts involve not only those with similar identities, e.g., two famous *pop stars*, but also those interacting with each other in the same event, e.g. two actors *co-starring* in the same movie. In this paper, we assemble in advance a large collection of persons, which contains approximately 160K person entities. For each person in the collection, we submit it to Baidu and extract its context words from its top 200 search results within the same text window (5 words on both sides) as above. The volume of the whole search result set is around 400GB In this manner, we generate a context word vector $v = (w_1, w_2, ..., w_K)$ for each person, in which w_i is a context word, and K is the total number of unique context words over the whole collection. The weight of w_i is calculated as:

$$W(w_i) = log(1 + tf_i) \cdot log(\frac{N}{qf_i}) \qquad (1)$$

where tf_i denotes the frequency of w_i in the context of the given person, qf_i denotes the number of persons in the collection whose context words contain w_i, and N denotes the total number of persons in the collection. We use logarithm on the frequency tf_i to reduce the influence of the words with extremely high frequency.

We extract candidate related persons for each query person q via selecting top 10 persons from the collection according to the contextual similarity with q. We compute the similarity between two context vectors v_i and v_j using Jensen-Shannon divergence (JSD), as it performs better than some other similarity computation methods, such as cosine similarity, in our experiments. We first normalize the input vectors by the sum of their components, and calculate the JSD as described in (Lee, 1999):

$$JSD(v_i, v_j) = \frac{1}{2}[KL(v_i \| v') + KL(v_j \| v')] \quad (2)$$

where KL denotes the Kullback-Leibler divergence between two vectors, and $v' = (v_i + v_j)/2$. Note that the larger the JSD is, the less similar two vectors are. Thus the similarity between vectors v_i and v_j is computed as $1 - JSD(v_i, v_j)$.

3.1.3 Query Text Co-occurrence

Web search queries represent the demand of information from the users. Queries are known to be noisy and of little syntactic structure. However, previous works have demonstrated that there is sufficient knowledge encoded in the query texts to perform information extraction tasks (Paca, 2007), and that extracting information within query logs can better represent the users' interests (Jain and Pennacchiotti, 2010).

We found from Baidu query logs that related persons are often searched together for users' curiosity about their relationships. Such pairs of persons consist of not only those with persistent relationships like *couples* and *friends*, but also those related in certain events, especially some hot news. In this spirit, we employ a Baidu query log containing approximately 9.08 billion raw queries to extract candidate related persons. For each query person q, we traverse the query log and extract persons that co-occur with q in the same queries. We filter out the persons that co-occur with q for less than N times (N is set 20 empirically in the experiments), and sort the left ones in descending order by the frequency of co-occurrence. Top 10 candidates are kept thereby.

3.2 Features for Regression

This paper recasts related person extraction as a regression problem. Given the candidates extracted as above, we train a regression model to score all the candidates and accordingly select the top-ranking ones as related persons. In this work, we investigate five features in the regression model.

Feature 1: Context Co-occurrence Feature (CCF). We design the first feature CCF to measure the co-occurring frequency of the query person q and a candidate related person c_j:

$$CCF(q, c_j) = \frac{Cooc(q, c_j)}{K} \quad (3)$$

where $Cooc(q, c_j)$ is the co-occurring frequency of q and c_j in the top K ($K = 200$) search results of q. Intuitively, the feature CCF is the average number of co-occurrences in each kept search result. We would like to stress that the feature computation is independent of candidate extraction, i.e., the feature CCF is available for all candidates extracted in the three manners above. This is also the case with the following features.

Feature 2: Contextual Similarity Feature (CSF). The contextual similarity described above is also taken as a feature. Given the context vectors v_q and v_j for the query person q and a candidate related person c_j, we devise the CSF feature as:

$$CSF(q, c_j) = 1 - JSD(v_q, v_j) \quad (4)$$

Feature 3: Query text Co-occurrence Feature (QCF). The QCF feature is designed to measure the frequency that the query person q and a candidate c_j are searched in the same queries. Here we define the QCF feature as the conditional probability of observing c_j in queries containing q:

$$QCF(q, c_j) = p(c_j|q) = n_{qj}/n_q \quad (5)$$

where n_q denotes the number of queries in the query log containing q, and n_{qj} denotes the number of queries containing both q and c_j.

In addition to the three features above, we also design two *joint-search* based features. Our motivation is that we can gather more clues about the relationship between two persons by searching them together and analyzing the search results. In practice, for each query person q and a candidate related person c_j, we form a joint-search query "q c_j" and submit it to Baidu. Roughly speaking, Baidu will first return results containing both q and c_j and then those containing either q or c_j. We keep top 200 search results and define the following two features:

Feature 4: Joint-search Co-occurrence Feature (JCF). A pair of related persons is supposed to co-occur in the joint-search results frequently. We thus use the JCF feature to measure the co-occurrence frequency of q and c_j in their joint-search results, which is defined as:

$$JCF(q, c_j) = \frac{2 \times s(q, c_j)}{s(q) + s(c_j)} \quad (6)$$

where $s(q)$ and $s(c_j)$ denote the numbers of sentences in the joint-search results that contain q and c_j respectively. $s(q, c_j)$ denotes the number of sentences containing both q and c_j.

Feature 5: Joint-search Distance Feature (JDF). The JDF feature takes the distance between q and c_j in the joint-search results into account. The underlying consideration is that related entities might appear closer to each other than irrelated ones. In practice, we only consider the cases in which q and c_j appear within the same sentences. The JDF feature is defined as:

$$JDF(q, c_j) = exp[-\frac{1}{S}\sum_{i=1}^{S} d_i(q, c_j)] \quad (7)$$

where S is the number of sentences in which q and c_j co-occur. $d_i(q, c_j)$ is their distance, i.e., the minimum number of words between them, in the i-th sentence they occur. We use the natural exponential function to restrict the range of the feature value.

3.3 SVM Regression Model

The judgment of the relatedness between persons is not binary. Closely related persons should receive more credit than loosely related ones. Thus we choose the regression scheme, which fits a continuous scoring function towards human annotated scores. We build SVM regression models using Gaussian kernel. The SVM toolkit we use in the experiments is SVM-Light v6.01[3], with its parameters at default setting. From the perspective of real application, for each new query person, we could generate its candidates as well as the features, and score them with the learned SVM regression model. However, in our experiments, we adopt 5-fold cross validation to validate the performance of the model. We will introduce the construction of the data sets in section 4.

[3]http://svmlight.joachims.org/

4 Experiments

4.1 Experimental Settings

4.1.1 Data Preparation

To construct the data set for model training and testing, we randomly sampled 200 Chinese query persons (i.e. queries that exclusively contain a single person entity) from the query logs of Baidu. For each query person, we extracted candidate related persons from the exploited resources as described in Section 3.1. In total, we acquired 4177 candidate related persons for the 200 sampled query persons, each of which has 20.9 candidates on average. We also obtained the top 10 related persons for the 200 queries produced by Renlifang for our comparison experiments. Renlifang is developed based on approximately 1 billion Web pages and object-level retrieval techniques (Nie et al., 2005; Nie et al., 2007; Nie et al., 2007), and is one of the most famous entity search engines in Chinese. Two native Chinese speakers were asked to rate all the candidates extracted by our approach as well as Renlifang results on a 4-point scale, i.e., 0,1,2,3. Specifically, a potential related person p of a query person q gets the rating 0 if p and q are not related. Ratings ranging from 1 to 3 correspond to relationships of different strengths, namely, *mild*, *moderate*, and *strong*. The raters were given instructions and examples that explained how to decide the relation strength between two persons. Two raters each labeled half of the data and checked the labeling results for each other. Those labeling results that had not reached an agreement would be discussed together, so as to generate a final rating.

4.1.2 Evaluation Metrics

To examine the performance of the SVM regression model, we randomly split the 200 query persons, along with their candidate related persons, in to 5 equal-size subsets, and performed 5-fold cross validation. In each run, four subsets are used for training and the other one is used for testing. The candidate related persons of each test person were automatically rated by the regression model, and top 10 of them were kept for evaluation. We adopt two metrics in the evaluation. In the first one, all the system outputs with a rating larger than 0 (i.e., 1,2,3) are counted as correct related persons of the test person q, without regard to the difference in relation strength. We calculate $Prec@K$ ($1 \leq K \leq 10$) for the list of ranked related persons L_q of q and report the average $Prec@K$ on the whole data set:

$$AvgPrec@K = \frac{1}{N}\sum_{N}\frac{\sum_{k=1}^{K}\mathbf{1}(R_{L_q}(k) > 0)}{K} \quad (8)$$

where $R_{L_q}(k)$ is the human-assigned rating of the k-th related person for q, $\mathbf{1}(\cdot)$ is the indicator function that yields 1 if $R_{L_q}(k) > 0$ and 0 otherwise, N is the total number of test persons that have at least one candidate related person extracted.

The second evaluation metric takes relation strength difference into consideration and assesses the system outputs based on an average weighted $Prec@K$, which is defined as:

$$AvgWPrec@K = \frac{1}{N}\sum_{N}\frac{\sum_{k=1}^{K}R_{L_q}(k)}{K} \quad (9)$$

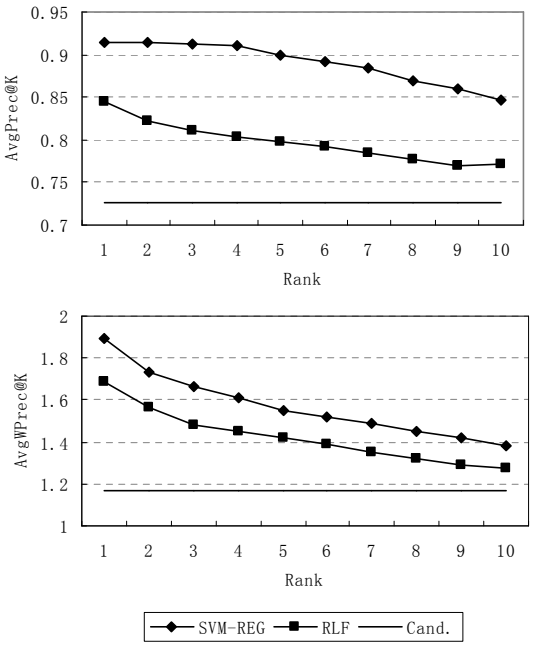

Figure 2: The comparison with Renlifang.

4.2 Overall Comparison

In our experiments, we first compared the performances of our method and Renlifang according to $AvgPrec@K$ and $AvgWPrec@K$. The comparison results are depicted in Figure 2. In detail, the upper part of Figure 2 shows the performances of two systems in terms of $AvgPrec@K$. As can be seen, our method (SVM-REG) consistently outperforms Renlifang (RLF) by 8%-13%. Specifically, the performance gaps between these two

Rank	Related Entity (Translation)	Relationship
1	巩俐 (Gong Li)	Co-starring; Similar identity
2	姜文 (Jiang Wen)	Co-starring; Similar identity
3	葛优 (Ge You)	Co-starring; Similar identity
4	朱军 (Zhu Jun)	In certain event
5	吴宇森 (John Woo)	Actor-Director; In certain event
6	陈玉莲 (Idy Chan)	Love affair; In certain event
7	成龙 (Jackie Chan)	Comparative; Similar identity
8	钟楚红 (Cherie Chung)	Co-starring; Similar identity
9	刘德华 (Andy Lau)	Comparative; Similar identity
10	周星驰 (Stephen Chow)	Comparative; Similar identity

Table 1: Example of top-10 related persons for query person "周润发".

methods are 8.28% (0.915 vs. 0.845), 12.9% (0.9 vs. 0.797), and 9.73% (0.846 vs. 0.771) at rank 1, 5, and 10. The comparison of $AvgWPrec@K$ (lower part of Figure 2) shows the same trend. At all ranks from 1 to 10, our approach significantly outperforms Renlifang by 9%-12%. Table 1 shows an example of the ranked results for query person "周润发" (Chow Yun-fat, Hong Kong actor).

To verify the effectiveness of the regression features, we carried out another series of experiments, eliminating one feature each time. The results are summarized in Figure 3. We can see that eliminating features CSF and JCF both result in a sharp decrease in the performance, which demonstrates the effectiveness of these two features. The performance also decreases when we ignore the QCF feature, but the drop is not evident. The other two features, namely CCF and JDF, seem useless in regression, since the performance is even slightly enhanced when they are eliminated.

Through observing the data, we find that the CCF feature seriously suffers from sparseness problem. In our experiments, only 2051 of the 4177 candidates have non-zero CCF value. Sparseness should be the main reason that invalidates the CCF feature. As to the JDF feature, throughout our analysis, there is no obvious correspondence between person relationship and their distance in the joint-search results, which means that the JDF feature is not discriminative.

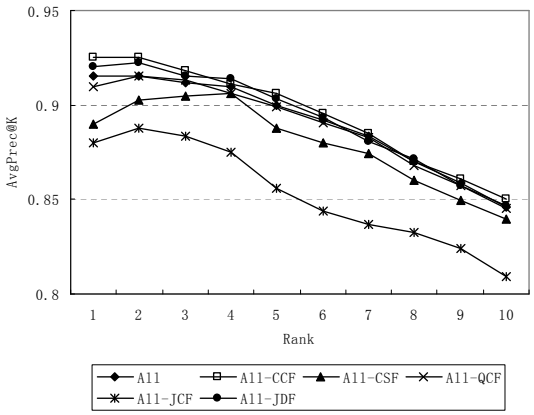

Figure 3: Evaluation of Feature Contribution.

	Con.	Sim.	Que.	All
# of test persons	196	200	178	200
# of candidates	1454	2000	1599	4177
# of cor. cands.	1229	1283	1359	3031

Table 2: Statistics of the candidate related persons extracted from three resources.

4.3 Contribution of Individual Resources

Recall that, in this work, the candidate related persons are acquired from three resources, based on contextual co-occurrence (Con.), contextual similarity (Sim.), and query text co-occurrence (Que.), respectively. It is therefore necessary to examine the contribution of each individual resource. Table 2 tabulates some statistics of candidate related persons extracted from three resources. Specifically, the first line of the table shows the number of test persons for which each resource can provide candidate related persons. The second line gives the total number of candidates yielded from each resource. The last line shows the number of correct candidates, namely, the candidates with ratings larger than 0.

We can find that each resource can provide a considerable number of candidate related persons. However, the qualities of the candidates differ a lot. In particular, the resource based on contextual similarity provides 10 candidate related persons for all the 200 test persons, but the precision is below 65%, which is the lowest. The other two

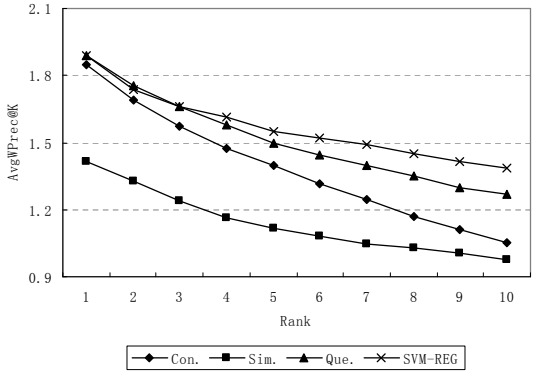

Figure 4: $AvgWPrec@K$ of ranked lists returned by individual resources and SVM regression model.

resources fail to provide candidates for some of the test persons, but their precisions are much higher, both of which exceed 84%. The last column of Table 2 shows the numbers of overall unique candidates and the correct ones. We can see that the overlap among three candidate sets is not large, indicating that all the three resources are contributing to the acquisition of candidate related persons.

To further investigate the quality, especially the relation strength, of the candidates acquired from each resource, we report $AvgWPrec@K$ of the raw ranked list of top 10 candidates from each resource in Figure 4. For the sake of comparison, we also include the $AvgWPrec@K$ results achieved by the SVM regression model using the whole feature set. The comparison results suggest that the $AvgWPrec@K$ scores of Que. and Con. come close to that of our SVM regression model when we only compare the top 3 or 4 candidates. However, the performance gap becomes larger as K grows. This is because the SVM regression model benefits from a much larger pool of candidates, from which it can select related persons of stronger relationships. We can also see that Sim. evidently underperforms Que. and Con., which is in accordance with the results reported in Table 2. In summary, the resource of Sim. assures the recall, while Que. and Con. provide relatively high-quality candidates, and the SVM regression model combines all evidences effectively.

5 Conclusions

In this paper, we make use of multiple resources provided by a search engine for acquiring related persons. The acquired candidates are rated and ranked with a SVM regression model that exploits various features. The following conclusions can be drawn from the experimental results:

First, the search engine facilitates the collection of needed resources in related entity extraction, with which we can easily collect ample web pages and query logs containing the queries of interest.

Second, the task of related entity extraction evidently benefits from the combination of multiple resources. We have observed significant improvement over the methods using each single resource.

Third, the SVM regression model is effective for rating and filtering the candidate related entities given discriminative features.

Our future work will be carried out along several directions. First of all, we will address the coreference resolution issue. The regression model will also be strengthened by employing more features. In addition, we will extend the method to other entity categories beyond person. We will also consider to extract cross-category related entities in the following work.

Abstract

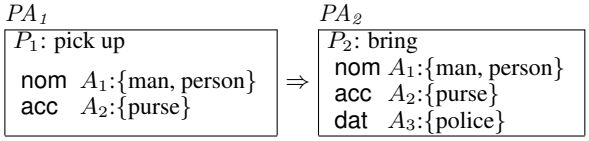
This paper proposes a method for automatically acquiring strongly-related events from a large corpus using predicate-argument co-occurring statistics and case frames. The strongly-related events are acquired in the form of strongly-related two predicates with their relevant arguments. First, strongly-related events are acquired from predicate-argument co-occurring statistics. Then, the remaining argument alignment is performed by using case frames. We conducted experiments using a Web corpus consisting of 1.6G sentences. The accuracy for the extracted event pairs was 96%, and the accuracy of the argument alignment was 79%. The number of acquired event pairs was about 20 thousands.

1 Introduction

Natural language understanding requires a wide variety of knowledge. One is the relation between predicate and argument. This relation has been automatically acquired in the form of case frames from a large corpus, and is utilized for parsing (Kawahara and Kurohashi, 2006). Another is the relation between events. The relation between events includes temporal relation, causality, and so on, and is useful for coreference resolution (Bean and Riloff, 2004) and anaphora resolution (Gerber and Chai, 2010).

This paper extracts two strongly-related events. Since the meaning of a predicate itself is often ambiguous, an event is treated as predicate-argument structure, namely the predicate with their relevant arguments. An example of two strongly-related events is shown below[1]:

[1] nom, acc, dat denotes nominative, accusative, dative, respectively.



In the above example, while the argument A_1 and A_2 appear both in PA_1 and PA_2, the argument A_3 appears only in PA_2. The argument A_3 works for specifying the meaning of the predicate P_2. The method that automatically extracts sets of events from unlabeled corpora (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009) relies on the coreference relation of arguments, and thus cannot extract an argument such as A_3.

In languages where an argument is often omitted, such as Japanese, sentences illustrating the above two events usually occur in the following form (for simplicity, the sentences are explained in English):

(1) a. A man picked up a purse and brought (ϕ) to the police.

b. (ϕ) picked up a purse and brought (ϕ) to the police.

In the sentence (1-a), the argument A_1 and A_2 are omitted in PA_2. Moreover, as an agent is specifically omitted, in the sentence (1-b), the argument A_1 in PA_1 is also omitted. The coreference-based method (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009) is hard to be applied to such a language since an argument rarely appears in both PA_1 and PA_2.

Our proposed method extracts strongly-related events in a two-phrase construct. First, since the arguments, such as A_2 and A_3, which specify the meaning of the predicate occur in at least one predicate-argument structure, the co-occurrence measure between "pick up purse" and "bring to police" can be calculated from their occurrences. Thus, we can regard "pick up purse" and "bring to police", whose mutual information is high, as strongly-related events.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1028–1036,
Chiang Mai, Thailand, November 8 – 13, 2011.

Next, we identify the remaining arguments by using case frames (Kawahara and Kurohashi, 2006). Case frames describe what kinds of arguments each predicate takes and what kinds of nouns can fill a case slot. With the similarity of noun distribution between an argument in a case frame assigned to PA_1 and an argument in a case frame assigned to PA_2, the remaining arguments can be aligned. In the above example, acc A_2 ("purse") in PA_1 corresponds to acc A_2 in PA_2, and nom A_1 ("man", "person") in PA_1 corresponds to nom A_1 in PA_2.

The rest of this paper is organized as follows: Section 2 reviews related work. Section 3 describes an overview of our proposed method. Section 4 describes predicate-argument structure pairs extraction. Section 5 explains co-occurrence statistics calculation between predicate-argument structures using an association rule mining, and Section 6 describes argument alignment based on case frames. Section 7 reports on our experiments.

2 Related Work

We describe manually constructed resources for event relations, and then explain automatic acquisition methods from a corpus.

2.1 Manually Constructed Resource

Singh and Williams constructed a common sense knowledge base concerned with ordinary human activity (Singh and Williams, 2003). The knowledge base consists of 80,000 propositions with 415,000 temporal and atemporal links between propositions. Espinosa and Lieberman proposed an EventNet, a toolkit for inferring temporal relations between commonsense events from the Openmind Commonsense Knowledge Base (Espinosa and Lieberman, 2005).

Recently, Regneri et al. collect natural language descriptions from volunteers over the Internet, and compute a temporal script graph (Regneri et al., 2010). They collected 493 event sequence descriptions for the 22 scenarios such as "eating in a fast-food restaurant" using the Amazon Mechanical Turk.

2.2 Automatic Acquisition of Event Relation from Corpus

There are several types in the event relation acquisition. One is the inference rule acquisition. Lin and Pantel extended the distributional hypothesis on words, and calculated two paths in a dependency tree (Lin and Pantel, 2001). If two paths tend to link the same sets of words, these are regarded as being similar. For example, they calculated the similarity between "X is the author of Y" and "X wrote Y".

Another type is the script-like knowledge acquisition. Chambers and Jurafsky learn narrative schemas, which mean coherent sequences or sets of events, from unlabeled corpora (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009). This method extracts two events that share a participant, called a *protagonist*. Since these methods rely on the coreference analysis result, they are hard to be applied to languages where omitted arguments or zero anaphora are often utilized.

Kasch and Oates proposed a method for extracting script-like structures from collections of Web documents (Kasch and Oates, 2010). Their method is topic-driven, and the experiment was performed on only one situation *eating at a restaurant*.

There is some work for acquiring two related events taking argument sharing approach (Torisawa, 2006; Abe et al., 2008). Torisawa proposed a method for acquiring inference rules with temporal constrains by using verb-verb co-occurrences in Japanese coordinated sentences and verb-noun co-occurrences (Torisawa, 2006). Abe et al. acquire semantic relations between events by coupling the pattern-based relation-oriented approach and the anchor-based argument-oriented approach (Abe et al., 2008). Their method first acquires candidate predicate pairs by exploiting a pattern-based method, and then seeks anchors indicative of the shared argument. If anchors are found, the predicate pair is verified. These methods can acquire only event relations that have a shared argument.

3 Overview of Our Proposed Method

This paper focuses on Japanese, and extracts two strongly-related events in the form as shown in Figure 1. Figure 2 depicts an overview of our proposed method. First, pairs of predicate-argument structures (PAs) that have a dependency relation are extracted from a Web corpus. Then, from a large number of extracted pair of PAs, strongly-related two predicates with their relevant arguments are extracted. Since the meaning of a predicate itself is often ambiguous, the predicate with

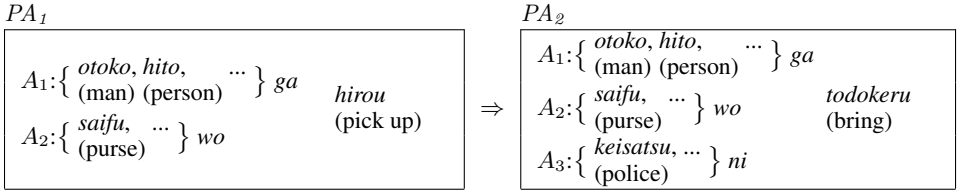


Figure 1: An example of strongly-related events. (*ga* (nom), *wo* (acc), and *ni* (dat) are Japanese case markers.)

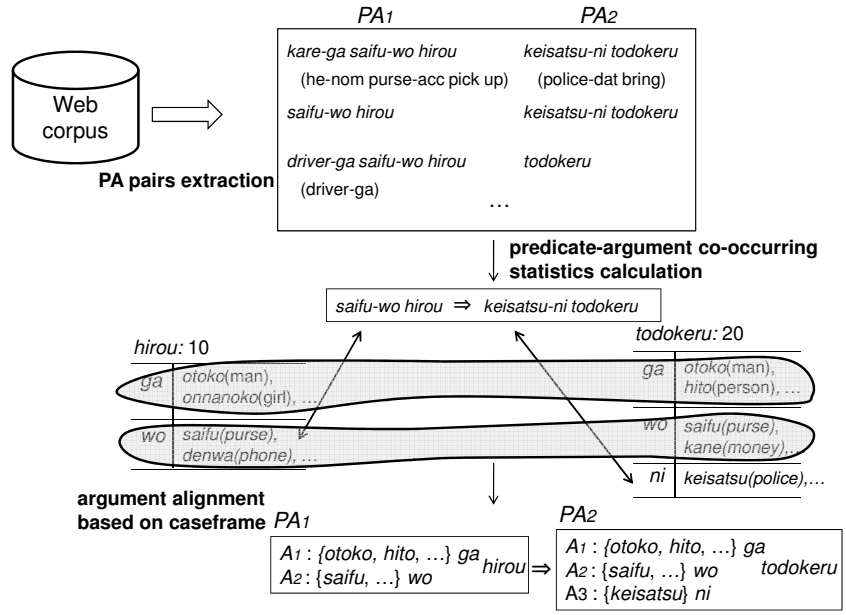

Figure 2: An overview of our proposed method.

their relevant arguments is extracted. For example, whereas the pair between "*hirou* (pick up)" and "*todokeru* (bring)" is not strongly related, the pair between "*saifu-wo* (purse-acc) *hirou*" and "*keisatsu-ni* (police-dat) *todokeru*" is. To extract the predicate with relevant arguments, the pointwise mutual information of the pair of arbitrary PAs is calculated, and the pair whose pointwise mutual information is high is regarded as strongly-related events. We adopt *association rule mining* (Agrawal et al., 1993) for the calculation of co-occurrence statistics between PAs effectively.

Next, the remaining arguments are identified using case frames. For the predicate "*hirou*(pick up)" whose argument takes "*saifu*(purse)-*wo*", what kinds of arguments are taken can be obtained from case frames. As shown in Figure 2, in the case frame 10 of "*hirou*"[2], where the argument *wo* takes "*saihu*", "*denwa*", the argument *ga* takes "*otoko*", "*onnanoko*", and so on. Similarly, in the case frame 20 of "*todokeru*", where the argument *ni* takes "*keisatsu*", the argument *ga* takes "*otoko*", "*onnanoko*", and so on, and the argument *wo* takes "*saihu*" and so on. With the similarity of noun distribution between an argument in PA_1 and one in PA_2, the remaining arguments can be aligned.

4 Predicate-Argument Structure Pairs Extraction

Strongly-related events appear in the form where they have a dependency relation with a variety of expressions (especially clause relation) in a text. For example, the event "*saifu*(purse)-*wo hirou*(pick up)" and the event "*keisatsu*(police)-*ni todokeru*(bring)" appear as follows:

(2) *saifu-wo hiro-te keisatsu-ni todoke-ta*
purse-acc pick up and police-dat brought
((A man) picked up a purse, and brought it to a police.)

We extract two strongly-related events from a large number of pairs of two PAs that have a dependency relation. From parsing results, a pair of PAs that have a dependency relation is first extracted. The extracted arguments are *ga* (nom), *wo* (acc), and *ni* (dat). If a predicate has an at-

[2]Each predicate has several case frames, and case frame 10 of "*hirou*" means 10th case frame for the predicate "*hirou*".

Table 1: Examples of clause relation and predicate-argument structure extraction.

1901	*douro* (road), *kokudou* (national highway), $\cdots$

tribute, such as negation, causative, and passive, the attribute is attached to the predicate as a flag. Table 1 shows examples of clause relation and predicate-argument structure extraction.

We consider PA pairs that occur with a clause relation sequence as standard. In the case of clause relation purpose, PA pairs occur in the following form: PA_2 *tame-ni* PA_1, and so PA_1 and PA_2 are transposed. In the case of the clause relation contradiction, the negation flag in the predicate of PA_2 is reversed.

Argument Generalization

An argument is generalized to its word class so as to alleviate the problem of data sparseness. As a word class, a large-scale clustering result of verb-noun dependency relations (Kazama and Torisawa, 2008) is used. The number of word class is 2,000, and this word class covers one million noun phrases. Table 2 shows examples of a word class and its words.

In pairs of the extracted PAs, the noun n is replaced with the word class $\langle c \rangle$ for which the probability $P(c|n)$ is maximal. For example, "PA_1: *ka*(mosquito) *ni sa-sareru* (bitten), PA_2: *hareru* (swollen)" is changed to "PA_1: $\langle 77 \rangle$ *ni sa-sareru*, PA_2: *hareru*" since "*ka*" belongs to the word class $\langle 77 \rangle$. In the same way, "PA_1: *hachi*(bee) *ni sa-sareru*, PA_2: *hareru*" is changed to "PA_1: $\langle 77 \rangle$ *ni sa-sareru*, PA_2: *hareru*", and thus, these two PAs can be identical.

5 Co-occurrence Statistics Calculation between Predicate-Argument Structures

Given a lot of PAs, as extracted in Section 4, the co-occurrence statistics between PAs is calculated. Since the number of pairs of arbitrary PAs is enormous, a question that arises is how to obtain related PAs effectively. To solve this problem, we adopt *association rule mining* (Agrawal et al., 1993) for the calculation of co-occurrence statistics between PAs. The association rule mining method can efficiently seek candidate items that satisfy specific conditions.

5.1 Association Rule Mining

Association rule mining is a method for discovering significant rules in a large database (Agrawal et al., 1993). This method is originally designed to discover rules such as "a customer who buys diapers tends to buy beer" in customer transactions.

Let $I = I_1, I_2, \cdots, I_m$ be a set of binary attributes, called items. Transaction t is defined as a set of items ($t \subseteq I$), and transaction database T is defined as a set of transactions ($T = t_1, t_2, \cdots, t_n$).

A *rule* is defined as an implication of the form $X \Rightarrow Y$ where $X, Y \subseteq I$ and $X \cap Y = \phi$. This signifies "if X occurs, Y tends to occur". The set of items X and Y are called antecedent (left-hand side, lhs) and consequent (right-hand side, rhs) of the rule respectively. For every rule, the following three measures are defined:

$$support(X \Rightarrow Y) = \frac{C(X \cup Y)}{|T|} \quad (1)$$

$$confidence(X \Rightarrow Y) = \frac{support(X \Rightarrow Y)}{support(X)} \quad (2)$$

$$lift(X \Rightarrow Y) = \frac{confidence(X \Rightarrow Y)}{support(Y)}, \quad (3)$$

Table 3: Examples of transaction data. (One line represents a transaction.)

PA_1		PA_2	
arguments	predicate	arguments	predicate
saifu(purse)-*wo*	*hirou* (pick up)	*keisatsu*(police)-*ni*	*todokeru* (bring)
kare(he)-*ga*, *saifu-wo*	*hirou*	*keisatsu-ni*	*todokeru*
saifu-wo	*hirou*		*todokeru*
	hirou	*keisatsu-ni*	*todokeru*
	...		
saifu-wo	*hirou*		*tewatasu* (hand)
saifu-wo	*hirou*	*kare*(he)-*ni*	*tewatasu*
otoko(man)-*ga*, *saifu-wo*	*hirou*		*tewatasu*
	...		

where $C(X)$ represents the number of transactions containing the item X.

The *support* is defined as the fraction formed the number of transactions that contain the itemset X and the total number of transactions in the database. The *confidence* is defined as the fraction formed from the transactions that contain $X \cup Y$ and the transactions that contain X. The *lift* corresponds to pointwise mutual information between X and Y.

Apriori algorithm (Borgelt and Kruse, 2002) is one of the well-known implementations for association rule mining. This algorithm exploits the observation that no superset of an infrequent itemset can be frequent, and uses breadth-first search and a tree structure to seek candidate items.

The input for Apriori algorithm is transaction data, the minimum support, and minimum confidence, and the algorithm enumerates all rules that satisfy the specified conditions.

5.2 Apriori Algorithm Application to Co-occurrence Calculation

The Apriori algorithm is applied to the calculation of co-occurrence statistics between PAs. An item introduced in Section 5.1 corresponds to a predicate or an argument, and a transaction is obtained from a pair of PAs. Examples of transaction data are shown in Table 3.

Since the rules we want to extract are supposed to satisfy the following conditions:

- X (left-hand side) consists of a predicate of PA_1, and zero or more arguments in PA_1
- Y (right-hand side) consists of a predicate of PA_2, and zero or more arguments in PA_2,

all the rules that do not satisfy these conditions are discarded. Among those that do, the rule for which the lift is higher than *lift-min* and less than *lift-max* is adopted. It is well-known that the pointwise mutual information (which corresponds to lift) for which the frequency is low gets extremely high, and thus rules for which the lift is greater than *lift-max* are discarded.

The Apriori algorithm naturally judges which argument is relevant for each predicate pair. For example, from the transaction data shown in Table 3, the following rule is obtained:

1. *saifu-wo hirou* $\Rightarrow$ *keisatsu-ni todokeru*

2. *saifu-wo hirou* $\Rightarrow$ *tewatasu*

The first rule implies that for the predicate pair "*hirou*" and "*todokeru*", "*saifu-wo*" for the predicate in PA_1 and "*keisatsu-ni*" for the predicate in PA_2 are relevant. Similarly, the second rule implies that for the predicate pair "*hirou*" and "*tewatasu*", "*saifu-wo*" for the predicate in PA_1 is relevant.

6 Argument Alignment based on Case Frames

As mentioned in Introduction, since an argument is often omitted in the extracted predicate-argument pairs, there is usually a lack of arguments in the extracted rules as described in the previous section. In the following rule, the argument of the *wo* case in PA_1 corresponds to the *wo* case in PA_2, and the argument that includes nouns such as "*otoko*(man)", "*hito*(person)" acts for the *ga* case both in PA_1 and PA_2.

saifu-wo hirou $\Rightarrow$ *keisatsu-ni todokeru*

Such alignment between arguments can be performed by case frames. The case frames are constructed automatically by clustering similar predicate usages from a raw corpus, and thus each predicate has several case frames. Examples of the case frames are shown in Table 4. When both a

Table 4: Examples of the automatically constructed case frames.

verb	case marker	examples
hirou:1 (pick up)	*ga*	*josei*(lady), *hito*(person), ···
	wo	taxi, *kuruma*(car), ···
	···	
hirou:10 (pick up)	*ga*	*otoko*(man), *onnanoko*(girl), ···
	wo	*saifu*(purse), *denwa*(phone) ···
	···	
todokeru:1 (deliver)	*ga*	staff, *syokuin*(staff), ···
	wo	*jyohou*(information), news, ···
	···	
todokeru:20 (bring)	*ga*	*otoko*(man), *hito*(person), ···
	wo	*saifu*(purse), *kane*(money), ···
	ni	*keisatsu*(police), ···
	···	

case in cf_1 assigned to PA_1 and a case in cf_2 assigned to PA_2 have a similar distribution of examples, the case in PA_1 and the case in PA_2 can be aligned.

The best combinations of the case frame in both PA_1 and PA_2 and the best alignment of cases are determined as follows:

1. If there is an argument, select case frames corresponding to the argument, otherwise, all case frames are candidates. In the above example, while in PA_1 the case frame 10 is selected according to the argument for the case *wo* ("*saifu*"), in PA_2 the case frame 20 is selected according to the case *ni* ("*keisatsu*").
2. Choose the best case frame pairs that maximize the following score:

$$\underset{cf_1,cf_2}{\operatorname{argmax}}\, max_{\mathbf{a}} \sum_{a\in\mathbf{a}} sim(arg_1, a(arg_1)) \quad (4)$$

where $\mathbf{a}$ denotes the alignment of case components between PA_1 and PA_2, arg_1 denotes an argument in PA_1, $a(arg_1)$ denotes an argument in PA_2 that aligned with arg_1, and sim denotes the cosine similarity of the case components distribution between arg_1 and $a(arg_1)$. In the example, the alignment between the case *ga* of the case frame 10 in PA_1 and the case *ga* of the case frame 20 in PA_2, and the case *wo* in PA_1 and the case *wo* in PA_2 is performed.

7 Experiments

7.1 Settings

Approximately 100 million Japanese Web pages were used to extract strongly-related events. These pages include 6 billion sentences, containing 100 billion words. Owing to the presence of many duplicate pages on the Web, such as mirror pages, duplicate sentences were discarded. Thus, 1.6 billion sentences containing approximately 25 billion words were acquired. The average number of characters and words in a sentence were 28.3 and 15.6, respectively.

The Web corpus was processed using the Japanese Morphological Analyzer JUMAN[3] and the Japanese parser KNP[4], and pairs of PAs were extracted. The number of extracted PAs was approximately 400 million.

In the application of Apriori algorithm explained in Section 5.2, the minimum support, confidence was set to 1.0×10^{-7}, 1.0×10^{-3} respectively, and *lift-min*, *lift-max* was set to 10, 10,000 respectively.

The case frames were automatically constructed from the Web corpus consisting 1.6G sentences with a method proposed by (Kawahara and Kurohashi, 2006). For 31,000 predicates, case frames were constructed; the average number of case frames of a predicate was 25; the average number of case slots of a case frame was 4.7.

Table 5: Accuracy of extracted rule and the argument alignment.

extracted rule	correct		incorrect
	96(96.0%)		4(4.0%)
argument alignment	correct	incorrect	
	76(79.1%)	20(20.8%)	–

7.2 Result and Discussion

7.2.1 Evaluation of Co-occurrence Statistics Calculation

We acquired approximately 20,000 rules described in Section 5, and evaluated the acquired rules. We chose 100 rules at random, and evaluated whether each is valid. The upper part in Table 5 shows the accuracy, and we found 96 valid rules of the 100, and the accuracy was 0.96. Examples of the extracted rules and its evaluation are shown in Table 6. A major error is the parsing error. In the example (8) in Table 6, the predicate "*ataru*" in PA_1 is correctly a part of function expressions.

7.2.2 Evaluation of Argument Alignment

We chose 96 instances that were judged as correct in the previous section, and calculated the accu-

(7)	A_1:{ *kodomo*, ... } *ga* (child)	*kekkon* (get married)	⇒ A_1:{ *kodomo*, ... } *ga* (child)	*iru* (have)	incorrect

racy of the argument alignment. The bottom part in Table 5 shows the accuracy, and we found 76 of 94 were valid, and the accuracy was 0.791. Table 7 shows examples of acquired strongly-related events. A major error is that the case component distribution between two cases in a PA is very similar. In the example (6), the alignment shown in Figure 3 is correct. This error was caused by the fact that the case *ga* and the case *ni* in PA_1 and the case *ga* and the case *ni* in PA_2 include nouns representing an agent.

Another error is that some constructed case frames do not have an indispensable case slot. In the example (7), the alignment shown in Figure 4 is correct. This error is due to the fact that the assigned case frame to PA_2 does not have the *ni* case. To cope with this problem, we are planning to increase the size of Web corpus for the case frames compilation.

7.2.3 Comparison with Coreference-based Method

Our method was compared with the coreference-based method (Chambers and Jurafsky, 2008). Since the accuracy of coreference resolution is not high (Sasano et al. report an F-score of approximately 0.75 in a newspaper domain (Sasano et al., 2007)), if a noun appears twice in a Web page, and it fills a syntactic relation of the predicate w and the predicate v, the noun is regarded as a corefer-

A_1:{ *watashi*, *hito*, ... } *ga* (I) (person)

A_1:{ *kodomo*, ... } *ga* (child)

Figure 4: The correct alignment of (7) in Table 7.

Table 8: Comparison of our method with the coreference-based method. (The covered ratio is the fraction formed the number of the acquired noun by the coreference-based method and the number of the nouns in the aligned argument by our method.)

case in PA_1	case in PA_2	covered ratio	
ga	*ga*	0.163	(3,768 / 23,180)
ga	*wo*	0.282	(549 / 1,944)
ga	*ni*	0.176	(474 / 2,689)
wo	*ga*	0.272	(753 / 2,764)
wo	*wo*	0.483	(7,106 / 14,713)
wo	*ni*	0.321	(1,054 / 3,284)
ni	*ga*	0.163	(344 / 2,113)
ni	*wo*	0.338	(1,042 / 3,086)
ni	*ni*	0.282	(549 / 1,944)

ence, following the method proposed by (Abe et al., 2008). The PMI score was calculated as follows:

$$pmi(e(w,d),e(v,g)) = \log \frac{P(e(w,d),e(v,g))}{P(e(w,d))P(e(v,g))} \quad (5)$$

where $e(w,d)$ is the verb/dependency pair w and d, and d and g have the coreferent relation.

In our acquired rules, we examined whether the k-most frequent noun in the aligned argument can be covered by the coreference-based method. In our experiment, k was set to be 5. The result is shown in Table 8. The number was classified according to the case in PA_1 and in PA_2. We found that most of the nouns in aligned argument cannot be acquired by the coreference-based method. Especially, the covered ratio of the pair of the case *ga* in PA_1 and the case *ga* in PA_2 was relatively low, which often corresponds to *agent*. In Japanese, since an *agent* is often omitted, it is hard to be acquired by the coreference-based method. However, our method can identify its use by using case frames.

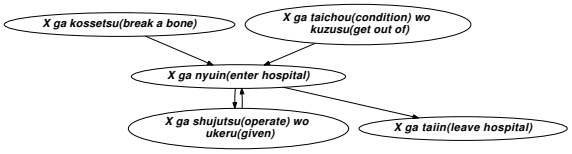

Figure 5: Network structure between events concerned with "enter hospital". (X: {*kodomo*(child), *musume*(daughter), ···})

7.2.4 Event Network Structure

Figure 5 is an example of a network structure between events concerned with "enter hospital", which is constructed from strongly-related events obtained by our proposed method. Anchor/coreference-based method cannot acquire the argument "*taichou*(condition)-*wo*" that presents in one node (which means this argument is shared by no events). In contrast, our proposed method can acquire such an argument.

8 Conclusion

This paper proposed a method for automatically acquiring strongly-related events from a large corpus using predicate-argument co-occurring statistics and case frames. Our method first extracted pairs of predicate argument structures that have a dependency relation are extracted from a Web corpus. Then, two events whose pointwise mutual information is high is extracted as strongly-related. We adopt association rule mining for the calculation of co-occurrence statistics between predicate-argument structures effectively. Then, the argument alignment was performed by using case frames.

For future work, since the acquired events include several relations such as temporal relation, causality, and means, we are planning to classify the relations automatically. Acquired event relations would then be utilized in Recognizing Textual Entailment (RTE) and Question Answer (QA) tasks.

Abstract

We present a novel relevance feedback (RF) method that uses not only the surface information in texts, but also the latent information contained therein. In the proposed method, we infer the latent topic distribution in user feedback and in each document in the search results using latent Dirichlet allocation, and then we modify the search results so that documents with a similar topic distribution to that of the feedback are re-ranked higher. Evaluation results show that our method is effective for both explicit and pseudo RF, and that it has the advantage of performing well even when only a small amount of user feedback is available.

1 Introduction

The main purpose of information retrieval (IR) is to provide the user with documents that are relevant to his/her information needs. However, it is difficult to achieve this by one-off retrieval, since user queries are typically short and often ambiguous (Jansen et al., 2000).

Relevance feedback (RF) is a technique to solve this problem. The basic procedure of RF is as follows. First, a system obtains initial search results for a given query, and presents them to the user. The user then annotates some of the documents in the search results as being relevant or not, and the system modifies the search results using this feedback.

There are a variety of RF methods that depend on different retrieval models. Rocchio's algorithm (Rocchio, 1971) and the Ide dec-hi method (Ide, 1971) are well-known RF methods for the vector space model (Salton et al., 1975). In the probabilistic model (Spärck Jones et al., 2000), the weight of terms can be modified by feedback. For language modeling approaches (Ponte and Croft, 1998), Zhai and Lafferty (2001) proposed a fundamental RF method.

As described above, many methods have been proposed for RF. However, most of the previous methods use only the surface information in texts. That is, they ignore the latent information in texts, which could assist in improving IR performance. For example, they do not and cannot use the information of words for RF that do not appear in user feedback even if these words are highly probable from the latent topics of the feedback.

In this paper, we explore a novel RF method for language modeling approaches. In the proposed method, we use not only the surface information in texts, but also the latent information contained therein. More specifically, we infer the latent topic distribution in user feedback and in each document in the search results using latent Dirichlet allocation (LDA), and then we modify the search results so that documents with a similar topic distribution to that of the feedback are re-ranked higher. Evaluation results show that our method is effective for both explicit and pseudo RF, and that it has the advantage of performing well even when only a small amount of user feedback is available.

2 Language Modeling Approaches to IR

In this section, we describe the language modeling approaches to IR that form the basis of our method.

2.1 Overview

Language modeling approaches can be classified into three types: the query likelihood model

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1037–1045,
Chiang Mai, Thailand, November 8 – 13, 2011.

(Ponte and Croft, 1998), the document likelihood model (Lavrenko and Croft, 2001), and the Kullback-Leibler (KL) divergence retrieval model (Lafferty and Zhai, 2001). In the query likelihood model, a document language model is constructed for each document in the collection. When a query is submitted by a user, the query likelihood is computed using the document model for each document. Then, the documents in the collection are ranked according to their likelihoods. In the document likelihood model, a query language model is constructed for a given query, and this is then used to compute the document likelihood for each document in the collection. The documents are then ranked by their likelihoods. In the KL-divergence retrieval model, both a query model and a document model are constructed, and the documents in the collection are ranked according to the KL-divergence between these models.

2.2 Language Model Construction

There are several ways of constructing a query model and a document model. One method is maximum likelihood estimation (MLE). The MLE of a word w_j with respect to a text $\boldsymbol{t}$ (e.g., query, document) is computed as

$$P_{\boldsymbol{t}}^{MLE}(w_j) = \frac{tf(w_j, \boldsymbol{t})}{|\boldsymbol{t}|}, \tag{1}$$

where $tf(w_j, \boldsymbol{t})$ represents the frequency of w_j in $\boldsymbol{t}$.

Dirichlet smoothed estimation (DIR) (Zhai and Lafferty, 2004) is also a well-known construction method. The DIR of w_j with respect to $\boldsymbol{t}$ is computed as follows.

$$P_{\boldsymbol{t}}^{DIR}(w_j) = \frac{tf(w_j, \boldsymbol{t}) + \mu P_{\boldsymbol{D}_{all}}^{MLE}(w_j)}{|\boldsymbol{t}| + \mu} \tag{2}$$

where $\boldsymbol{D}_{all}$ represents a collection, and μ represents the smoothing parameter that controls the degree of confidence in the frequency in $\boldsymbol{D}_{all}$ rather than in the frequency in $\boldsymbol{t}$.

2.3 RF for Language Modeling Approaches

Zhai and Lafferty proposed a fundamental RF method for the language modeling approaches (Zhai and Lafferty, 2001). When user feedback is given, they construct a language model for the feedback. Then, a new query model is constructed by interpolating the feedback model with the original query model, which is used to obtain the initial search results. Finally, they modify the search results using the new query model. They show the effectiveness of their method through their experiments, and report that the performance is better than that of Rocchio's algorithm.

3 LDA

In this section, we explain LDA, which is employed in the proposed method.

3.1 Overview

LDA (Blei et al., 2003) is one of the most popular topic models, and is viewed as an Bayesian extension of Probabilistic Latent Semantic Indexing (PLSI) (Hofmann, 1999). In PLSI, it is assumed that each document has a unique topic proportion $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_K)$. In contrast, LDA posits that $\boldsymbol{\theta}$ can take any values in the $(K-1)$ simplex, a topic proportion that means a point of the simplex is drawn from a Dirichlet distribution $\mathrm{Dir}(\boldsymbol{\alpha})$. Note that the parameter $\boldsymbol{\alpha}$ is a K-vector with components $\alpha_k > 0$. In LDA, the probability of a document $\boldsymbol{d}_i$ in the training data is calculated as follows.

$$\begin{aligned} &P(\boldsymbol{d}_i|\boldsymbol{\alpha}, \boldsymbol{\beta}) \\ &= \int P(\boldsymbol{\theta}|\boldsymbol{\alpha}) \left(\prod_{j=1}^{J} \left(\sum_{k=1}^{K} P(w_j|z_k, \boldsymbol{\beta})\, P(z_k|\boldsymbol{\theta}) \right)^{tf(w_j, \boldsymbol{d}_i)} \right) d\boldsymbol{\theta} \end{aligned}$$

where $z_k (k = 1, \ldots, K)$ represents a topic, and $\boldsymbol{\beta} = (\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_K)$ represents the distributions over words for each topic z_k.

3.2 Parameter Estimation

In LDA, the expectation-maximization algorithm cannot be used to estimate the parameters, since the computation of the posterior distribution of latent variables is intractable. Thus, a wide variety of techniques using the variational method and Gibbs sampling, have been proposed to estimate the parameters (Blei et al., 2003; Griffiths and Steyvers, 2004). Here, we explain the technique using the variational method, as this is employed in the proposed method.

First, variational parameters $\boldsymbol{\gamma}_i = (\gamma_{i1}, \ldots, \gamma_{iK})$ and $\boldsymbol{\phi}_i = (\boldsymbol{\phi}_{i1}, \ldots, \boldsymbol{\phi}_{iJ})$ are introduced for each document $\boldsymbol{d}_i$ in the training data. Then, the optimal values of these are found by repeatedly computing the following pair of

update equations:

$$\phi_{ijk} \propto \beta_{kj} \exp\left(\Psi(\gamma_k) - \Psi\left(\sum_{k'=1}^{K} \gamma_{k'}\right)\right) \quad (3)$$

$$\gamma_{ik} = \alpha_k + \sum_{j=1}^{J} \phi_{ijk}\, tf(w_j, \boldsymbol{d}_i) \quad (4)$$

where Ψ is the first derivative of the log Γ function.

Next, $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are updated using $\boldsymbol{\gamma}_i$ and $\boldsymbol{\phi}_i$ for each $\boldsymbol{d}_i$. In the original paper, a Newton-Raphson method was used to estimate $\boldsymbol{\alpha}$ (Blei et al., 2003). However, estimation with the Newton-Raphson method has the disadvantages that it takes a long time and each estimated α_k can be a negative value under certain circumstances. It is known that the fixed-point iteration method (Minka, 2000) is a better estimation technique, and hence, we present the update equations based on this method. The update equations for $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are given below.

$$\beta_{kj} \propto \sum_{i=1}^{I} \phi_{ijk}\, tf(w_j, \boldsymbol{d}_i)$$

$$\alpha_k = \frac{\sum_{i=1}^{I}\{\Psi(\alpha_k + n_{ik}) - \Psi(\alpha_k)\}}{\sum_{i=1}^{I}\{\Psi(\alpha_0 + |\boldsymbol{d}_i|) - \Psi(\alpha_0)\}} \alpha_k^{old}$$

where $n_{ik} = \sum_{j=1}^{J} \phi_{ijk}\, tf(w_j, \boldsymbol{d}_i)$, $\alpha_0 = \sum_{k'=1}^{K} \alpha_{k'}$, and α_k^{old} represents α_k before the update.

Finally, the updates of $\boldsymbol{\gamma}_i$ and $\boldsymbol{\phi}_i$ for each $\boldsymbol{d}_i$ and those of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are iterated until convergence. Once all the parameters have been estimated, we can obtain the probability of a word w_j given a document $\boldsymbol{d}_i$ as

$$P_{\boldsymbol{d}_i}^{LDA}(w_j) \simeq \frac{\sum_{k=1}^{K} \beta_{kj}\gamma_{ik}}{\sum_{k=1}^{K} \gamma_{ik}}. \quad (5)$$

3.3 Inference of Unseen Texts

One major advantage of LDA over PLSI is that it has a natural way of inferring the probabilities of unseen texts, which are not included in the training data. When we compute the probabilities of an unseen text $\boldsymbol{t}$, the variational parameters $\boldsymbol{\gamma_t}$ and $\boldsymbol{\phi_t}$ are estimated using Eqs.(3) and (4). Then, for example, the probabilities of words given $\boldsymbol{t}$ can be obtained using Eq.(5).

3.4 LDA in IR

Certain works using LDA for IR are closely related to our work. Wei and Croft (2006) incorporate LDA into a query likelihood model, while Zhou and Wade's work can be viewed as a study that incorporates LDA into a KL-divergence retrieval model (Zhou and Wade, 2009). Such works successfully utilize the latent information in texts through LDA, and report that the latent information is effective for ad-hoc retrieval. Although there are many differences between our work and those mentioned above, one of the biggest differences is that whereas the other works explored the effectiveness of the latent information for ad-hoc retrieval, we explore it for RF beyond ad-hoc retrieval.

4 Proposed Method

4.1 Overview

An overview of the proposed method is illustrated in Figure 1. First, when a query is submitted by a user, we obtain the initial search results (Step 1). Next, for each document in the search results, we construct a hybrid language model that contains not only the surface information, but also the latent information in the document (Step 2). Then, when user feedback is given, we also construct a hybrid language model for it (Step 3). Finally, we construct a new query model by interpolating the original query model with the feedback model. We also re-rank the initial search results using this new model so that documents with a similar topic distribution to that of the user feedback are re-ranked higher (Step 4). In the following subsections, we describe each step in detail.

4.2 Acquisition of Initial Search Results

In the proposed method, we employ a KL-divergence retrieval model (Lafferty and Zhai, 2001) to obtain the initial search results for a given query. First, we construct the MLE-based query model $P_{\boldsymbol{q}}^{MLE}(\cdot)$ for a query $\boldsymbol{q}$ using Eq.(1). Then, for each document containing $\boldsymbol{q}$ in the collection, the KL-divergence between the DIR-based document model and the MLE-based query model is computed. That is, the score of a document $\boldsymbol{d}$ for a query $\boldsymbol{q}$ is defined as follows.

$$initial\_score(\boldsymbol{d}, \boldsymbol{q}) = -KL(P_{\boldsymbol{q}}^{MLE}(\cdot)||P_{\boldsymbol{d}}^{DIR}(\cdot))$$

Finally, the initial search results $\boldsymbol{D_q} = (\boldsymbol{d}_1, \ldots, \boldsymbol{d}_{|\boldsymbol{D_q}|})$ are obtained by ranking the documents according to their scores.

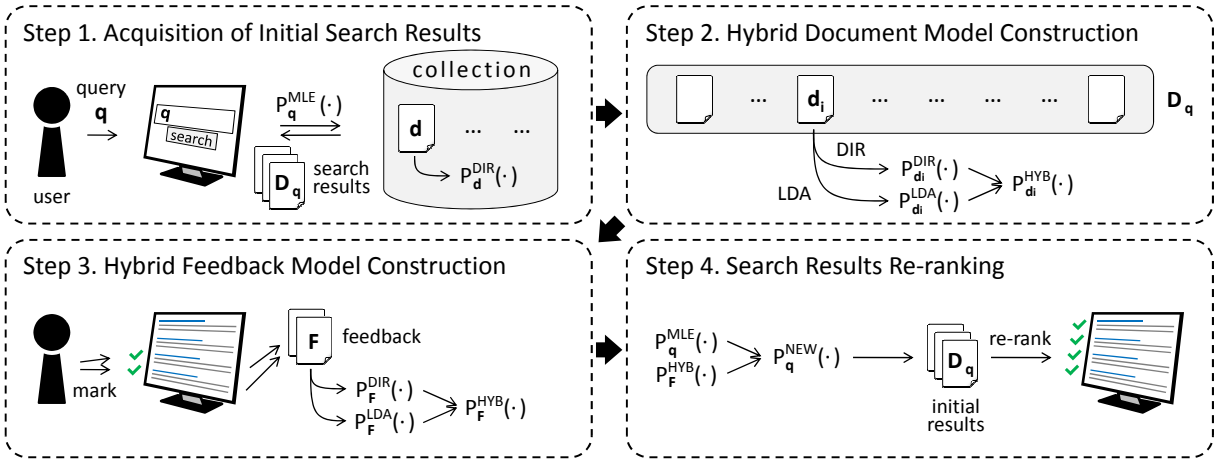

Figure 1: Overview of the proposed method.

4.3 Hybrid Document Model Construction

For each document in the search results, we construct a hybrid language model, which we call the HYB-based language model. In this model, we take into account the latent information in documents as well as the surface information.

First, an LDA-based document model that contains the latent information in the document is constructed for each document. We perform LDA on $\boldsymbol{D_q}$ to infer the topic distribution in each document $\boldsymbol{d}_i$, and estimate the parameters $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}_i$ for each $\boldsymbol{d}_i$ as described in Section 3.2. Then, the LDA-based document model is constructed by computing the probabilities of words given $\boldsymbol{d}_i$ using Eq.(5). In this model, we can allocate high probability to words that are highly probable from the latent topic distribution of a document.

Next, for each $\boldsymbol{d}_i$, we construct an HYB-based document model $P^{HYB}_{\boldsymbol{d}_i}(\cdot)$ by interpolating the DIR-based document model with the LDA-based document model as follows.

$$P^{HYB}_{\boldsymbol{d}_i}(w_j) = (1-a)P^{DIR}_{\boldsymbol{d}_i}(w_j) + aP^{LDA}_{\boldsymbol{d}_i}(w_j)$$

where a is a parameter that controls the reliability of the LDA-based document model.

This interpolation is motivated by significant improvements reported in (Wei and Croft, 2006). They also interpolate a DIR-based document model with an LDA-based document model, and perform LDA on the whole collection to construct the LDA-based document model. However, executing LDA throughout the whole collection requires high computational cost. In the proposed method, we can avoid this problem by performing LDA only on the set of search results, which is much smaller than the whole collection.

4.4 Hybrid Feedback Model Construction

When feedback is given, we also construct an HYB-based language model for it. First, we obtain feedback $\boldsymbol{F} = (\boldsymbol{f}_1, \ldots, \boldsymbol{f}_{|\boldsymbol{F}|})$ that is relevant to the user's information need. Note that, in this study, we are not concerned with whether $\boldsymbol{F}$ is explicit, implicit, or pseudo feedback. Moreover, we have no preference of whether each $\boldsymbol{f}_i$ is a whole document or part of a document (e.g., title, snippet).

Next, we perform LDA on $\boldsymbol{F}$ to infer the topic distribution in $\boldsymbol{F}$, and construct the LDA-based feedback model $P^{LDA}_{\boldsymbol{F}}(\cdot)$. To be more precise, we generate a virtual relevant document $\boldsymbol{f}$ by combining each $\boldsymbol{f}_i$, and infer the variational parameter $\boldsymbol{\gamma}_{\boldsymbol{f}}$ as described in Section 3.3. Then, $P^{LDA}_{\boldsymbol{F}}(\cdot)$ is constructed using Eq.(5).

Finally, we construct the HYB-based feedback model $P^{HYB}_{\boldsymbol{F}}(\cdot)$, which contains the surface and latent information in $\boldsymbol{F}$. $P^{HYB}_{\boldsymbol{F}}(\cdot)$ is constructed in the same manner as $P^{HYB}_{\boldsymbol{d}_i}(\cdot)$. That is,

$$P^{HYB}_{\boldsymbol{F}}(w_j) = (1-a)P^{DIR}_{\boldsymbol{F}}(w_j) + aP^{LDA}_{\boldsymbol{F}}(w_j)$$

where $P^{DIR}_{\boldsymbol{F}}(\cdot)$ is constructed using Eq.(2).

4.5 Search Results Re-ranking

We construct a new query model, which is used to re-rank the initial search results. The new query model $P^{NEW}_{\boldsymbol{q}}(\cdot)$ is constructed by interpolating the original query model $P^{MLE}_{\boldsymbol{q}}(\cdot)$ with the hybrid feedback model $P^{HYB}_{\boldsymbol{F}}(\cdot)$ as follows.

$$P^{NEW}_{\boldsymbol{q}}(w_j) = (1-b)P^{MLE}_{\boldsymbol{q}}(w_j) + bP^{HYB}_{\boldsymbol{F}}(w_j)$$

where b is a parameter that controls the reliability of the feedback model. This interpolation is based

on Zhai and Lafferty's linear combination method (see Section 2.3).

Then, for each document $\boldsymbol{d}_i$ in the search results $\boldsymbol{D_q}$, we compute the KL-divergence between $P^{HYB}_{\boldsymbol{d}_i}(\cdot)$ and $P^{NEW}_{\boldsymbol{q}}(\cdot)$. That is, the score of document $\boldsymbol{d}_i$ for query $\boldsymbol{q}$ and feedback $\boldsymbol{F}$ is defined as

$$re\text{-}ranking\_score(\boldsymbol{d}_i, \boldsymbol{q}, \boldsymbol{F}) = -KL(P^{NEW}_{\boldsymbol{q}}(\cdot)||P^{HYB}_{\boldsymbol{d}_i}(\cdot)).$$

Finally, we obtain the revised search results by re-ranking the documents in $\boldsymbol{D_q}$ according to their re-ranking scores.

5 Experiments

5.1 Overview

We conducted three experiments to evaluate the performance of our method. An overview of each experiment is given below.

Experiment 1. Effectiveness with Respect to Explicit and Pseudo RF

We examined how well our method performed in re-ranking the initial search results using explicit and pseudo feedback. In the experiment with explicit RF, we obtained the top 100 documents with the highest initial scores as the initial search results for a given query, and re-ranked them using our method with two relevant documents that were given explicitly. In our experiments, we employed the queries and the relevant documents provided by NTCIR (see Section 5.3). Then, we compared the results with the following three (re-)ranking results.

INIT This is the ranking of the initial search results obtained based on the KL-divergence retrieval model.

WORD This is the ranking of the search results obtained after simple RF, where we used only the surface information (i.e., words) in the feedback and the documents in the search results. This ranking is equivalent to the ranking obtained using our method with $a = 0$.

REPR This is the re-ranking result obtained using Zhai and Lafferty's RF method (Zhai and Lafferty, 2001). The process of the method is almost the same to that of WORD. The main difference is that it modifies the probabilities of words in feedback by a background word distribution (see their paper). We chose their method as it is a representative RF method for language modeling approaches.

Our method can also be applied to pseudo RF. Hence, we also explored the effectiveness of our method in this regard. With pseudo RF, the top n documents in the initial search results are assumed to be relevant, and the search results are re-ranked based on this assumption. We implemented pseudo RF using our method for $n = 10$, and compared the results with the three (re-)ranking results described above.

Experiment 2. Effect of the Amount of Feedback

It is important to know how well our method performs when only a small amount of feedback is obtained, because in practice users generally cannot be bothered to provide feedback, and thus sufficient feedback is rarely obtained. We investigated how the amount of explicit feedback affected the performance of our method. To be more precise, we reduced the amount of available explicit feedback little by little, and observed the change in precision at 10 top re-ranked documents (P@10). For this experiment, we used seven different amounts of explicit feedback: 2^1, 2^0, 2^{-1}, 2^{-2}, 2^{-3}, 2^{-4}, and 2^{-5} relevant documents. Note that, for example, 2^{-1} documents means that we used half a document's worth of words in the relevant documents given as explicit feedback. In this case, half the words were sampled randomly from the feedback, and only these words were used for RF.

Experiment 3. Sensitivity to Parameters

It is also important to know how the reliability of the LDA-based document model and the HYB-based feedback model affect the performance of our method. Hence, we investigated how sensitive our method is to parameters a and b. We re-ranked the initial search results using different values for these parameters ranging from 0 to 1 in steps of 0.1, and measured how the performance of our method changed according to these values.

5.2 Configuration of Our Method

The configuration of our method is given below. For the DIR estimation, we set the smoothing parameter $\mu = 1,000$. This setting was also employed in other works (Zhai and Lafferty, 2001; Wei and Croft, 2006). The number of topics K for LDA was set to 20, since with this setting we obtained better results in the preliminary experiments, in which we performed LDA with K rang-

ing from 10 to 100 in steps of 10. We set the initial values of $\alpha_k (k = 1, \ldots, K)$ to 1, and the initial values of $P(w_j|z_k, \boldsymbol{\beta})$ to random values. The number of iterations for the variational parameters and that for $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ were set to 10. Additionally, we limited the size of the vocabulary in LDA, designated as J in Section 3, to $1,000$. We selected $1,000$ words based on their importance to the search results. Note that the importance of a word w_j to the search results $\boldsymbol{D_q}$ is defined as $df(w_j, \boldsymbol{D_q}) * \log(|\boldsymbol{D}_{all}|/df(w_j, \boldsymbol{D}_{all}))$, where $df(w_j, \boldsymbol{D})$ represents the document frequency of w_j in documents $\boldsymbol{D}$.

5.3 Data Set

In our experiments, we employed the test collection used in the Web Retrieval Task in the Third NTCIR Workshop (Eguchi et al., 2002). The NTCIR Workshops are a series of evaluation workshops designed to enhance research in information access technologies. The test collection consists of $11,038,720$ Japanese Web pages and 47 information needs. For each information need, about $2,000$ documents are rated as highly relevant, fairly relevant, partially relevant, or irrelevant. We used only 40 information needs in our experiments. The remaining 7 (with identification numbers: 0011, 0018, 0032, 0040, 0044, 0047, and 0061) were not used, because we could not retrieve 100 documents for each (see Section 5.1).

Figure 2 gives an example of an information need for the Web Retrieval Task in the Third NTCIR Workshop. The meaning of each element is given below.

⟨NUM⟩ gives the identification number of the information need.

⟨TITLE⟩ provides up to three terms that are similar to the actual query submitted to a real search engine.

⟨DESC⟩ describes the user's information need in a single sentence.

⟨RDOC⟩ provides up to three identification numbers of examples of relevant documents for the information need.

We employed the terms in the ⟨TITLE⟩ tag as the query, and the documents in the ⟨RDOC⟩ tag as explicit feedback. Note that since the numbers of terms and documents differed depending on the information need, we employed the first two terms in the ⟨TITLE⟩ tag and the first two documents in the ⟨RDOC⟩ tag for each information need.

5.4 Evaluation Method

We used P@10, mean average precision (MAP), normalized discounted cumulative gain at 10 top (re-)ranked documents (NDCG@10), and NDCG@100 (Järvelin and Kekäläinen, 2002) in the evaluation. In the calculation of P@10 and MAP, documents that were rated as highly relevant, fairly relevant and partially relevant were regarded as relevant, while documents rated as irrelevant and unrated documents were regarded as irrelevant. Note that MAP was calculated using all the (re-)ranked documents (i.e., 100 documents). In calculating NDCG, we assessed the relevance score of documents rated highly relevant, fairly relevant and partially relevant as 3, 2, and 1 respectively.

To evaluate the effectiveness of explicit RF, we decided in advance which documents would be used as explicit feedback as described in Section 5.3, and if these were included in the initial search results and the re-ranked results, we removed them from both sets of results. One common problem in the evaluation of the effectiveness of explicit RF is how to handle documents that users have marked as relevant (i.e., the input to RF methods) (Hull, 1993). If the initial search results and the re-ranked results are compared in a straightforward manner, the latter have an advantage. This is due to the fact that documents that are known to be relevant tend to be re-ranked higher. However, if we remove them from the re-ranked results, they have a disadvantage. This is especially true if there are few relevant documents. Therefore, we removed the documents used as explicit feedback from both the initial search results and the re-ranked results in the experiments with explicit RF.

In contrast, we did not apply extra care in Experiment 1 with pseudo RF, and measured the performance of each method using its raw (re-)ranked results.

5.5 Experimental Results

Experiment 1. Effectiveness with Respect to Explicit and Pseudo RF

Table 1 gives the results for explicit RF. Owing to space limitations, we only show the optimal results in terms of P@10 for each method. The optimal results for WORD were obtained using our

Table 2: Effectiveness with respect to pseudo RF.

	P@10	MAP	NDCG@10	NDCG@100
INIT	0.298	0.112	0.243	0.268
WORD	0.303	0.111	0.258	0.274
REPR	0.300	0.112	0.250	0.270
OURS	0.330	0.112	0.283	0.278

method with $a = 0$ and $b = 0.7$, while those for OURS (our method) were obtained with $a = 0.2$ and $b = 0.7$.

Based on this table, we can confirm that our method is effective with respect to explicit RF. Our method significantly improved the initial search results across all metrics. Additionally, it outperformed two other baseline RF methods, with the differences in all metrics being statistically significant (Wilcoxon signed-rank test, $p < 0.05$). There were no significant differences between the baseline methods, since they were similar in process to each other. These results suggest that the latent information in the user feedback and each document in the search results is useful for explicit RF.

As a result of the investigation, we found that our method made good use of the words that did not appear in the feedback but were highly probable from the latent topic distribution of the feedback. Consider the information need in Figure 2 as an example. The documents employed as user feedback did not contain the words "technique" or "level", which are related to the information need. As such, the baseline methods could not use these words. In contrast, our method allocated a certain degree of probability to these highly probable words using LDA, despite the words not appearing in the feedback, and hence raised the score of relevant documents in the search results containing these words.

Table 2 gives the results for pseudo RF. The values of the parameters for WORD and OURS were determined as: $a = 0, b = 0.7$, and $a = 0.1, b = 0.6$, respectively. Note that the results of INIT in Table 2 differ from those in Table 1. This is because although we removed the documents used as user feedback from the initial search results (and the re-ranked results) in the experiment with explicit RF, we did not remove them from any of the results in this experiment.

From this table, we can see that our method significantly improved the initial search results. Additionally, our method outperformed the baseline methods. From these results, we can conclude that our method is also effective with respect to pseudo RF.

Experiment 2. Effect of the Amount of Feedback

Figure 3 shows the effect of the amount of explicit feedback on the performance of our method. For comparison with baseline methods, we also present their results. The parameters for each method were identical to those used in Experiment 1 with explicit RF.

From this figure, we can see that our method achieved consistently high performance. For example, when 2^0 relevant documents (i.e., one relevant document) were given as user feedback, our method improved the initial search results by about 35% in P@10. Additionally, a notable feature is that although the improvements in the baseline methods almost disappeared, our method performed well when only a small amount of feedback was obtained. For example, improvement of about 18% was achieved even with only 2^{-5} documents, which constituted an average of 52 words in our experiment. The reason for this is, once again, that our method is able to use not only the surface words in the feedback, but also the highly probable words from its latent topic distribution.

As described above, our method can re-rank search results using a small amount of feedback. This suggests that our method is practically useful, and that it performs well even if only a part of a document (e.g., title, snippet), the relevance of which is easier to determine than that of the whole document, are given as user feedback.

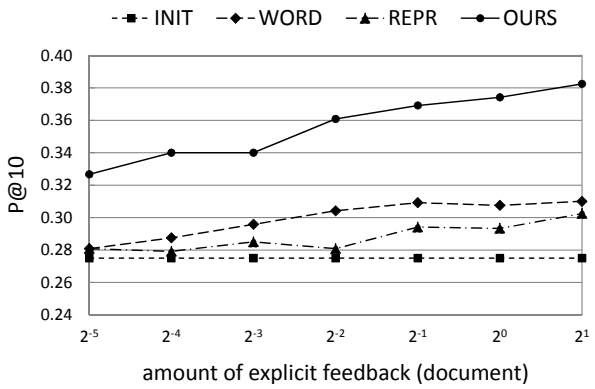

Figure 3: Effect of the amount of feedback.

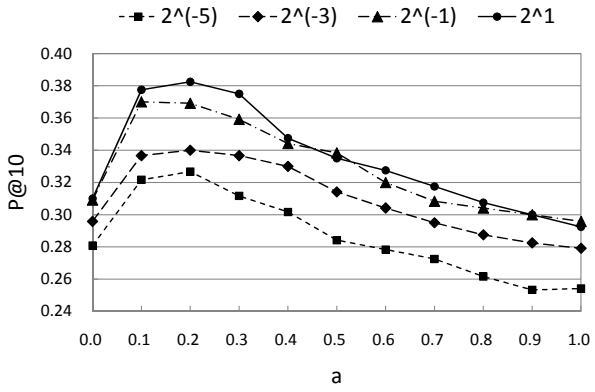

Figure 4: Sensitivity to parameter a.

Experiment 3. Sensitivity to Parameters

The sensitivity of the performance to a is illustrated in Figure 4. Each line in the figure represents the results with different amounts of explicit feedback: 2^{-5}, 2^{-3}, 2^{-1}, and 2^{1} relevant documents. The value of the other parameter b was fixed to 0.7. From this figure, we can see that the performance of our method is sensitive to the value of a, and that the optimal value is about 0.2. Despite the goal and setting being different to ours, this optimal value is similar to that reported in (Wei and Croft, 2006), where the DIR- and LDA-based document models were interpolated as in our work.

The sensitivity to b is depicted in Figure 5. The value of a was fixed to 0.2. According to this figure, we can see that the setting of b also affected the performance of our method. Additionally, this figure shows that if we set the value appropriately, the interpolated new query model is more effective than both the original query model on its own (i.e., $b = 0.0$) and the feedback model on its own (i.e., $b = 1.0$). These findings concur approximately with the results presented in (Zhai and Lafferty, 2001).

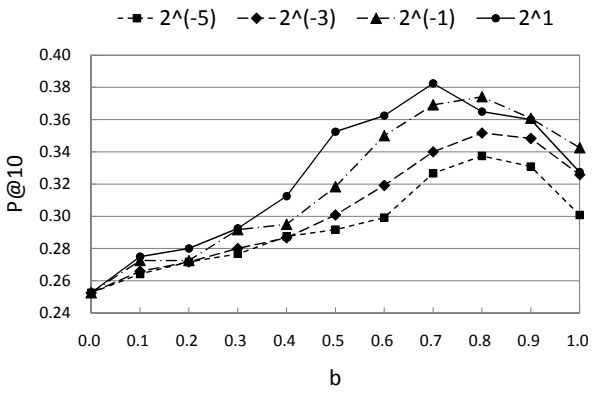

Figure 5: Sensitivity to parameter b.

5.6 Discussion

Although our method achieved good performance in our experiments, we also encountered a problem in that the method took a long time to execute. More specifically, our method required about one minute to estimate the parameters of LDA in Step 2. (On the other hand, the time required for Steps 1, 3, and 4 was only a few seconds.) Thus, we need to explore ways of reducing the time for parameter estimation so that our method can be used in real situations. One way of doing this is to choose a faster estimation technique. For example, collapsed variational methods may provide a viable solution (Teh et al., 2006; Asuncion et al., 2009). Another alternative is to decrease the size of the vocabulary, designated as J in Section 3. For example, we conducted an additional experiment, in which we set $J = 100$, and confirmed that the time for parameter estimation fell to about 10 seconds without any significant change in performance.

6 Conclusion

In this paper, we proposed a novel RF method using latent information, and discussed the effectiveness thereof. Using LDA, our method infers the distributions over latent topics in the feedback and in each document in the search results. Then, documents whose topic distribution resembles that of the feedback are regarded as being relevant to the user's information need, and are re-ranked higher. Through our experiments, we confirmed that our method achieves good performance for both explicit and pseudo RF, and that it provides the benefit of performing well even when only a small amount of feedback can be obtained. As future work, we aim to explore ways of reducing the execution time of our method so that it can be used in practical situations.

Abstract

In this paper, we propose a keyword-based passage retrieval algorithm for information extraction, trained by distant supervision. Our goal is to be able to extract attributes of people and organizations more quickly and accurately by first ranking all the potentially relevant passages according to their likelihood of containing the answer and then performing a traditional deeper, slower analysis of individual passages. Using Freebase as our source of known relation instances and Wikipedia as our text source, we collected a weighted set of keywords indicative of each relation and then use it to re-rank the passages retrieved by the Lemur search engine. Experiments show that our algorithm significantly outperforms state-of-the-art passage retrieval techniques in evaluations of both individual passage retrieval and end-to-end information extraction.

1 Introduction

Large-corpus information extraction involves the extraction of pre-specified types of relations and events from large corpora. For example, the Knowledge Base Population (KBP) slot-filling task (Ji et al., 2010) involves finding, from a large corpus, a few dozen attributes of a specified person or organization.

In many cases we do not have the time to perform in-depth extraction for all attributes over the entire corpus. Consequently, addressing this task typically involves a blend of traditional question answering (QA) and information extraction (IE) methods. Like QA, we need to begin with passage retrieval, where a passage can range from a sentence to a piece of text or a document. However, unlike QA, we have a fixed inventory of relations and a fixed set of expected answer types (e.g. employer of a person). This allows us to bring to bear the more specialized learning methods of IE to tune the passage retrieval for each relation of interest.

To the best of our knowledge, we are the first to systematically study the passage retrieval algorithm for information extraction and propose a novel distant supervision approach to obtain a list of weighted keywords for each relation. Distant supervision (Mintz et al., 2009) makes use of noisy training data generated automatically from a related, but different, type dataset to solve problems on another type of data. Instead of a handful of human-selected keywords, we automatically learn hundreds or thousands of indicative keywords from a freely available online resource, Freebase, which is similar to Wikipedia Infoboxes. Passages are ranked and retrieved based on these keywords indicative of certain relations. We then feed individual passages to a traditional IE system or to an answer extraction component as used in QA systems to obtain the final outputs. Both the training and testing procedures of our method require only statistics of surface words and named entities in the text and thus are time efficient.

This paper addresses the following questions:

1) How can we tune passage retrieval for a particular relation?

2) How do distant learning methods apply to the passage retrieval task?

3) How much do these methods improve over typical QA passage retrieval?

We will measure the improvement in two ways:

1) ability to find a relevant passage, such as reduction in the number of passages the system must examine and increase in the proportion of relevant passages in top-ranked ones;

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1046–1054,
Chiang Mai, Thailand, November 8 – 13, 2011.

2) improvement in the precision and recall of information extraction by taking passage relevance into account.

2 Previous Work

Relatively little work has been done to investigate in detail the quality of the IR for large-corpus IE and take advantage of the more constrained relations of interest compared to traditional QA. The Knowledge Base Population (KBP) track at TAC 2010 (Ji et al., 2010) evaluates the ability of automated systems to discover information about named entities. Its slot-filling task is to find answers to queries asking a few dozen attributes of a specified entity, such as the 'employee_of' attribute of a given PERSON entity. We refer to the given entity as the *target entity*, and the attributes of entities as *slot types*. In past KBP competitions, many participants (Li et al., 2009; Byrne and Dunnion, 2010; Chen et al., 2010) exploited a QA system to fill slots by constructing queries based on target entities and slot types. However, their query templates contain only a few additional query terms other than the target entity name, which are mostly obtained manually.

Most of QA systems use the question words as-is or with expansion to form the retrieval system query. Various query expansion approaches have been used to tackle the passage-query mismatch problem, including relevance feedback (Derczynski et al., 2008), ontologies (Bhogal et al., 2007), semantic lexica (Ofoghi et al., 2006), etc. As a data-driven approach, relevance feedback is sensitive to the quality of first time retrieval. Our use of Freebase, a freely available large semantic database, to provide distant supervision requires neither labeled data nor costly constructed knowledge models.

Some researchers (Grishman and Min, 2010; Chrupala et al., 2010; Surdeanu et al., 2010) integrated IR and IE together. Surdeanu et al. (2010) coupled the entity name with a handful of hand-selected trigger words for each slot type as queries to IR system in an effort to boost the ranking of sentences likely to contain the relations of interest. Chrupala et al. (2010) proposed one of the most customized passage retrieval components for large-corpus IE. Besides the target name entity, they take into account the type of expected named entity (such as ORGANIZATION for the 'employee_of' relation) and expand queries by predefined words that are predictive for specific slot types (such as 'work' for the 'employee_of' relation). There are also relevant works emerging from the IR community in the Related entity Finding (REF) task in the TREC Entity Track (Balog et al., 2010), which is to return a ranked list of related entities given an expected type of entity and a brief description (query) of the relation in free text. Fang et al. (2010) ranked entities by their relevance to the query at the document, passage and entity level, primarily based on the similarity between terms.

In all this previous work, the limited number of query terms has become the performance bottleneck of the passage retrieval for large-corpus information extraction.

Perhaps most similar to our distant supervision keyword learning approach for passage retrieval is the semi-automatic method of Nguyen et al. (2007), who extract only several keywords for each relation from Wikipedia and study only the dependency subtrees that contain those keywords. In contrast to their tf-idf model followed by a manual selection step, our algorithm allows us to fully automatically extract hundreds or even thousands of keywords with a weight indicating their relevance to each relation.

Mintz et al. (2009) proposed a distant supervision approach for relation extraction using a rich-featured logistic regression model. Like us, they used Freebase as a source of known relation instances and Wikipedia as a text source to create noisy training data and tested on the Wikipedia data. Our approach differs from theirs in several ways. First, our main concern is the speed required for large-corpus IE and reducing the amount of text to process by passage retrieval, while they use deep NLP features such as parsing and process the whole corpus. Second, we assure the quality of output by using a supervised information extraction system trained on golden data, while their performance is constrained by noisy training data. Third, we evaluate on a corpus that consists of news and web data, while they test on Wikipedia data that is from the same source as the training data. We prove that our method is adaptive to new domains because it is based on lexical statistics and thus tolerant to noise in the training data.

3 Freebase and Wikipedia

Freebase[1] is a freely available online database of structured knowledge. It collects information about approximately 20 million entities (such as

[1] http://www.freebase.com

people, places, books, etc.) from a wide variety of sources, including Wikipedia, MusicBrainz (music), NNDB (biographical information), user editing, etc.

Following the literature (Mintz et al., 2009), we refer to each attribute of a person or organizations as an ordered, binary 'relation' between entities. We refer to individual entity pairs in a relation as relation instances. For example, the 'employee_of' relation indicates a person's employment history with zero to many companies, of which an instance can be <Steve Jobs, employee_of , Apple Inc.>.

Freebase provides us a set of relations and entity pairs that participate in those relations. Often understood as a Wikipedia-turned-database, Freebase also distinguishes similar names and includes exact wiki articles for many entities, and thus forms a perfect source for training texts. We will later discuss the effectiveness and adaptivity of using Wikipedia as training corpus at the end of Section 4 and in Section 7.

4 Learning Indicative Keywords for Relations from Freebase

Our intuition in this research is that there exist some keywords that provide clues to the text passages containing the relationship. For example, a sentence or a couple of successive sentences which contain words like 'hire', 'work', 'appoint', and so on, are highly likely to express the 'employee_of' relation.

We identify such keywords using a distant supervision approach. First, we obtain entity pairs for a certain relation and the Wiki articles of these entities from Freebase. Then we locate the entities in the training corpus to collect sample sentences for each relationship. Finally, we rank the words based on their frequency in those sample sentences versus all sentences in the training corpus.

Like previous work (Nguyen et al., 2007; Mintz et al., 2009), our distant supervision assumption is that if two entities participate in a relation, a sentence that contains those two entities might express that relation. For our training corpus, we choose Wikipedia in this paper since it well supports Freebase data and is believed to have high grammatical correctness compared to that of the web overall. It is also feasible to use another corpus as long as it potentially contains text about the relationships of interest and the known entity pairs.

Unlike (Mintz et al., 2009), which considers any sentences containing the pair of entities, we take advantage of the fact that Wikipedia records only one article per language for a real world entity. Any sentences in the person's Wiki article that contains the person name or pronouns ('she' or 'he') and his/her employer name are considered positive examples, others as negative examples. This setting can capture more true positive examples. What is more, Freebase includes name variants of a real world entity and thus gives a better chance to match the person name back to his/her Wiki pages.

We then determine if a word is indicative and to what degree for a certain type of relation based on its occurrence in positive and negative examples. We use the morphological base forms to replace their inflectional variants in the process. The indicative score I of word w for relation R is calculated by the following formula:

$$I(w,R) = \frac{Pos}{Pos+Neg} \times \frac{Pos}{Pos+\alpha} \qquad (1)$$

where $Pos = |S_{pos}(w,R)|$ and $Neg = |S_{neg}(w,R)|$, $S(w,R)$ are all the positive/negative sentences for relation R which contain word w. The larger the weight the more likely the word indicates the relationship. The first factor $Pos/(Pos+Neg)$ favors words which are more frequent in positive sentences versus all sentences. The factor $Pos/(Pos+\alpha)$ is used to reduce low frequency word noise, where α is a constant to be set experimentally. All the words with $Pos > Neg$ are extracted to form a weighted keyword list for each relation.

Table 1 shows the top-weighted keywords learned for the 'employee_of' and 'member_of' relations, using the January 2011 data dump of Freebase. The Freebase contains 10702 instances of 'employee_of' relation (named '/business/ employment_tenure/' in Freebase), among which 4497 are found in its corresponding Wikipedia articles. In total, 6574 positive, 93756 negative examples and a weighted set of 2436 keywords indicative of the relation are extracted. For 'member_of' relation (named '/organization/ organization_membership/' in Freebase), there are 586 instances in Freebase, 244 positive and 13749 negative examples extracted from Wikipedia pages. With many fewer training examples provided by Freebase for the 'member_of' relation, only 290 keywords are learned, but they proved to be effective in the experiments in Section 7.

employee_of		
1-10	**11-20**	**21-30**
faculty	currently	headquarter

membership	hence	sector

Table 1. List of top-weighted keywords

It is very interesting that many keywords found may not be intuitive, such as "currently", "until", and "supermarket" for the 'employee_of' relation. Though they do not directly imply the occurrence of the relations, they tend to co-occur with the relations, thus helpful in retrieval. Moreover, our system does not rely on only one keyword to make decisions and thus is robust. We also notice that the 'member_of' relation in Freebase has a bias towards the education domain; however, this has little impact in general performance, as shown in Section 7, because the keyword set still covers the most common keywords such as 'member' and 'founder' while the more domain-specific words are rarely seen in the text. This is likely because usually the queried entity helps in disambiguating the relation words and focusing on the right subset of the relation words.

5 Passage Retrieval for Information Extraction

5.1 Lemur

Our goal is to develop a speedy passage retrieval model for the IE task without using complex NLP techniques.

We first employ the high-performance Lemur passage retrieval engine to select relevant passages about the target named entity from a large corpus. Lemur (Metzler and Croft, 2004) implements a model combining language modeling and an inference network and has been widely used in large-corpus IE and QA systems. We define a passage as a natural paragraph in the texts and use Lemur's default setting, which shows a satisfactory capability to retrieve most passages containing a given entity in experiments.

Then, we re-rank the retrieved passages in descending order of their probability of containing the target relation R (e.g. 'employee_of').

5.2 Baseline

Our baseline passage retrieval algorithm for information extraction is derived from the state-of-the-art methods used in the IE community (Chrupala et al., 2010; Surdeanu et al., 2010), IR community (Zhao and Callan, 2008) and Question Answering community (Tellex et al., 2003; Hickl et al., 2007; Moldovan et al., 2007; Gómez et al., 2007). The baseline (and our proposed approach) are intended to involve minimal human-constructed knowledge, annotated data and complex NLP processing.

In the baseline method, the ranking score B of a passage P, with respect to relation R and target entity E, consists of four elements:

$$B(P,R,E) = W_1(P,E) + W_2(P,R) + W_3(P,R) + W_4(P,E) \quad (2)$$

Please note that the constants c in each scoring functions $\boldsymbol{W}$ are only used to define cascading criteria, e.g. any passage that contains the target named entity will be ranked higher than those do not, and thus can be set rather arbitrarily.

1) **The target named entity ($\boldsymbol{W_1}$):** We ensure that passages that (partly) include the string of entity names rank higher than those only containing pronouns.

$$W_1(P,E) = \begin{cases} c_{1a}, if\ P\ contains\ E \\ c_{1b}, if\ P\ partly\ contains\ E \\ c_{1c}, if\ P\ contains\ pronouns \\ 0,\ otherwise \end{cases} \quad (3)$$

where $c_{1a} > c_{1b} > c_{1c}$ are arbitrary constants larger than any possible value of $W_2 + W_3 + W_4$. The passage partly contains the entity when it shares at least a word in common with the entity name.

2) **The named entity of the expected type (W_2):** The named entity of the type that is to be found for the relation is called the expected named entity, (e.g. 'ORGANIZATION' for relation 'employee_of'). We run the Stanford Named Entity Recognizer (Finkel et al., 2005) on Lemur's passage retrieval outputs, preferring passages that contain a named entity of the sought type, and more strongly preferring names that have not appeared in previously retrieved passages (novel names).

$$W_2(P,R) = \begin{cases} c_2 + c_3, if\ P\ contains\ novel\ expected\ entity \\ c_3, if\ P\ contains\ expected\ entity \\ 0, otherwise \end{cases} \quad (4)$$

where c_2 and c_3 are arbitrary constants larger than any possible value of $W_3 + W_4$.

3) **The expansion terms (W_3):** The expansion terms include predefined words that are predictive of or related to a specific relation. We adapt the indicative word list used by Surdeanu et al. (2010) in their KBP system, which include several words for each relation. We also use a list containing 635 common title words as related terms for the 'employee_of' relation. This effort is to simulate the usage of WordNet and ontologies for term expansions but is considered to be more accurate and comprehensive since these terms are collected for the purpose of these particular relations.

$$W_3(P,R) = \begin{cases} c_4, if\ P\ contains\ related\ terms\ of\ R \\ 0, otherwise \end{cases} \quad (5)$$

where c_4 is a arbitrary constant set not less than 1 (thus W_4).

4) **The original rank in Lemur (W_4):** We also take into account the rank from Lemur's passage retrieval.

$$W_4(P,E) = \frac{1}{LemurRank(P,E)} \quad (6)$$

where $LemurRank(P,E)$ is the rank of the passage P as returned from Lemur when querying for entity name E.

5.3 Passage Retrieval using Indicative Keywords Learned from Freebase (IKFB)

As in the baseline, we give top priority to the passages that contain the target named entity and at least a named entity of the expected type for the relation. We discard other weighting schema in Section 5.2 but apply our learned list of weighted indicative keywords instead.

$$K(P,R,E) = W_1(P,E) + W_2(P,R) + W_5(P,R) \quad (7)$$

5) The indicative keywords (W_5):

$$W_5(P,R) = \sum_{w \in L_{distant}(R) \cap w \in Top_n(P)} I(w,R) \quad (8)$$

where $L_{distant}(R)$ is the set of indicative keywords obtained by the approach described in Section 4, $Top_n(P)$ is the set of top n words weighted by $I(w,R)$ which appears in passage P. The number n is experimentally set as 5 in this paper; it serves to prevent preferring longer passages while decreasing the relevance of extremely short passages.

6 Evaluation Issues

6.1 Test Data

In this paper, we use the KBP corpus as test data, which includes about 1.3 million documents of newswire and 0.5 million of web data.

We evaluate passage retrieval algorithms on one of the most frequent relations in the KBP task (Ji et al., 2010; Chen et al., 2010): 'employee_of'. We also experiment on 'member_of' relation, but due to limitations of space we only present MRR values for this relation. The KBP 2010 training data prepared by the Linguistic Data Consortium and by the participants, including 67 person entities, 54 instances each for 'employee_of' and 'member_of' relation, are used as test data in our experiments. Please note that one entity may be involved in multiple relation instances, e.g. a person may have multiple employers.

6.2 Evaluation Metrics

We evaluate the passage retrieval algorithms in two ways. First, we measure the performance of passage retrieval as an independent system, in the context of IR and QA. Second, we examine its impact on the end-to-end information extraction pipeline, in the context of IE.

6.2.1 Evaluation of Individual PR system

Following the literature of passage retrieval (Gómez et al., 2007; Roberts and Gaizauskas, 2004) and question answering, we use three metrics in the experiments, *Coverage*, *Redundancy* and *Mean Reciprocal Rank (MRR)*.

Let Q be the relation query set, D all possible passages which are retrieved by Lemur, $A_{D,q}$ the subset of D which contains correct answers for $q \in Q$, and $F^S_{D,q,n}$ the n top-ranked passages in D retrieved by a retrieval system S responding to query q.

The *coverage* of a retrieval system S for a query set Q and passage collection D at rank n is defined as:

$$coverage^S(Q,D,n) \equiv \frac{\left|\{q \in Q | F^S_{D,q,n} \cap A_{D,q} \neq \emptyset\}\right|}{|Q|} \quad (9)$$

The *answer redundancy* (or simply redundancy) is defined as:

$$redundancy^S(Q,D,n) \equiv \frac{\sum_{q \in Q}\left|F^S_{D,q,n} \cap A_{D,q}\right|}{|Q|} \quad (10)$$

The *Mean Reciprocal Rank (MRR)* (Voorhees, 1999) is defined as:

$$mrr^S(Q,D,n) \equiv \frac{\sum_{q \in Q} rr\left(q, F^S_{D,q,n}\right)}{|Q|} \quad (11)$$

where rr is the Reciprocal Rank which is the inverse of the rank of the first returned passage which contains the answer; or 0 if the answer is not found in the top n retrieved passages. The function is defined as:

$$rr\left(q, F^S_{D,q,n}\right) \equiv \begin{cases} {}^1/_k, if\ \exists k: k = \underset{1 \le i \le n}{\operatorname{argmin}}\left(F^S_{D,q,i} \cap A_{D,q} \neq \emptyset\right) \\ 0, otherwise \end{cases} \quad (12)$$

The coverage gives the proportion of relation instances (correct answers to the query) that can be found within the top n passages retrieved for each query. The redundancy gives the average number, per question, of passages within the top n ranks retrieved which contain a correct answer. The MRR is the average of the reciprocal ranks of the first ranked passage containing a correct answer.

6.2.2 Evaluation of End-to-End IE system

We also evaluate the impact of the passage retrieval algorithm on the final output of a large-corpus information extraction system.

6.2.2.1 Traditional IE Pipeline

We exploit a simple two-stage pipeline architecture for the KBP task. First, we retrieve passages related to the target entity. Then we apply to those passages a traditional information extraction system (Grishman et al., 2005; Ji and Grishman, 2008) to extract relations, which was originally created for the NIST Automatic Content Extraction (ACE) Evaluations. Its relation extraction component uses maximum entropy models, incorporating diverse lexical, syntactic, semantic and ontological knowledge.

To generate the final results, there could be different strategies. We use a simple strategy in this paper, which suffices to show the capability of our system, outputting the answers of the m top-ranked passages that provide an answer (possibly duplicate). A more delicate design is not a focus of this research.

6.2.2.2 QA-like Pipeline

The new passage retrieval IKFB system also allows us to create a QA-like pipeline for large-scale information extraction. Besides applying a sophisticated IE system to the retrieved passages using deep NLP techniques, such as coreference resolution, we can exploit answer extraction/selection components similar to many QA systems. Some common answer extraction/selection approaches, e.g. using distance from keywords, can possibly boost the speed by avoiding deep analysis and improve recall/precision by finding answers that the traditional IE system misses.

Consider the target entity "John Dewey" for example; the IE system failed to extract any employment information from the corpus. Our IKFB algorithm assigns top rank to the following passage:

"An institution that sees itself as an unconventional alternative to other colleges, the New School was founded in 1919 by a group of professors, including the philosopher and education reformer John Dewey, who had resigned in protest from Columbia. They could not abide by a stance taken by Columbia's president at the time, Nicholas Murray Butler, that faculty members had to support America's entry into World War I."

We investigate the potential value of passage ranking by implementing a simple answer extraction component and using its output when the IE pipeline failed to provide any answers to the probe query. The primitive method is to find the organization name that is closest to the target entity in the first top ranked passage, e.g. "Columbia" for the above passage (note: "New School" is missed by the Stanford named entity tagger). A distance-based answer extraction component is good at dealing with complicated language phenomena, since it is less likely to face data sparsity problem or syntactic analysis errors than many IE approaches do.

6.2.2.3 Measurement Metrics

In this framework, we use the traditional measures for evaluating IE, *precision* and *recall*. Following the symbols defined in section 6.2.1, *precision* and *recall* are defined as:

$$precision^S(Q,D,m) \equiv \frac{\sum_{q\in Q}|T^S_{D,q,m} \cap B_{D,q}|}{\sum_{q\in Q}|T^S_{D,q,m}|} \quad (14)$$

$$recall^S(Q,D,m) \equiv \frac{\sum_{q\in Q}|T^S_{D,q,m} \cap B_{D,q}|}{\sum_{q\in Q}|B_{D,q}|} \quad (15)$$

where m is as mentioned in Section 6.2.2.1 about the output generating strategies, $T^S_{D,q,m}$ are the system output, and $B_{D,q}$ are the golden answers.

7 Experiment Results

As we described in Section 6, we carry out experiments for the "employee_of" relation on the training data from KBP 2010, which includes 67 entities and 54 instances of the relation (involving 30 entities) as keys. Using the January 2011 data dump of Freebase as our sources of known relation instances and Wikipedia as out text source, we collect a weighted set of keywords indicative of the relation and then use it to re-rank the passages retrieved by the Lemur engine.

Three passage retrieval algorithms are compared:

- **Lemur**: the passage retrieval functionality provided by Lemur using only the target entity name. An example query looks like this: #combine[p](#5(John Dewey).
- **Baseline**: a baseline approach that prioritizes the passages retrieved by Lemur which contain the expected answer type, relevant terms of the relation, etc.
- **IKFB**: our proposed approach using the weighted keywords learned by distant supervision on Freebase data.

The constants in the ranking formulas were set as follows: $c_{1a} = 30000$, $c_{1b} = 20000$, $c_{1c} = 10000$, $c_2 = 1000$, $c_3 = 100$, $c_4 = 1$. Other values of these constants would be equally effective, as long as they distinguish the priority of each scoring criteria.

7.1 Performance of Individual Passage Retrieval

In Figure 1, we can see the improvement of our passage retrieval algorithm for information extraction usage with respect to the Lemur search engine and baseline system.

The coverage gives the proportion of correct answers that can be found within the top n passages retrieved for each query, if using a perfect information extraction system. For 31.5% of relation instances, only one passage had to be examined to retrieve the employment information using IKFB, while this number is 16.7% for the baseline system, 9.3% for Lemur. The coverage of the baseline and IKFB converge as the number

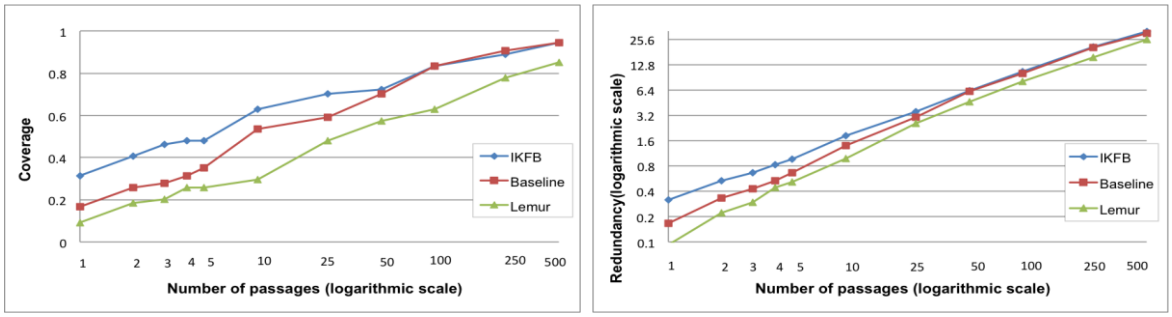

Figure 1. Performance of Individual Passage Retrieval Systems

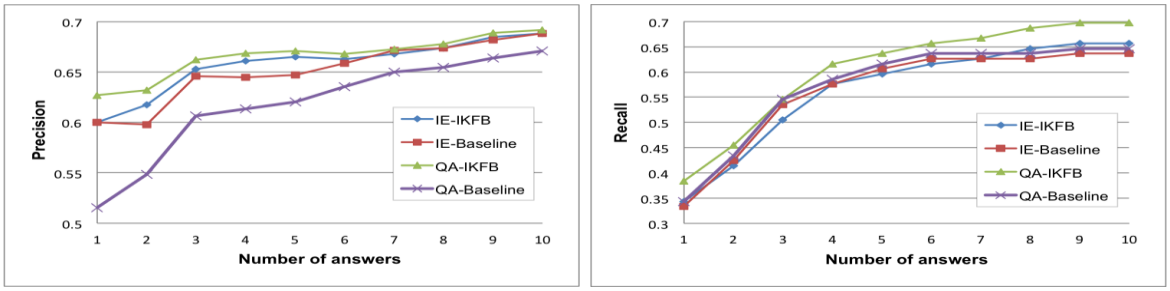

Figure 2. Performance of End-to-End IE
extracting answers for top-ranked passages for each target entity

of passages retrieved increases.

The redundancy gives the average number of passages within the top n retrieved passages which contain a correct answer. On average 18.7% of the top 10 ranked passages by IKFB contain answers, while the number is 5.93% for baseline system.

Table 2 represents the Mean Reciprocal Rank of all three systems and evaluations for all passages ($n = \infty$ in Formula 11). In the previous figure, we can appreciate that the difference in both coverage and redundancy decreases with the number of passages.

System	employee_of	member_of
IKFB	0.409	0.260
Baseline	0.269	0.149
Lemur	0.180	0.079
p-value	0.0092	0.0044

Table 2. Comparision of MRR
p-value: comparing IKFB to Baseline

The paired, two-tailed Student's t test (Smucker et al., 2007) shows that our proposed algorithm IKFB is significantly superior to the baseline in terms of MRR.

7.2 Impact of Passage Retrieval on Information Extraction

Figure 2 represents the performance of an end-to-end information extraction system that extracts the top m ($m = 1{\sim}10$) answers using different passage retrieval algorithms. Both QA and IE pipelines are shown.

Because the information in the training data is incomplete, the output answers were examined manually; another 45 relation instances were discovered besides the given 54 keys in KBP data. IKFB achieves somewhat higher precision with similar recall. It ranks the passages containing the answer higher, while ranking the passages containing the correct answers ahead of those which may suggest wrong answers to the IE system.

There is great room for improvement on answer extraction, such as using a QA-pipeline. It is not uncommon that the information extraction system fails to extract the right answers even when the passages containing them are retrieved and ranked at top. The IE system can only successfully locate 7 out of the 54 given keys in 2.4% of the top 10 ranked passages by IKFB, although 17 keys are contained in 18.7% of these retrieved passages.

Of the total 67 person entities in our test data, the IE-pipeline is not able to extract any employment information for 12 of them. However, using the primitive QA-pipeline, we are able to recover 4 of them while introducing 6 new errors. As shown in Figure 2, the integration of the QA-pipeline to the IE-pipeline improves the end-to-end system performance by 3-5%, since low recall is the most crucial problem of traditional IE systems. Good ranking is particularly important to the IE+QA pipeline; as Figure 2 shows, adding QA to the baseline produces a considerable loss of precision.

8 Conclusions and Future Work

We have presented a novel method to extract keywords from Wikipedia articles and rank passages for information extraction. The key features of our method includes: (1) combining the advantages of question answering and information extraction techniques; (2) involving no complicated or time consuming processes; (3) requiring no costly annotation but making use of freely available Wikipedia and Freebase.

Given the success of our primitive QA-pipeline, we plan to implement a more competitive and customized question answering system for information extraction tasks. We also consider looking more deeply into the adaptiveness from Wikipedia to texts from other sources in order to further improve the quality of weighted keywords.

Using Context Inference to Improve Sentence Ordering for Multi-document Summarization

Peifeng Li **Guangxi Deng** **Qiaoming Zhu**

Abstract

In this paper, we propose a novel context inference-based approach for sentences ordering in multi-document summarization application. Our method first detects whether or not two summarization sentences should be adjacent according to the similarity between one summarization sentence and the context of the other one, and then it computes the reliability of the adjacent summarization sentences based on the similarity and their relative position. To be specific, the first sentence will be selected according to features of sentence, and the second sentence will be selected if and only if it has the maximum reliability with previous sentence. Evaluation result shows that our method outperforms the state-of-the-art ones on DUC2004 corpus.

1 Introduction

Multi-document summarization is an automatic procedure aimed at extraction of information from multiple texts written about the same topic. Whereas, sentence ordering, the last task of multi-document summarization, will finally affect the quality of summarization. Furthermore, the task of sentence ordering in multi-document summarization is harder than that in single document summarization because multiple documents are created by different authors who have different writing styles and backgrounds. Therefore, no natural order of texts can be extracted as the basis of sentence ordering judgment. How to conduct an efficient and effective method for sentences ordering is a difficult but important task for both multi-document summarization and other text processing job, e.g. Question Answering.

Currently, a variety of studies have been reported on sentence ordering. Some methods adopted chronological information (McKeown et al., 1999; Lin et al., 2001; Barzilay et al., 2002; Okazaki et al., 2004) while others learned the natural order of sentences from source documents or large corpus (Lapata, 2003; Barzilay and Lee, 2004; Nie et al., 2006; Ji and Nie, 2008). However, chronological information cannot be easily extracted from those non-news documents and constructing a large corpus also is not so easy. Furthermore, those results of all above methods are far from satisfactory. Therefore, how to achieve coherent summarization still is an issue for us.

This paper proposes a novel method to infer the order of summarization sentences for multi-document summarization according to their context. We first judge whether or not two summarization sentences should be adjacent based on the similarity between one summarization sentence and the context of the other one, and then compute the reliability based on the similarity and relative position of the adjacent summarization. To be specific, the first sentence will be selected based on its features, and the second sentence will be selected if and only if it has the maximum adjacency reliability with previous sentence. The experimental results on DUC2004 corpus show that our method outperforms state-of-the-art ones.

The reminder of this paper is organized as follows. In Section 2, the related work is introduced. The motivation of our method is discussed in Section 3. In Section 4, the context inference-based sentence ordering algorithm is described. In Section 5, the experiments and evaluation are presented. Conclusions and future work are given in Section 6.

2 Related Work

So far many studies on sentence ordering have

been proposed. They can be divided into two categories: chronology-based method and natural order-based method. To be specific, chronology-based methods determine sentence ordering according to the chronological order of events while natural order-based methods infer sentence ordering according to some cues that are learned from source documents and corpus.

Barzilay et al. (2002) proposed a chronology-based method to sort sentence, they assumed the theme of sentences were the cues of sentence ordering. Based on it, they presented a strategy according to the first published date of the theme; then sorted sentences based on their order of presentation in the same article.

Okazaki et al. (2004) proposed an approach to improve the chronological sentence ordering method by using precedence relation technology. They assumed the presupposed information should be transferred to reader in advance before the sentence was interpreted. They first arranged sentences in a chronological order and then estimated the presupposed information for each sentence by using the content of the sentences located in before each sentence in its original article.

Generally speaking, the articles in news domain usually contain descriptions of date and events accompanying the publication sequences. Therefore, chronology-based method is practical for news domain. However, chronological information is not ubiquitous in a large number of multi-document summarization tasks. So, some studies began to focus on general domain, and they sorted sentences according to the source documents and corpus.

McKeown et al. (2001) and Barzilay et al. (2001) presented a majority ordering algorithm to sort sentences. They classified sentences of source documents into different themes or topics using summarization sentences. If sentences from theme 1 preceded sentences from theme 2 when they appeared in same text, then putted theme 1 was preceding theme 2. The order of summarization sentences was determined by the order of themes. However, there were some potential issues in this kind of method. Firstly, it was not easy to correctly cluster sentences into topics. Secondly, some summarization sentences may belong to a same topic. Finally, the relative order between two topics may be not steady.

Lapata (2003) provided an unsupervised probabilistic model for sentence ordering. The model assumed that sentences were represented as a set of features that could be automatically extracted from the corpus without manual annotation. The conditional probability of sentence pairs can be learned from a training corpus. By computing conditional probability of each sentence pairs, the approximate optimal global sentence ordering can be achieved using a simple greedy algorithm.

Bollegala et al. (2005) combined three ordering methods together, said chronological ordering, probabilistic ordering and topic relatedness ordering, and adopted a machine learning approach for sentence ordering. The mixed system can achieve better performance than any of the three individual one. To be extended, they also proposed a bottom-up approach for sentence ordering (Bollegala et al., 2010). They defined four criteria (chronology, topical-closeness, precedence and succession) between two textual segments, and adopted SVM classifier to learn the relative order of them. They repeatedly concatenated two textual segments into one segment based on the relative order until all sentences were arranged.

Nie et al. (2006) adopted adjacency of sentence pairs to sort sentences. Sentence adjacency was calculated based on adjacency of features of each sentence pairs. Adjacency between two sentences represented how closely they should be putted together in a set of summarization sentences. Ji et al. (2008) extended the above adjacency model. They proposed a cluster-adjacency based method to map each sentence of source documents to a theme by using semi-supervised classification method. The adjacency of sentences pair was learned from source documents according to adjacency of clusters they belonged to.

Our method is different from above ones in two aspects. First, we try to find the indirect relations of summarization sentences according to source documents. Second, the source documents are topic-related and most summarization sentences or their similar ones appear in more than one source document. Meanwhile, there are more than two summarization sentences or their similar ones may co-occur in a source document. Therefore, we can infer the order of summarization sentences by using the indirect relation between summarization sentences.

3 Motivation

Different documents have different writing styles and backgrounds. Besides, sentences that used to

describe a same topic may have different forms. Therefore, source documents maybe cannot provide the direct information for sentence ordering. However, they still provide some indirect information which can be used to infer the order of summarization sentences.

Each source document for multi-document summarization is not an information island. They may have some overlapped information. For example, there are three documents to report a same news event. The first document describes its background and cause. The second one describes the origin, process and result. The third one describes the effect and comment. Each document has its own key point, but they have some overlapped information. The first and the second one report the cause in both while the second and the third one report the effect in both.

Each summarization sentence is extracted from a source document even though it is created or rewritten manually, it also can link to one or more sentences in source documents. Therefore, each summarization sentence is also not isolated and there are many sentences surrounding them in the source document. We call these sentences as the context of the summarization sentence. Furthermore, the source documents are in same topic and most of summarization sentences are presented in more than one document. In a word, a summarization sentence may have some similar sentences in source documents.

Accordingly, we provide a method to infer the order of summarization sentences by using their context. Let us consider an example: there are two documents, d_1 and d_2, sketched in Figure 1, where ss_1 and ss_2 are two summarization sentences or their similar ones in source documents, $s1_i$ and $s2_i$ are the context sentence of ss_1 and ss_2 respectively.

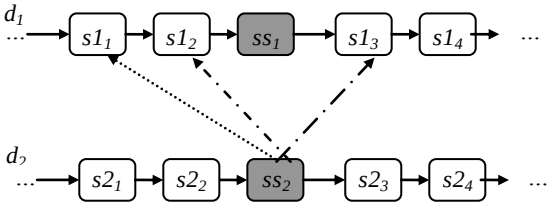

Figure 1. An example of summarization sentences and their context

If ss_2 is similar to $s1_1$, we have reason to believe that ss_2 and ss_1 should be adjacent and ss_2 should be in front of ss_1 because $s1_1$ is front of ss_1. The highly similarity between ss_2 and $s1_1$, the highly probability that ss_2 is in front of ss_1.

If ss_2 is not similar to $s1_1$, but it is similar to $s1_2$, we also consider ss_2 should be in front of ss_1, but the probability will higher because $s1_2$ is closer to ss_1 than $s1_1$. Similarly, if ss_2 is similar to $s1_3$, ss_1 should be in front of ss_2.

4 Context Inference-based Sentence Ordering Algorithm

From the analysis in section 3, we can infer the order of sentence by using the similarity between summarization sentences and their context. We compute the adjacent credibility of two sentences and then use a directed graph with weight to represent the order of summarization sentences. A vertex denotes a sentence. If two sentences are adjacent then an edge exists of them. The weight of edge is the adjacency credibility of two sentences. Figure 2 shows the order relation among summarization sentences, there is an edge from s_1 to s_3 and the weight is 0.5, which means s_1 and s_3 are adjacent, and the credibility of them is 0.5. From figure 2, we can find a path contained all vertexes, which has the maximum weight. The order of the path is considered as the best logical order of summarization sentences.

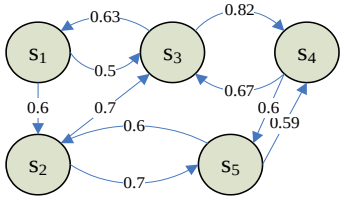

Figure 2. Graph of summarization sentences and their relation

Due to finding an optimal path in a graph is a typical NP problem; we will use an algorithm to find an approximate optimal path. We assume that the document set $D= \{d_1, d_2... d_n\}$, a document $d_j = \{s_{j,1}, s_{j,2}, ..., s_{j,m}\}$ where $s_{j,i}$ is the ith sentence in d_j, the summarization sentences set $SS= \{ss_1, ss_2, ..., ss_k\}$, the Graph $G=NULL$. For a sentence ss_i in d_j, its context sentence set is $\{d_j - ss_i\}$. The algorithm is described as follows.

Input: D, SS and G

Output: P, an ordered list that contains all summarization sentences.

BEGIN

Step 1: For each ss_i in SS, add a vertex to graph G;

Step 2: For each ss_i in d_j, compute the similarity $sim(ss_k, s_{j,l})$ between each ss_k ($ss_k \in \{SS - ss_i\}$) and each $s_{j,l}$

($s_{j,l} \in \{d_j - ss_i\}$) respectively. ss_i and ss_k are directed adjacent if existing a $sim(ss_k, s_{j,l}) > \theta$ where $s_{j,l} \in \{d_j - ss_i\}$.

If $s_{j,l}$ is in front of ss_i, the credibility $weight(ss_i, ss_k)$ that ss_k is in front of ss_i is computed as follow:

$$weight(ss_i, ss_k) = w * sim(ss_k, s_{j,l}) + (1-w) * \frac{rank(s_{j,l})}{rank(ss_i)} \quad (1)$$

where $rank(ss_i)$ is the sequence of ss_i in the document it belongs to (e.g. the rank of second sentence of document is 2), w is the contribution of sentence similarity to the credibility, $sim(ss_k, s_{j,l})$ is the similarity between ss_k and $s_{j,l}$. If there is no edge from ss_k to ss_i in G, then add an edge to G; else if $weight(ss_i, ss_k)$ is greater than the weight of existing edge, then update the edge.

If ss_i is in front of $s_{j,l}$, the credibility $weight(ss_i, ss_k)$ is computed as follows:

$$weight(ss_i, ss_k) = w * sim(ss_k, s_{j,l}) + (1-w) * \frac{Len(d_j) - rank(s_{j,l})}{Len(d_j) - rank(ss_i)} \quad (2)$$

where $len(d_j)$ is the total number of sentences contained in d_j. If there is no edge from ss_i to ss_k in G, then add an edge to G; else if $weight(ss_i, ss_k)$ is greater than the weight of the existing edge, update the edge.

Sentence similarity between sentences s_1 and s_2 can be computed based on TF-IDF or WordNet (Achananuparp, 2008). Sentences similarity based TF-IDF can be calculated as follow:

$$sim(s_1, s_2) = \vec{V}_1 \cdot \vec{V}_2 = \frac{\sum_{i=1}^{n} x_i \cdot y_i}{\sqrt{\sum_{i=1}^{n} x_i^2} * \sqrt{\sum_{i=1}^{n} y_i^2}} \quad (3)$$

where $V_1 = \{x_1, x_2 ... x_n\}$, $V_2 = \{y_1, y_2 ... y_n\}$, V_1, V_2 are TF-IDF vectors of sentences s_1 and s_2.

Sentence similarity $sim(s_1, s_2)$ based on WordNet is defined as

$$sim(s_1, s_2) = \frac{\sum_{w \in s1} Sim(w, s_2) + \sum_{w \in s2} Sim(w, s_2)}{length(s_1) + length(s_2)} \quad (4)$$

where $sim(w, s_i)$ is the maximum semantic similarity between word w and sentence s_i, $length(s_i)$ is the length of sentence s_i.

Step 3: We use a feature-based method to find the first sentence, assume that there is a null sentence at the beginning of each source document and it contains a null feature (Nie, 2006). The probability of a sentence ss_i is the first one is defined as follow:

$$Prob_i = \frac{1}{K} \sum_{t=1}^{K} \frac{freq(feature_t, nullfeature)}{freq(feature_t)} \quad (5)$$

where K is the number of features in sentence s_i. $freq()$ is the frequency function, $freq(feature_t)$ denotes the frequency of $feature_t$ in the source documents, $freq(feature_t, nullfeature)$ denotes the frequency of $feature_i$ and the *null feature* co-occurring in the source documents within a limited range (one or several sentences, we assign 3 to the range). Select the sentence with the maximum probability as the first sentence. Add the first sentence to P.

Step 4: Get the trail sentence of P, select the next sentence and add it to P. Given an already ordered sentence serial P: $ss_1, ss_2 ... ss_i$ which is a subset of the summarization sentences set SS. The next sentence can be found by formula (6):

$$ss_j = \arg \max_{s_j \in SS-P} (weight(ss_i, ss_j)) \quad (6)$$

Step 5: If P contains all summarization sentences then exit; otherwise go to step 4.

END

5 Experiments and Evaluation

5.1 Test Set and Evaluation Metrics

Due to current methods provided their experiment results using DUC04 corpus, we also use it to conduct our experiment. DUC04 provide 50 source document sets and four manual summaries for each document set in its Task2. Each document set consists of 10 documents. In the DUC04, sentences in summaries are not directly come from the source documents and they are created by manually. Therefore, we need map them back to the sentences in source documents. For each manual summarization sentence, we find a sentence in source document sets that has the maximal similarity with it as its source sentence. These source sentences of each summarization are taken as inputs to ordering model, but sequential information is neglected. The output ordering of various models are compared with the specified ones in manual summaries. A number of metrics can be used to evaluate the difference between two orderings. In this paper, we adopt Kendall's τ (Lebanon, 2002), which was defined as:

$$\tau = 1 - \frac{2(number\_of\_inversions)}{N(N-1)/2} \quad (7)$$

where N is the number of objects to be ordered (i.e., sentences), *number_of_inversions* is the minimal number of interchanges of adjacent

objects to transfer an ordering into another. Intuitively, τ can be considered as how easily an ordering can be transferred to another. The value of τ varies from -1 to 1, where 1 denotes the best situation where two orderings are the same, and -1 denotes the worst situation where two orderings are completely reversed. Given a standard ordering, randomly produced orderings of the same objects would get an average τ of 0. For example, Table 1 lists three numbers of sequences, their natural sequences and the corresponding τ values.

Examples	Natural sequences	τ values
1 2 4 3	1 2 3 4	0.67
1 5 2 3 4	1 2 3 4 5	0.40
2 1 3	1 2 3	0.33

Table 1: Ordering Examples

5.2 Experimental Results

In order to get the best performance, we adjusted the parameters of our approach (θ and w). We adopted DUC02 as the development set to adjust parameters θ and w. In DUC02, it provide 60 document sets of approximately 10 documents each and one manual summarization of about 100 words for each document set in Task2. Figure 3 show the experiment results, from it, we can finally get the optimal value of θ and w (0.3 and 0.6 respectively).

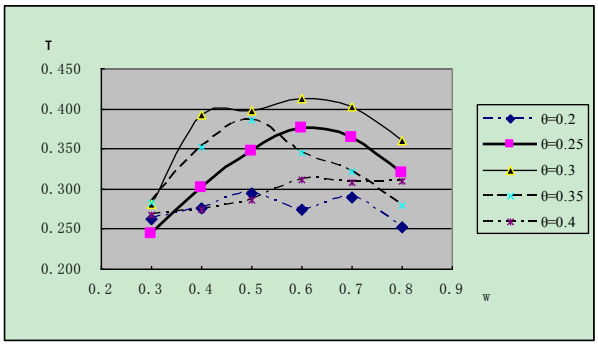

Figure 3. Graph of adjusting parameters

We assume Rd, Mo, Pr, Fa and Ca to denote random ordering, majority ordering, probabilistic model, feature-adjacency based model and cluster-adjacency based model which have been mentioned in section 2 respectively. Due to other methods didn't report their results on DUC04 corpus; we do not compare our method with them in this paper. We define our Context-based approach as Co. Table 2 shows the results of different methods. The τ value of our approach reaches 0.43, which outperforms other approaches. Also, the performance of WordNet-based similarity measure is slightly better than the TF-IDF based one. The reason may be that some authors will express the same meaning by using some different but synonymous words.

Models	τ	Similarity Measure
Rd	-0.007	
Mo	0.143	
Pr	0.144	
Fa	0.316	
Ca	0.415	
Co	0.424	TF-IDF
Co	0.432	WordNet

Table 2: Experimental results (θ=0.3, w=0.6 in Co)

We conduct another experiment, correction ratio of sentence inference from correctly ordered previous sentences, to see why our method gets better performance. The result is listed in table 3.

Models	1st sentence →2nd sentence	2nd sentence →3rd sentence
Mo	24.4%	10%
Pr	25.0%	25%
Fa	31.8%	50%
Ca	56.2%	61.6%
Co (TF-IDF)	62.5%	64.2%
Co (WordNet)	63.2%	65.4%

Table 3. Comparison of correct sentence inference

From table 3, our method has the highest correction ratio of sentence inference, which mean that our method's strategy to choose next sentence is reasonable than that of others. Probabilistic ordering, a statistical method, tries to find the ordering clue from the corpus, but they ignore the importance of source documents. Basically, we know that people can easily find the order of summarization sentences according to the source documents. But it's difficult to give the order for the sentence base on a corpus without the source documents even for a knowledgeable man. Therefore, we believe the source documents can give us some effective and efficient information. Fa and Ca models sort sentences by using sentence adjacency, which is calculated based on adjacency of feature pairs. However, how to choose effective features is a potential issue of this kind of method. Besides, it

doesn't always mean two sentences are likely to be adjacent when some words of them are adjacent. Our method is different from other ones in that we find the indirect relations between summarization sentences based on the context and make full use of the information which provided by source documents.

Table 4 shows a further comparison among all methods. "Positive ordering" means that the result of ordering is better than that of random ordering and "Negative ordering" denotes the output ordering which gets a negative τ. From it, we can review that our method generates the most positive orderings while with the least negative orderings. Precision of first sentence of our method is less than that of Ca. If we assume the first sentence of summarization is known in advance, experiments show that the average τ value of our method could reach 0.562.

Models	Precision of 1st sentence	Positive Orderings	Negative Orderings
Rd	14.0%	48.4%	44.6%
Mo	21.6%	61.8%	31.8%
Pr	40.8%	62.5%	29.5%
Fa	59.5%	71.5%	19.0%
Ca	65.5%	81.0%	15.5%
Co (TF-IDF)	59.5%	84.5%	10.5%
Co (WordNet)	59.5%	84.8%	10.1%

Table 4. Correction ratio of 1st sentence ranking

6 Conclusion and Future Work

This paper presents a novel method for sentence ordering in multi-document summarization application. The proposed method first computes the similarity between summarization sentences and context of other summarization sentences, judge whether or not two sentences should be adjacent, and then compute the reliability according to the similarity. The experimental results review that our method outperforms other sentence ordering methods on DUC04 corpora.

For further work, we will change the strategy to improve the accuracy of first summarization sentence; therefore, the τ value could have an obvious improvement. In addition, we will conduct more experiments to verify the effectiveness and efficient of our method using manual evaluation.

Enhancing extraction based summarization with outside word space

Christian Smith, Arne Jönsson
Santa Anna IT Research Institute AB

Abstract

We present results from improving vector space based extraction summarizers. The summarizer uses Random Indexing and Page Rank to extract those sentences whose importance are ranked highest for a document, based on vector similarity. Originally the summarizer used only word vectors based on the words in the document to be summarized. By using a larger word space model the performance of the summarizer was improved. Along with the performance, robustness was improved as random seeds did not affect the summarizer as much as before, making for more predictable results from the summarizer.

1 Introduction

Many persons have, for various reasons, problems assimilating long complex texts. Not only persons with visual impairments or dyslexia, but also, for instance, those having a different mother tongue or persons in need of a quick summary of a text. A tool for automatic summarization of texts from different genres as an aid in reading can thus be useful for many persons and purposes.

Automatic summarization can be done in various ways. A common distinction is extract versus abstract summaries. An extract summary is created by extracting the most important sentences from the original text so that the result is a shorter version of the original text with some information still present, for instance the most important sentences or words. An abstract summary on the other hand is a summary where the text has been broken down and rebuilt as a complete rewrite to convey a general idea of the original text. Furthermore, the summaries can be indicative (for instance only providing keywords as central topics) or informative (content focused) (Firmin and Chrzanowski, 1999). The former might be more usable when a reader needs to decide whether or not the text is interesting to read and the latter when a reader more easily needs to get a grasp of the meaning of a text that is supposed to be read.

In this paper we will examine and try to increase the performance of an automatic extraction-based summarizer. Previously, the summarizer has been functioning without aid of outside corpora or training material. While the performance have been good, some improvements utilizing an outside corpus can be achieved.

The technique behind the summarizer will first be described in more detail, after which some results are presented which indicates that the performance can be enhanced by using outside training material.

2 The word space model

The word space model, or vector space model (Eldén, 2007), is a spatial representation of a word's meaning that can reduce the linguistic variability and capture semantically related concepts by taking into account the positioning of words in a multidimensional space, instead of looking at only shallow linguistic properties. This facilitates the creation of summaries, since the positioning in the word space can be used to evaluate the different passages (words or sentences for instance) in relation to a document with regards to informational and semantic content.

Every word in a given context occupies a specific point in the space and has a vector associated to it that can be used to define its meaning.

Word spaces are constructed according to the distributional hypothesis and the proximity hypothesis. In the distributional hypothesis, words that occur in similar contexts have similar meanings so that a *word* is the sum of its contexts and the *context* is the sum of its words, where the *con-*

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1062–1070,
Chiang Mai, Thailand, November 8 – 13, 2011.

text can be defined as the surrounding words or the entire document. The proximity hypothesis states that words close to each other in the word space have similar meaning while those far from each other have dissimilar meaning.

The word space can be constructed from a matrix where text units are columns and the words in all text units are rows in the matrix. A certain entry in the matrix is nonzero iff the word corresponding to the row exists in the text unit represented by the column. The resulting matrix is very large and sparse which makes for the usage of techniques for reducing dimensionality and get a more compact representation. Latent Semantic Analysis is one such technique that, however, can be computationally expensive unless used with alternative algorithms (Gorrell, 2006). Random Indexing (Sahlgren, 2005; Kanerva, 1988) is another dimension reduction technique based on sparse distributed representations that provide an efficient and scalable approximate solution to distributional similarity problems.

3 The summarizer

COGSUM is an extraction based summarizer, using the word space model Random Indexing (RI), c.f. Hassel (2007) and a modified version of PageRank (Brin and Page, 1998).

In Random Indexing context vectors are accumulated based on the occurrence of words in contexts. Random Indexing can be used with any type of linguistic context, is inherently incremental, and does not require a separate dimension reduction phase as for instance Latent Semantic Analysis.

Random Indexing can be described as a two-step operation:

Step 1 A unique d-dimensional *index vector* is assigned and randomly generated to each context (e.g. each document or each word). These index vectors are sparse and high-dimensional. They consist of a small number, ρ, of randomly distributed +1s and -1s, with the rest of the elements of the vectors set to 0.

Step 2 *Context vectors* are produced on-the-fly. As scanning the text, each time a word occurs in a context, that context's d-dimensional index vector is added to the context vector for the word. The context window defines a region of context around each word, and the number of adjacent words in a context window is called the context window size, w. For example, with $w = 2$, i.e. a 2x2 context window, the word o_n is represented by the context window c_m as:

$$c_m = [(o_{n-2})(o_{n-1})o_n(o_{n+1})(o_{n+2})],$$

and the context vector of o_n in c_m would be updated with:

$$C_m =$$

$$R(o_{n-2}) + R(o_{n-1}) + R(o_{n+1}) + R(o_{n+2}),$$

where $R(x)$ is the random index vector of x. This process is repeated every time we observe o_n in our data, adding the corresponding information to its existing context vector C. If the context c_m is encountered again, no new index vector will be generated. Instead the existing index vector for c_m is added to C to produce a new context vector for o_n.

Words are thus represented by d-dimensional context vectors that are effectively the sum of the index vectors of all the contexts in which the word appears.

Additionally, the vectors within the sliding contex window can be weighted according to the distance to the focus word. One example is $2^{(1-distance)}$, or $[0.5, 1, 0, 1, 0.5]$ for a 2x2 context window providing a larger weight for words closest to the focus word (Karlgren and Sahlgren, 2001).

After the creation of word context vectors, the similarity between words could be measured by calculating the cosine angle between their word vectors, by taking the scalar product of the vectors and dividing by their norms such as:

$$cos(x, y) = \frac{x \cdot y}{|x|\,|y|} \quad (1)$$

Random Indexing is useful for acquiring the context vectors of terms, it is however not clear how a bigger context, such as a sentence, could be built from the word vectors. A crude way of creating sentence vectors from word vectors would be to simply summarize the vectors of the words in the sentence after they have been normalized to unit length. However, as the number of words in

a sentence increases, so will the sentence similarity to the mean vector. Comparing sentences or documents in this way using cosine will make for larger similarity just by a larger number of words, regardless of relatedness. To alleviate this problem, the mean document vector is subtracted from each of the sentence's word vectors before summarizing the vectors (Higgins and Burstein, 2007), see Equation 2.

$$\vec{sent}_j = \frac{1}{S}\sum_{i=1}^{S}(\vec{w}_i - \vec{doc}) \quad (2)$$

where S denotes the number of words, w, in sentence j and $\vec{doc}$ is calculated as in Equation 3.

$$\vec{doc} = \frac{1}{N}\sum_{i=1}^{N}\vec{w}_i \quad (3)$$

where N denotes the number of unique words.

Words that are similar to the document vector will come closer to the zero vector, while those dissimilar to the document vector will increase in magnitude. When later summarizing the vectors, those of greater magnitude will have increased impact on the total sentence vector so that common, non-distinct, words not contribute as much to the sentence vector. As this reduces the impact of common non-distinct words, there is essentially no need for a stop word list.

COGSUM also uses the Weighted PageRank algorithm in conjunction to its RI-space to rank the sentences (Chatterjee and Mohan, 2007).

The method of using graph-based ranking algorithms for extracting sentences in summarization purposes was proposed by Mihalcea (2004), who introduce the TextRank model. In graph-based algorithms such as TextRank the text need to be represented as a graph, where each vertex depicts a unit of text and the edges between the units represent a connection between the corresponding text units. Graph-based ranking algorithms may be used to decide the importance of a vertex within a graph, by taking into account global information from the entire graph, rather than from only the local context of the vertices. The ranks are thus recursively computed so that the rank of a vertex depends on all the vertices' ranks. In TextRank, PageRank is used to rank the sentences, although it is noted that other ranking algorithms are possible. PageRank is a graph-based ranking algorithm which originally was used to rank home pages automatically and objectively in the Google search engine (Brin and Page, 1998). In TextRank, for the task of sentence extraction, each sentence in a text is represented as a vertex and the relation between sentences are based on their overlap or "similarity", denoted by Equation 4.

$$Similarity(S_i, S_j) = \frac{|\{w_k | w_k \in S_i \& w_k \in S_j\}|}{log(|S_i|) + log(|S_j|)} \quad (4)$$

Thus, if a sentence adresses certain concepts, the other sentences that share content will get recommended by that sentence in the recursive fashion provided by PageRank.

To use PageRank and Random Indexing for summaries an undirected fully connected graph is created where a vertex depicts a sentence in the current text and an edge between two different vertices is assigned a weight that depicts how similar these are based on a cosine angle comparison of their meaning vectors, see Figure 1. As it is fully connected, all vertices are connected with each other and all out-links are also considered as in-links.

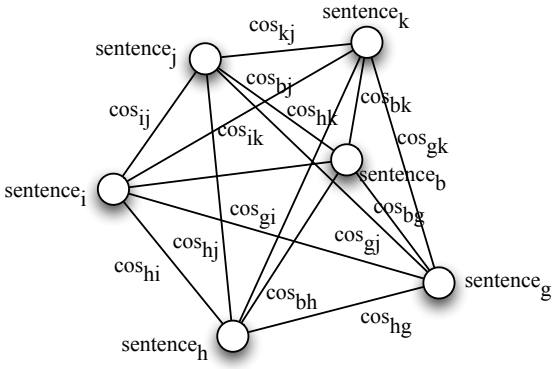

Figure 1: A simplified graph where sentences are linked and weighted according to the cosine values between them.

The algorithm rank ingoing and outgoing links to pages depending on the number of links as follows, Equation 5:

$$PR^W(s_i) = (1-d) + d * \sum_{s_j In(s_i)} w_{ji} \frac{PR^W(s_j)}{\sum_{s_k \in Out(s_j)} w_{kj}} \quad (5)$$

where s_i is the sentence under consideration, $In(s_i)$ is the set of sentences that link to s_i, $Out(s_j)$ is the set of sentences that link from s_i and d is the damping factor.

The damping factor was originally set to account for the possibility of a surfer clicking a random web link when (s)he gets bored (Brin and Page, 1998). With regards to the ranking of sentences, we see the damping factor as the possibility of a sentence containing some implicit information that a certain reader might consider more important at the time, following an analogy by Mihalcea and Tarau (2004). The PageRank-algorithm utilizes the ”random surfer model” and using weighted PageRank in text comparison utilizes ”text surfing” in the context of text cohesion. The links in the sentence graph might be attributed to links between connected concepts or topics semantically, creating a ”web” of understanding on which a reader might surf.

The computation is carried out on all sentences iteratively until node weights converge, see Figure 2.

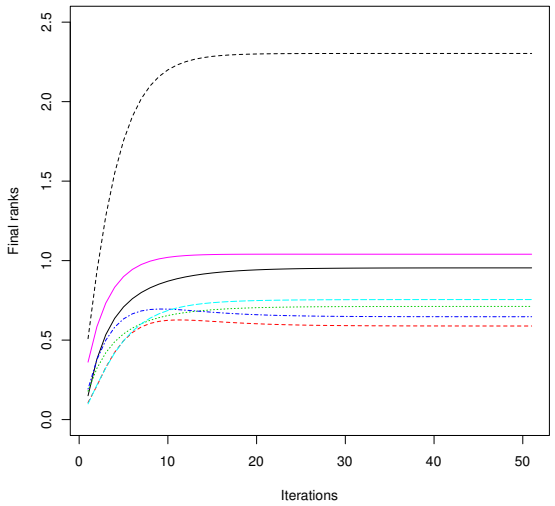

Figure 2: Each line represents a sentence from a single text with its weight plotted on the y-axis on each iteration on the x-axis. 50 iterations are plotted.

The ranking algorithm does not rely only on local context information (vertex) but draws information recursively from the entire graph. Sentences with similar content will then contribute with positive support to each other through a recommendation process, where the sentences' ranks are increased or decreased each iteration. This does not exclusively depend on the number of sentences supporting a sentence, but also on the rank of the linking sentences. This means that a few high-ranked sentences provide bigger support than a greater number of low-ranked sentences. This leads to a ranking of the sentences by their importance to the document at hand and thus to a summary of desired length only including the most important sentences.

When the text has been processed using RI and PageRank, the most important sentences are extracted using the final ranks on the sentences, for instance 30% of the original text, resulting in a condensed version of the original text with the most important information intact, in the form of extracted sentences. Since all sentences are ranked, the length of the summary is easy to specify, in COGSUM this is implemented as a simple slider. COGSUM is designed for informative summaries, but it is also possible to have indicative summaries by clicking a ”keywords” check box.

COGSUM is written in Java and utilizes a Random Indexing toolkit available at Hassel (2011a). No outside material is used which makes the summarizer highly portable and usable for several languages and domains.

Previous evaluations of COGSUM with human users show that summaries produced by COGSUM are useful, considered informative enough and readable (Jönsson et al., 2008). COGSUM has also been evaluated on gold standards for news texts and authority texts showing that it is better than another Swedish summarizer, SweSum, (Dalianis, 2000) on authority texts and almost as good on news texts, texts that the other summarizer was especially adapted to handle (Gustavsson and Jönsson, 2010).

4 Multi-document word vectors

COGSUM has previously worked without aid from any outside source making it highly portable and more or less language independent. However, some problems have been detected. We identified some abruptness in the resulting summaries, affected by the random factor of the index vectors. This was regardless of setting of dimensionality and other parameters.

To investigate the effect of randomness several summaries with different index vectors were created. The final ranks of the sentences in a text after the summarization process were calculated and plotted on each random seed that held its own distribution of the ones in the index vectors, Figure 3. The figure shows 10 different summaries

with their own seeds. The final values after the ranking are plotted on the y-axis mapped to each seed on the x-axis. A straight line would mean that the results are predictable and not affected as much by randomness. As can be seen in Figure 3 there is quite some randomness in which sentences that are chosen depends on the seed to the Random Indexing algorithm.

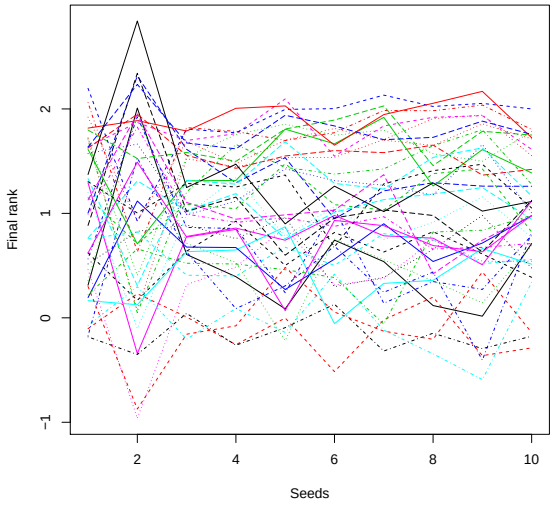

Figure 3: Ten different seeds without pretrained space. Each series represents a sentence in a text. The values on the y-axis are the final values of each sentence after the PageRank-algorithm.

For CogSum, we wanted to extend the method by using an outside larger RI-space. Using a large RI-space, a better semantic representation of the words can be acquired (Sahlgren, 2006). By extending the method to use an outside training space we thus believe that the quality and robustness of the summaries can be improved.

CogSum takes as input the text to be summarized, but now also a previously trained RI-space is supplied, containing the semantic vectors of the words.

The RI-space was created from several Swedish texts from different genres, all in all approximately 240 000 words. The articles consisted of a number of novels in a subset of the Stockholm-Umeå Corpus (Ejerhed et al., 2006), a set of newspaper articles available at the concordances of Språkbanken, specifically from the Parole corpus (Ridings, 2011), and some popular science articles from the same place.

The text is processed by assigning each of the words the corresponding semantic vector from the space. Sentence vectors are constructed as proposed by Chatterjee and Mohan (2007) and Higgins and Burstein (2007), i.e. the words in a sentence are summarized after the subtraction of the mean space vector, and divided by the number of words in the sentence, as in Equation 2.

To investigate the effect on randomness we created 10 summaries with different seeds, the same way as in Figure 3. Figure 4 shows 10 trials on different seeds as before on the same text, but using the larger outside RI-space described above. Comparing figures 3 and 4 reveals a more straight line when using a large RI-space. Thus, by using an outside RI-space, the effect of randomness is reduced and a more predictable result between seeds is achieved.

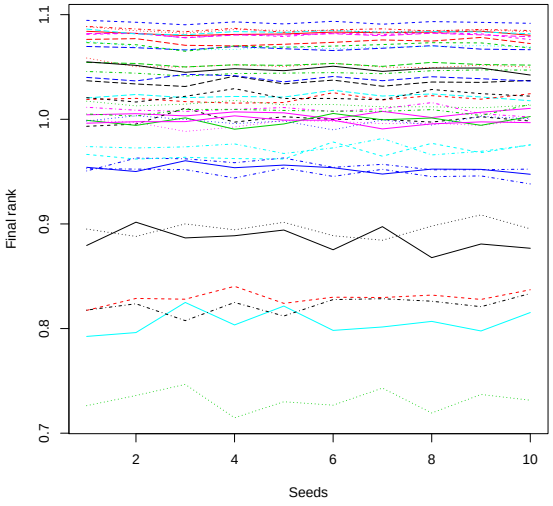

Figure 4: Ten different seeds with pretrained space, each line representing a sentence in a text. The values are the final ranks of each sentence after the PageRank algorithm.

Another problem that has emerged is that the weighted PageRank sometimes fail to converge. This might happen in the original PageRank when the number of outlinks from a vertex is zero (Eldén, 2007). The corresponding phenomenon in the weighted PageRank-algorithm is when the sum of the out weights from a given sentence is zero or close to zero. One reason is that since sentence similarity can be both positive and negative it is possible that they even out. Also, nearly orthogonal sentence vectors makes for weights around zero. This only happens when

not using an outside space. Since a small document does not contain the distribution of words across a large number of context, it is likely that several sentences contain words that occur only in that sentence. When the context vectors for the sentences thereby are created, their vectors may be too sparse and the angle between them becomes nearly orthogonal, and the weights sum up to zero.

Figure 5 is produced similar to Figure 2 , where each line represents a sentence. The ranks in the graph are plotted on the y-axis and each iteration on the x-axis. It is clear that the values fail to converge and stabilize which might be a problem when extracting sentences based on the ranks. This does not happen when using a large RI-space, since the sentence vectors are built from context vectors using a large number of contexts.

The problem can be alleviated simply by redoing the random indexing-phase using a different random seed, which is what is done in the current implementation when not using any outside source.

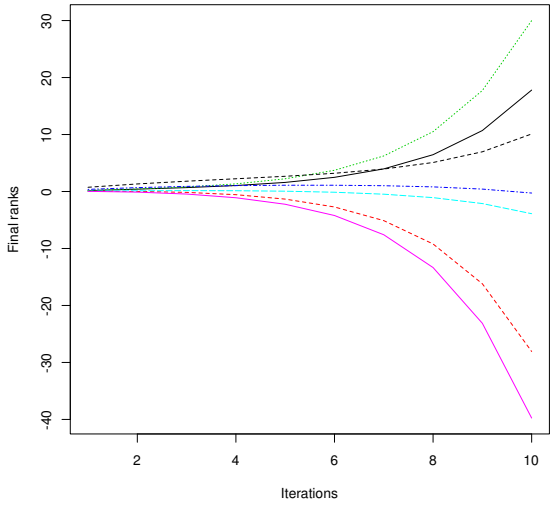

Figure 5: No convergence during the weighted PageRank-algorithm. Each line represents a sentence in a text with the rank plotted on the y-axis and the corresponding iteration during the PageRank on the x-axis. The first ten iterations are plotted.

5 Evaluation

By equipping the summarizer with a better semantic understanding an evaluation was also performed investigating the information quality of the summarizer.

By using a pre-trained RI-space it was hypothesized not only that the random factor could be eliminated, but also that the quality of the summaries would improve. A comparison was made between using an outside text source and using only the document to be summarized to build the RI-space. Since several random seeds provided different summaries on the same text, the average performance measure of 10 seeds for each text was calculated when not using an outside random index space.

The pre-trained RI-space used a dimensionality of 1800, a window size, $w = 2$ with a weighting of $[0.5, 1, 0, 1, 0.5]$, and 8 non-zeroes in the index vectors, similar to Karlgren and Sahlgren (2001).

Using no pre-trained space, the dimensionality was set to 100, window size, $w = 2$ with the same weighting as above, and 4 non-zeroes, to account for a much smaller space, as in Chatterjee and Mohan (2007).

For the evaluation 13 Swedish newspaper articles with a length ranging from 100 to 800 words, see Table 1, were summarized to 30% and compared to human created gold standard summaries of the same length, available at KTHeXtractCorpus (Hassel, 2011b).

Several automatic evaluation packages are available, most notably ROUGE (Lin, 2004). We used, however, also the more recent package AutoSummENG (Giannakopoulos et al., 2008) since it is reported as having a higher correlation with human evaluations than ROUGE (Giannakopoulos, 2009). For AutoSummENG, the comparison was performed by means of graph-value similarity taking content similarity between different texts on character level into consideration. The texts are represented as graphs where each vertex depicts a character n-gram. The graphs from the model and system summaries are then compared resulting in a similarity measure denoting the performance of the system.

It should be noted that no preprocessing in terms of stop word removal and stemming were performed during the ROUGE evaluation since the package is tuned for English and no Swedish lexicon for that purpose were available at the time.

Table 2 shows the values acquired using AutoSummENG for each text and we see that for most texts the summaries produced using the larger RI-space are better than the ones without RI-space.

	Words	Sentences
Text1	110	7
Text2	688	40
Text3	701	37
Text4	400	27
Text5	227	13
Text6	153	9

Text8	179	10
Text9	483	33
Text10	838	67
Text11	388	24
Text12	169	9
Text13	471	32

Table 1: Text characteristics, the number of words and sentences on each text.

Using no space, the mean value from all texts of the comparison was 0.420. By using an outside space, the mean value was 0.547 which is a significant improvement ($p < .05$).

As a comparison, evaluations using the more known ROUGE package was performed. When using ROUGE a similar result is obtained, see table 3. Comparing the results of AutoSummENG and ROUGE yields a correlation of $\approx .96$.

6 Conclusion

By using a large word space model the performance of the extraction based summarizer COGSUM could be improved. Along with the performance, robustness was improved, as the random factor between seeds was reduced, making for more predictable results from the summarizer. The performance was evaluated using AutoSummENG, a tool to compare generated texts with gold standard texts created by humans. The evaluation was performed without input from humans, although humans created the gold standard and thus affected the results indirectly, no measures regarding readability were taken. Thus, the measure does not capture readability, only that the extracted sentences can be seen as the most important for the document and that they correspond to human created gold standards.

Evaluations were also performed using ROUGE to have a point of reference since AutoSummENG is a lesser known method of evaluation and the results from these two different packages correlated strongly.

Further improvements can be seen with regards to stabilizing weights in the weighted PageRank-algorithm. By using a large word space the sentence vectors become more dense since they are built from context vectors from a large number of contexts. The sentence vectors are thus not as likely to be nearly orthogonal which becomes a problem when summarizing the weights as outlinks, since the sum then might be close to zero.

An increased quality in semantic representation however comes with some tradeoffs. A large word space reduces the portability somewhat, and increases the computational effort since a large space uses a much larger dimensionality. Also, the word space makes it language dependent, a previously strong argument for this method. Creating a larger RI-space for a new language is, however, not such a difficult task if a large enough corpus is available.

The word space that was used was produced from rather general texts and it would be interesting for the future to investigate the effect of different RI-spaces on different genres and domains, both in terms of training material but also on the quality of the summaries. Since Random Indexing is incremental, it is easy to add documents to the semantic space.

Although previous work (Smith and Jönsson, 2011) have looked at readability and concluded that the readability may be increased using extraction based summarization, it is still unclear exactly how cohesive they are. Mihalcea and Tarau (2004) draws an analogy between the PageRank "random surfer model" and "text surfing" which relates to the concept of text cohesion. The links in the graph might be attributed to links between connected concepts or topics in a semantic way so it would not be surprising to find that the summaries have acceptable cohesion. Future research will have to conclude the cohesiveness of the summaries and how they may need to be improved.

We have, however, shown that the quality and robustness can be improved by using an outside previously trained random indexing space in the process of vector space model extraction based automatic summarization.

Abstract

Parsing discourse is a challenging natural language processing task. In this paper we take a data driven approach to identify arguments of explicit discourse connectives. In contrast to previous work we do not make any assumptions on the span of arguments and consider parsing as a token-level sequence labeling task. We design the argument segmentation task as a cascade of decisions based on conditional random fields (CRFs). We train the CRFs on lexical, syntactic and semantic features extracted from the Penn Discourse Treebank and evaluate feature combinations on the commonly used test split. We show that the best combination of features includes syntactic and semantic features. The comparative error analysis investigates the performance variability over connective types and argument positions.

1 Introduction

Automatic discourse processing is considered one of the most challenging NLP tasks due to its dependency on lexical and syntactic features and on the inter-sentential relations. While automatic discourse processing of structured documents or free text is still in its infancy, a number of applications of this technology in practical NLP systems have been proposed. For instance, Somasundaran et al. (2009) describe the use of discourse structure for opinion analysis. Other applications include conversational analysis and dialog systems (Tonelli et al., 2010).

In this work we divide the whole task of discourse parsing into two sub-tasks: connective classification and argument segmentation and classification. Several successful attempts have already been made in the direction of automatic classification of connectives, while token-level argument segmentation has not been explored. Therefore in this paper we will focus on the segmentation and labeling of discourse arguments (`Arg1` and `Arg2`) with full spans, as defined in the annotation protocol of the Penn Discourse Treebank (PDTB) (Prasad et al., 2008).

We present a methodology that, given explicit discourse connectives, automatically extracts discourse arguments by identifying `Arg1` and `Arg2` including the corresponding text spans. We call this approach *shallow* following Prasad et al. (2010) as opposed to tree-like representations of discourse, as in Rhetorical Structure Theory (Mann and Thompson, 1988). Indeed, we provide a flat chunk classification of discourse relations, building a non-hierarchical representation of the relations in a text.

The discourse parser is designed as a cascade of argument-specific CRFs trained on different sets of lexical, syntactic and semantic features. The evaluation is made in terms of exact and partial match of arguments. The partial match condition may be useful in the case of noisy input or for applications that do not require exact alignment.

The paper is structured as follows: in Section 2 we present related work to discourse parsing. In Section 3 we detail argument annotation in PDTB and we report some statistics about the PDTB corpus. In Section 4 the pipeline implemented for the argument segmentation and classification task is presented while in Section 5 two different feature sets used for classification are detailed and compared. In Section 6 the experimental setup is described, together with an extensive evaluation and error analysis. Finally, we draw some conclusions in Section 7.

2 Related Work

The task that we address in this paper – automatic extraction of discourse arguments for given ex-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1071–1079,
Chiang Mai, Thailand, November 8 – 13, 2011.

plicit discourse connectives – has been attempted a number of times. Soon after the initial release of the PDTB, it was realized that sentence-internal arguments may be located and classified using techniques similar to semantic role detection and classification methods. Wellner and Pustejovsky (2007) were the first to carry out such an experiment on the PDTB, and Elwell and Baldridge (2008) later improved over their results. However, their task was limited to retrieving the argument *heads*. In contrast, we integrate discourse segmentation in the parsing pipeline because we believe that spans are necessary when using the discourse arguments as input to applications such as opinion mining, where attributions need to be explicitly marked. Besides, no gold data are available for head-based discourse parsing evaluation and they have to be automatically derived from parse trees with a further processing step. With our approach, instead, we can directly use PDTB argument spans both for training and for testing.

Dinesh et al. (2005) extracted complete arguments with boundaries, but only for a restricted class of connectives. The recent work by Prasad et al. (2010) is also limited, since their system only extracts the *sentences* containing the arguments.

In our work, we assume that explicit discourse connectives are given beforehand, either taken directly from a gold standard or automatically identified. The second task based on PDTB was tackled among others by Pitler et al. (2008) and Pitler and Nenkova (2009).

In addition to the work on finding explicit connectives and their arguments, there has been recent work on classification of *implicit* discourse relations, see for instance Lin et al. (2009). In a similar classification experiment, Pitler et al. (2009) investigated features ranging from low-level word pairs to high-level linguistic cues, and demonstrated that it is useful to model the sequence of discourse relations using a sequence labeler. Although they both outperformed their respective baselines, this task is very difficult and performances are still very low.

3 The Penn Discourse Treebank (PDTB)

The Penn Discourse Treebank (Prasad et al., 2008) is a resource including one million words from the Wall Street Journal (Marcus et al., 1993), annotated with discourse relations.

Based on the observation that "no discourse connective has yet been identified in any language that has other than two arguments" (Webber et al. (2010), p. 15), connectives in the PTDB are treated as discourse predicates taking two text spans as *arguments*, i.e. parts of the text that describe events, propositions, facts, situations. Such two arguments in the PDTB are just called `Arg1` and `Arg2` and are chosen according to syntactic criteria: `Arg2` is the argument syntactically bound to the connective, while `Arg1` is the other one. This means that the numbering of the arguments does not necessarily correspond to their order of appearance in text.

In the PDTB, discourse relations can be overtly expressed either by *explicit* connectives, or by *alternative lexicalizations* (AltLex). The first group of connectives corresponds primarily to a few well-defined syntactic classes, while alternative lexicalizations are generally non-connective phrases used to express discourse relations, such that the insertion of an explicit connective would lead to redundancy. There is also a third type of relations - the *implicit* ones - which can be inferred between adjacent sentences, even if no discourse connective is overtly realized.

Every kind of relation (i.e. explicit, implicit and AltLex) in the PDTB is assigned a sense label based on a three-layered hierarchy: the top-level *classes* are the most generic ones and include EXPANSION, CONTINGENCY, COMPARISON and TEMPORAL labels (see below resp. examples from *a* to *d*). Then, each class is further specified at *type* and *subtype* level. Since the state of the art in automatic surface-sense classification (at *class* level) has already reached the upper bound of inter-annotator agreement (Pitler and Nenkova, 2009), we do not include this task in our pipeline. Instead, we use the *class* label as one of our features, because we can expect to achieve similar performance both with gold standard and with automatically assigned classes.

As for the relations considered, we focus here exclusively on *explicit* connectives and the identification of their arguments, including the exact spans. This kind of classification is very complex, since `Arg1` and `Arg2` can occur in many different configurations. Consider for example the following explicit relations annotated in the PDTB[1]:

[1] In all examples of this paper, `Arg1` is reported in italics, `Arg2` appears in bold and discourse connectives are underlined. At the end of the sentence we specify the *class* label

(a) *I never gamble too far.* In particular **I quit after one try, whether I win or lose.** [EXPANSION]

(b) Since **McDonald's menu prices rose this year**, *the actual deadline may have been more.* [CONTINGENCY]

(c) As an indicator of the tight grain supply situation in the U.S., market analysts said **that late Tuesday the Chinese government**, *which often buys U.S. grains in quantity,* **turned** instead **to Britain to buy 500,000 metric tons of wheat.** [COMPARISON]

(d) When **Mr. Green won a $240,000 verdict in a land condemnation case against the State in June 1983**, he says, *Judge O'Kicki unexpectedly awarded him an additional $100,000.* [TEMPORAL]

An explicit connective can occur between two arguments (a) or before them (b). It can also appear inside the argument as shown in (c), where Arg2 is composed of three discontinuous text spans and Arg1 is interpolated. Furthermore, Arg1 and Arg2 need not to be adjacent, as shown in (d), where "he says" does not belong to any argument span. The latter case is annotated as an *Attribution* in the PDTB, because it ascribes the assertion in text to the agent making it. Attributions occur in 34% of all explicit relations in the PDTB, and represent one of the major challenges in identifying exact argument spans, especially for Arg2. However, given the fact that Arg2 is syntactically bound to the connective, its identification is generally considered an easier task than the detection of Arg1 (Prasad et al., 2010). As shown in Table 1, the position of Arg1 w.r.t. the discourse connective is highly variable and, when it does not occur in the same sentence of the connective, it can be very distant from Arg2, even in a preceding paragraph.

Explicit connectives (tokens)	18,459
Explicit connectives (types)	100
Arg1 in same sentence as connective	60.9%
Arg1 in previous, adjacent sentence	30.1%
Arg1 in previous, non adjacent sentence	9.0%

Table 1: Statistics about PDTB annotation from Prasad et al. (2008).

Another element increasing the complexity of Arg1 and Arg2 identification is the fact that discourse connectives can be expressed by subordinating and coordinating conjunctions as well as by discourse adverbials, and each type is subject to different discourse constraints. Furthermore, argument spans range from clauses, even single verb phrases, to multiple sentences, and they do not necessarily match single constituents in the syntax because they can be discontinuous. For all these reasons, the identification of Arg1 has been only partially addressed in previous works (see for instance Prasad et al. (2010).

The PDTB achieved high-valued inter-annotator agreement. Overall agreement for identifying both the arguments (Arg1 and Arg2) of explicit connectives reached 90.2%, with a general tendency of lower scores for Arg1 and higher scores for Arg2. When considering a matching technique that gives credit also to partial overlap, the agreement reaches 94.5% for explicit connectives (Wellner, 2009).

4 Processing pipeline

We show that discourse annotation can be performed *in a pipeline* handling all types of explicit connectives and argument positions. The fundamental idea is to divide the whole complex task into several small and simpler independent subtasks, in order to feed the output of each step into the following one. An overview of the pipeline is given in Fig. 1. Note that, this representation includes data pre-processing, training and testing.

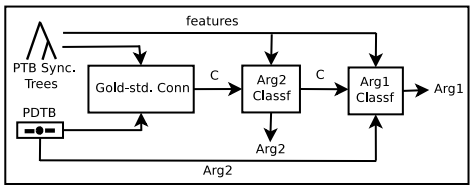

Figure 1: Argument parsing pipeline given Gold-Std Connective(C)

In contrast to previous works, our shallow parsing strategy combines the identification of non-overlapping sequences as connective arguments and the tagging of such text chunks with Arg1 and Arg2 labels.

Since our experiments are based on gold-standard parse trees, we take advantage of the overlap between the PDTB and the Penn Treebank documents (Marcus et al., 1993) in order to map PDTB discourse annotation onto PTB parse trees. We extract the gold-standard connectives with the corresponding top-level sense label from PDTB relations, since this sense label is also one of the

features used by our system. This feature is denoted as C in Fig. 1. Besides, we also extract from the PTB trees all syntactic features needed by the system for the first parsing subtask, which is the identification of Arg2.

After the identification of Arg2 given the connective sense label and feature(s) from the gold parse trees, we proceed with the classification of Arg1. This step-by-step methodology is different from previous approaches like the one by Wellner and Pustejovsky (2007), where the authors select *pairwise* the best heads of Arg1 and Arg2 in order to capture their dependencies, and also by Elwell and Baldridge (2008), who additionally develop *connective-specific* models. Our approach is motivated by two intuitions: first, the identification of Arg2 and Arg1 may require different features, since the two arguments have different syntactic and discourse properties, as discussed in Section 3. Second, the identification of Arg2 is much easier than the identification of Arg1, because the former is syntactically bound to the connective. For this reason, a two-step decision architecture seems more appropriate, because we can start with the easier classification task and then exploit additional output information to tackle the second task.

5 Feature description

We report in Table 2 the list of all features considered in the argument labeling task and we explain them in the light of the example in Fig. 2.

Despite the complex task, the feature set is quite small for both arguments. For the identification of Arg1, we include one additional features which corresponds to Arg2 gold standard labels. Note that the best performing set of features does not include all those listed in the table (see feature analysis in Tables 4 and 5).

Features used for Arg1 and Arg2 segmentation and labeling.	
F1.	Token (T)
F2.	Sense of Connective (CONN)
F3.	IOB chain (IOB)
F4.	PoS tag
F5.	Lemma (L)
F6.	Inflection (INFL)
F7.	Main verb of main clause (MV)
F8.	Boolean feature for MV (BMV)
F9.	Previous sentence feature (PREV)
Additional feature used only for Arg1	
F10.	Arg2 Labels

Table 2: Feature sets for Arg1 and Arg2 segmentation and labeling.

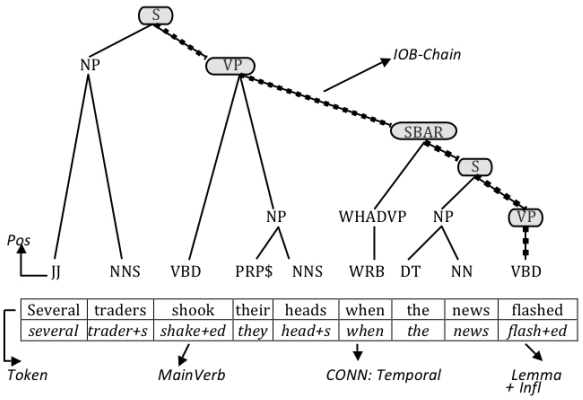

Figure 2: Example sentence with system features

The sense of the connective (F2) refers to one of the four top-level classes in PDTB sense hierarchy, namely TEMPORAL, COMPARISON, CONTINGENCY and EXPANSION. In the sentence reported in Fig. 2, for example, only "when" bears the *temporal* label, while all other tokens are assigned as a "null".

The IOB(Inside-Outside-Begin) chain[2] (F3) is extracted from a full parse tree and corresponds to the syntactic categories of all the constituents on the path between the root note and the current leaf node of the tree. Experiments with other syntactic features proved that IOB chain conveys all deep syntactic information needed in the task, and makes all other syntactic information redundant, for example clause boundaries, token distance from the connective, constituent label, etc. In Fig. 2 the path between "flashed" and the root node is highlighted. The corresponding feature would be *I-S/E-VP/E-SBAR/E-S/C-VP*, where B-, I-, E- and C- indicate whether the given token is respectively at the beginning, inside, at the end of the constituent, or a single token chunk. In this case, "flashed" is at the end of every constituent in the chain, except for the last VP, which dominates one single leaf.

In order to extract the morphological features needed, we use the *morpha* tool (Minnen et al., 2001), which outputs lemma (F5) and inflection information (F6) of the candidate token. The latter is the ending usually added to the word root to convey inflectional information. It includes for example the *-ing* and *-ed* suffixes in verb endings as well as the *-s* to form the plural of nouns. In our

[2]We extracted this feature using the Chunklink.pl script made available by Sabine Buchholz at http://ilk.uvt.nl/team/sabine/chunklink/README.html

example sentence, this feature would be for example *s* for "traders" and "heads", etc.

As for features (F7) and (F8), they rely on information about the main verb of the current sentence. More specifically, feature (F7) is the main verb token (i.e. *shook* in our example), extracted following the head-finding strategy by Yamada and Matsumoto (2003), while feature (F8) is a boolean feature that indicates for each token if it is the main verb in the sentence or not.[3]

The previous sentence feature "Prev" (F9) is a connective-surface feature and is used to capture if the following sentence begins with a connective. Our intuition is that it may be relevant to detect `Arg1` boundaries in inter-sentential relations. The feature value for each candidate token of a sentence corresponds to the connective token that appears at the beginning of the following sentence, if any. Otherwise, it is equal to 0.

We also add gold-standard `Arg2` labels (F10) as an extra information for `Arg1` identification.

6 Experiments

All data used in our experiments are taken from PTB and PDTB. In particular, folders $02-22$ are used to train the model, while folders $00-01$ belong to the development set, and folders 23 and 24 are meant for testing. Our goal is to classify discourse arguments given the connectives by focusing on one relation at time. Since this results in a large search space for the classifier, we prune the search space trying to preserve the relevant contextual information related to the arguments. For this reason, the data given as input to the classifier include a window of two sentences before and after the given connective. This allows us to reduce the search space by more than 90%. In Table 3 we give the statistics of the explicit relation instances for the whole PDTB corpus and span limit sets. Most of the explicit relations (95%) occur within the five sentence window (two preceding and two following the sentence including the connective token).

We use the CRF++ tool (`http://crfpp.sourceforge.net/`) for sequence labeling classification (Lafferty et al., 2001), with second-order Markov dependency between tags. Beside the individual specification of a feature in the feature description template, the features in various combinations are also represented. We used this tool because the output of CRF++ is compatible to CoNLL 2000 chunking shared task, and we view our task as a discourse chunking task. On the other hand, linear-chain CRFs for sequence labeling offer advantages over both generative models like HMMs and classifiers applied at each sequence position. Also Sha and Pereira (2003) claim that, as a single model, CRFs outperform other models for shallow parsing.

[3]We used the head rules by Yamada & Matsumoto (`http://www.jaist.ac.jp/~h-yamada/`)

Number of all explicit relations in PDTB	18459
Number of explicit relations with `Arg1` entirely *inside* the window	94%
Number of explicit relations with `Arg1` entirely *inside or overlapping* the window	95%

Table 3: Statistics about explicit relations and `Arg1` extension.

6.1 Evaluation methodology

We present our results using precision, recall and F1 measures. Following Johansson and Moschitti (2010), we use three scoring schemes: *exact*, *intersection* (or *partial*), and *overlap* scoring. In the exact scoring scheme, a span extracted by the system is counted as correct if its extent exactly coincides with one in the gold standard. However, we also use the two other scoring schemes since exact scoring may be uninformative in some situations where it is enough to have a rough approximation of the argument spans. In the overlap scheme, an expression is counted as correctly detected if it overlaps with a gold standard argument, i.e. if their intersection is nonempty. The intersection scheme assigns a score between 0 and 1 for every predicted span based on how much it overlaps with a gold standard span, so unlike the other two schemes it will reward close matches.

6.2 Feature analysis

Our feature set includes a small set of lexical, syntactic and semantic features, which convey the essential information needed to represent the arguments' position and the clausal boundaries, as well as the internal clause structure. We first take into account the features commonly used in similar works, for example by Wellner and Pustejovsky (2007) and Elwell and Baldridge (2008), and then carry out a selection step in order to identify only the feature combination that performs best in our parsing task. Note that both Wellner and Puste-

jovsky (2007) and Elwell and Baldridge (2008) limit their classification to argument heads, thus they may employ features that are not very relevant to our approach.

We follow the hill-climbing (greedy) feature selection technique proposed by Caruana and Freitag (1994). In this optimization scheme, the best-performing set of features is selected on the basis of the best F1 "exact" scores. Therefore, we increase the number of features at each step, and report the corresponding performance. In order to understand better the contribution of each feature and also to avoid sub-optimal solutions, we also run an ablation test by leaving out one feature in turn from the best-performing set. We use the development split to generate results for the feature analysis to find the best performing feature set, whereas the train split is used to built model. Final results are generated using only the test split.

The results of our feature analysis are reported in Table 4 for `Arg2` and Table 5 for `Arg1`. We do not report the scores having zero as F1-measure.

Features	P	R	F1
Features in Isolation			
Token (T)	0.25	0.08	0.13
Connective (CONN)	0.58	0.50	0.54
IOB_Chain (IOB)	0.22	0.06	0.10
PoS	0.26	0.03	0.05
Lemma (L)	0.26	0.09	0.13
Morph(L+INFL)	0.27	0.05	0.09
Hill-Climbing Feature Analysis			
T+CONN	0.80	0.73	0.76
T+CONN+IOB	0.83	0.75	0.79
T+CONN+IOB+Morph	**0.84**	**0.76**	**0.80**
T+CONN+IOB+Morph+Prev	0.83	0.75	0.79
T+CONN+IOB+Morph+Prev+PoS	0.85	0.75	0.79
Token+CONN+IOB+PoS +Morph+BMV+Prev	0.84	0.74	0.78
Token+CONN+IOB+PoS +Morph+MV+BMV+Prev	0.82	0.72	0.77
Feature Ablation			
T+CONN+IOB	0.83	0.75	0.79
T+CONN+Morph	0.80	0.69	0.74
IOB+CONN+Morph	0.84	0.72	0.77
T+IOB+Morph	0.29	0.16	0.20

Table 4: Results with Single and Combined Features for `Arg2`

Both the feature-in-isolation procedure and the ablation test show that the connective sense feature is the most relevant feature for `Arg1` and `Arg2`, whereas the analysis results for `Arg1` show that the "Prev" feature is also important.

We observe that the performance of the lemma increases if integrated with the inflection feature, while inflection in isolation scores a null Precision, Recall and F1. Therefore, we consider lemma and inflection together as a single feature, which we call *Morph*.

We show that the best performing set for `Arg1` includes eight features, whereas the best feature combination for `Arg2` classification is achieved using only four features, namely token, IOB chain, connective sense and *Morph*.

Features	P	R	F1

Table 5: Results with Single and Combined Features for `Arg1`

The best combination for `Arg1` classification includes all features from our initial set described in Table 2, except MV and PoS. This is probably due to the fact that PoS information becomes redundant for the classifier and BMV and MV convey the same kind of information.

6.3 Results

We compute a baseline (Table 6 between parenthesis) for each parsing subtask, i.e. `Arg1` and `Arg2` identification with the test dataset. To obtain this baseline, we take into account that *i*) `Arg2` is the argument immediately adjacent to the connective and *ii*) 90% of the relations in PDTB are ei-

ther intra-sentential or involve two contiguous sentences. Thus, Arg2 baseline is computed by labeling as Arg2 the text span between the connective and the beginning of the next sentence. The other baseline, on the other hand, is computed by labeling as Arg1 all tokens in the text span from the end of the previous sentence to the connective position. In case the connective occurs at the beginning of a sentence, then the baseline classifier tags the previous sentence as Arg1.

		P	R	F1
Arg2	**Exact**	**0.83** (0.53)	**0.75** (0.46)	**0.79** (0.49)
	Partial	0.93 (0.80)	0.84 (0.85)	0.88 (0.82)
	Overlap	0.97 (0.98)	0.88 (0.85)	0.92 (0.91)
Arg1	**Exact**	**0.70** (0.19)	**0.48** (0.19)	**0.57** (0.19)
	Partial	0.83 (0.50)	0.62 (0.68)	0.71 (0.58)
+Prev	Overlap	0.91 (0.70)	0.63 (0.68)	0.74 (0.69)
Arg1	**Exact**	**0.70** (0.19)	**0.38** (0.19)	**0.50** (0.19)
	Partial	0.83 (0.50)	0.49 (0.68)	0.62 (0.58)
-Prev	Overlap	0.92 (0.70)	0.50 (0.68)	0.65 (0.69)

Table 6: Results of Arg1 and Arg2 extraction with test dataset. Baseline results between parentheses.

In Table 6 we report for each parsing subtask Precision, Recall and F1 achieved with the best performing feature set (see Section 6.2) using the test split, with the corresponding baseline between parenthesis. Note that before evaluation, all spans were normalized by removing leading or trailing punctuation. The best results and features are highlighted in Table 4 and 5 for Arg2 and Arg1 respectively.

We compute the confidence intervals using a resampling method (Hjorth, 1993). For Arg1 identification, we observe that the confidence interval (95%) without "Prev" feature ranges from 0.48 to 0.52 and the same interval is between 0.55 and 0.59 with "Prev" feature, if the exact F1 measure is taken into account. For Arg2 identification the confidence interval (95%) is between 0.78 and 0.81, when the exact F1 measure is taken into account. A statistical significance test run on previous and current results of Arg1 identification shows also that the difference is significant ($p < 0.0001$).

We observe in the results that recall is consistently lower than precision in all tables. This is probably due to the fact that CRF is more conservative while tagging data with argument label compared to other classifiers, which may lead to a lower coverage.

As expected, Arg2 parsing subtask achieves a better performance than Arg1 subtask because Arg2 position and extension are easier to predict. This is confirmed by the fact that the baseline precision of Arg2 *overlap* is 0.98. Also, the major improvement w.r.t. the baseline is achieved in the *exact* setting.

6.4 Error Analysis

We carry out a further analysis on the test set in order to characterize parser errors on different test set partitions. Since Arg1 may occur in a previous sentence w.r.t. the connective, we want to assess the impact of Arg1 position on the parsing task. Therefore, we separately evaluate Arg1 precision, recall and F1 on intra-sentential and inter-sentential discourse relations. Results are reported in Table 7. We also show the changes before and after adding the lexical feature targeting inter-sentential cases.

		Arg1-Results		
		P	R	F1
Intra-Sentential	Exact	0.73	0.61	0.66
	Partial	0.86	0.77	0.81
w/o Prev_feat	Overlap	0.95	0.78	0.86
Inter-Sentential	Exact	0.19	0.01	0.02
	Partial	0.27	0.02	0.04
w/o Prev_feat	Overlap	0.31	0.02	0.04
Intra-Sentential	Exact	0.77	0.61	0.68
	Partial	0.88	0.79	0.81
with Prev_feat	Overlap	0.96	0.77	0.85
Inter-Sentential	Exact	0.52	0.27	0.36
	Partial	0.68	0.40	0.50
with Prev_feat	Overlap	0.79	0.40	0.54

Table 7: Results of Arg1 parsing for intra- and inter- sentential partitions. In the test set, the number of intra- and inter- sentential relations are 1028 and 617 respectively.

The "Prev" feature is critical to the parser to achieve reasonable baseline Arg1 performance for the inter-sentential partition of the test set.

We also carry out a comparative analysis of the parsing performance in the *exact* evaluation setting by considering separately coordinating, subordinating and adverbial connectives. We make the above-mentioned distinction following the suggestion by Elwell and Baldridge (2008), because each connective type has a different behavior w.r.t. its arguments: coordinating connectives (e.g. *and*, *but*) usually have syntactically similar arguments, subordinating ones (e.g. *since*, *before*) are dominated or adverbially linked to Arg1 and are syntactically bound to Arg2, while adverbial connectives (i.e. *nevertheless*, *for instance*) can occur in different positions in the sentence and are not necessarily bound to Arg1.

The evaluation results are presented in Table 8.

In previous works, e.g. Elwell and Baldridge (2008), adverbial connectives were usually considered the most difficult connective type to classify. This is confirmed by our results obtained on Arg1, which show that adverbial connectives negatively affect both precision and recall, with a higher impact on recall. As for Arg2, the parsing results on the three connective types are more homogeneous.

We also observe that the "Prev" feature significantly improves Arg1 parsing with any connective type because it increases recall, while precision decreases with coordinating and adverbial connectives.

Conn. Type	P	R	F1
Results for Arg2			
Coordinating	0.81	0.75	0.78
Subordinating	0.86	0.78	0.82
Adverbial	0.83	0.74	0.78
Results for Arg1(w/o Prev)			
Coordinating	0.73	0.42	0.54
Subordinating	0.73	0.45	0.56
Adverbial	0.68	0.26	0.37
Results for Arg1 (with Prev)			
Coordinating	0.69	0.59	0.64
Subordinating	0.76	0.50	0.61
Adverbial	0.64	0.34	0.44

Table 8: Exact evaluation for each connective type. Coordinating connectives appear in around 40% of the relations, while subordinating and adverbials are respectively 25% and 35% of all connectives.

In order to understand the most common mistakes done by the classifier, we present two example relations where resp. Arg1 (e) and Arg2 (f) are wrongly identified[4]. Note that in example (f) Arg1 appears in the previous sentence, which we do not report here.

(e) Many analysts said the September increase was a one-time event, *coming* as **dealers introduced their 1990 models** [CONTINGENCY]

(f) However, Jeffrey Lane, president of Shearson Lehman Hutton, said **that Friday's plunge is "going to set back" relations with customers**, "because it reinforces the concern of volatility [COMPARISON]

In (e), the classifier tagged the whole text from "the September" to "coming" as Arg1 instead of only "coming", since it takes clausal boundaries as a relevant factor for identifying the argument spans. In (f) the classifier is unable to detect Arg2 probably because the argument does not occur immediately next to the connective.

A manual inspection of misclassified relations confirms that the parser is more accurate in the identification of the sentences containing the arguments rather than in the detection of their exact spans. Also, mistakes concern mostly the classification of inter-sentential relations (especially as regards the Arg1 classifier), thus we will need to focus on these specific cases for future improvements.

7 Conclusions

We cast the complex task of discourse argument parsing as a set of cascading subtasks to be tackled in sequence, and we showed that in this way we achieved a reasonable parser accuracy by handling the whole labeling process in a pipeline.

Since we consider this discourse parsing task as a token-level sequence-labeling task, we were able to detect connective arguments and the corresponding boundaries avoiding the computationally complex approaches described in previous works.

We trained a CRF classifier with lexical, syntactic and semantic features extracted from PDTB and PTB gold annotation. We tested these features both in isolation and in different combinations in order to achieve an optimized performance. To make training time manageable, we pruned the search space by 90%, though leaving out only around 5% of all Arg1 in PDTB.

We also presented a comparative error analysis (subsection 6.4), where we showed that Arg1 classification on intra-sentential relations achieves a performance comparable to Arg2 classification (Table 6). Since the main open issue in our approach is the correct classification of Arg1 in inter-sentential relations, we plan to improve it through more feature engineering. We already extended our experimental framework by including automatically annotated parse trees and connectives in the pipeline (Ghosh et al., 2011).

Relational Lasso
—An Improved Method Using the Relations among Features—

Abstract

Relational lasso is a method that incorporates feature relations within machine learning. By using automatically obtained noisy relations among features, relational lasso learns an additional penalty parameter per feature, which is then incorporated in terms of a regularizer within the target optimization function.

Relational lasso has been tested on three different tasks: text categorization, polarity estimation, and parsing, where it was compared with conventional lasso and adaptive lasso (Zou, 2006) when using a multi-class logistic regression optimization method. Relational lasso outperformed these other lasso methods in the tests.

1 Introduction

As machine learning methods scale up and now deal with millions of features, we ideally want to add all possible features without having to manually verify or consider the effectiveness of each feature with respect to the performance. In other words, we need an automatic way to exploit any usable information that can be obtained from features. However, with current machine learning methods, adding noisy features could lower performance, so the user still has to decide which features are worth adding.

Regularization methods have recently received greater interest because of this need. Regularization is expressed as a constraint term within an optimization function, where the term is given as a function regarding the importance weight of each feature. Regularization provides a means of importance control embedded within the target optimization problem. Among the various regularizers, *lasso*, proposed by (Tibshirani, 1996) is the most widely used because of its mathematical comprehensiveness.

This paper describes a method, which we call *relational lasso*, that improves upon the conventional lasso method. We show that relational lasso improves the overall performance of classification compared with that of other lasso methods. This study was motivated through a limitation we observed in conventional lasso: that features could be inter-related, but such dependences are not incorporated within the current regularization. Therefore, the conventional method tends to favor correlated features, which can lead to the importance of non-correlated features being neglected.

Relational lasso overcomes this limitation of conventional lasso by introducing an additional penalty parameter for each feature; this parameter is estimated automatically given the noisy relations among features, where the relations are also automatically generated. While the proposed method does not add to the computational complexity of the conventional regularization method, it improves the quality of classification. We explain the method and show empirical results from tests based on three different text classification and parsing tasks.

Regularization was originally proposed as a way to avoid over-fitting by favoring some small number of features. Our method presented in this article exploits this approach further and attempts to estimate the importance of each feature within the relations it has with other features. As explained in more detail in the following section, attempts along the same line have been made to incorporate underlying relations among features, such as by *fused lasso* through the ordering among features (Tibshirani et al., 2005), or by *group lasso* through groups among features (Yuan and Lin, 2006). However, fused lasso assumes problems with features that can be ordered in some meaningful way, and group lasso requires under-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1080–1088,
Chiang Mai, Thailand, November 8 – 13, 2011.

lying group information to be configured before the method is applied. The closely related work to ours is *adaptive lasso* (Zou, 2006), which introduces an additional parameter per feature. However, since adaptive lasso does not explicitly process relations among features, the estimation of this additional parameter is completely different from our method. Moreover, as will be empirically shown, our method outperforms adaptive lasso, which in fact performed worse than even the conventional method.

Related work on regularization techniques has shown the potential of regularization not only to prevent over-fitting, but also to serve as a kind of feature selection. Relational lasso provides another step along this line. Here, we show that our method outperforms other lasso methods in different classification tasks. Moreover, it works well even when noisy features are added, something that degrades the performance of other lasso methods.

2 Related Work

As explained, feature selection is the key to our method's effectiveness, and here we summarize the related work done along this line. A substantial number of studies have been done on feature selection techniques, and these techniques can be classified into three categories according to (Guyon and Elisseeff , 2003): wrapper methods, filter methods and embedded methods.

The wrapper is the most naïve way of selecting a subset of features through predictive accuracy (Kohavi and John, 1997). The user searches the possible feature space greedily using an induction algorithm and selects the best subset with the best predictive accuracy. Wrappers with greedy algorithms can be computationally expensive and the stepwise selection is often trapped into a local optimal solution. Since the possible number of subsets for a set is exponential to the number of features in the original set, in practice the user typically defines the subset arbitrarily depending on the category of features, as was tested by (Scott and Matwin , 1999). This makes impossible any fine adjustment as to which individual features to use.

Filter methods, on the other hand, select good features according to some criteria, thus providing the means for selecting individual features. These methods have been extensively studied, and a good overview is available in (Manning, 1999). The representatives of the evaluation function for choosing good/bad features are chi-squares and mutual information, and features having higher scores for these functions are considered good features. While filtering methods are effective and therefore often used, these methods are independent of the learning method that they are used with. Moreover, the performance is not guaranteed to improve even though feature selection is used.

The last category is embedded methods, where the feature selection is embedded within the overall classification problem. The decision tree is an example of an embedded method, and machine learning techniques using pruning steps have been studied (Perkins et al., 2003). *Lasso*, an acronym for "least absolute shrinkage and selection operator", using the L_1 norm (Tibshirani, 1996) is a computationally efficient method for simultaneously achieving the estimation and feature selection.

Although lasso helps achieve an effective model, the L_1 norm could cause biased estimation among features (Knight and Fu, 2000) by not being able to distinguish between truly significant and noisy features.

To cope with this problem, (Zou and Hastie, 2005) proposed the *elastic net* method, which is expressed as the conjunct of L_1 and L_2 norms of the feature weights. They show that this method works when the number of features substantially exceeds the number of learning data, and also when there is strong correlation between some features. Another proposal is *fused lasso*, which incorporates the order of features (as found in their numbers, such as found in the case when each image pixel value forms a feature) (Tibshirani et al., 2005). Here, the target application is protein mass spectroscopy and gene expression data, and the method is only applicable to a target where the order among features is explicit, as in the case of gene or image pixels. (Yuan and Lin, 2006) proposed *grouped lasso*, which incorporates underlying groups among features. The fused and grouped lasso methods require configuration of the structure among features.

Recently, a new approach called *weighted lasso* is proposed which calculates the L_1 norm on features, each of which is weighted. As one method, (Zou, 2006) proposed a two-step approach called

adaptive lasso. This paper proposes an alternative weighted lasso method, in which the estimation of the weights is processed differently from that of adaptive lasso. Although the procedure of adaptive lasso is closest to relational lasso, the learning of adaptive lasso does not explicitly handle the relations among features.

All these methods are attempts to incorporate the relations, or structure, among features —such as dependence, ordering and groups— into machine learning through the framework of regularization. Although such dependence is not always given or tractable, we believe this information can be learned from some automatically generated noisy relation among features.

3 L1-Regularization of Multi-Class Logistic Regression

Before going on to the main points of relational lasso, let us summarize the regularization framework that we adopt. Regularization is the general method used in classification. The target function has two terms, one for fitting and another for regularization. This second term penalizes the weights acquired by each feature, typically by incorporating the addition of their norms into a target function for the classifier. This prevents the target function becoming too over-fitted by favoring some specific sets of features. In this sense, the regularization term can be considered as serving for feature selection.

Of the various ways to define the target function, in this paper we focus on the multi-class logistic regression model and L1-regularization; namely, the lasso method.

The fitting function adopted in this paper is a multi-class logistic regression model, denoted as LR in the following. LR is used to model the relationship between the input vectors $\boldsymbol{x} = \mathbb{R}^n$ and labels $y \in \boldsymbol{Y}$. The conditional probability for a label y given x is defined as

$$\begin{aligned} p(y|x;\boldsymbol{w}) &= \frac{1}{Z(\boldsymbol{x})}\exp\left(\boldsymbol{w}^T\phi(\boldsymbol{x},y)\right) \\ Z(x) &= \sum_{y'}\exp\left(\boldsymbol{w}^T\phi(\boldsymbol{x},y')\right), \end{aligned}$$

where $\phi(\boldsymbol{x},y) \in \mathbb{R}^m$ is the feature vector and $\boldsymbol{w} \in \mathbb{R}^m$ is the weight vector. When the training examples $\{(x_i,y_i)\}(i=1,\cdots,l)$ are given, minimization of the loss function

$$L(\boldsymbol{w}) = -\sum_i \log p(y_i|\boldsymbol{x}_i;\boldsymbol{w}),$$

is equivalent to the maximum likelihood estimation.

Regularization makes it possible to obtain a good model for LR, without restricting the number of features, by imposing appropriate restrictions on weight $\boldsymbol{w}$. Of the different ways of regularization, in this paper we adopt (Tibshirani, 1996)'s method of imposing an L_1 norm on parameters because of its mathematical simplicity, especially when applied with LR. This method is called lasso and facilitates both estimation and automatic variable selection. When applying this lasso to logistic regression, the MAP estimation of weights for each feature is given by the following formula, the target function to be optimized:

$$\boldsymbol{w}^* = \arg\min_{\boldsymbol{w}} L(\boldsymbol{w}) + \lambda\sum_i |w_i|, \qquad (1)$$

where λ is the parameter defining the strength of the regularization term's influence on the optimization.

Although our proposal applies in general to various types of target function, in this paper we examine its effectiveness within this particular target function. This target function was chosen because the target function of LR-lasso is mathematically comprehensive, so multi-class logistic regression and lasso are widely applied. Further investigation to determine whether our method works well for other target functions will be part of our future work.

4 Relational Lasso —The Proposed Method

The limitation of conventional lasso is that relations among features cannot be incorporated. For example, highly correlated features which lead towards a higher performance could all acquire relatively large weights. This would lead to favoring a single aspect that counts for the classification and neglecting other minor but still important aspects which would enable better classification. This happens when a high correlation is found among features. Therefore, when one feature is favored, the other correlated features must be heavily penalized, so that features which count

for classification from a different aspect are more favored.

To express this, we adopt the weighted lasso approach, so an additional penalizing parameter α_i for each feature i is introduced in the second term of formula (1):

$$\boldsymbol{w}^* = \arg\min_{\boldsymbol{w}} L(\boldsymbol{w}) + \lambda \sum_i \alpha_i |w_i|. \qquad (2)$$

The solution found here, subject to the L_1 regularizer, is equivalent to the solution obtained from the constrained optimization problem:

$$\begin{aligned} \underset{\boldsymbol{w}}{\text{minimize}} \quad & L(\boldsymbol{w}), \\ \text{s.t.} \quad & \sum_i \alpha_i |w_i| \leq \gamma. \end{aligned}$$

The parameter γ corresponds to λ of formula (2). Each parameter α_i determines the penalty for w_i and directly affects the importance of the ith feature.

Previous work on adaptive lasso (Zou, 2006) also introduces an additional parameter, such as α_i, in addition to the weight parameter. Adaptive lasso focuses on the presence of oracle properties[1], and works in two stages of optimization. First weight w_i is learned with conventional lasso. Second, L_1 norm is re-weighted with the parameters α_i as $\alpha_i = 1/|\hat{w}_i|^\delta$ being set from initial lasso estimator $\hat{\boldsymbol{w}}$ using a parameter δ, and the optimization problem is processed using $\boldsymbol{\alpha}$. Therefore, their way of learning this additional parameter does not explicitly concern the exploitation of additional information different from the original weight w_i. On the other hand, our α is estimated given a noisy relation among features, thus it plays a different role from w. In this sense, the way to handle this additional parameter for relational lasso is completely different from adaptive lasso. In other words, the originality of our method lies in using α to express the relations between underlying features.

The relations between features are denoted as R, which is provided to the proposed algorithm and used to estimate α. R denotes a pairwise dependence relation between features. That is, if there are m features in total, $R \subset (1, \cdots, m) \times (1, \cdots, m)$. Unlike previous work such as fused (Tibshirani et al., 2005) and grouped lasso (Yuan and Lin, 2006), R in our work is a noisy relation which can be automatically obtained by scanning through features.

Although there are various possibilities for obtaining R, one way is through the *inclusion* relation among features. Given a pair of features p and q, the feature q *includes* p, if in every data of the learning data, when the value of feature q is non-zero, the value of feature p is always non-zero. For example, for the case of the adjective "economic" and its stem "econom", the latter includes the former while also being a stem for other terms such as "economy" and "economist". In the final classification, it is unknown which of "econom" and "economic" counts. For part-of-speech tagging, "econom" would not provide much information since it does not have a complete form, but for topic estimation, "econom" might provide sufficient information by representing the terms "economic", "economy" and "economist". In both cases, when the two words appear as features, they share a tight relation and when one is given high importance, the other will as well in conventional lasso. In relational lasso, if one representative is selected, then other similar features in the same group will acquire less importance by having a larger penalty.

The overall procedure is shown in Procedure 1. The procedure obtains three kinds of learning data input, a relation among features, and parameter values. Before optimizing the target function, denoted in the second line from the bottom, the procedure calculates α depending on the given relation R among features. This procedure is expressed in terms of a while-structure, which enables the adjustment of penalty parameters for highly correlated features. The processed feature is held in set F to avoid any duplicate processing of features.

In the while-structure, features are selected one at a time in the order of larger values of $\frac{\partial L(\boldsymbol{w})}{\partial \boldsymbol{w}}$, with $\boldsymbol{w}$ being the zero vector[2]. The number of the selected feature is denoted as k^*. Then, for all ks which are related to k^* in R, the α is enlarged by a

[1] Oracle property (Fan and Li , 2001) is satisfied if the optimization problem can correctly select the nonzero weights with probability converging to one and the estimators of the nonzero weights are asymptotically normal with the same means and covariance that they would have if the zero coefficients were known in advance.

[2] There are other possibilities for this order of processing features, such as randomizing the order. In the Grafting method (Perkins et al., 2003), the processed feature is selected by calculating $\frac{\partial L(\boldsymbol{w})}{\partial \boldsymbol{w}}$ every time in the while-structure, which is also possible with relational lasso. This however remains as future work.

Procedure 1 Relational Lasso

Input:

- $(x_i, y_i)(i = 1, \cdots, n)$
- Parameters λ, a_1, a_2
- Relation among m features $R \subset (1, \cdots, m) \times (1, \cdots, m)$

$\boldsymbol{\alpha} = \mathbf{1}, \boldsymbol{w} = \mathbf{0}, F = \{\}$
$\boldsymbol{v} = \frac{\partial L(\boldsymbol{w})}{\partial \boldsymbol{w}}$
while $|F| < m$ **do**
  $k^* = \arg\max_{k \notin F} |v_k|$
  for all $k \notin F$ and $(k^*, k) \in R$ **do**
    $\alpha_k = \alpha_k + a_1$
  end for
  for all $k \notin F$ and $(k, k^*) \in R$ **do**
    $\alpha_k = \alpha_k + a_2$
  end for
  $F = F \cup k^*$
end while
$\boldsymbol{w} = \arg\min_{\boldsymbol{w}} L(\boldsymbol{w}) + \lambda \sum_k \alpha_k |w_k|$
return $\boldsymbol{w}$

certain constant a_1 and a_2, depending on whether the feature k is included or k^* is included. When the while procedure ends, F includes all the features. Finally, $\boldsymbol{w}$ is estimated in terms of LR-lasso, where the second term is weighted further with the thus estimated α. When some specific w_k becomes zero, this means that the weight is considered as not selected for the classification task.

One further improvement that might be possible for the above procedure is to repeat the while-structure and the estimation of w, so that α and w perform co-training; this also remains for our future work. Moreover, the procedure presented here remains an ad hoc modification of conventional lasso based on our motivation. A more proper mathematical reformulation of this method will be part of our future work.

5 Evaluation

5.1 Experimental Settings

We will consider the following two feature sets.

- Standard features
- Standard and additional features

Here, an additional feature set is introduced so that it can be noisy with respect to the classification. Therefore, the interest lies in whether the performance is better when we have the additional features than it is when we have only the standard features.

We consider three methods:

- Conventional lasso (Tibshirani, 1996)
- Adaptive lasso (Zou, 2006)
- Relational lasso (proposed method)

We are interested in whether relational lasso performs better than the other methods. In practice we can select the best λ parameter used for lasso methods, using cross-validation, although we examined multiple λs, which determine the strength of the regularizers' influence as shown in formulas (1) and (2) of Sections 3 and 4.

The other parameters introduced in Section 4 are set as follows. Adaptive lasso has the parameter $\delta = 1$, which is set as the common choice in (Krämer et al., 2009) and the parameter α_i is defined from initial estimator $\hat{\boldsymbol{w}}$ as follows:

$$\alpha_i = \max\left\{\frac{1}{|\hat{w}_i|}, 1\right\}.$$

For relational lasso, parameters a_1 and a_2 were each set to 1. For L_1 regularized LR, a coordinate descent method is implemented by modifying LIBLINEAR[3]. Coordinate descent methods have been widely applied elsewhere because of their suitability for application to higher-order problems (Yuam et al., 2010).

For each pair of a feature and a method, we considered the following three problems of text classification, polarity estimation, and statistical parsing. The next three sections explain the standard and additional feature sets, the relation among features R, and the evaluation scores.

Task 1: Text Classification

Twenty Newsgroups (20NG)[4] were used as the dataset for text classification. This collection contains 18,846 English documents partitioned across 20 different news groups.

The data was sorted by date, with the first 60% used as a training set and the remaining 40% used as a test set. A simple bag of words was used

[4] provided by Jason Rennie, `http://people.csail.mit.edu/jrennie/20Newsgroups/`

Table 1: Features used for dependency parsing

unigram	for w in $w_{i-1}, w_i, w_j, w_{j+1}, w_{j+2}, w_{j+2}$	pos(w), lex(w)
	for w in w_{i-1}, w_i, w_j,	pos(w^{left}), lex(w^{left})
	for w in w_{i-1}, w_i,	pos(w_i^{right}), lex(w_i^{right}), pos(w_i^{head}),lex(w_i^{head})
bigram	for (v, w) in $(w_i, w_j), (w_{i-1}, w_j)$	pos(v)pos(w),pos(v)lex(w),lex(v)pos(w),lex(v)lex(w)
add bigram	for (v, w) in $(w_i, w_{j+1}), (w_j, w_{j+1})$	pos(v)pos(w),pos(v)lex(w),lex(v)pos(w),lex(v)lex(w)
add preposition	for w in $w_{j+1}, w_{j+2}, w_{j+3}$ (if w_j is a preposition)	lex(w_i)lex(w_j)pos(w), pos(w_i)lex(w_j)lex(w)

as the standard feature sets, whereas all stems of all words were used as additional features. R was defined as the relation between each word and its stems.

A multi-class classification task is typically evaluated by macro and micro F1 values, so we also provided these values.

Task 2: Polarity Estimation

Polarity dataset v2.0[5] was used as the second data set. The content of each data was a movie review in text, tagged with the sentiment of positive or negative. The data consisted of 1,000 positive and 1,000 negative reviews. Since the data set was small, the average accuracy was obtained through 10-fold cross validation.

Feature sets were basically the same as for Task 1, where the standard was a bag of words, the additional set consisted of word stems, and relation R was the relation among words and their stems.

The evaluation was based on the accuracy of the binary classification of positive/negative.

Task 3: Parsing

We also tested the methods on a parsing task, which was a task drastically different from tasks 1 and 2. We used CoNLL-X formatted sentences from the Wall Street Journal section of the Penn Tree-bank. Sections 2-21 were used as training data (39,832 sentences), and section 23 was used as test data (2,416 sentences).

The parsing algorithm we tested is the standard shift-reduce parsing proposed by (Nivre, 2003), where the parsing proceeds by successive determination of the relation between two words (denoted as w_i and w_j). Such a determination is considered a 4-class classification problem that is modeled and learned by LR, augmented by the three lasso methods being evaluated.

[5]provided by Bo Pang, `http://www.cs.cornell.edu/people/pabo/movie-review-data/`

The standard features used are listed in Table 1. Here, pos(w) indicates the part of speech of the word w, where w_i indicates the ith word of a given sentence, and w_i^{left} indicates the already parsed dependent word of w_i placed to its farthest left side. The additional feature set included all dependent words involving w_i and w_j, and all bigrams concerning words used as features in the standard set. In our dependency parsing task, we measured the word accuracy which was defined as the ratio of words assigned correct heads divided by the total of all words.

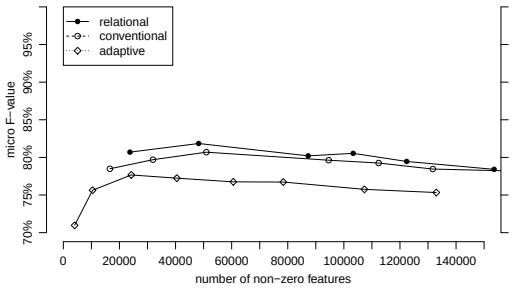

Figure 1: Task 1: Micro F1 values for the number of non-zero features

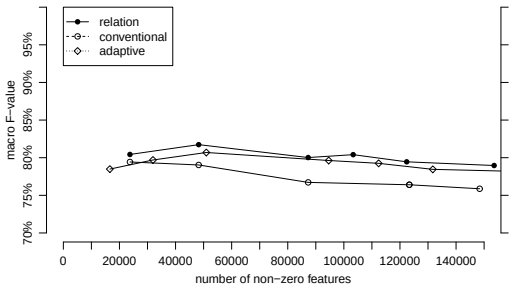

Figure 2: Task 1: Macro F1 values for the number of non-zero features

5.2 Results

Figures 1 and 2 show the results for Task 1, Figure 3 those for Task 2, and Figure 4 those for Task 3. Horizontal axes show the number of features and vertical axes show accuracy. Each graph has three lines, indicating the conventional, adaptive and relational lasso methods applied to the standard and additional features all together. Each line has five points, each corresponding to a different value of λ. The horizontal coordinate was determined by counting how many features remained non-zero for each value of λ.

Overall, all figures, except for Figure 3 show that relational lasso outperformed the adaptive and conventional lasso methods. This was to be expected, since relational lasso has the relation R as input, unlike the conventional lasso method. This confirms that information from the underlying R does improve lasso performance. Curiously, the performance of adaptive lasso for some figures was lower than that of the conventional method. The reason for this will be given later in this section.

As Figure 3 and Figure 4 show, the performance was competitive among the three lasso methods, when the number of features were small. However, with a large number of features, relational lasso generally outperforms the other lassos.

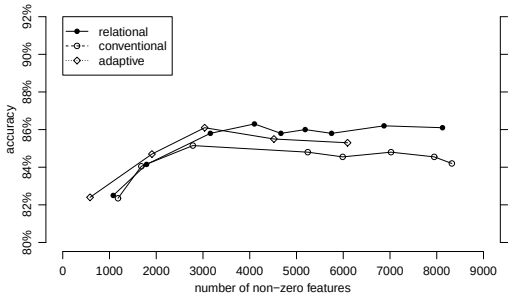

Figure 3: Task 2: Accuracy for the number of non-zero features

It is difficult to compare the performance since different λ values lead to different levels of performance, so the maximum performance obtained by changing the λ value is shown in Table 2. Columns are for different lasso methods with standard and additional feature sets, whereas rows represent different tasks. Note that the best values of λ differ depending on the pairs of methods and features.

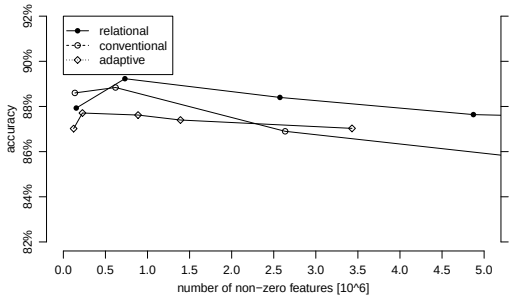

Figure 4: Task 3: Word accuracy for the number of non-zero features

Overall, the last column presents the highest performance in each row, thus suggesting the effectiveness of relational lasso.

For Task 2, when features of standard and additional sets were used, the performance of the conventional method decreased compared to that when only the standard set was used. This could happen if the additional feature set is noisy and the regularizer cannot exploit the useful information from the additional set of features. On the other hand, the performance of relational and adaptive lasso for the same task was improved by extracting the useful information; that is, the performance was higher than when using only the standard features. This shows that the use of underlying information among features enhances the overall performance.

For Tasks 1 and 3, adding features led to better performance than when using only the standard set. Note, though, that the performance increase was greatest for relational lasso. Thus, relational lasso is the best among the three lasso methods at exploiting information, and thus performs better in terms of accuracy.

In this table, too, we see that for Task 2, the performance of adaptive lasso is below that of the conventional lasso. We consider the reason for this to be as follows. Since the optimization for adaptive lasso is done in two stages, some of the features are dropped within the first stage. In the second stage, these features will never re-acquire any importance. In other words, the feature selection must be done at the very end in order to preserve the possibility of some features to re-acqure the importance through learning.

Before ending, we must note the impact of relational lasso on the speed of overall processing.

Table 2: Maximum Performance among Various Values of λ for Three Lasso Methods

Lasso Methods	Conventional		Adaptive		Relational	
Feature Sets	Std	Std+Add	Std	Std+Add	Std	Std+Add
Task 1 (micro)	79.67%	81.03%	76.78%	77.16%	78.87%	**81.81**%
Task 1 (macro)	79.43%	80.69%	76.53%	77.67%	78.52%	**81.72**%
Task 2	85.81%	84.95%	85.56%	86.1%	84.82%	**86.45**%
Task 3	75.87%	88.81%	74.64%	87.71%	75.97%	**89.23**%

The pre-processing to obtain α is very fast, since it only scans the number of features once. The bottleneck of the procedure lies in the estimation of w since this requires convergence through a repetitive procedure. Therefore, the computational complexity of relational lasso will not change even with α within the regularizer, and the overall speed of relational lasso is almost the same as that of the conventional method. In contrast, adaptive lasso requires twice as much time since the bottleneck part is done twice. In this sense, our method outperforms adaptive lasso in speed and is not significantly slower than conventional, at least for the settings we have examined in this section.

6 Conclusion

Relational lasso utilizes relations among features to better exploit information through regularization, especially through lasso methods. The conventional lasso method is not designed to incorporate relations among features, and this leads to biased weighting of a group of features having similar behavior. Relational lasso controls such relations underlying features by introducing a penalty parameter for each feature. The penalty increases when a feature is related to some other feature having less of a penalty. This parameter score is incorporated as the regularization term of the target machine learning function for the optimization objective.

We compared relational lasso to the conventional method and the adaptive lasso proposed by (Zou, 2006), which also uses an additional parameter per feature. We evaluated the methods based on how well they performed three tasks of text categorization, polarity estimation, and parsing. Relational lasso outperformed the other lasso methods in these tasks. Moreover, the performance of the conventional lasso methods deteriorated when noisy features were added, while relational lasso successfully extracted useful information from these features and its performance improved.

As part of our future work, we plan to investigate whether our method works for other tasks such as tagging, and with other target functions. Moreover, there are many directions we can take to further improve the method, such as through co-training. Last, it will be interesting to see how our method can be mathematically reformulated.

Abstract

Recent large-scale hierarchical classification tasks typically have tens of thousands of classes as well as a large number of samples, for which the dominant solution is the top-down method due to computational complexity. However, the top-down method suffers from accuracy deficiency, that is, its accuracy is generally lower than that of the flat approach of 1-vs-Rest. In this paper, we employ meta-classification technique to enhance the classifying procedure of the top-down method. We analyze the proposed method on the aspect of accuracy, and then test it with two real-world large-scale data sets. Our method both maintains the efficiency of the conventional top-down method and provides competitive classification accuracies.

1 Introduction

Test categorization, as a key technology of data mining, has received intensive study for decades. Recently, real-world applications have raised some large-scale tasks that typically have tens of thousands of classes, where many established techniques such as the 1-vs-Rest multiclass classification fail due to computational complexity. Meanwhile, those large-scale tasks usually employ hierarchies to organize the huge number of classes that they have, which provides a clue to solve them. Such kind of tasks include categorizing patent documents into the taxonomy of International Patent Classification (IPC) (Fall et al., 2003; Fujii et al., 2007) and categorizing web pages into the directories of Open Directory Project (ODP) or Yahoo! (Labrou and Finin, 1999; Liu et al., 2005).

The existing approaches to hierarchical classification mainly fall into two categories. One category aims at raising classification accuracy, which generally takes hierarchies as additional clue for classifying a sample besides its content. Such researches include hierarchical support vector machines (SVM) (Cai and Hofmann, 2004; Tsochantaridis et al., 2005), hierarchical Rocchio-like classifiers (Labrou and Finin, 1999), min-max modular network (Lu and Ito, 2002; Lu and Wang, 2009) and ensemble classifications (Punera and Ghosh, 2008).

The other category aims at reducing computational complexity. The main approach in this category is an ensemble classification method called top-down method (Bennett and Nguyen, 2009; Ceci and Malerba, 2007a; Koller and Sahami, 1997; Liu et al., 2005; Montejo-Ráez and Ureña-López, 2006; Sun and Lim, 2001; Xue et al., 2008; Yang et al., 2003). Top-down method builds a tree of classifiers which is isomorphic with the hierarchy of classes.

Top-down method classifies a test sample as follows. The sample is filtered down the tree of classifiers from the root node. For each parent node that the sample reaches, those child nodes whose confidence values predicted by the base-classifiers exceed a predefined threshold are invoked to carry the sample on. When the sample reaches the bottom leaf nodes eventually, the predictions can be made (Liu et al., 2005; Montejo-Ráez and Ureña-López, 2006; Yang et al., 2003). As this classifying process employs the threshold strategy of comparing the scores with thresholds, which is named score-cut (S-cut) in the context of flat multiclass classification (Yang, 2001), we call this kind of

conventional top-down method the S-CUT Top-Down method (ScutTD) so as to distinguish it from the later variant top-down methods in this paper.

ScutTD is far more efficient than the normal flat approach of 1-vs-Rest in handling the classification tasks that has a large number of classes. The computational complexity of 1-vs-Rest is linear to the number of classes, while that of ScutTD is approximately logarithmic (Ceci and Malerba, 2007a; Liu et al., 2005; Wang and Lu, 2010; Yang et al., 2003). As an practical example, in an classification experiment on 492 617 training documents, 275 364 test documents and 132 199 categories of Yahoo!, ScutTD costs only 2.1 hours on training and 0.12 hours on classifying, while 1-vs-Rest costs 310 hours on training and 54 hours on classifying (Liu et al., 2005).

However, ScutTD has a well-known deficiency of classification accuracy, that is, its performance is generally worse than the flat 1-vs-Rest approach (Bennett and Nguyen, 2009; Ceci and Malerba, 2007a; Wang and Lu, 2010; Xue et al., 2008). As a persuasive evidence, in the 2009 PASCAL challenge on large-scale hierarchical text [1], flat methods rank highest, hybrid methods rank next and top-down methods rank lowest.

The main reason for the accuracy deficiency of ScutTD is that its classifying procedure actually consists of cascaded decisions about which child nodes should be invoked from a parent node. Each of these decisions is made upon the score of local base-classifiers only, and not changeable after that. Thus a wrong decision inevitably leads to a group of wrong predictions. This problem is usually called error propagation (Wang and Lu, 2010; Xue et al., 2008). Sun et al. study a special case of this problem, the wrong decision of rejecting a child node at high layers, and call it the blocking problem (Sun et al., 2004). Liu et al. compare this classifying procedure to a Pachinko-machine (Liu et al., 2005). As a solution, Ceci and Malerba has proposed a bottom-up thresholding strategy (Ceci and Malerba, 2007a)

In this paper, we propose a 'global' classifying method for top-down method to reduce its error propagation. The idea is to treat combining the predictions of the base-classifiers as a meta-classification task, for which we name our method Meta-classification Top-down method (MetaTD).

[1] http://lshtc.iit.demokritos.gr/

There is one point that needs to be clarified. There are two kinds of hierarchical classification tasks in real-world applications. One kind is mandatory leaf-node classification where only the leaf nodes are the validate labels or classes (Dumais and Chen, 2000; Freitas and de Carvalho, 2007; Silla and Freitas, 2010). In contrast, the other is non-mandatory leaf-node classification correspondingly, where both the internal nodes and the leaf nodes are validate labels (Lewis et al., 2004; Liu et al., 2005). In this paper, we handle the first kind of hierarchical classification – mandatory leaf-node classification.

The rest of paper is organized as follows. The proposed MetaTD as well as the conventional S-cutTD is formally presented in Sec. 2. We then provide some ideas on the classification accuracy of MetaTD in Sec. 3. After that we test MetaTD with two real-world data sets in Sec. 4. Finally we conclude this paper in Sec. 5.

2 Methods

In this section, we present the formal descriptions of the proposed MetaTD. We first review the conventional ScutTD. We then present MetaTD in detail. After that an example is given to illustrate MetaTD.

2.1 S-cut Top-down Method

Suppose H is a hierarchy of classes which records all the relations of parent nodes and their children,

$$H = \{(p, c) | p \text{ is a parent node}, \\ c \text{ is one of its children}\}$$

where (p, c) is called a parent-child relation. Suppose T,D and E are the training, development and test sets respectively.

Applying ScutTD consists of the following three steps.

First, train base-classifiers. One classifier will be trained for each parent-child relation (p, c) of the hierarchy H, noted as f_c, through the following local training set,

$$T_{pc} = \{(x, y) | x \in T_p, y = +1 \text{ if } x \in T_c, \\ y = -1 \text{ otherwise}\} \quad (1)$$

where T_* is the subset of training samples that belong to the node $*$.

Second, find optimal thresholds for the base-classifiers. The approaches to this step actually have alternatives. Micro-F_1 is taken as the criterion optimization target which balances both pre-

cision and recall, as follows (Bennett and Nguyen, 2009; Liu et al., 2005).

$$t_c = \underset{t}{argmax}\, F_1(D_{pc}, f_c, t) = \underset{t}{argmax}\, \frac{2P(D_{pc}, f_c, t)R(D_{pc}, f_c, t)}{P(D_{pc}, f_c, t) + R(D_{pc}, f_c, t)}, \quad (2)$$

$$P(D_{pc}, f_c, t) = \frac{n_r}{|\{x|(x,y) \in D_{pc}, f_c(x) \geq t\}|},$$
$$R(D_{pc}, f_c, t) = \frac{n_r}{|D_{pc}|},$$
$$n_r = |\{x|(x,y) \in D_{pc}, f_c(x) \geq t, y = 1\}|,$$

where t_c and f_c are the local threshold and base-classifier, D_{pc} is the local development subset which is similar with the T_{pc} defined by Eq. 1), P and R are the precision and recall, and n_r is the number of correct predict labels.

Third, classify the test instances. The algorithm of this step is presented in Fig. 1. With the trained base-classifiers f_c and the thresholds t_c, the test set E can be classified.

2.2 Meta-classification Top-down method

To describe the proposed MetaTD, we first introduce the definition of meta-samples as follows,

$$\mathcal{M}(u, l, f_*) = (\mathcal{M}_x(u_x, l, f_*), \mathcal{M}_y(u_y, l, f_*)) \quad (3)$$

$$\mathcal{M}_x(u_x, l, f_*) = \{(n_i, f_{n_i}(u_x))|n_i \in p_l\}$$
$$\mathcal{M}_y(u_y, l, f_*) = \begin{cases} +1, & l \in u_y \\ -1, & l \notin u_y \end{cases}$$

where $\mathcal{M}$ is the meta-mapping that consists of meta-input $\mathcal{M}_x$ and meta-output $\mathcal{M}_y$, H is a hierarchy, $u = (u_x, u_y)$ is a base-sample where u_x is the input part and u_y is the label set, l is a leaf node (or a label), that is, a validate label for base-samples, $p_l = (n_0, n_1, \ldots, n_k)$ is a path from the root to l where $n_0 = root$, $n_k = l$, $(n_i, n_{i+1}) \in H$, and f_* are base-classifiers.

However, the above definition yields one meta-sample for each class, which may cause a problem of computational complexity on large-scale tasks. Hence a method of selecting label candidates for each base-sample is employed so that only a small fraction of labels need to be delivered into meta-classification. We note this selection method as $L(u_x, f_*, H)$.

MetaTD is based on the above two settings, and its workflow is described in Fig. 2.

Require: a test instance x
a hierarchy H=$\{(p,c)|(p,c)$ is a parent-child $\}$
base-classifiers $\{f_c|(p,c) \in H\}$
thresholds $\{t_c|(p,c) \in H\}$
Ensure: a predicted label set y
$q \leftarrow [Root]$, $y \leftarrow \{\}$
while q is not empty **do**
  $p \leftarrow$ pop out the first item of q
  if p is a leaf node **then**
    $y \leftarrow y \cup \{p\}$
  else
    for all $c, (p,c) \in H$ **do**
      $s_c \leftarrow f_c(x)$
      if $s_c \geq t_c$ **then**
        append c into p
      end if
    end for
  end if
end while
return y

Figure 1: ScutTD algorithm

The training phase consists of three steps as follows,

1. Train base-classifiers f_* on a training data set T, which is the same with ScutTD.
2. Construct a meta-training set with the base-classifiers and a development set D, $M_T = \cup_{u \in D}\{\mathcal{M}(u, l, f_*, H)|l \in L(u_x, f_*, H)\}$.
3. Train a meta-classifier g on M_T.

The whole training phase requires the base-level training set T and development set D, the description of the hierarchy H, and produces a set of base-classifiers f_* and a meta-classifier g.

The classifying phase also consists of three steps as follows,

1. Construct a group of meta-samples from a test base-sample u_x (its label u_y is unknown), $M_E = \{\mathcal{M}_x(u_x, l, f_*)|l \in L(u_x, f_*, H)\}$.
2. Present these meta-samples to the meta-classifier g,
$$g(M_E) = \{g(\mathcal{M}_x(u_x, l, f_*))|l \in L(u_x, f_*, H)\} = \{g_{u_x,l}|l \in L(u_x, f_*, H)\}.$$
3. Interpret the predictions into base-level labels. The interpretation is generally simple and

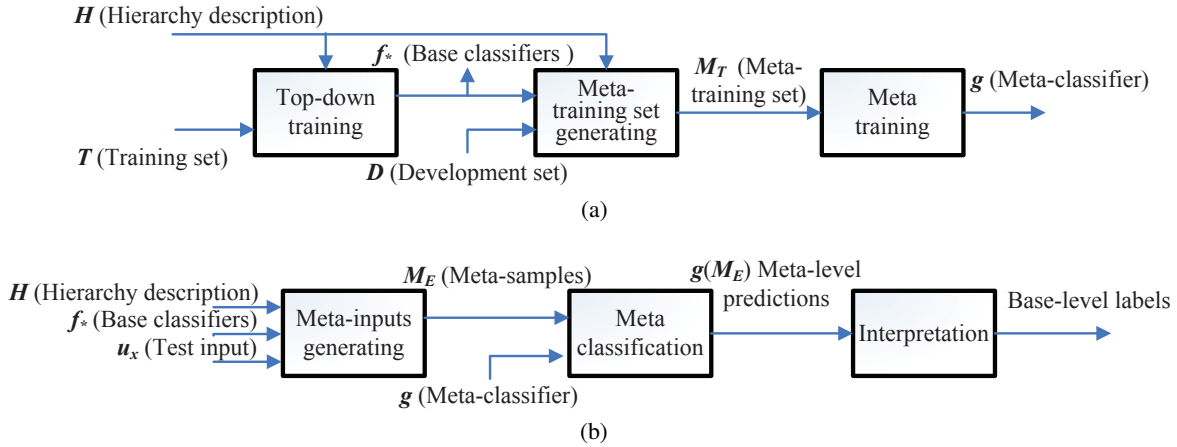

Figure 2: Workflows of meta-classification top-down method: (a) training phase; (b) classifying phase.

straightforward, and just outputs the labels with large scores. The practical interpretation depends on the data sets, and will be described in the section of experiments.

The remained problems now are how to implement meta-sample representations $\mathcal{M}_x(u_x, l, f_*)$ and selection of label candidates $L(u_x, f_*, H)$, which are solved in the next two subsections.

2.2.1 Representations of Meta-samples

In this subsection, the meta-samples will be made into real numerical vectors that are ready to be used by meta-classifiers. We use sparse vector to represent meta-samples through the following steps:

First, encode the scores of the related base-classifiers into a sparse vector. All the nodes except the root are numbered with integers, which serve as the dimensions of the sparse vector.

Second, augment the representations with the features about the global attributes of the root-to-leaf paths in the hierarchy. The purpose of this step is to raise classification accuracy, as these global attributes may be helpful to decide whether a path is true. The following three additional features are used according to our pilot experiments,

1. the *average* score of nodes along a path;
2. the *minimum* score of nodes along a path;
3. the fraction of nodes whose scores exceed the thresholds employed in ScutTD, named *pass-rate*.

In the end, the values of meta features are transferred into a sensible interval in order to fit the training of meta-classifiers (Liu, 2005; Liu et al., 2004). Two types of transformation functions are used according to our pilot experiments. For the additional features, the following standard scaling function is used,

$$z_s = \frac{s - \mu_s}{\sigma_s}$$

where s is the value of an additional feature, μ_s and σ_s are the corresponding mean and variance.

For the basic features, the following sigmoid function is used,

$$z_s = \frac{1}{1 + e^{-(s-\mu_s)}}$$

where s is a score at a node n, and μ_s is the average score at node n. This function is a simplification of the Platt' sigmoid fitting (Platt, 1999; Cesa-Bianchi et al., 2006), and it is more robust than the original one in the context of hierarchical classification according to our pilot experiements.

2.2.2 Selection of Label Candidates

How should label candidates be selected? In fact, the method of selecting label candidates is kind of like a classification method as both of them take in samples and give out the labels most likely to be right. However, the method of selecting label candidates should output more labels than a normal classifying method, in order to provide a wider coverage on truly correct ones. To find such a 'loose' classifying method, we refer to flat multi-class classification where another threshold strategy of Rank-cut (R-cut), besides the S-cut introduced above, is also widely used (Montejo-Ráez and Ureña-López, 2006; Yang, 2001). R-cut is to accept the top r labels with the highest confident scores, where r is a predefined integer.

Applying R-cut to the context of the top-down method is straightforward. The top-r children are

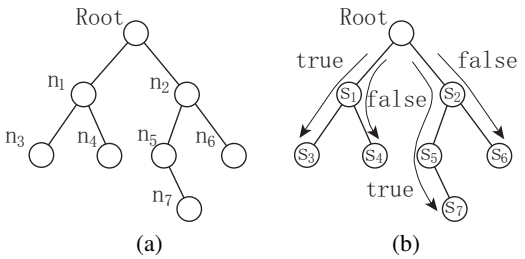

Figure 3: An illustration of solving hierarchical classification with MetaTD: (a) the class hierarchy; (b) the paths as meta-samples.

invoked from their parent node regardless of their scores, and the rest procedure is the same with ScutTD (see Fig. 1). We name this method RcutTD, and employ it to select label candidates in the proposed MetaTD. Note that RcutTD has been discussed before and is considered improper for the classifying procedure of the top-down method (Liu et al., 2005).

2.3 Illustration of Meta-classification Top-down Method

In this subsection we illustrate MetaTD with an example. Suppose a hierarchical classification task has the hierarchy of classes shown by Fig. 3a, where n_0 is the root, and the leaf nodes n_3, n_4, n_6 and n_7 are validate labels.

Further suppose that a tree of base-classifiers have been built through the top-down training. Here comes a sample with n_3 and n_7 as its correct labels. Fig. 3b shows that each base-classifier yields a relevant score s_i.

MetaTD converts each possible label (or leaf node) into a meta-sample – the target is whether this leaf node is a correct label and the features are the scores of the base-classifiers along the path (Fig. 3b). For this example, the following four meta-samples can be generated,

$$\begin{array}{ll} \text{true} & n_0 \to (n_1, s_1) \to (n_3, s_3) \\ \text{false} & n_0 \to (n_1, s_1) \to (n_4, s_4) \\ \text{true} & n_0 \to (n_2, s_2) \to (n_5, s_5) \to (n_7, s_7) \\ \text{false} & n_0 \to (n_2, s_2) \to (n_6, s_6). \end{array} \tag{4}$$

These meta-samples are then interpreted into numerical sparse vectors. Suppose that n_1 to n_7 are numbered with integers 1–7, then the numerical sparse vectors can be generated (see Tab. 1).

With more meta-samples like above, a meta-classifier can be trained. Later this meta-classifier can be applied to the meta-samples made from a base-level test sample to pick out the right labels. In this way, MetaTD fulfills the original base-level classifying task.

No.	Basic			Extension		
1	1:s_1 [a]	3:s_3		8:a_{13} [b]	9:m_{13}	10:p_{13}
2	1:s_1	4:s_4		8:a_{14}	9:m_{14}	10:p_{14}
3	2:s_2	5:s_5	7:s_7	8:a_{257}	9:m_{257}	10:p_{257}
4	2:s_2	6:s_6		8:a_{26}	9:m_{26}	10:p_{26}

[a] dimension:value

[b] $a_{i_1 i_2 \ldots i_k}$, $m_{i_1 i_2 \ldots i_k}$, $p_{i_1 i_2 \ldots i_k}$ denote the average, minimum, and pass-rate of s_{i_1}, $s_{i_2} \ldots s_{i_k}$ respectively.

Table 1: Representing meta-samples with sparse vectors

3 Accuracy Analysis

The classification accuracy of top-down methods is actually not very clear or predictable. To our best knowledge, no strict accuracy analyses on the conventional ScutTD have been reported yet. Here we just provide some general ideas about the comparison of accuracy between MetaTD and ScutTD.

First, whether pruning possible labels with RcutTD or not has minor impact on the overall classification result. The labels rejected by RcutTD all have quite low scores on some parent-child relations and are very likely to be filtered out by the successive meta-classifier.

Second, ignoring the impact of selecting label candidates, the conventional top-down method of ScutTD can be actually seen as a weak meta-classifier in the framework of MetaTD. Suppose here is a meta-sample (a sparse vector),

$(n_1{:}z_1,\ n_2{:}z_2,\ \ldots,\ n_k{:}p_k,\ n_a{:}z_a,\ n_m{:}z_m,\ n_p{:}z_p)$

where n_i and p_i are a node number and its value, and n_a,n_m,n_p are the additional features. Then ScutTD works like,

$$\text{Output} = \begin{cases} \text{True} & \text{if } p_i > t_i \text{ for all } i = 1 \ldots k \\ \text{False} & \text{otherwise} \end{cases}$$

where t_i is the threshold of node n_i. Clearly this formula is a cascaded of binary decisions, which is weaker than some common classifiers such as weighted voting.

4 Experiments

In this section, after describing the experimental settings, we present the performance comparisons between MetaTD and baseline methods as well as historical records on the entire data sets. We then

Data	No. Sample			Feature		Class	
	Train.	Dev.	Test	No.	Avg.[a]	No.	Avg. [b]
LSHTC	93k	34k	34k	381k	173	12k	1.0
NTCIR	2 762k	374k	359k	694k	108	49k	2.7

[a] average features per sample, that is, average unique terms per document.
[b] average labels per sample.

Table 2: Statistical information of data sets

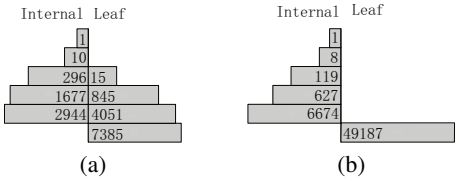

Figure 4: Number of internal and leaf nodes at each level of the hierarchy: (a) LSHTC; (b) NTCIR.

report the comparison with flat 1-vs-Rest approach on several subsets.

4.1 Experimental Settings

4.1.1 Data Sets

Two real-world data sets, the data set of web pages in the PASCAL2 Large-scale Hierarchical Text Classification challenge (LSHTC)[2] and the data set of patent documents from NII Test Collection for IR Systems Project (NTCIR)[3], are used in our experiments.

The PASCAL2 Large-scale Hierarchical Text Classification (LSHTC) challenge is held at 2009, aimed at promoting the study of classification methods for large hierarchies. The challenge attracts 19 participants with a variety of approaches (Kosmopoulos et al., 2010).

International Patent Classification (IPC) is a real-world taxonomy maintained by World Intellectual Property Organization (WIPO) [4]. The data set that we use is provided by NTCIR which is freely available for research purpose (Fall et al., 2003; Fujii et al., 2007). This data set consists of 3 496 137 Japanese patent documents submitted to Japan Patent Office from 1993 to 2002.

The statistics of two data sets and their hierarchies are presented in Tab. 2 and Fig. 4. Note that LSHTC's is a single-labeled task while NTCIR's is a multi-labeled ones.

4.1.2 Performance Measurement and Baseline Methods

Different performance measurements and baseline methods are adopted for the two data sets due to their difference of single-label and multi-label. NTCIR is multi-labeled, so the most commonly used criterion for general multi-labeled classifications, micro-F_1, is taken as the performance measurement. ScutTD is taken as the baseline method.

LSHTC is single-labeled, so accuracy is taken as the performance measurement. However, there is a problem about baseline method as ScutTD is not proper for single-labeled task. As a matter of fact, single-labeled hierarchical classifications are easier than multi-labeled ones, and it is natural to activate the child node with the largest score during top-down classification, like (Koller and Sahami, 1997). This method happens to be RcutTD with the parameter r=1. In addition to this baseline method, the evaluation records of LSHTC are also used for comparison.

4.1.3 Settings of MetaTD

The representation of meta-samples follows the description in Sec. 2.2.1. RcutTD is employed to select label candidates as described in Sec. 2.2.2. We set the parameter r=2 due to a trade-off between classification accuracy and time cost according to several pilot experiments.

The recent implement of SVM, Liblinear, is adopted as the meta-classifier (Fan et al., 2008).

Meta-to-base interpreters are needed to transfer the meta-level predictions into base-level labels. LSHTC is single-labeled, so it's natural to take the label with the largest meta-level scores. NTCIR is multi-labeled, and the strategy of S-cut in flat multi-class classification is employed.

4.1.4 Other Settings

The bag-of-word model with the term weight of TFIDF is adopted as the base-level sample representation in this paper (Sebastiani, 2002). To handle the Japanese text in the NTCIR's data set, we use the segment tool of Chasen [5] (Jin et al., 2010), and remove the function words from the result.

The base-level classifier is SVM^{light} with linear kernel. The default cost factor of SVM^{light} is used on NTCIR, while the cost factors are tuned by the development sets on LSHTC.

4.2 Performance on Entire Data Sets

In this subsection we compare MetaTD with baseline methods on the entire data sets of LSHTC and NTCIR from the aspects of accuracy and efficiency.

4.2.1 Accuracy Comparisons

The experimental results on the single-labeled LSHTC as well as the challenge records are presented in Tab. 3. MetaTD turns out to be between the second and third place, while the baseline method of RcutTD ranks between the sixth and seventh place. The method at the second place is a committee of two flat approaches – variants of the OOZ algorithm (Madani and Huang, 2008) and the passive-aggressive algorithm (Crammer et al., 2006). The methods at both the third and seventh places are both top-down methods enhanced by flattening the original hierarchy. Deep classification ranks at the fifth place (Xue et al., 2008). In short, MetaTD outperforms the conventional and several variant top-down methods.

The results on the multi-labeled NTCIR are presented in Tab. 4. MetaTD achieves a much higher micro-F_1 than the baseline method of ScutTD.

Method	Training		Classify.[a]
LSHTC, 12 294 classes			
RcutTD	Train base-classifiers	$10h$	0.108
MetaTD	Train base-classifiers	$17h$	0.131
	Prepare meta-train. set	$1h$	
	Meta-training	$18s$	
NTCIR, 49 187 classes

No. Class.	LSHTC			NTCIR		
	Train.	Dev.	Test	Train.	Dev.	Test
$1k$	$7k$	$2k$	$2k$	$38k$	$16k$	$17k$
$5k$	$39k$	$12k$	$12k$	$155k$	$64k$	$68k$
$10k$	$76k$	$23k$	$23k$	$253k$	$102k$	$104k$
$15k$	–[a]	–	–	$320k$	$129k$	$129k$

[a] there is not enough classes in the original data set.

Table 6: Numbers of classes and samples at the subsets of LSHTC and NTCIR

4.2.2 Efficiency Comparisons

The training and classifying time costs of MetaTD and baseline methods are presented in Tab. 5. In the training phrase, training base-classifiers causes most time cost. The additional cost of meta-classification MetaTD is only 5%–10% of that cost. Meta-training unexpectedly costs very little time, while preparing meta-training sets costs most additional time cost.

On the aspect of classifying, the time cost of MetaTD is about twice as much as the conventional top-down methods. According to our observation, considerable time is spent on reading samples and loading classifiers.

4.3 Comparison with Flat Approach of 1-vs-Rest on Subsets

In this subsection we compare the performance of top-down methods with the flat approach of 1-vs-Rest multiclass classification. Given the great computational complexity of the flat approach, several subsets are made from the entire data sets of LSHTC and NTCIR through randomly picking up classes and samples (see Tab. 6).

All the experimental settings here are consistent with previous experiments on the entire data sets. For the flat approach of 1-vs-Rest, the SVM^{light} is

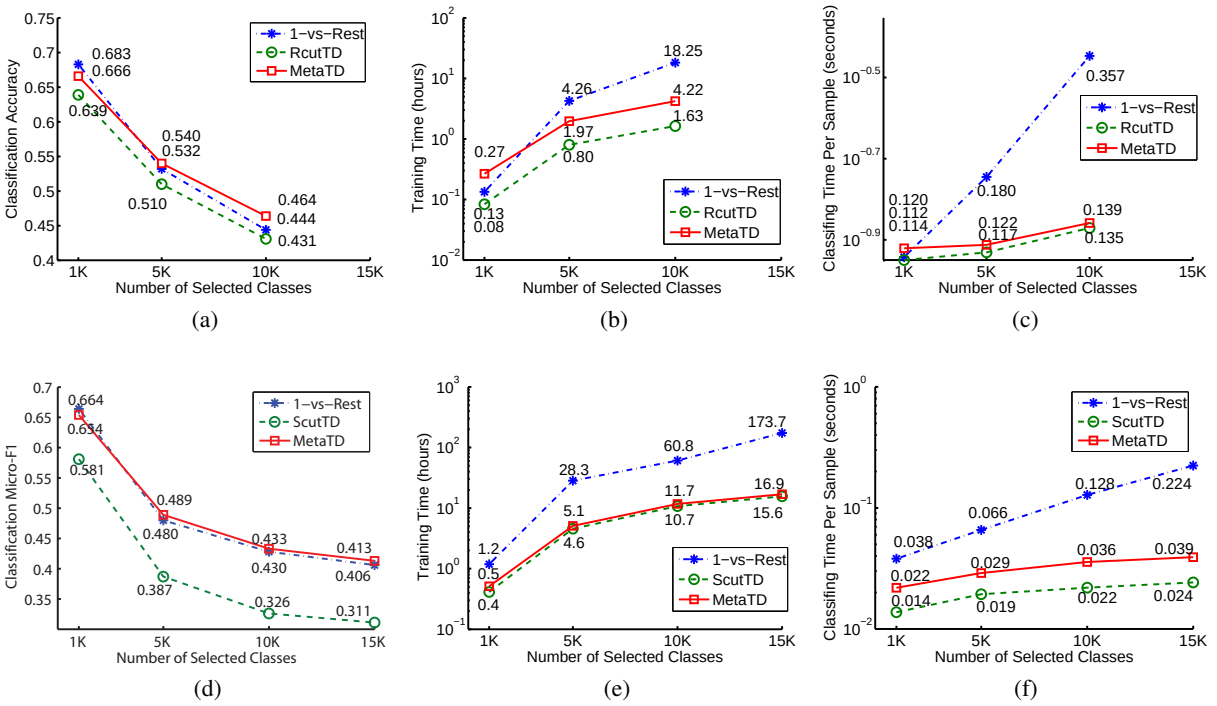

Figure 5: Performance comparison of flat 1-vs-Rest approach, conventional top-down methods and MetaTD on subsets of various sizes: (a) through (c) for LSHTC; (d) through (f) for NTCIR.

taken as the base-classifier.

The experiment results are presented in Fig. 5. On the aspect of classification accuracy, MetaTD catches up with the 1-vs-Rest approach. In particular, MetaTD slightly outperforms 1-vs-Rest approach on both data sets when the number of classes exceeds 5 thousands.

On the aspect of computational complexity, MetaTD is close to the conventional top-down methods, and they all show a great superiority over the 1-vs-Rest approach on both training and classifying as expected.

5 Conclusions

In this paper, we propose a meta-learning top-down method (MetaTD) in order to reduce the error propagation of the conventional ScutTD while remain its capability for large-scale hierarchical classification. In the experiments, MetaTD outperforms ScutTD and catches up with the flat 1-vs-Rest approach on classification accuracy. On the aspect of computational complexity, MetaTD only costs 5%-10% extra time in training and classifying, so it is suitable for most applications where ScutTD are being used.

Abstract

Multi-modality manifold-ranking is recently used successfully in topic-focused multi-document summarization. This approach is based on Bag-Of-Words (BOW) assumption where the pair-wise similarity values between sentences are computed using the standard cosine similarity measure (TF*IDF). However, the major limitation of the TF*IDF approach is that it only retains the frequency of the words and disregards the syntactic and semantic information. In this paper, we propose the use of syntactic and shallow semantic kernels for computing the relevance between the sentences. We argue that the addition of syntactic and semantic information can improve the performance of the multi-modality manifold-ranking algorithm. Extensive experiments on the DUC benchmark datasets prove the effectiveness of our approach.

1 Introduction

Text summarization is a good way to compress a huge amount of information into a concise form by selecting the most important information and discarding redundant information. According to Mani (2001), automatic text summarization takes a partially-structured source text from multiple texts written about the same topic, extracts information content from it, and presents the most important content to the user in a manner sensitive to the user's needs. In contrast to summarizing one document that is termed as single document summarization, multi-document summarization deals with multiple documents as sources that are related to one main topic under consideration. As compared to generic summarization that must contain the core information central to the source documents, the main goal of topic-focused multi-document summarization (i.e. query-based multi-document summarization) is to create from the documents a summary that can answer the need for information expressed in the topic or explain the topic (Wan et al., 2007). In this paper, we consider the problem of producing extraction-based[1] topic-focused multi-document summaries given a collection of documents.

In recent years, a variety of manifold-ranking based methods are applied successfully to topic-focused multi-document summarization. The basic manifold-ranking method is a typical graph-based summarization method that makes uniform use of the sentence-to-sentence relationships and the sentence-to-topic relationships in a manifold-ranking process (Wan et al., 2007). In the multi-modality manifold-ranking algorithm, sentence relationships are classified into within-document relationships and cross-document relationships, and each kind of relationships are considered as a separate modality (graph) (Wan and Xiao, 2009). These methods are based on Bag-Of-Words (BOW) assumption where the pair-wise similarity values between the sentences are computed using the standard cosine measure (TF*IDF). The major limitation of the TF*IDF approach is that it only retains the frequency of the words and does not take into account the sequence of them (word ordering). It ignores the syntactic and semantic structure of the sentences and thus, cannot distinguish between "The police shot the gunman" and "The gunman shot the police". Traditionally, information extraction techniques are based on the BOW approach augmented by language modeling. But when the task like *multi-document summarization* requires the use of more

[1] An extract summary consists of sentences extracted from the document while an abstract summary employs words and phrases not appearing in the original document (Mani and Maybury, 1999).

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1098–1106,
Chiang Mai, Thailand, November 8 – 13, 2011.

complex semantics, the approaches based on only BOW are often inadequate to perform fine-level textual analysis. Although some improvements on BOW are given by the use of dependency trees and syntactic parse trees (Hirao et al., 2004), (Punyakanok et al., 2004), (Zhang and Lee, 2003b), but these too are not adequate in terms of documents having very long and articulated sentences or even paragraphs. Shallow semantic representations could prevent the sparseness of deep structural approaches and the weakness of BOW models (Moschitti et al., 2007). Thus, attempting an application of syntactic and semantic information in measuring the relevance between the sentences seems natural and hardly controversial.

In this paper, we extensively study the impact of syntactic and semantic information in computing the similarity between the sentences in the multi-modality manifold learning framework for topic-focused multi-document summarization. We believe that the augmentation of the similarity measures based on the syntactic and semantic information could be helpful to characterize the relation between the sentences in a more effective way than the traditional TF*IDF based similarity measures alone. To include syntactic and semantic information into the multi-modality manifold-ranking framework, we apply the tree kernel functions (Collins and Duffy, 2001) and re-implement the syntactic and shallow semantic tree kernel model according to Moschitti et al. (2007). We run our experiments on the DUC[2]-2006 benchmark dataset, and the results show that the addition of syntactic and semantic information improves the performance of the BOW-based multi-modality manifold-ranking approach. The rest of this paper is organized as follows: Section 2 focuses on the related work, Section 3 describes the multi-modality manifold ranking model, Section 4 discusses the syntactic and shallow semantic kernels, Section 5 presents the experimental details with evaluation results and finally, Section 6 concludes the paper.

2 Related Work

In recent years, researchers have become more interested in topic-focused summarization and hence, different methods have been proposed ranging from heuristic extensions of generic summarization schemes (by incorporating topic-biased information) to novel ones. For instance, Nastase (2008) expands the query by using encyclopedic knowledge in Wikipedia and use the topic expanded words with activated nodes in the graph to produce an extractive summary. Hal Daumé and Marcu (2006) present BAYESUM ("Bayesian summarization"), a sentence extraction model for query-focused summarization.

Wan et al. (2007) propose a manifold-ranking method to make uniform use of sentence-to-sentence and sentence-to-topic relationships whereas the use of multi-modality manifold-ranking algorithm is shown in Wan and Xiao (2009). However, these methods use the standard cosine similarity measure to compute the relatedness between the sentences ignoring the syntactic and semantic information. The importance of syntactic and semantic features in finding textual similarity is described by Zhang and Lee (2003a), Moschitti et al. (2007), and Moschitti and Basili (2006). An effective way to integrate syntactic and semantic structures in machine learning algorithms is the use of *tree kernel* functions (Collins and Duffy, 2001) which has been successfully applied to question classification (Zhang and Lee, 2003a; Moschitti and Basili, 2006). In this paper, we use the tree kernel functions and to the best of our knowledge, no study has used tree kernel functions before to encode syntactic/semantic information for more complex tasks such as computing the relatedness between the sentences in the multi-modality manifold ranking algorithm for topic-focused multi-document summarization.

3 Multi-Modality Manifold-Ranking Model

In this section, we present the theoretical details of the manifold-ranking method (Zhou et al., 2003a; Zhou et al., 2003b), a universal ranking algorithm. This method is employed to rank data points and has been successfully applied in topic-focused document summarization in Wan et al. (2007) where the data points refer to the topic description and all the sentences in the documents. The manifold-ranking process for the summarization task can be formalized as follows (Wan and Xiao, 2009):

Given a set of data points , the first point represents the topic description (query point) and

[2]http://duc.nist.gov/

the rest points represent all the sentences in the documents (data points to be ranked). The basic manifold-ranking algorithm treats the sentence relationships in a single modality (Wan et al., 2007) whereas, in Wan and Xiao (2009), the relationships between the sentences in a document set are classified as either within-document relationship or cross-document relationship to form two separate modalities to reflect the local information channel and the global information channel between the sentences, respectively. The two modalities are applied in the multi-modality manifold-ranking algorithm for ranking the sentences effectively. Based on each kind of modality, an undirected graph is built to reflect each kind of sentence relationships. Let be the within-document affinity matrix containing only the within-document links for the data points, where is the cosine similarity[3] value between and if and belong to the same document or one of and is ; Otherwise, is set to . Similarly, let be the cross-document affinity matrix containing the cross-document links, where is the cosine similarity value between and if and belong to different documents or one of and is ; Otherwise, is set to . All the relationships between the topic, and any document sentence are included in both and . Then, and are normalized by ¯ ¯ and ¯ ¯, respectively, where and are the diagonal matrices with -element equal to the sum of the th row of and , respectively. Then the multi-modality learning task for topic-focused summarization is to infer the ranking function from , and : .

Linear Fusion: For fusing the two modalities, we use the linear fusion scheme as this was shown to perform the best in Wan and Xiao (2009). This scheme fuses the constraints from , and simultaneously by a weighted sum. The cost function associated with is defined as:

(1)

where , , and capture the trade-off between the constraints[4].

As discussed previously, the basic multi-modality manifold-ranking model lacks sensitivity to the context in which the words appear since it is solely based on the BOW assumption. It ignores the internal structure of the sentences and does not consider word orders. Our aim in this paper is to propose a similarity measure in which syntactic and/or semantic information can be added to enhance the multi-modality manifold-ranking model by encoding the relational information between the words in sentences. We claim that for a complex task like topic-focused multi-document summarization where the relatedness between the document sentences is an important factor, the multi-modality manifold algorithm for ranking sentences would perform more effectively if we could incorporate the syntactic and semantic information with the standard cosine measure (i.e. TF*IDF) in calculating the similarity between sentences. In the next section, we describe how we can encode syntactic and semantic structures in calculating the similarity between sentences.

4 Syntactic and Shallow Semantic Structures

Given a sentence (or query[5]), we first parse it into a syntactic tree using a parser like (Charniak, 1999) and then, calculate the similarity between the two trees using the *tree kernel* (discussed in Section 4.1). However, syntactic information is often not adequate when dealing with long and articulated sentences or paragraphs. Shallow semantic representations, bearing a more compact information, could prevent the sparseness of deep structural approaches (Moschitti et al., 2007). Initiatives such as PropBank (PB) (Kingsbury and Palmer, 2002) have made possible the design of accurate automatic Semantic Role Labeling (SRL) systems like ASSERT (Hacioglu et al., 2003).

[3]We augment syntactic and/or semantic information with this measure in our proposed model using the syntactic and/or shallow semantic kernels described in Section 4 and argue that the combined measure performs better.

[4]The first two terms of the right-hand side in the cost function are the smoothness constraints for the two modalities while the last term denotes the fitting constraint.

[5]The query is denoted as the first point in the data space of the manifold ranking framework and represented by .

Figure 1: Example of semantic trees

For example, consider the PB annotation:

```
[ARG0 all][TARGET use][ARG1
the french franc][ARG2
as their currency]
```

Such annotation can be used to design a shallow semantic representation that can be matched against other semantically similar sentences, e.g.

```
[ARG0 the Vatican][TARGET use]
[ARG1 the Italian lira][ARG2
as their currency]
```

In order to calculate the semantic similarity between the sentences, we first represent the annotated sentence (or query) using the tree structures like Figure 1 which we call Semantic Tree (ST). In the semantic tree, arguments are replaced with the most important word-often referred to as the semantic head. We look for noun first, then verb, then adjective, then adverb to find the semantic head in the argument. If none of these is present, we take the first word of the argument as the semantic head. This reduces the data sparseness with respect to a typical cosine measure representation used in the basic multi-modality manifold-ranking model.

4.1 Tree Kernels

Once we build the trees (syntactic or semantic), our next task is to measure the similarity between the trees. For this, every tree is represented by an dimensional vector , where the i-th element is the number of occurrences of the i-th tree fragment in tree . The tree fragments of a tree are all of its sub-trees which include at least one production with the restriction that no production

Figure 2: (a) An example tree (b) The sub-trees of the NP covering "the press".

rules can be broken into incomplete parts. Figure 2 shows an example tree and a portion of its subtrees.

Implicitly we enumerate all the possible tree fragments . These fragments are the axis of this m-dimensional space. Note that this needs to be done only implicitly, since the number is extremely large. Because of this, (Collins and Duffy, 2001) defines the tree kernel algorithm whose computational complexity does not depend on .

The tree kernel of two trees and is actually the inner product of and :

(2)

We define the indicator function to be 1 if the sub-tree is seen rooted at node and 0 otherwise. It follows:

where, and are the set of nodes in and respectively. So, we can derive:

(3)

where, we define = .
Next, we note that can be computed in polynomial time, due to the following recursive definition:

1. If the productions at and are different then

2. If the productions at and are the same, and and are pre-terminals, then

3. Else if the productions at and are not pre-terminals,

(4)

where, is the number of children of in the tree; because the productions at and are the same, we have . The i-th child-node of is . *TK* is the similarity value (tree kernel) between the sentences (and/or the query sentence) based on the syntactic structure. For example, for the following sentence and query we get the following score:

Query (q): Describe steps taken and worldwide reaction prior to introduction of the Euro on January 1, 1999. Include predictions and expectations reported in the press.

Sentence (s): Europe's new currency, the euro, will rival the U.S. dollar as an international currency over the long term, Der Spiegel magazine reported Sunday.

Score: 65.5

4.2 Shallow Semantic Tree Kernel (SSTK)

The tree kernel (TK) function computes the number of common subtrees between two trees. Such subtrees are subject to the constraint that their nodes are taken with all or none of the children they have in the original tree. Though, this definition of subtrees makes the TK function appropriate for syntactic trees but at the same time makes it not well suited for the semantic trees (ST). The critical aspect of steps (1), (2) and (3) of the TK function is that the productions of two evaluated nodes have to be identical to allow the match of further descendants. This means that common substructures cannot be composed by a node with only some of its children as an effective ST representation would require. (Moschitti et al., 2007) solve this problem by designing the Shallow Semantic Tree Kernel (SSTK) which allows to match portions of a ST. The SSTK is based on two ideas: first, it changes the ST by adding *SLOT* nodes. These accommodate argument labels in a specific order i.e. it provides a fixed number of slots, possibly filled with *null* arguments, that encode all possible predicate arguments. Leaf nodes are filled with the wildcard character * but they may alternatively accommodate additional information. The slot nodes are used in such a way that the adopted TK function can generate fragments containing one or more children. As previously pointed out, if the arguments were directly attached to the root node, the kernel function would only generate the structure with all children (or the structure with no children, i.e. empty). Second, as the original tree kernel would generate many matches with slots filled with the null label, we have set a new step 0 in the TK calculation:
(0) if (or) is a pre-terminal node and its child label is *null*, ;
and subtract one unit to , in step 3:

The above changes generate a new *C* which, when substituted (in place of original *C*) in Eq. 3, gives the new SSTK. For example, for the following sentence and query we get the semantic score:

Query (q): Describe steps taken and worldwide reaction prior to introduction of the Euro on January 1, 1999. Include predictions and expectations reported in the press.

Sentence (s): The Frankfurt-based body said in its annual report released today that it has decided on two themes for the new currency

history of European civilization and abstract or concrete paintings.

Score: 9

5 Experiments and Results

5.1 Task Description

In this paper, we re-implement the multi-modality manifold ranking algorithm for topic-focused multi-document summarization by encoding the syntactic and semantic information to measure sentence relationships. We use the linear approach for fusing the modalities as this was shown to perform the best (Wan and Xiao, 2009). The purpose of our experiments is to study the impact of the syntactic and semantic representation in the multi-modality manifold-ranking framework.

Over the past three years, complex questions have been the focus of much attention in both the automatic question-answering and multi-document summarization (MDS) communities. While most current complex QA evaluations (including the 2004 AQUAINT Relationship QA Pilot, the 2005 Text Retrieval Conference (TREC) Relationship QA Task, and the 2006 GALE Distillation Effort) require systems to return unstructured lists of candidate answers in response to a complex question, recent MDS evaluations (including the 2005, 2006 and 2007 Document Understanding Conferences (DUC)) have tasked systems with returning paragraph-length answers to complex questions that are responsive, relevant, and coherent. The DUC conference series is run by the National Institute of Standards and Technology (NIST) to further progress in summarization and enable researchers to participate in large-scale experiments. We use the main task of DUC 2006 for evaluation. The task was: "Given a complex question (topic description) and a collection of relevant documents, the task is to synthesize a fluent, well-organized 250-word summary of the documents that answers the question(s) in the topic". To accomplish this task, we generate summaries for a subset of 10 topics of DUC 2006 dataset by each of our six systems as defined below:

(1) COSINE: This system is the original multi-modality manifold ranking method described in Section 3 that uses the standard cosine similarity measure based on TF*IDF and does not consider the syntactic/semantic information.

(2) SYN: This system measures the similarity between the sentences using the *syntactic tree* and the *general tree kernel* function defined in Section 4.1.

(3) SEM: This system measures the similarity between the sentences using the *shallow semantic tree* and the *shallow semantic tree kernel* function defined in Section 4.2.

(4) COSINE+SYN: This system measures the similarity between the sentences using both standard cosine similarity measure and the syntactic tree kernel.

(5) COSINE+SEM: This system measures the similarity between the sentences using both standard cosine similarity measure and the shallow semantic tree kernel.

(6) COSINE+SYN+SEM: This system measures the similarity between the sentences using standard cosine similarity measure, syntactic tree kernel, and shallow semantic tree kernel.

5.2 Automatic Evaluation

We carried out automatic evaluation of our candidate summaries using ROUGE (Lin, 2004) toolkit, which has been widely adopted for automatic summarization evaluation. *ROUGE* stands for "Recall-Oriented Understudy for Gisting Evaluation". It is a collection of measures that determines the quality of a summary by comparing it to reference summaries created by humans. The measures count the number of overlapping units such as n-gram, word-sequences, and word-pairs between the system-generated summary to be evaluated and the ideal summaries created by humans. For all our systems, we report the widely accepted important metrics: ROUGE-2 and ROUGE-SU. We also present the ROUGE-1 scores since this has a high correlation with the human judgement. All the ROUGE measures were calculated by running ROUGE-1.5.5 with stemming but no removal of stopwords. ROUGE run-time parameters were set as the same as DUC 2007 evaluation setup. They are:

ROUGE-1.5.5.pl -2 -1 -u -r 1000 -t 0 -n 4 -w 1.2 -m -l 250 -a

Table 1 to Table 3 show the ROUGE-1, ROUGE-2, and ROUGE-SU scores of our six different systems. In the experiments, the regularized parameter for the fitting constraint is fixed at 0.4, as in Wan et al. (2007). We kept as it was shown to be the most effective choice for the

linear fusion scheme in Wan and Xiao (2009).

Systems	Recall	Precision	F-score
COSINE	0.3619	0.3043	0.3305

COSINE+SYN	0.3627	0.3105	0.3346
COSINE+SEM	0.3737	0.3140	0.3412
COSINE+SYN+SEM	0.3648	0.3117	0.3360

Table 1: ROUGE-1 measures

Systems	Recall	Precision	F-score
COSINE	0.0584	0.0488	0.0532
SYN	0.0638	0.0558	0.0595
SEM	0.0732	0.0555	0.0631
COSINE+SYN	0.0611	0.0522	0.0563
COSINE+SEM	0.0691	0.0581	0.0631
COSINE+SYN+SEM	0.0658	0.0560	0.0605

Table 2: ROUGE-2 measures

Systems	Recall	Precision	F-score
COSINE	0.1262	0.0890	0.1043
SYN	0.1190	0.0903	0.1025
SEM	0.1406	0.0818	0.1033
COSINE+SYN	0.1278	0.0937	0.1081
COSINE+SEM	0.1334	0.0944	0.1104
COSINE+SYN+SEM	0.1282	0.0939	0.1083

Table 3: ROUGE-SU measures

For all the systems, Table 4 shows the F-scores of the reported ROUGE measures. From these results, we clearly see the positive impact of syntactic and semantic information in the multi-modality manifold ranking method for topic-focused multi-document summarization. The SYN system improves the ROUGE-1 and ROUGE-2 scores over the COSINE system by 0.45%, and 11.84% while underperforms the ROUGE-SU score by 1.75% respectively. The SEM system improves the ROUGE-2 scores over the COSINE system by 18.60% while underperforms the ROUGE-1 and ROUGE-SU scores by 0.18%, and 0.96% respectively. The COSINE+SYN system improves the ROUGE-1, ROUGE-2, and ROUGE-SU scores over the COSINE system by 1.24%, 5.82%, and 3.64% respectively. The COSINE+SEM system improves the ROUGE-1, ROUGE-2, and ROUGE-SU scores over the COSINE system by 3.23%, 18.60%, and 5.84% respectively. Lastly, the COSINE+SYN+SEM system improves the ROUGE-1, ROUGE-2, and ROUGE-SU scores over the COSINE system by 1.66%, 13.72%, and 3.83% respectively. Deep analysis of all these results yields that the proposed systems (that encode the syntactic and/or semantic information in the multi-modality manifold ranking framework) considerablely outperform the standard cosine similarity based manifold approach. The results also denote that encoding the syntactic and/or semantic information on top of the standard cosine similarity measure often outperform the systems that consider only syntactic and/or semantic information. From all our six systems, we can see that the *SEM* and *COSINE+SEM* are the best performing systems on average while performance of the *COSINE+SYN+SEM* decreases a bit indicating the fact that encoding both syntactic and semantic information on top of the standard cosine similarity measure has a negative impact on the multi-modality manifold ranking method. This may be due to the fact that the SYN system does not perform too well as seen from the results and thus deteriorates the performance of the COSINE+SYN+SEM system.

Systems	R-1	R-2	R-SU
COSINE	0.3305	0.0532	0.1043
SYN	0.3320	0.0595	0.1025

COSINE+SYN+SEM	0.3360	0.0605	0.1083

Table 4: ROUGE F-scores for different systems

In Table 5, the proposed methods are compared with the NIST baseline. The NIST baseline is the official baseline system established by NIST that generated the summaries by returning all the leading sentences (up to 250 words) in the
field of the most recent document(s). We also list the average ROUGE scores of all the participating systems for DUC-2006 (i.e. AverageDUC). From the tables, we can see that the proposed multi-modality manifold ranking methods based on the syntactic and semantic measures mostly outperform the NIST baseline system. They can also achieve higher ROUGE scores as comparable to the average scores of all the participating systems of DUC-2006.

Confidence Intervals We also show 95% confidence interval of the important evaluation metrics for our systems to report significance for doing meaningful comparison. We use the ROUGE tool for this purpose. ROUGE uses a randomized method named bootstrap resampling to com-

Systems	ROUGE-1	ROUGE-2

COSINE+SYN+SEM	0.0436 - 0.0795	0.0949 - 0.1205

Table 6: 95% confidence intervals for different systems

5.3 Manual Evaluation

Even if the ROUGE scores had significant improvement, it is possible to make bad summaries that get state-of-the-art ROUGE scores (Sjöbergh, 2007). So, we conduct an extensive manual evaluation in order to analyze the effectiveness of our systems. Two university graduate students judged the summaries for linguistic quality and overall responsiveness according to the DUC-2007 evaluation guidelines[6]. The given score is an integer between 1 (very poor) and 5 (very good) and is guided by consideration of the following factors: 1. Grammaticality, 2. Non-redundancy, 3. Referential clarity, 4. Focus and 5. Structure and Coherence. They also assigned a content responsiveness score to each of the automatic summaries. The content score is an integer between 1 (very poor) and 5 (very good) and is based on the amount of information in the summary that helps to satisfy the information need expressed in the topic. Table 7 presents the average linguistic quality and overall responsive scores of all our systems. These results also justify our claim by showing positive impacts of encoding syntactic and/or semantic information in the multi-modality manifold ranking framework. From these results, we can see that the proposed syntactic and/or semantic measure based systems outperform the COSINE system by a considerable margin.

6 Conclusion

In this paper, we proposed to encode the syntactic and semantic information for measuring sentence relationships in the multi-modality manifold ranking algorithm for topic-focused multi-document summarization and reported that adding syntactic and/or semantic information on top of the standard cosine measure improves the performance over the cosine measure alone. We parsed the sentences into the syntactic trees using the Charniak parser and applied the general tree kernel functions to measure the similarity between sentences. We used the shallow semantic tree kernel to measure the semantic similarity between two semantic trees. To the best of our knowledge, no other study has used syntactic and semantic information in the multi-modality manifold ranking model to improve its performance. We evaluated our systems automatically using ROUGE and conducted an extensive manual evaluation. Experimental results proved our claim by showing the effectiveness of the proposed methods.

Abstract

Domain adaptation (DA), which involves adapting a classifier developed from source to target data, has been studied intensively in recent years. However, when DA for word sense disambiguation (WSD) was carried out, the optimal DA method varied according to the properties of the source and target data. This paper describes how the optimal method for DA was determined depending on these properties using decision tree learning, given a triple of the target word type of WSD, the source data, and the target data, and discusses what properties affected the determination of the best method when Japanese WSD was performed.

1 Introduction

Classifiers in standard supervised machine learning have been trained for data in domain A using manually annotated data in domain A, e.g., to train classifiers for newswires using newswires. However, classifiers for data in domain B have sometimes been necessary when there have been no or few manually annotated data, and there have only been manually annotated data in domain A, which have been related to domain B. Domain adaptation (DA) involves adapting the classifier that have been trained from data in domain A (source domain) to data in domain B (target domain). This has been studied intensively in recent years.

However, the optimal method of DA varied according to the properties of the data in the source domain (the source data) and the data in the target domain (the target data) when DA for word sense disambiguation (WSD) was carried out. (We will show it in Section 4.)

We define a case as a triple of the target word type of WSD, the source data, and the target data. This paper describes how the optimal method for DA was determined depending on these properties using decision tree learning given a case and discusses what properties affected the determination of the best method when Japanese WSD was performed.

This paper is organized as follows. Section 2 reviews related works on DA and Section 3 explains how a DA method is automatically determined. Section 4 describes the data we used. How to label the data and how to train the classifiers using these are explained in Section 5. We present the results in Section 6 and discuss them in Section 7. Finally, we conclude the paper in Section 8.

2 Related Work

The DA problem can be categorized into three types depending on the information for learning, i.e., supervised, semi-supervised, and unsupervised approaches. A classifier in a supervised approach is developed from a large amount of labeled source data and a small amount of labeled target data with the aim of classifying target data better than a classifier developed only from the target data. A classifier in a semi-supervised approach is developed from large amounts of labeled source data and unlabeled target data with the aim of classifying target data better than a classifier developed only from the source data. Finally, a classifier is developed from a large amount of labeled source data with the aim of classifying target data accurately in the unsupervised approach. We focused on the supervised DA of WSD in this paper.

Many researchers have investigated DA within or outside the area of natural language processing. Chan and Ng (2006) carried out the DA of WSD by estimating class priors using an EM algorithm. Chan and Ng (2007) also conducted the DA of WSD by estimating class priors using the EM algorithm, but this was supervised DA using

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1107–1115,
Chiang Mai, Thailand, November 8 – 13, 2011.

active learning.

In addition, Daumé III (2007) worked on the supervised DA. He augmented an input space and made triple length features that were general, source-specific, and target-specific. This was easy to implement, could be used with various DA methods, and could easily be extended to multi-domain adaptation problems. Daumé III et al. (2010) extended the work in (Daumé III, 2007) to semi-supervised DA. It inherited the advantages of the supervised version and outperformed it by using unlabeled target data.

Agirre and de Lacalle (2008) worked on the semi-supervised DA of WSD. They applied singular value decomposition (SVD) to a matrix of unlabeled target data and a large amount of unlabeled source data, and trained a classifier with them. Agirre and de Lacalle (2009) worked on the supervised DA using almost the same method, but they used a small amount of labeled source data instead of the large amount of unlabeled source data.

Jiang and Zhai (2007) demonstrated that performance increased as examples were weighted when DA was applied. This method could be used with various other supervised or semi-supervised DA methods. In addition, they tried to identify and remove source data that misled DA, but they concluded that it was only effective if examples were not weighted.

Zhong et al. (2009) proposed an adaptive kernel approach that mapped the marginal distribution of source and target data into a common kernel space. They also conducted sample selection to make the conditional probabilities between the two domains closer.

Raina et al. (2007) proposed self-taught learning that utilized sparse coding to construct higher level features from the unlabeled data collected from the Web. This method was based on unsupervised learning.

Tur (2009) proposed a co-adaptation algorithm where both co-training and DA techniques were used to improve the performance of the model.

The research by Blitzer et al. (2006) involved work on semi-supervised DA, where they calculated the weight of words around the pivot features (words that frequently appeared both in source and target data and behaved similarly in both) to model some words in one domain that behaved similarly in another. They applied SVD to the matrix of the weights, generated a new feature space, and used the new features with the original features.

The closest work to ours is that by McClosky et al. (2010) who focused on the problem where the best model for each document is not obvious when parsing a document collection of heterogeneous domains. They studied it as a new task of *multiple source parser adaptation*. They proposed a method of parsing a sentence that first predicts accuracies for various parsing models using a regression model, and then uses the parsing model with the highest predicted accuracy. The main difference is that their work was about parsing but ours discussed here is about Japanese WSD. They also assumed that they had labeled corpora in heterogeneous domains but we have not. We determined the best DA method using the decision tree learning given a triple of the target word type of WSD, the source data, and the target data and found what features affected the determination of the best method.

Harimoto et al. (2010) measured the distance between domains to conduct DA using a suitable corpus in parsing. In addition, van Asch and Daelemans (2010) reported that performance in DA could be predicted depending on the similarity between source and target data using automatically annotated corpus in parsing. They focused on how corpora were selected for use as source data according to the distance between domains, but here we focus on how to select a method of DA depending on properties such as the distance between domains.

3 Automatic determination of DA method

We expected the average accuracy of WSD, when DA methods that were determined automatically were used for all cases, to be higher than when the original methods were used collectively. Hence, we would be able to determine the best DA method automatically using decision tree learning. A decision tree would indicate what features affect the determination of the optimal method of DA.

3.1 DA methods for WSD

Two methods were used as the DA methods for WSD in this study.

- *Target Only*: Train a classifier with a small amount of target data that are randomly selected and manually labeled but without source data.

- *Random Sampling*: Train a classifier with source data and a small amount of target data that are randomly selected and manually labeled.

Ten word tokens of the target data were randomly selected and manually labeled in all the experiments.

Libsvm (Chang and Lin, 2001), which supports multi-class classification, was used as the classifier for WSD. A linear kernel was used according to the results obtained from preliminary experiments. Seventeen features were introduced to train the classifier.

- Morphological features
  - Bag-of-words（4 features）
  - Part-of-speech (POS)（4 features）
  - Finer subcategory of POS（4 features）
- Syntactic feature（1 feature）
  - If the POS of a target word is a noun, the verb which the target word modifies
  - If the POS of a target word is a verb, the case element of "ヲ" (wo, objective) for the verb
- Semantic features
  - Semantic classification code（4 features）

Morphological features and semantic features were extracted from the surrounding words (two words to the right and left) of the target word. POS and finer subcategory of POS can be obtained using a morphological analyzer. We used ChaSen [1] as a morphological analyzer, the Bunruigoihyo thesaurus (National Institute for Japanese Language and Linguistics, 1964) for semantic classification codes, and CaboCha [2] as a syntactic parser. Five-fold cross validation was used in the experiments.

3.2 Labels of Decision Tree

One of the following labels was given to every case depending on the most accurate method and as we shall explain later, two labels (TO and RS) or three labels (TO, RS, and SA) were used for classification. Note that the decision tree determines which DA method should be used, *Random Sampling* or *Target Only*, given the properties of the source and target data for each case.

- TO: The cases in which *Target Only* had higher accuracy than *Random Sampling*.
- RS: The cases in which *Random Sampling* had higher accuracy than *Target Only*.
- SA: The cases in which *Random Sampling* and *Target Only* had the same accuracy.

3.3 Features of Decision Tree

We think the optimal method for DA varies depending on the distribution of the source data and the target data, the distance between them, and so on. The following 40 features (consisting of 24 types) in total were used for decision tree learning.

1. Simulation accuracy of *theOther*: The accuracy of WSD when a classifier was trained with the source data and tested with ten labeled word tokens of the target data.
2. Simulation accuracy of *Target Only*: The accuracy of WSD when a classifier was trained with ten labeled word tokens of the target data and tested using a leave-one-out cross-validation method.
3. Ratio of two simulation accuracies: (1) / (2).
4. Number of source data: The number of word tokens in the whole source data.
5. Number of target data: The number of word tokens in the whole target data.
6. Number of source data / target data: (4) / (5).
7. The number of word senses that appeared in the whole source data set.
8. The number of word senses that appeared in ten word tokens of the target data.
9. The number of word senses of the WSD target words in the dictionary.
10. The number of word tokens of the most frequent sense (MFS) of the whole source data.
11. The number of word tokens of MFS in the ten labeled word tokens of the target data.

[1] http://sourceforge.net/projects/masayu-a/
[2] http://sourceforge.net/projects/cabocha/

12. Whether the MFS of the whole source data and the ten labeled word tokens of the target data were the same or not.

13. Percentage of MFS in source data: (10) / (4).

14. Percentage of MFS in ten word tokens of target data: (11) / the number of word tokens in the labeled target data (=10).

15. Percentage of MFS in ten word tokens of target data in source data: The number of source data word tokens with MFS in ten labeled word tokens of the target data / (4).

16. Percentage of MFS of source data in ten word tokens of target data: The number of word tokens with MFS in the source data in ten labeled word tokens of the target data / the ten word tokens.

17. The JS divergence between the distribution of word sense IDs of 4/5 of the whole source data and the distribution of word sense IDs of ten labeled word tokens of target data. Abbreviated as "JSD (word sense)".

18. The JS divergence between the feature distributions for WSD of the whole source and the whole target data (17 kinds, cf. Section 3.1) Abbreviated as "JSD (*)". *is a feature name in Section 3.1.

19. The summation of 17 kinds of JS divergences (18). Abbreviated as "JSD (Feature_plus)".

20. The JS divergence between the distribution of the whole source data and the whole target data feature units, when a unit is the sequence of 17 kinds of WSD features. Abbreviated as "JSD (Feature_all)".

21. The number of word senses that did not appear in ten labeled word tokens of the target data but did in the whole source data.

22. The number of common word senses between the whole source data and ten labeled word tokens of the target data.

23. Percentage of common word senses between whole source data and ten word tokens of target data in ten word tokens: the number of word tokens whose word senses appeared in both the whole source data and ten labeled word tokens of the target data in the ten word tokens / the ten word tokens.

24. Percentage of common word senses between whole source data and ten word tokens of target data in source data: the number of word tokens whose word senses appeared in both the whole source data and ten labeled word tokens of the target data in the source data/ (4).

The C4.5 of Quinlan (1993) was used as the algorithm for decision tree learning and a binary tree was generated. The experiments were conducted with five-fold cross validation. The threshold values for pruning were optimized with preliminary experiments using 1/4 of the training data set as a development data set. Here, the entropy of a node was tuned as the threshold value in 0.1 increments. The value of a smaller tree was used when more than one threshold value gave the same accuracy.

4 Data

Three data were used for the experiments: (1) the sub-corpus of white papers in the Balanced Corpus of Contemporary Japanese (BCCWJ) (Maekawa, 2008), (2) the sub-corpus of documents from a Q&A site on the WWW of BCCWJ, and (3) Real World Computing (RWC) text databases (newspaper articles) (Hashida et al., 1998). DAs were conducted in six directions according to various source and target data. Word senses were annotated in these corpora according to a Japanese dictionary, i.e., the Iwanami Kokugo Jiten (Nishio et al., 1994). It has three levels for sense IDs, and we used the fine-level sense in the experiments. Multi-sense words that appeared equal or more than 50 times in both source and target data were selected as the target words in the experiment. There were 24 word types for white papers ⇔ Q&A site, 22 for white papers ⇔ newspaper articles, and 26 for Q&A site ⇔ newspaper articles. Twenty-eight word types and 144 cases were used in the experiments in total. Table 1 lists the minimum, maximum, and average number of word tokens in each case. Table 2 shows the list of target words.

Table 3 summarizes the results from the DA experiments when the source data and the target data were swapped [3]. These results were the av-

[3]Multi-sense words that appeared less than 50 times in source or target data were included as the target words in the

erage accuracies of all the target words of WSD. *Self*, which is standard supervised learning with the target data, assuming that fully annotated data were obtained and could be used for learning and *theOther*, which is standard supervised learning only with the source data, were tested as references. We found that the optimal method of DA varied depending on the corpora that were used as the source and target data.

5 Labeling of data and learning of decision tree

We tried to generate decision trees in various ways and compared their accuracies to find the most effective way of generating the best decision tree.

5.1 Labeling of data

TO, RS, or SA was given to every case depending on the most accurate method. SA was particularly given to cases in which *Random Sampling* and *Target Only* had the same accuracy.

The difference between accuracies and the definition of SA was treated in two ways.

- *Equal*: The SA label was assigned when the WSD accuracies of *Target Only* and *Random Sampling* were totally equal.
- *Chi-square*: The SA label was assigned when the WSD accuracies of *Target Only* and *Random Sampling* were not significantly different according to a chi-square test. The level of significance in the test was 0.05.

Table 4 indicates the number of cases and the total word types given TO or RS labels according to *Equal* and *Chi-square*.

5.2 Treatment of SA in decision tree learning

The third label, SA, was assigned to cases with no difference between the accuracies of *Random Sampling* and *Target Only* and was treated in two ways in the experiments.

experiment of this figure.

22	手	hand
	出る	leave

- *Ternary classification with SA*: Perform ternary classification of TO, RS, and SA in training and the testing.
- *Binary classification without SA*: Remove cases with SA labels from training data set and perform binary classification of TO and RS. All the cases are used for the testing.

Figure 1 shows the frame format for five-fold cross validation of decision tree learning when *Binary classification without SA* was used. There was a total of 144 cases, and only data with TA or RS labels were used as a training data set for decision tree learning. There were 129 cases when *Equal* was used and 69 cases when *Chi-square* was used (dark gray parts). A classifier was developed from 4/5 of the training data set (white

Table 3: Results from DA experiments when source and target data were swapped

DA method	Accuracy	
Source data	Q&A site	white papers

theOther	79.65%	83.35%
Random sampling	85.40%	83.86%
Target Only	88.20%	77.74%
self	95.97%	91.65%

Table 4: Number of cases and total word types given TO or RS labels according to *Equal* and *Chi-square*

Source data	Target data	*Equal*	*Chi*
white papers	Q&A site	21	13
white papers	newspaper	18	9
Q&A site	newspaper	25	12
Q&A site	white papers	25	12
newspaper	white papers	20	11
newspaper	Q&A site	20	12
Total cases		129	69
Total word types		27	20

parts) and tested using 1/5 of the whole cases (light gray part) in one execution of five-fold cross validation. (Three-quarter of the training data (3/5 of the whole data set) and 1/4 of the training data (1/5 of the whole data set) was used for the training data and the test data of the parameter tuning respectively.)

We calculated the accuracies of WSD using the DA method for the labels (*Target Only* for TO and *Random Sampling* for RS). We used *Random Sampling* for cases with SA labels when *Ternary classification with SA* was used. When *Binary classification without SA* was used, we had no correct answers for the cases of SA in the test phase. However, either label could be given to them because they were cases in which *Random Sampling* and *Target Only* had the same accuracy. Therefore, we assigned TO or RS to them depending on the decision tree that was generated.

5.3 Classification

As Table 1 indicates, some cases had many word tokens and some had few. For example, a case had 58 word tokens when the source data were from the RWC newspaper articles, the target data were from the BCCWJ white papers, and the target

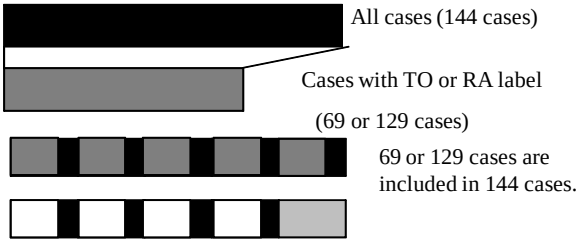

Figure 1: Five-fold cross validation of decision tree learning when *Binary classification without SA* was used

word type was “言う”. (This case had 58 word tokens because the word appeared 58 times). Therefore, the average accuracy of WSD could be improved if cases that had more word tokens could be predicted more precisely. We also classified cases with weighted word tokens, as well as just classified cases, in two ways.

- *Case classification*: Perform decision tree learning on the assumption that every case has the same weight.
- *Classification with weighting of word tokens*: Perform decision tree learning with weighting on the assumption that every case has the weight of the number of word tokens in the case.

The weights of the cases were used to calculate entropy.

6 Results

Table 5 lists the average accuracies of WSD when the original methods were used collectively. The average accuracies were calculated from 232,116 word tokens in 144 cases. (They were micro-averaged over the word tokens.) Table 5 indicates that *Target Only* outperformed *Random Sampling* and its accuracy was 81.23%. Here, *Selected Source Only* is a DA method where train a classifier with only selected source data that are similar to the target data. We used 0.8 of cosine distance as a threshold value. We did not include this method as a DA method that is automatically determined but showed as reference.

Table 6 summarizes the average accuracies of WSD when the DA methods that were determined were used for every case. There were nine ways of determining the DA methods: eight automatic and one manual. The eight automatic approaches

Table 5: Average accuracy of WSD when methods were used collectively

DA method	Accuracy of WSD
Target Only	81.23 %
Random Sampling	80.28 %
Selected Source Only	82.27 %

Table 6: Average accuracy of WSD when methods that were determined automatically were used

Way to determine a method	Accuracy of WSD
Equal_3_case	82.36%
Equal_3_token	82.44%
Chi_3_case	83.49%
Chi_3_token	83.42%
Equal_2_case	**83.50**%
Equal_2_token	81.88%
Chi_2_case	82.55%
Chi_2_token	82.92%
manually	85.25%

were all combinations of the two choices in Sections 5.1, 5.2, and 5.3. Abbreviations of the ways in Table 6 are in the format of a_b_c where a is the choice for Section 5.1, b is that for Section 5.2 and c is that for Section 5.3. The "3" and "2" represent *Ternary classification with SA* and *Binary classification without SA*, and "case" and "token" represent *Case classification* and *Classification with weighting of word tokens*, respectively. When the manual approach was used, the DA method with the highest accuracy was chosen manually for every case. Its average accuracy was in the upper bound for our proposed method.

Table 6 shows that the automatic way with the highest average accuracy was Equal_2_case. The accuracy was 83.50%, and it significantly outperformed *Target Only* and *Selected Source Only* in Table 5 (81.23% and 82.27%) . This means that the average accuracy of WSD when DA methods that were determined automatically were used was higher than when the original methods were used collectively.

7 Discussion

7.1 Comparison of ways of determining DA methods

We compare the results for ways of determining DA methods in this section. First, usually *Chi-square* was better for labeling of data, but *Equal* was better when *Binary classification without SA* and *Case classification* were used simultaneously. Second, usually *Ternary classification with SA* was better for treating SA in decision tree learning, but *Binary classification without SA* was better when *Equal* and *Case classification* were used simultaneously. Finally, we could not find any patterns of the results for *Case classification* or *Classification with weighting of word tokens*.

The approach with the highest accuracy in the eight automatic ways was where SA labels were applied when the accuracies of WSD for the two methods were totally equal, binary classification was performed without SA, and cases were classified without weighted word tokens (Equal_2_case). Significant differences were found in the three comparisons above when they were evaluated with a Chi-square test when the other conditions were the same.

The accuracy of decision tree learning was 60.42% when the Equal_2_case was used. This value was not very high, which may be due to the optimizing threshold value of pruning with a development data set. We think the reason low classification accuracy with decision trees did not critically influence the average accuracy of WSD was that most errors were for cases where *Random Sampling* and *Target Only* had almost the same accuracy.

7.2 Discussion on learned decision tree

We present the decision tree with the highest accuracy in an appendix in five executions of five-fold cross validation in the decision tree learning of the Equal_2_case, whose average WSD accuracy was the highest in the eight automatic ways of learning, and we discuss the features and their values that contributed to the generation of the tree.

First, TO was assigned when the "ratio of two simulation accuracies $>= 0.40$" was false in the root node of the decision tree. Therefore, TO was assigned to cases whose ratio of "Simulation accuracy of *theOther* / Simulation accuracy of *Target Only*" was lower than 0.40. That is, TO was assigned to the cases when the accuracy of WSD when a classifier was trained with ten labeled word tokens of the target data and tested using a leave-one-out cross-validation method was higher than the accuracy of WSD when a classifier was trained with the source data and tested using ten labeled

word tokens of the target data. In other words, this indicates that the simulation using ten manually labeled word tokens of the target data was an important clue in predicting the optimal DA method.

Next, TO was selected when JSD (bag-of-words of one word to the left of the target word) was equal to or more than 0.61 in the node with level one. This indicated that a classifier should only be trained with ten labeled word tokens of target data, without source data, when the distributions of the feature of bag-of-words of one word to the left of the WSD target word differed between the source and target data.

Moreover, TO was selected when JSD (semantic classification code of one word to the right of the target word) was equal to or more than 1.00 in the node with level two. This indicated that a classifier should only be trained with ten labeled word tokens of target data, without source data, when the distributions of the semantic classification code features of one word to the right of the WSD target word differed between the source and target data.

The decision tree in the appendix is small and simple, but the second best tree (there is a difference in only one case) consists of 13 questions. According to the tree, TO tends to be assigned when JS divergences such as JSD (word sense), JSD (Feature_plus), and JSD (Syntactic feature) are large, and RS tends to be assigned when they are small. Large JS divergence indicates that the distributions of a feature are different, and small JS divergence indicates that the distributions of a feature are close. This indicates that when the distributions of the important feature for WSD are different and the source data are not sufficiently close to the target data, the source data should not be used.

8 Conclusion

We described how the optimal method of DA could be determined depending on the properties of the source and target data using decision tree learning and found what properties affected the determination of the best method when Japanese WSD was performed. We defined a case as a triple of the target word type of WSD, the source data, and the target data, all of which were classified into two labels (TO and RS) or three labels (TO, RS, and SA). Here, the case with TO should only be trained with a small amount of target data, the case with RS should be trained with source data and a small amount of target data, and SA represents a case with no difference between the accuracies for the two methods. The average accuracy of WSD when the DA methods that were determined automatically were used was significantly higher than when the original methods were used collectively. We automatically generated a decision tree in eight ways, the most accurate of which was with SA label when the WSD accuracies of the two methods were totally equal, performed binary classification without SA, and classified cases without weighted word tokens. The top node in the tree that was generated indicated that simulation using ten manually labeled word tokens of the target data was an important clue enabling the optimal DA method to be predicted.

Abstract

Tense prediction can be useful for many language processing tasks, such as temporal inference and machine translation. In this paper, we investigate using diverse contextual features for Chinese tense prediction under a statistical learning framework. Because of lack of annotated training data, we propose to leverage Chinese-English parallel corpora to automatically generate reference tense for model training. We also propose to use an iterative learning framework to deal with the noisy reference data to improve learning. Evaluation is performed using both automatically generated reference data and a manually annotated set with verb tense. Our results demonstrate the effectiveness of our proposed learning framework that maps annotation from one language to another using parallel data. Furthermore, we show better performance using our proposed iterative bootstrapping learning method compared to using the original automatically created training data.

1 Introduction

Tense is used in languages to indicate the time at which an action or event described by the sentence takes place. Lacking correct tense information can cause confusion and misunderstanding in communication. Predicting tense information is very useful for different natural language processing tasks: both monolingual applications such as speech recognition (Karlgren, 1996) and multilingual applications such as machine translation (MT) (Buschbeck et al., 1991).

In inflectional languages like English, tense is often expressed by verb inflections, which can be easily recognized. For example, "*I worked till 5pm yesterday*" uses the past-tense verb "*worked*" to describe an event in the past. However, in languages such as Chinese, no verb inflections exist to indicate any tense information (Xiao and McEnery, 2002). The morphology of a verb itself never changes when used to express different tenses. The following examples (1a) and (1b) indicate a past-tense sentence and a future-tense sentence respectively; however, the form of the Chinese verb "到(arrive)" is the same in the two cases.

Example 1:
1a. 几天前(several days ago)我(I)到(arrive)
了(n/a)上海(Shanghai).
I arrived at Shanghai several days ago. (past)
1b. 今天晚上(tonight)7点(7 pm)我(I)将(will)
到(arrive)上海(Shanghai).
I will arrive at Shanghai at 7 pm tonight. (future)

This lack of inflections in Chinese verbs imposes some challenges in many applications. For instance, in a Chinese-English machine translation (MT) system, it is almost impossible to determine the tense for the corresponding English verb if solely based on the Chinese verb morphology. However, tense information does exist in Chinese language, and it is expressed lexically instead of morphologically. There are useful contextual cues that can help determine the tense for the whole Chinese sentence or individual verbs, such as temporal adverbs or phrases, aspect auxiliary words and prepositions. For instance, in example (1a), the aspect particle "了(a particle word in Chinese, there is no literal translation to English)" and temporal phrase "几天前(several days ago)" together indicate the past tense of the sentence, and thus the correct translation of the sentence is "*I arrived at Shanghai several days ago*".

Most of the previous work on tense prediction (Li et al., 2004; Cao et al., 2004; Ye and Zhang, 2005; Lin, 2006) has been conducted using relatively small data sets (e.g., hundreds of

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1116–1124,
Chiang Mai, Thailand, November 8 – 13, 2011.

Chinese sentences) and typically news article domain. They often require hand crafted rules in the systems. In this paper, we adopt a statistical classification framework for Chinese tense prediction. This study is different from previous work in that (a) we propose to utilize the parallel Chinese-English corpora to automatically generate reference tense information, which overcomes the limitation of insufficient training data as in previous work; (b) we evaluate a variety of linguistic contextual features for this task; and (c) we propose to use a modified bootstrapping iterative learning method in order to select more reliable and informative instances, which addresses the problem that the automatically derived training data is noisy. We evaluate our system by comparing with the automatically derived references as well as human annotations. Our experimental results have shown that our tense prediction system performs reasonably well, suggesting we can leverage the parallel data to learn information for one language from the other language, and that the iterative learning approach we proposed is effective.

2 Related Work

Time Expression Recognition and Normalization (TERN) was a task evaluated in the Automatic Content Extraction (ACE) program. It requires that certain temporal expressions mentioned in the documents be detected and recognized. Such temporal expressions include both absolute and relative expressions, durations, event-anchored expressions, and sets of times. The tense prediction task we investigate in this paper is related to the TERN task in that identifying temporal expressions may be helpful to determine the verb tense. Lin (Lin, 2003; Lin, 2006) outlined a framework for temporal interpretation in Chinese from a theoretical perspective. Hundreds of rules and situations were induced to determine the appropriate tense for Chinese sentences, based on information such as viewpoint aspect, verbal semantics, temporal adverbials, and complement and relative clauses. (Li and Wong, 2002; Li et al., 2001) used a rule-based approach to combine different types of temporal indicators for temporal relation classification. These indicators include time word, time position word, temporal adverb, auxiliary word, preposition word, auxiliary verb, trend verb, and some special verbs. (He et al., 2008) explored an error-driven strategy to derive heuristic rules to recognize time expression. (Cheng, 2008) investigated using dependency structure analysis for temporal relation identification.

Machine learning methods have been adopted for the tense prediction task in recent years. (Li et al., 2004) and (Cao et al., 2004) investigated linguistic features including eleven temporal indicators and one event class, and compared several classifiers (e.g., decision trees, naive Bayes classifier). Their results showed that adopting collaborative bootstrapping approach was able to reduce the human efforts required for the task, though it also degraded the classification accuracy. (Ye and Zhang, 2005) applied conditional random fields for tense classification on Chinese news documents, and reported an overall sentence and paragraph level accuracy of around 58%.

In this paper, we attempt to automatically predict tense information using a classification framework with diverse contextual information, especially around the verbs in the sentence. To address the problem of lacking annotated data, we develop effective methods that leverage the aligned English sentences to obtain reference tense for Chinese. Similar mapping methods have been investigated recently for some natural language processing applications (Bentivogli et al., 2004; Ye and Zhang, 2005; Feldman et al., 2006; Pado and Lapata, 2009; Chen and Ji, 2009; Schwarck et al., 2010), where there are parallel corpora and annotation is only available for one language, thus allowing us to derive information for the other language based on the alignment. Since such automatically extracted labels are noisy, we further adopted a modified bootstrapping method for more effective learning. Bootstrapping or self-training has shown promising results in many different tasks by utilizing labeled and unlabeled data, such as named entity classification (Collins and Singer, 1999), parsing (McClosky et al., 2006), web page classification (Blum and Mitchell, 1998), relation and pattern extraction (Ravichandran and Hovy, 2002; Pasca et al., 2006), machine translation (Ueffing, 2006) and ontology population (Carlson et al., 2009).

3 Approaches for Chinese Tense Prediction

In this study, we focus on the prediction of absolute tense information, which indicates the rela-

tionship between the speech time and the event time under the Reichenbachian theory (Thompson, 2005). We consider four basic tenses: present, past, future, and infinitive. Other detailed tense and aspect information such as progressive and perfect is not used in this paper.

3.1 Problem Definition

The tense prediction task can be formulated as a classification task. We use a verb-based tense prediction setup, where our goal is to develop a classification system to assign each verb in the sentence a tense tag (from 4 basic tenses mentioned above). As illustrated in Example 2, tags of "1,2,3,4" denote infinitive, past, present, future tense respectively. Note that in the example the aspect particle "了(a particle word in Chinese, there is no literal translation to English)" not only is the indicator of past tense (as in Example 1), but also is used in the context of future tense. This shows the ambiguity and the challenges of the tense prediction problem.

Example 2:
上星期(last week) 没有(not) 完成(finish)/**2** 任务(the task)，我们(we) 计划(plan)/**3** 招募(recruit)/**1** 更多(more) 人(people)，因为(because) 下周五(next Friday) 我们(we) 就要(will) 汇报(submit)/**4** 结果(the results) 了。

Last week we did not finish the task, we plan to recruit more people because we will submit the results next Friday.

Compared to sentence-based framework, this verb-based setting is more flexible and has advantages especially for complex sentences. In addition, we expect that the verb-based setup is more beneficial for other applications, such as providing richer annotation for machine translation.

3.2 Leveraging Contextual Features for Tense Prediction

We use a supervised learning framework for tense classification of every verb. In this initial study, we investigate using some basic lexical features (i.e., words) and simple syntactic features (POS tags). The following lists all the features we used.

Bag of words (BOW) features: For each verb, we consider words before and after that verb within a predefined window length (5 in our experiments).

Words and POS patterns (WP): These include combinations of the word/POS tag of the current verb and those from either the previous or the following adjacent word. These features are expected to capture some expression patterns unique to some tense class. For example, the pattern "verb+了(a particle word with no literal translation to English)" means a verb followed by a word "了", which is often a good indicator of past tense.

Local bigram features: We hypothesize that in addition to information from the immediate previous and the following words of the verb, other adjacent words and patterns around the verb may also be good indicators for tense. They may form a temporal expression or part of it, such as "几天前(several days ago)". We thus extract the word bigrams before and after the verb within a 3-word window.

Global bigram features: We observe that useful cues to predict a verb's tense can appear anywhere in a sentence, therefore, we include all the bigrams in the sentence as the global feature.

Dependency features (DEP): We automatically derived dependency features for each verb as features, which are expected to capture long-distance temporal evidence through dependency relation.

Note that we limited the feature scope to within one sentence since we noticed that information from other sentences is often noisy and not helpful to determine the tense for verbs in the current sentence.

3.3 Automatic Extraction of Tense Reference based on Parallel Data

An important part of supervised learning is the collection of labeled data. For the tense prediction task, we need reference tense information for each Chinese verb. Currently there is no labeled data publicly available for this task. To avoid the time-consuming manual labeling efforts, we propose to leverage the parallel Chinese-English corpus to automatically obtain the tense annotation for Chinese verbs using the corresponding English data. The following describes our procedure.

POS tag and parse the English sentences, and generate tense information for each verb.

POS tag the Chinese sentences.

Align the English and Chinese sentences at the word level.

For each identified verb in the Chinese sentences, if it is aligned to one English verb,

or if it is aligned to multiple English verbs but with no conflicting tense types, then we use the corresponding English verb tense as the reference tag for that Chinese verb; otherwise, we do not include that Chinese verb in the training set.

This process of generating reference tense for the Chinese verbs is not perfect due to errors in English parsing and tense assignment, word alignment between Chinese and English, and Chinese POS tagging. In addition, tenses are not always well-alignable between two different languages. However, it can effectively make use of the large amount of existing parallel corpora and provides an efficient way to create a large set of labeled data automatically. In addition, most learning frameworks have the potential power to deal with noisy data and thus we expect this data set may still allow us to build an effective model for tense prediction. Furthermore, since one of our future plans is to use tense information in Chinese to help Chinese to English machine translation, we believe that using information derived from English suits this goal. (Ye and Zhang, 2005) also used a parallel Chinese-English corpus to obtain tense information, however, it was done manually. In contrast, our method is automated, which allows us to utilize a large amount of existing parallel data.

3.4 Iterative Learning Using Noisy Training Data

Since the reference data automatically derived from parallel corpora is noisy, we propose to use an iterative method to address this problem for more effective learning. Our method is similar to bootstrapping (or self-training), but different in that: (i) we do not have a gold-standard seed set to start with; (ii) our data is not fully unlabeled, instead it has the labels obtained from the mapping process using parallel data; and (iii) we use different data labeling and selection methods in the iterative learning process. Our algorithm is shown in Algorithm 1, with more detailed description below.

Algorithm 1 Iterative learning algorithm from noisy data

Let be the automatically labeled training data
Train classifier on
Select initial training set based on self-testing using
for to **do**
  Train classifier on
  Classify using
  Assign a label to each instance in
  Rank instances in each class
  Select top data samples in each class,
  Update training data,
end for

Create an initial set.

Unlike self-training, we do not have an initial human annotated seed set. Therefore we will select a reliable small set from our noisy data for iterative learning. Our expectation is that when testing the classifier on the data set used for training, the noisy data points (i.e., instances with incorrect initial labels) are likely to have wrong predictions or low confidence (note that there are other impacting factors such as the features and the classifier used). We define the confidence score for the classifier's output as the ratio between the probability of the predicted label and the probability of the second most probable label. Using this measure, we created an initial set containing 10% of the entire data that have the highest confidence scores. We also compared this confidence measure with using the standard posterior probabilities from the classifier, and found this performed better.

In each iteration, assign labels to instances in the set of unselected samples.

In each iteration, we first apply the currently trained classifier to label each instance that is not yet selected by the iterative process, and then assign a final label to an instance using information based on the current iteration classifier ( ) and the initially self-trained classifier (, which is trained using the entire data set). This is different from traditional bootstrapping where there is only one classifier during the iterations. When the two classifiers agree on the most likely tag for an instance, it is straightforward to assign this tag. When there is a disagreement, we need to resolve the conflict. For this, we use confidence score from each classifier (the same confidence measure as used above), and use the label from the classifier with a higher confidence score. To take into account of the difference of the score range, we normalize the

confidence score: _ ————.
Rank instances.

This is needed for better selection of reliable and informative instances for model training. We rank instances in each tense category (their labels are determined from the previous step) based on the confidence score from the current classifier . We found this performed better than other metrics, such as Kullback-Leibler distance and Gap ratio.
Select top-ranked instances to add to the training set.

Based on the above ranking, we selected the top (p is empirically set to 0.5 in this work) of instances in each class and added them to the training set for next iteration training. Some previous studies (e.g., (Carlson et al., 2009)) showed that constraints are useful for self-learning or semi-supervised learning in terms of quality control. Therefore, in addition to the ranking scores above, during the selection process we consider more constraints. Specifically, for each instance we compare the labels generated based on three sources: original automatically derived label, prediction from the current classifier, and prediction from the initial self-trained classifier. We filter out cases using two different constraints: (a) Constraint I: neither the prediction from the current classifier nor the self-trained one is the same as the automatically derived label. (b) Constraint II: none of those three labels agree with others, that is, they are all different.

4 Experiments and Results

4.1 Data and Experimental Setup

The training data we used is from the Chinese-English parallel MT data collection provided by LDC for the DARPA GALE program. It comes from various domains: broadcast news, broadcast conversation, newswire, weblog, and newsgroup. We split the data into sentences when there is a period, question mark, or exclamation mark. All of the English sentences were parsed using the Charniak parser (Charniak and Johnson, 2005). The English verbs were then labeled with tense tags based on the parses. We used the Chinese POS tagger from (Huang et al., 2007) and Chinese dependency parser from (Chang et al., 2009). After preprocessing the source and target language data (mainly word segmentation for Chinese and tokenization for English), we used GIZA++ (Och and Ney, 2003) to obtain a word-level alignment. After applying heuristic rules to eliminate verbs that have no aligned English verbs or are aligned to multiple verbs with conflicting tenses (see Section 3.3 for reference tense creation), we finally created a training set consisting of 279,379 verb instances and 38,087 sentences.

We chose the maximum entropy (ME) model as the classifier for tense prediction, because ME can effectively utilize many features and performs competitively with other approaches in many classification tasks. We used the ME implementation from (Zhang, 2006) with a Gaussian prior of 0.1 and 100 iterations in the model training.

4.2 Cross Validation Evaluation Using Automatically Generated Reference

First we directly use the automatically created training set and measure the cross validation performance, mainly to evaluate the modeling approach and features for tense prediction. We use classification accuracy as the performance measurement in this experiment. Table 1 shows the 5-fold cross validation results using different feature sets described in Section 3.2. The baseline is calculated when assigning the majority tag in the training set to all the test instances.

Features	Accuracy (%)
Baseline	34.70
BOW	56.89
+ WP	63.13
+ Local-Bigram	63.39
+ Global-Bigram	64.90
+ Dependency	65.02

Table 1: Classification accuracy using different feature sets for verb-based tense prediction. Results are based on 5-fold cross-validation using automatically generated tense labels.

We found that adding contextual feature sets improves performance incrementally. When only bag of words (BOW) features are used, the accuracy is 56.89%, substantially better than the baseline of 34.70%. Adding "word and POS pattern" (WP) around verbs yields significant improvement, resulting in the accuracy of 63.13%, 7.8% gain compared to using BOW features only. This suggests that such combination of word and POS may represent some syntactic characteristics

and is more indicative of tense information. As expected, adding local bigram features slightly improves the performance and global bigram features can further boost the tense classification performance, yielding an accuracy of 64.90%. This shows that for verb tense prediction, global bigrams can provide some helpful information complementary to local features in recognizing tense information. Interestingly, adding dependency features only slightly improved the performance, which could be due to the low quality of dependency extraction on speech data. On the other hand, incrementally adding features might not clearly indicate the contribution of each feature type due to overlap problem. We further conducted experiments to see the effects of excluding each feature type at one time. The results show similar patterns to the above, showing the "BOW" and "Global-Bigram" features are most important features, and "Local-Bigram" and "Dependency" features are least important features.

Note that the training data is noisy due to the automatic process. To have a better understanding of the data quality, we decided to sample a small subset of the data and create human annotation. We randomly selected 2 files in the training data and asked a native Chinese speaker to manually label the first 150 utterances of each file. The annotator was asked to decide which verbs to label and assign the appropriate tense labels. No other explicit instructions were provided. During annotation, the human annotator found that many cases are ambiguous and felt tense labeling is quite subjective, suggesting creating human annotation for tense is very challenging as investigated in (Xue et al., 2008). Using this small data set, we found that the percentage of correct tense labels by the automatic alignment process was 78.52% (329 out of 419 instances), which seems quite satisfying, although further inspection is still needed.

4.3 Evaluation on Human Annotated Data

Another setting we use to evaluate the automatic tense prediction performance is by comparing to human annotation. We performed a pilot annotation for verb tense. The same native Chinese speaker as that who created the small sample training set manually annotated the verbs with tense types using 900 utterances from 6 randomly selected files in the GALE MT 2007 development set. In total, 2484 verbs were labeled by the human annotator, and these are used as the references to measure the performance of our automatic tense prediction system.

Because the POS tagger may miss some verbs and thus there will be no system hypothesis for those verbs, two different metrics are used in this evaluation. One is the labeled recall rate, defined as the percentage of the correctly labeled verbs out of the human labeled verbs; the other metric is the tense classification accuracy measured using only those verbs that are identified by both the POS tagger and the human annotator. As dependency features do not seem to be reliable enough, we trained two models from the automatically generated data set to validate its effectiveness on test data: one is using all the features (ALL) and the other one excludes dependency features (W/O Dependency). The results are shown in Table 2. To make a more competitive baseline system, instead of using the majority category of all the verbs on the training set, we used the majority tag for each individual verb.

System	Recall(%)	Accuracy(%)
Baseline	52.79	56.52
ALL	71.50	74.80
W/O Dependency	73.09	76.49

Table 2: Verb tense prediction performance on the human annotated test data.

We can see that the POS tagging errors (i.e., missing verbs) have a noticeable impact on system performance. Note that there is a difference between the baseline performance using the human annotation vs. the automatically created data set. There are two reasons for this. First is the different class distributions in the two data sets, for example, about 28%, 34%, 32%, and 16% for infinitive, past, present, and future tense respectively in the automatically labeled set, and 15%, 35%, 42%, and 8% in human annotation. Second, the baseline results in Table 2 are word-based, rather than the majority class for the entire set.

Our results show that using parallel data to derive reference annotations is a promising approach for a statistical learning framework, achieving the best performance of 76.49% compared with the baseline of 56.52%. Although adding dependency features obtained small improvement for the cross validation result, it degraded the performance on test set (see last row in Table 2). Therefore we exclude that feature for subsequent experiments. We

also observe that the performance is much better compared to Table 1, even though the class distributions are different in training and testing (which may affect statistical learning). One explanation might be that noisy labels from automatically generated training data may harm the cross validation performance. In addition, statistical learning can deal with the noisy data for training a robust model on unseen test data. We will show how the effects of noisy labels can be further reduced by iterative learning in next section.

4.4 Iterative Learning Results

Table 3 shows the best results for three iterative learning settings evaluated using the human annotated data set. These are from different numbers of iterations with different combinations of label assignment and instance ranking methods. We can see that using iterative learning generally improved tense classification in different settings – achieving the best accuracy of 77.49% compared to the original 76.49%, and the best recall rate of 74.02% compared to the original 73.09%. It suggests that our proposed learning method can effectively overcome some negative impact of the noisy training data, by iteratively selecting more likely trustworthy instances for model training. The best performance was obtained by applying constraint II (74.02%/77.49%), while adding constraint I degraded the performance a lot, which could be because using constrain I mislead the iterative process as more rules would miss out some useful training instances in the early stage. It suggests that adding appropriate constrains in the iterative bootstrapping process can provide better quality control for improved performance.

Selection Constraint	Recall (%)	Accuracy (%)
W/O Constraints	73.85	77.31
Constraint I	72.31	75.72
Constraint II	74.02	77.49

Table 3: Verb tense prediction performance on the human annotated test data using iterative learning. The results using the original training data are 73.09 and 76.49 for recall and accuracy.

For the iterative learning algorithm, we also examined its learning curve. Figure 1 shows the curves for the above best system using Constraint II. The horizontal dotted line is the baseline result when we just use the original data without iterative learning. We notice that performance in the early iterations generally increases (with some fluctuations) as more data samples are added for model training. After certain number of iterations, the performance starts dropping, since some added instances are noisy and do not help learning. Based on the trend shown in the curve, we expect that when the classifier itself improves, such as when incorporating more discriminative features, the learning curve could potentially increase further. The curves for other settings show similar patterns, with the best results achieved at different number of iterations.

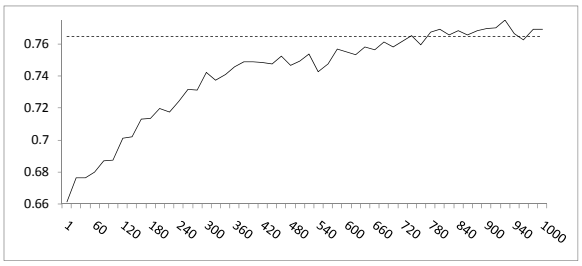

Figure 1: Learning curve of the iterative learning approach.

Another question we try to answer is how much we can attribute the performance improvement to iterative learning, or whether simply resampling can achieve similar performance. We examined re-sampling methods based on confidence measure (as described in iterative learning) to select similar number of samples as used in the iterative learning system above (using its optimal number of iterations), and then evaluated the classifier trained using this subset of the data. The results shows that simple re-sampling only obtained the accuracy of 74.58%, which is even worse than using the entire data set. Therefore we can conclude that the improvement we observe is mainly from the iterative learning method.

4.5 Error Analysis

Example 3 illustrates some examples of errors from our analysis. We identified several reasons causing the errors of our tense prediction system:

> Imperfect Chinese word segmentation and POS tagging results can directly affect the correct identification of Chinese verbs. In example (3a), the named entity "戴尔(Dell)" was incorrectly segmented as two Chinese words, and "戴" was further tagged as a verb due to its verb meaning "wear". In

Example 3:
3a) 戴/3 尔(Dell) 公司(Inc.) 新闻(media) 发言人 (spokesman) JessBlackburn 表示(indicate)/2 ， 该(the) 公司 (company) 正在(is) 评估(evaluating)/3 Google 的 软件 (software) 。

The spokesman of Dell Inc. indicated that, the company is evaluating the software from Google.

3b) 小时(hour) 工部(department) 分(divide)/3 职位(position) 技能(skill) 要求(require)/3 不(not) 高(high)/1， 如(such as) 食品(food) 促销 员(salesman)/3 、 理 货 员(shelf stockers) 等(etc) ， 失业(unemployment) 人员(people) 经过(by) 简单 (simple)/3 的 培训(training) 即可(can) 上(take)/3 岗(job) 。

Some positions for hourly workers require less job skills, such as the food salesman, shelf stockers, etc., the unemployed can take the job after simple training.

3c) 负责人(manager) 称(claim)/2，他们(they) 会(will) 在 (by) 2005 年(year) 底(end) 完成(finish)/4 这项(the) 工程 (project) 。

The manager claimed that they would finish the project by the end of 2005.

example (3b), the phrase "小 时 工(hourly worker)部 分(some)职 位(position)" was incorrectly segmented and the resulting word "分(divide)" was incorrectly tagged as a verb. In addition, some adjectives were also wrongly recognized as verbs, such as "高(high)", "简单(simple)".

There is limitation using our current feature set and it needs deep understanding to derive the correct tense. In example (3c), the system assigns future tense to the Chinese verb "完成(finish)" mainly because of the evidence "会(will)". To correct this, the system needs to determine that "the end of 2005" already passed based on knowledge or other long distance context (e.g., "But they didn't." in the following sentence).

The Chinese verb may not always be translated into English verbs, and vice versa. Training noises plus the imperfect alignment tools and other propagated errors from other preprocessing modules contributed another portion of errors.

Human annotation is not perfect. In some cases, both the system's output and human annotation are acceptable but they are not consistent. On the one hand, it shows the challenges of this task; on the other hand it suggests that investigation of inter-agreement among human subjects is needed in the future.

5 Conclusion and Future Work

In this paper, we have developed a classification approach to predict tense for Chinese verbs. We proposed an automatic mechanism to generate reference tense for the Chinese verbs that utilizes the Chinese-English parallel corpora, thus can efficiently create a large training set without relying on the time-consuming human annotation efforts. Our experimental results have shown that various contextual features around verbs can be effectively used to determine tense information, and this method of leveraging parallel corpora is feasible for Chinese tense prediction. In addition, the bootstrapping approach we explored in this paper further improves performance, proving to be an effective way to select training samples iteratively from noisy data.

In our future work, we will refine the process to automatically create the training set to better deal with problems from POS tagging, parsing, and alignment. A better data set will likely improve the tense prediction model. In addition, inter-agreement of human annotation on tense information is worth studying, especially for conversational style data. Finally, we will investigate using richer syntactic information and other semi-supervised methods (e.g. co-training in (Bergsma et al., 2011)) for tense prediction, and more importantly, develop methods using tense information derived in our system for machine translation and other applications.

Acknowledgments

We thank Eugene Charniak for providing his tools to obtain the tense information for the English verbs, Mary Harper for providing the parses for English and POS tagger for Mandarin, and Mari Ostendorf for useful discussions. This work was supported by DARPA under Contract No. HR0011-06-C-0023. Distribution is unlimited.

Abstract

This paper describes a new Markov Logic approach for Japanese Predicate-Argument (PA) relation extraction. Most previous work built separated classifiers corresponding to each case role and independently identified the PA relations, neglecting dependencies (constraints) between two or more PA relations. We propose a method which collectively extracts PA relations by optimizing all argument candidates in a sentence. Our method can jointly consider dependency between multiple PA relations and find the most probable combination of predicates and their arguments in a sentence. In addition, our model involves new constraints to avoid considering inappropriate candidates for arguments and identify correct PA relations effectively. Compared to the state-of-the-art, our method achieves competitive results without large-scale data.

1 Introduction

Predicate-argument (PA) relation extraction is one of the challenging problems in Natural Language Processing. The analysis extracts semantic information such as "who did what to whom", which is often useful to various applications like information extraction, document summarization, and machine translation.

Predicate-argument relation extraction is often called semantic role labeling. In English, it has been researched on large corpora such as FrameNet (Fillmore et al., 2001) and PropBank (Palmer et al., 2005). CoNLL Shared Task 2008 (Surdeanu et al., 2008) is a representative work of semantic role labeling based on these corpora. Japanese PA relation extraction is a kind of semantic role labeling but an argument is often called *case*. A typical example of Japanese PA relation is shown in Figure 1. In this example, "行った (went)" is a predicate and there are two arguments for the predicate, that is, a nominative case role (ga) is "彼 (He)" and a dative case role (ni) is "図書館 (library)".

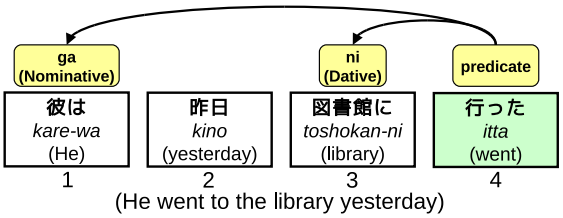

Figure 1: Example of Predicate-Argument Structure

In Japanese, Taira et al. (2008) and Imamura et al. (2009) tackled PA relation extraction on NAIST Text Corpus (Iida et al., 2007). They created three separated models corresponding to each of the case; ga (Nominative), wo (Accusative), and ni (Dative).

Even though some English semantic role labeler apply global models, most of them solve problems on a *per-predicate* basis (Toutanova et al., 2008; Watanabe et al., 2010). In this work, we propose an approach to Japanese PA relation extraction on a *per-sentence* basis and utilize important dependencies between one PA relation and another in the same sentence. In order to use such dependencies as global constraints, we apply a Markov Logic approach to Japanese PA relation extraction. In recent years, in English semantic role labeling, a Markov Logic model has achieved one of the state-of-the-art results (Meza-Ruiz and Riedel, 2009a). With global constraints between multiple PA relations, a Markov Logic model can avoid inconsistencies between several PA relations and improve performance of extraction.

In addition, we introduce new global constraints to effectively delete inappropriate argument candidates which are unrelated to PA relations. We consider that extraction of PA relations and dele-

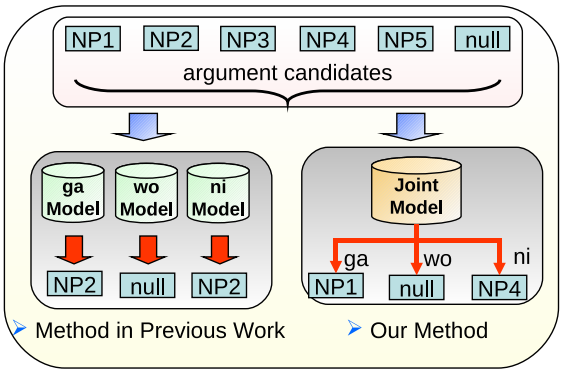

Figure 2: Difference in Methods

tion of the other phrases are two sides of the same coin. We jointly perform such extraction and deletion with Markov Logic.

Through our experiments, we report the effectiveness of the Markov Logic approach to Japanese PA relation extraction in detail. We show that our model with global constraints outperforms the model without them. Comparison with previous work shows that our Markov Logic approach achieves competitive results without selectional preference features obtained from large-scale unlabelled data. In qualitative analysis, we find that our global model resolves some difficult cases such as PA relations in relative clauses.

The remainder of this paper is organized as follows: Section 2 describes related work; Section 3 introduces Markov Logic; Section 4 explains our proposed Markov Logic Network; Section 5 presents and discusses the experimental setting and the results; and in Section 6 we conclude and present ideas for future research.

2 Related Work

In Japanese, PA annotated corpora such as Kyoto Text Corpus (KTC) (Kawahara et al., 2002) and NAIST Text Corpus (NTC) (Iida et al., 2007) have been developed and utilized. [1] CoNLL Shared Task 2009 (Hajič et al., 2009) included Japanese PA relation extraction on the data from KTC.

The data we used in this work is from NTC. NTC is based on the same text as KTC, which contains 38,384 sentences from 2,929 news articles. [2] The annotation in NTC has the three case roles: "ga (Nominative)", "wo (Accusative)", and "ni (Dative)". The predicate-argument annotation in NTC is based on deep cases and is more difficult to analyze than the surface case annotations which KTC employs. Note that KTC includes morphological information, base phrase segmentation, and syntactic dependency structure. We can merge these annotation from KTC and deep case annotation from NTC.

There are two main previous work with NTC. First, Taira et al. (2008) researched extraction of PA relations by SVM classifiers and decision lists. Their approach focused on not only verbal predicates but also nominal predicates. Secondly, Imamura et al. (2009) combined a Maximum Entropy model with a language model learned from large-scale corpora and achieved the state-of-the-art results.

Both Taira et al. and Imamura et al. created an independent model for each of the cases *ga, wo*, and *ni* (the left box in Figure 2). So, their models neglect the dependencies between cases. For example, the method in previous work produces "NP2" for both ga and ni cases. Though it is unlikely that the same noun phrase occupies two argument positions of a predicate, it is possible with their models.

However, our Markov Logic approach creates a joint model for the three cases and finds the most probable assignments taking into consideration the dependency between them. As a result, our model can prevent such an unlikely result (See the right box in Figure 2).

Moreover, in contrast to Imamura's work, our method does not exploit large-scale corpora. They depended on their language model derived from large-scale corpora to decide the selectional preference between a predicate and an argument. On the other hand, we handle the problem by global optimization *per-sentence* without using large-scale corpora.

In the CoNLL Shared Task 2009 (Hajič et al., 2009), a competition of multilingual semantic role labeling was held and Japanese was one of the target languages. In the shared task, Meza-Ruiz and Riedel (2009b) proposed a joint approach with Markov Logic. They also reported their Markov Logic approach for English semantic role labeling in detail (Meza-Ruiz and Riedel, 2009a). Their method divided the problem into four subtasks: predicate identification, argument identification, sense disambiguation, and role labeling. The subtasks are solved jointly. [3] We adapt their model to

[1] KTC is annotated with surface cases and NTC is annotated with deep cases

[2] These articles are from a Japanese newspaper, "Mainichi Shinbun"

[3] Note, in the CoNLL *2009* Shared Task, predicate identification is not necessary. So, they used the CoNLL *2008* Shared Task data in their work.

Japanese PA relation extraction on NTC. In order to compare with Taira et al. (2008) and Imamura et al. (2009), we perform only argument identification and role labeling.

About joint models of semantic role labeling without using Markov Logic, there are various previous work on CoNLL Shared Task Data. For example, Toutanova et al. (2008) and Watanabe et al. (2010) proposed joint models on the data of CoNLL Shared Task 2005 and 2009, respectively. While their models solve the problem on a *per-predicate* basis, our Markov Logic model solves it on a *per-sentence* basis. An optimization on a per-sentence basis is necessary and desirable for PA relation extraction on NTC since NTC has deep case annotations without case-frame dictionaries corresponding to them.

3 Markov Logic

It has long been clear that local classification alone cannot adequately solve all prediction problems we encounter in practice. This observation motivated a field within machine learning, often referred to as Statistical Relational Learning (SRL), which focuses on the incorporation of global correlations that hold between statistical variables (Getoor and Taskar, 2007).

One particular SRL framework that has recently gained momentum as a platform for global learning and inference in AI is Markov Logic (Richardson and Domingos, 2006), a combination of first-order logic and Markov Networks. It can be understood as a formalism that extends first-order logic to allow formulae that can be violated with some penalty. From an alternative point of view, it is an expressive template language that uses first order logic formulae to instantiate Markov Networks of repetitive structure. In the field of NLP, the Markov Logic approach has been applied to various tasks such as entity resolution (Singla and Domingos, 2006), information extraction (Poon and Domingos, 2007), and coreference resolution (Poon and Domingos, 2008), among others.

From a wide range of SRL languages we chose Markov Logic because it supports discriminative training (as opposed to generative SRL languages such as PRM (Koller, 1999)). Moreover, several Markov Logic software libraries exist and are freely available (as opposed to other discriminative frameworks such as Relational Markov Networks (Taskar et al., 2002)).

A *Markov Logic Network* (MLN) M is a set of pairs (ϕ, w) where ϕ is a first order formula and w is a real number (the formula's weight). It defines a probability distribution over sets of ground atoms, or so-called *possible worlds*, as follows:

$$p(\mathbf{y}) = \frac{1}{Z} \exp\left(\sum_{(\phi,w)\in M} w \sum_{\mathbf{c}\in C^{\phi}} f_{\mathbf{c}}^{\phi}(\mathbf{y}) \right) \quad (1)$$

Here each $\mathbf{c}$ is a binding of free variables in ϕ to constants in our domain. Each $f_{\mathbf{c}}^{\phi}$ is a binary feature function that returns 1 if in the possible world $\mathbf{y}$ the *ground formula* we get by replacing the free variables in ϕ with the constants in $\mathbf{c}$ is true, and 0 otherwise. C^{ϕ} is the set of all bindings for the free variables in ϕ. Z is a normalization constant. Note that this distribution corresponds to a Markov Network (the so-called *Ground Markov Network*) where nodes represent ground atoms and factors represent ground formulae.

Designing formulae is only one part of the game. In practice, we also need to choose a training regime (in order to learn the weights of the formulae we added to the MLN) and a search/inference method that picks the most likely set of ground atoms (PA relations in our case) given our trained MLN and a set of observations. However, implementations of these methods are often already provided in existing Markov Logic interpreters such as *Alchemy* [4] and *Markov thebeast*. [5]

4 Proposed Markov Logic Network

This section describes our Markov Logic model for Japanese PA relation extraction. We will describe our proposed Markov Logic Network (MLN) in detail. First, let us define logical predicates for our MLN. The three *hidden* predicates are listed in Table 1.

predicate	definition
$isArg(i)$	Bunsetsu i is an argument
$delete(i)$	Bunsetsu i is deleted
$role(i, j, r)$	Bunsetsu i has an argument j with role r

Table 1: Hidden Predicates

Note that Japanese dependency parsing is based on *bunsetsu* units, which are similar in concept to English base phrases. In order to exploit information parsed in this way, we handle all logical predicates by bunsetsu phrases (not tokens).

The hidden predicates model the decisions we

[4] http://alchemy.cs.washington.edu/
[5] http://code.google.com/p/thebeast/

logical predicate	description	example
$word(i, w)$	Bunsetsu i has word form w	行った (went), 彼 (he)
$stem(i, s)$	Bunsetsu i has stem s	行く (go)
$pos(i, p)$	Bunsetsu i has POS tag p (coarse-grained)	名詞 (noun)
$dpos(i, p)$	Bunsetsu i has POS tag p (fine-grained)	名詞-一般 (noun-general)
$ne(i, n)$	Bunsetsu i has named entity tag n (from NE tagger)	PERSON, LOCATION
$kana(i, k)$	Bunsetsu i has kana (Romanization) k	itta, kare
$isPred(i)$	Bunsetsu i is a predicate	True or False
$numeric(i)$	Bunsetsu i has a number character	True or False
$definite(i)$	Bunsetsu i contains the article corresponding to DEFINITE "the", such as "sore" or "sono"	True or False
$demonstrative(i)$	Bunsetsu i contains the article corresponding to DEMONSTRATIVE "this" or "that", such as "kono" or "ano"	True or False
$particle(i)$	Bunsetsu has a particle such as "wa","ga","wo", "ni"	True or False
$goiCate(i, g)$	Bunsetsu i has lexical category tag g in Nihongo Goi Taikei (Ikehara et al., 1997)	スポーツ (sport), 女性 (female)
$goiMatch(i, j)$	Bunsetsu phrases i and j satisfy the selectional restriction of Nihongo Goi Taikei	True or False
$dep(i, j, d)$	Dependency label between i and j is d	True or False
$path(i, j, l)$	Syntactic path between i and j is l	↑↓ (sibling), ↑↑ (ancestor)

Table 2: Observed Predicates

need to make: whether a bunsetsu phrase i is an argument of some predicate (argument identification); whether a bunsetsu phrase i is deleted (phrase deletion); whether a bunsetsu phrase j is an argument of the predicate i with semantic role r (role labeling).

Here the first two types of decision can be modeled through unary logical predicates $isArg(a)$ and $delete(i)$, while the other type can be represented by a ternary logical predicate $role(p, a, r)$. Because we do not know their information at test time, we call them *hidden*.

Our Markov Logic approach is based on English semantic role labeling with Markov Logic as proposed by Meza-Ruiz and Riedel (2009a). As mentioned earlier, they divided the problem into four subtasks and defined five hidden predicates (*isPredicate, isArgument, hasRole, role*, and *sense*). In order to be comparable with the previous work in Japanese PA relation extraction (Taira et al., 2008; Imamura et al., 2009), we deal with only argument identification and role labeling in our research. Therefore, we define only the three hidden predicates in Table 1.

In addition to the hidden predicates, we define *observed* logical predicates representing information at test time. For example, in our case we could introduce a predicate $word(i, w)$ which indicates that a phrase i has the word form w. We list the all observed predicates in Table 2.

With our predicates defined, we can now go on to incorporate our intuition about the task using weighted first-order logic formulae. In the following we will explain the formulae of our proposed MLN. Sections 4.1 and 4.2 describe our local and global formulae for *isArg* and *role*, respectively. Section 4.3 mentions the formulae for deletion.

4.1 Local Formulae

We say that a formula is *local* if its groundings relate any number of observed ground predicates to exactly one hidden ground predicate. Local formulae are defined with some observed predicates from Table 2 and a hidden predicate from Table 1.

The local formulae for *isArg* and *delete* capture the relation of the bunsetsu phrases with their lexical and syntactic properties (simple phrase property). The formula describing a local property of word form is

$$word(a, +w) \Rightarrow isArg(a) \qquad (2)$$

which implies that a bunsetsu a is an argument with a weight that depends on the word form. Note, the + notation indicates that the MLN contains one in-

Type	Formula	Description
hard	$isArg(a) \Rightarrow \exists p.\exists r.role(p,a,r)$	Every argument must relate to at least one predicate
hard	$role(p,a,r) \Rightarrow isArg(a)$	If a plays the role r for p, then a has to be an argument
hard	$role(p,a,r_1) \wedge r_1 \neq r_2 \Rightarrow \neg role(p,a,r_2)$	There is exact one case role between a predicate and an argument

Table 3: Global Formulae for *isArg* and *role*

stance of the rule, with a separate weight, for each assignment of the variables with a plus sign.

The local formulae for *role* represent properties between two bunsetsu phrases (linked phrases property). For example, the following formula

$$ne(a,+n) \wedge dep(p,a,+d) \Rightarrow role(p,a,+r) \quad (3)$$

denotes a local property of named entity and syntactic dependency.

As in Formula (3), some observed predicates (*goiMatch, dep*, and *path*) in Table 2 construct formulae using other observed predicates in this table.

First-order logical formulae such as Formulae (2) and (3) become the feature templates of MLN. Each template produces several instantiations. An example of a template instantiation based on Figure 1 is

$$ne(1,PERSON) \wedge dep(4,1,\text{“}D\text{”}) \Rightarrow role(4,1,\text{ga}) \quad (4)$$

which is a typical expansion from Formula (3).

4.2 Global Formulae

The intuition behind the previous formulae can also be captured using a local classifier. However, Markov Logic also allows us to say more:

$$isArg(a) \Rightarrow \exists p.\exists r.role(p,a,r) \quad (5)$$

In this formula, we made a statement about more global properties of a PA relation extraction that cannot be captured with local classifiers. This formula ensures the consistency between predicate and argument, that is, arguments belong to at least one predicate. This type of rule forms the core idea of our global model.

Global formulae involve two or more atoms of hidden predicates and enable us to jointly deal with argument identification, phrase deletion, and role labeling. With global formulae, our MLN considers not only a single decision at a time but also handles several decisions, simultaneously. Our global formulae for argument identification and role labeling are shown in Table 3.

All the formulae in Table 3 are hard constraints which enforce consistency between the hidden predicates. In MLN, formulae of hard constraint are defined as special formulae with *infinite* weights. A possible world which violates hard constraints is never chosen as a correct answer. For example, Formula (5) is such a global formula. Another formula ensuring the consistency between *role* and *isArg* is

$$role(p,a,r) \Rightarrow isArg(a) \quad (6)$$

which indicates “If a phrase a plays the role r for p, then a must be an argument”.

The last global formula

$$role(p,a,r_1) \wedge r_1 \neq r_2 \Rightarrow \neg role(p,a,r_2) \quad (7)$$

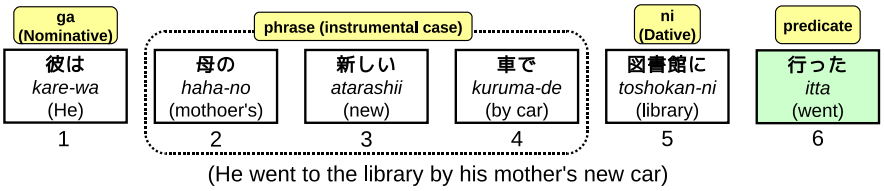
implies that there is only one case role between a predicate p and an argument a. Formula (7) enables us to prevent the contradiction shown in Figure 2.

4.3 Deletion Formulae

Let us explain formulae for deletion in this section, independently. The main idea of our deletion is to delete bunsetsu phrases which are unrelated to PA relations and to help extract correct arguments. Extraction of correct arguments and deletion of non-arguments are two sides of the same idea. An example is shown in Figure 3. We have a main verb “行った (went)” as a predicate and there are five argument candidates for it. We want to extract correct arguments, “彼は (He)” for ga-case and “図書館 (library)” for ni-case among the five candidates. Here, if we can remove an instrumental case, “母の新しい車で (by mother’s new car)”, extracting the correct arguments becomes much easier.

Notably, our significant contribution is doing this deletion processes with extraction of PA relations, simultaneously. Deleting too many bunsetsu phrases often hurts the recall because it often deletes correct arguments. We call this phenomena *over-deletion*. Performing extraction and deletion by one joint model prevents over-deletion and improves the performance of PA relation extraction.

Deletion formulae are also divided into local and global. However, local formulae implement the same properties for *isArg* we mentioned in Section 4.1. As an exception, a characteristic local formula



(He went to the library by his mother's new car)

Figure 3: Example of PA Relation with Instrumental Case

is

$$dep(i, j, +d) \wedge isPred(j) \Rightarrow \neg delete(i). \quad (8)$$

which implies the PA relations with syntactic dependencies are not deleted. It implements the fact that PA relations often have syntactic dependency relations. Actually, we can find that dependency relations are dominant in Table 5 and Formula (8) contributes to improve performance.

However, the local formulae address the deletion of a single bunsetsu phrase and we cannot expect a large improvement by adding *delete*. The main contributions of *delete* come from the global deletion formulae.

The global formulae for *delete* have three hard and one soft constraints. We show the global formulae in Table 4. The first three formulae in this table show the hard constraints which ensure the consistency between *delete* and the other two hidden predicates (*isArg* and *role*). The most important formula of them is

$$delete(i) \Rightarrow \neg isArg(i) \quad (9)$$

which implies that the deleted phrase does not become an argument.

The last formula in Table 4 is defined as a soft constraint:

$$word(h, +w) \wedge pos(h, +p) \wedge dep(h, m, +d) \wedge delete(h) \Rightarrow delete(m) \quad (10)$$

which denotes "if a head phrase h is removed, then the child phrases m should be deleted". This formula does not always hold but the remaining uncertainty with regard to this formula is captured by a weight trained from corpora. This constraint implements the important deletion concept as we mentioned earlier.

Considering the example in Figure 3, Formula (10) is grounded as,

$$word(4, \text{"車で"}) \wedge pos(4, \text{NOUN+PARTICLE}) \wedge dep(4, 2, \text{"}D\text{"}) \wedge delete(4) \Rightarrow delete(2) \quad (11)$$

which implies that "if '車で (by car)' is removed, '母の (mother's)' should be also removed". Figure 4 shows the dependency parsed tree extracted from

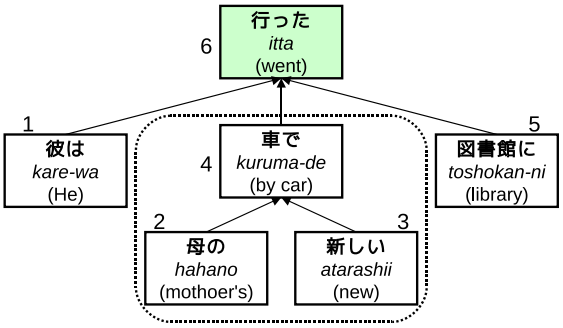


Figure 4: Deletion of Instrumental Case

the sentence in Figure 3. The subtree under "車で (by car)" should be deleted by Formula (11).

Note that Japanese dependency parsing usually targets only unlabeled parsing. Almost all labels are "D". [6] Therefore, we exploit the *word* and *pos* of head bunsetsu phrases as a substitution. In Japanese, word form and POS implicitly give us information similar to dependency labels. However, if we exploit our method in English, labeled information such as *probj* or *amod* should be helpful to train proper weights for Formula (10).

5 Experimental Results

5.1 Experimental Setup

Our experimental setting is based on previous work (Taira et al., 2008; Imamura et al., 2009) which was performed on NAIST Text Corpus.

Let us summarize our used data and tools. The data used, NAIST Text Corpus version 1.4β, has news articles and editorials. As training examples, we use articles published from January 1st to January 11th and editorials from January to August. As development data, we use articles published on January 12th and 13th and editorials in September. For evaluation, we use articles dated January 14th to 17th and editorials dated October to December. This way to split the data is same as Taira et al. (2008). We show the statistics of the evaluation data in Table 5.

As seen in this table, "ga-case" is dominant. PA relations which have syntactic dependency re-

[6] We sometimes have "P", "A", and "I" labels but it is not enough to model our deletion idea.

Type	Formula	Description
hard	$isArg(a) \Rightarrow \neg delete(a)$	If a is an argument then it is not deleted.
hard	$delete(i) \Rightarrow \neg isArg(i)$	If a bunsetsu i is deleted then it is not an argument.
hard	$role(p,a,r) \Rightarrow \neg delete(p) \wedge \neg delete(a)$	If a is an argument of p with the role r then neither p nor a is deleted.
soft	$word(h,+w) \wedge pos(h,+p) \wedge dep(h,m,+d) \wedge delete(h) \Rightarrow delete(m)$	If a head phrase h is deleted with word w and POS p then a child phrase m is deleted.

Table 4: Global Deletion Formulae

	ga	wo	ni
Dep.	13,086	5,192	3,645
Zero-Intra	4,556	376	231
Total	17,642	5,568	3,876

delete	86.6	90.4	88.4	94.3	97.9	96.1
role	86.3	72.5	78.8	85.5	**77.7**	81.4

Table 6: Local vs Global

lations (Dep.) are much more common than intra-sentential zero-anaphoric PA relations (Zero-Intra). However, in Japanese, we often find zero-anaphoric PA relations called *case ellipsis*. More detailed descriptions of PA relation types are shown in (Iida et al., 2006). Note that we target only PA relations which occur in a sentence (*intra-sentential* PA relations). The joint approach using Markov Logic is computationally hard even if it targets only *intra-sentential* PA relations. Therefore, extraction of *inter-sentential* PA relations which are crossing sentence boundaries is intractable. Moreover, our approach finds the most optimized PA assignments in a whole sentence. To keep consistency in a sentence, we delete the sentences which have inter-sentential PA relations.

For extracting features, we exploit the annotation of Kyoto Text Corpus as the POS and the syntactic dependency of bunsetsu phrases. We perform named entity tagging using CaboCha version 0.53. [7] Based on Taira's work, we introduce selectional restriction features from a Japanese Thesaurus, Nihongo Goi Taikei (Ikehara et al., 1997). Learning and inference algorithms for our joint model are provided by Markov thebeast, a Markov Logic engine tailored for NLP applications.

5.2 Results

First, let us show the comparison between the models with/without global constraints in Table 6. ***Global*** is the model with global constraints and ***Local*** is without them. Note that the local and global formulae of deletion are also included in ***Local*** and ***Global***, respectively. Table 6 shows Precision (P), Recall (R), and F1-value (F) of each hidden predicate. We can find that ***Global*** yielded clear improvements for all hidden predicates. These improvements are statistically significant. [8] These results suggest that the three target subtasks (argument identification, phrase deletion, and role labeling) can cooperate with each other. For PA relation extraction (*role*), the recall was mainly improved (the value in bold type).

We perform a simple analysis of hidden predicate removal. For each hidden predicate, a model was trained with that predicate removed and all other predicates retained. For PA relation extraction (*role*), Table 7 shows the model performance with removal of the *isArg* and *delete* predicates.

The removal of *delete* drops the model performance larger than that of *isArg*. While the removal of *isArg* drops the precision and saves the recall, the removal of *delete* is the other way around.

Next, we evaluate the results of PA relation extraction (*role*) by each case, "ga (Nominative)", "wo (Accusative)", and "ni (Dative)" in Table 8. All scores in the table are F1-value. Our ***Global*** model is more advantageous in "Zero-Intra" than ***Local*** model. Especially, in ga-case of Zero-Intra the score jumped from 42.1pt to 54.1pt (+12pt). Again, with global constraints, our global model finds the most probable state in the sentence. It is often difficult to extract Zero-Intra PA relations with only local features because syntactic dependencies between them are weak. Therefore, our global constraints contribute to find correct assignments of PA relations and we got a large improvement in Zero-Intra.

Let us compare our results with the state-of-the-art (Taira et al., 2008; Imamura et al., 2009). In Table 8, we show the best scores in bold types for

Table 7: Effect of Hidden Predicate Removal

each case. For ga-case, our model, ***Global***, outperformed the others. On the other hand, for wo-case and ni-case, our results were relatively lower than them. Because our approach deals with the all three cases by one joint model and ga-case is dominant in the data, it extracts more numbers of ga-case than the others. However, ga-case is often the most important for PA relation extraction and sometimes called *indispensable case*. Our method can extract such important information better than previous work. Although our model did not exploit large-scale corpora, our results are competitive to the results of Imamura et al. (2009).

Error Analysis

(this) この 1 (reason) ため 2 , (Gray Wolf) 灰色狼の 3 (**revival in the US**) 米復活を 4
(plan) 進める 5 (**FWS**) 魚類野生動物局が 6 (in Canada) カナダで 7 (capture) 捕獲した 8
(wild) 野性の 9 (**twelve wolves**) 十二匹を 10 (transport by air) 空輸 11 .

(Form this reason, FWS which plans to revive Gray Wolf in the US captured twelve wolves in Canada and transported them by air.)

In the above sentence, we have three predicates (gray boxed) and three arguments (underlined). The relations between predicates and arguments are complex with relative clause and often cause misunderstandings.

About this sentence, our ***Local*** model output:

$$\{role(5,6,ga), role(5,4,wo), role(8,6,ga), \underline{role(11,2,ga)}, role(11,10,wo)\}$$

It did not output wo-case of "捕獲した (capture)". Because we do not have case-frame dictionary in NTC, our models did not know that "捕獲した" usually requires wo-case (Accusative).

Another error is underlined that ga-case of "空輸 (transport by air)" is identified as "ため (reason)", because "ため" is only a phrase dependent on "空輸".

On the other hand, ***Global*** improved the errors as

$$\{role(5,6,ga), role(5,4,wo), role(8,6,ga), \underline{role(8,10,wo)}, \underline{role(11,6,ga)}, role(11,10,wo)\}.$$

By global optimization in a sentence, our ***Global*** model overcame the lack of semantic features and successfully identified "十二匹を" as wo-case of "捕獲した". This PA relation is in a relative clause and often hard to identify. Though Abekawa and Okumura (2005) resolved Japanese PA relations in relative clauses by exploiting large-scale corpora, our Markov Logic approach handles this problem by global optimization. Moreover, in global model, $\{delete(1), delete(2), delete(7)\}$ are also output and "この" and "ため" did not become argument candidates. As a result, "魚類野性動物局が" was correctly selected as a ga-case of "空輸".

6 Conclusion

In this paper, we proposed a new Markov Logic approach for Japanese predicate-argument (PA) relation extraction. Our model exploited global constraints between multiple PA relations and introduced phrase deletion. Our global constraints successfully improved the performance of PA relation extraction. In comparison to the state-of-the-art, our approach achieved competitive results with no large-scale data.

As future work, we will introduce utilizing features derived from large-scale data following Imamura's work. Selectional preference features from large-scale corpora are expected to improve the performance for extracting wo-case and ni-case. We will also investigate the state-of-the-art technique of sentence compression in related to our deletion approach. It might be interesting to evaluate our approach in sentence compression tasks. Adding sentence compression might make the PA relation extractor more efficient and allow us to extract *inter-sentential* PA relations, too.

Word Meaning in Context: A Simple and Effective Vector Model

Stefan Thater and **Hagen Fürstenau** and **Manfred Pinkal**

Saarland University
{stth, hagenf, pinkal}@coli.uni-saarland.de

Abstract

We present a model that represents word meaning in context by vectors which are modified according to the words in the target's syntactic context. Contextualization of a vector is realized by reweighting its components, based on distributional information about the context words. Evaluation on a paraphrase ranking task derived from the SemEval 2007 Lexical Substitution Task shows that our model outperforms all previous models on this task. We show that our model supports a wider range of applications by evaluating it on a word sense disambiguation task. Results show that our model achieves state-of-the-art performance.

1 Introduction

Distributional vector-space models of word meaning have proven helpful for a number of basic natural language processing tasks, such as word sense discrimination (Schütze, 1998) and disambiguation (McCarthy et al., 2004), or modeling of selectional preferences (Erk, 2007), and have been successfully used in a variety of applications like information retrieval (Manning et al., 2008) or question answering (Tellex et al., 2003). Standard distributional models of meaning are attractive because they are simple, have wide coverage, and, in particular, can be acquired using unsupervised methods at virtually no cost. Vector-space models of meaning lend themselves as a basis for determining a soft and gradual concept of semantic similarity (e.g., through the *cosine* measure), which does not rely on a fixed set of dictionary senses with their well-known problems (Kilgarriff, 1997).

The sensitivity of word meaning to the context of use, however, poses a major challenge for distributional semantics. Meaning vectors are based on co-occurrence counts for *words* across all word senses and usages. This means that, for instance, any occurrence of the verb *charge*, such as in the expressions *charge a fee* or *charge a battery*, is assigned the same vector representation, ignoring the difference of word sense. On the other hand, the fact that *charge* and *impose* are near-synonyms in *charge/impose a fee* will not be properly reflected in their respective meaning vectors, since the former, but not the latter, includes (context words reflecting) the "supply electricity" sense of *charge*.

The problem of modeling context-sensitivity in a distributional framework has first been addressed in the seminal paper of Schütze (1998), who uses second-order bag-of-words vectors for the task of word sense discrimination. Recently, the issue has been taken up by several approaches that include some kind of syntactic information, in part under the heading of "distributional compositionality" (Mitchell and Lapata, 2008; Erk and Padó, 2008), in part as "syntax-sensitive contextualization" (Thater et al., 2010). These approaches have in common that the contextual influence on the meaning of a target word w is modeled through vector composition: The meaning of w in context c is represented by a vector obtained by combining the vectors of w and c using some operation such as component-wise multiplication or addition.

The results published during the last couple of years show a considerable increase of performance, but at the price of an increasing complexity and lack of intuitive transparency of the models. In this paper, we will demonstrate that one can keep the model simple and at the same time outperform the state of the art. We achieve this as follows: First, we take a different, more general view on the basic operation of contextualization. Like the aforementioned approaches, we model contextualization as modification of the target vector, but we do not restrict this operation to variants of vector composition, but consider a broader range of

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1134–1143,
Chiang Mai, Thailand, November 8 – 13, 2011.

operations, which *re-weight* individual vector components. Second, we identify the distributional similarity score between the words defining the vector components on the one hand, and the actual context words in a given syntactic position on the other hand as the most effective basis for this re-weighting.

We evaluate our method on two different tasks: *paraphrase ranking* and *word sense disambiguation*. The paraphrase ranking task has been used in several approaches and provides benchmarks for our system, and the controlled conditions of the experiment make it easy to assess the influence of different design decisions on the performance. In practical terms, we will use a paraphrase ranking task derived from the SemEval 2007 Lexical Substitution Task (McCarthy and Navigli, 2007). We exceed the state of the art by almost 6% in terms of generalized average precision.

The application to word sense disambiguation (WSD) demonstrates that our model is more generally applicable. We phrase the WSD task as a paraphrase ranking task: Roughly speaking, finding the contextually appropriate word sense amounts to identifying the WordNet synset containing the best paraphrase candidate for the target. We evaluate our system on the SemEval 2007 coarse-grained unsupervised WSD task (Navigli et al., 2007). Our results are competitive to the results reported in the literature.

Plan of the paper. We will first review related work in Section 2, before we present our model in Section 3. We evaluate our model's performance on a paraphrase ranking task in Section 4 and on the task of word sense disambiguation in Section 5. Section 6 concludes.

2 Related work

Inspired by earlier work of Kintsch (2001), who proposes a network algorithm to extract context-specific vector representations for words in context, Mitchell and Lapata (2008) investigate the systematic combination of distributional representations of word meaning along syntactic structure. They propose to represent the meaning of a complex expression that consists of two syntactically related words w and w' by a vector obtained by combining the word vectors of w and w', and find that component-wise multiplication performs best for the task under consideration. They consider their proposal primarily under the aspect of compositionality, but it can also be taken to be a method to contextualize a target word through its dependents.

Erk and Padó (2008) propose structured vector representations, where each word is characterized by a standard co-occurrence vector, plus separate vector representations for the (inverse) selectional preferences for subject, object, and other syntactic relations. Contextualization is modeled by combining, e.g., the basic vector of the target verb with the selectional preferences of subject and object.

Thater et al. (2010) propose a similar approach, where word meaning is modeled as a second-order vector obtained by summing over first-order vectors representing the inverse selectional preferences of a word's syntactic arguments. Contextualization is modeled as above in terms of vector composition. Among the aforementioned approaches, their proposal performs best, but at the cost of a rather complex and unintuitive concept of second-order co-occurrence vectors.

Other approaches achieve good results without using vector composition. Dinu and Lapata (2010) represent word meaning in context by using a latent variable model, where context-dependence is modeled by conditioning the latent variable on the context in which a word occurs. Similar proposals have been made by Reisinger and Mooney (2010a) and Li et al. (2010).

A different approach has been taken by Erk and Padó (2010) and Reisinger and Mooney (2010b). Instead of "refining" vector representations ranging over all words in a corpus by means of vector composition, they start out from "token" vectors for individual instances of words in context, and then group these token vectors into different sense-specific clusters.

3 The model

We propose a model of word meaning that allows the computation of vector representations for *individual uses* of words, characterizing the specific meaning of a word in its sentential context. For instance, the vector of the verb *charge* in the expression *charge a tax* should reflect its monetary sense, while its vector in the expression *charge a battery* should be representative of its "supply electricity" sense.

We derive a *contextualized* vector from the basic meaning vector of a target word by *reweighting* its components on the basis of the context of the occurrence, where we take the context to be made

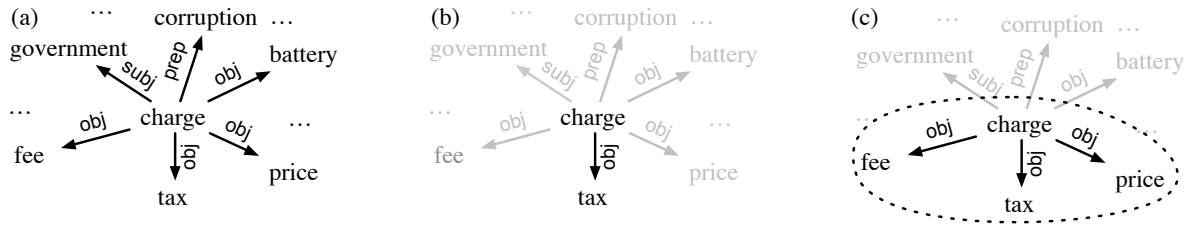

Figure 1: Graphical representation for a basic vector for *charge* (a), and two contextualized vectors for *charge* in context *charge a tax*, obtained by (b) a strict and (c) our more sophisticated contextualization method based on semantic similarity.

up of the direct syntactic dependents of the target (and its direct inverse dependents). The dimensions of both basic and contextualized vectors represent co-occurring words in specific syntactic relations. Fig. 1a shows the basic vector for *charge* as an example, where we use arrows to indicate the internal structure of the vector; the weights of the vector components are omitted for simplicity.

The operation of contextualization reinforces those dimensions of the basic vector that are licensed by the context of the specific instance under consideration. The easiest way of adapting the vector of a word to its context of use is to retain only those dimensions corresponding to its syntactic neighbors, which results in an extremely sparse vector with zero values for most of its dimensions. For instance, contextualizing the vector for *charge* in *charge a tax* (Fig. 1b) would zero out all (r,w) components with $r \neq \text{OBJ}$ or $w \neq tax$, retaining only one non-zero dimension (the one for *tax*).

As we will see in Section 4, this simple approach is surprisingly successful. However, we achieve substantially better results by leveraging *semantic similarity information* about the context words. Instead of considering only the dimensions of the context words themselves, we retain dimensions of those words that are distributionally similar to the context words, weighted by their similarity score. The vector for *charge* in *charge a tax* will then contain additional non-zero dimensions for all words similar to *tax* (Fig. 1c). In a way, similarity-based contextualization is a formalization of the intuitive concept of "the meaning of w in the context of a word *like* w'."

Formal description. We assume a set W of words and a set R of syntactic relations. The latter includes dependency relation labels such as SUBJ or OBJ for *subject* and *object*, as well as the corresponding inverse relations such as SUBJ^{-1}. We represent the meaning of any word $w \in W$ by a vector in the vector space V spanned by the set of basis vectors $\{\mathbf{e}_{(r,w')} \mid r \in R, w' \in W\}$. Such a vector records the association strength between w and any context word w' occurring in relation r. Specifically, we associate a word $w \in W$ with a vector $\mathbf{v}(w) \in V$ by setting

$$\mathbf{v}(w) := \sum_{r \in R, w' \in W} f(w,r,w') \cdot \mathbf{e}_{(r,w')}$$

where f is a function that assigns a weight to the dependency triple (w,r,w'). In the simplest case, this could be the frequency of w occurring together with w' in relation r in a corpus of dependency trees. In the experiments reported below, we use *pointwise mutual information* (Church and Hanks, 1990) instead, as it proved superior to raw frequency counts:

$$PMI(w,r,w') = \log \frac{p(w,w' \mid r)}{p(w,\cdot \mid r)p(\cdot,w' \mid r)}$$

Here the dots stand for marginalization over the relevant variables.

Given an occurrence of a word w in the context of another word w_c, related by the syntactic relation r_c, we now define a contextualized version of $\mathbf{v}(w)$ by *reweighting* the vector components. We set

$$\mathbf{v}_{r_c,w_c}(w) := \sum_{r \in R, w' \in W} \alpha_{r_c,w_c,r,w'} \cdot f(w,r,w') \cdot \mathbf{e}_{(r,w')}$$

Here, the weights $\alpha_{r_c,w_c,r,w'}$ quantify the degree to which a vector dimension (r,w') is compatible with the observed context (r_c,w_c). We consider three alternative definitions of these weights, corresponding to the three cases shown in Figure 1:

No contextualization: $\alpha_{r_c,w_c,r,w'} := 1$

In this case the definition of $\mathbf{v}_{r_c,w_c}(w)$ coincides with that of $\mathbf{v}(w)$.

Strict contextualization:

$$\alpha_{r_c,w_c,r,w'} := \delta_{r_c,r}\delta_{w_c,w'} = \begin{cases} 1 & \text{if } r_c = r \text{ and } w_c = w' \\ 0 & \text{else} \end{cases}$$

Here, we only retain the one dimension (r_c, w_c) that is licensed by the context and set all other dimensions to 0.

Similarity-based contextualization:

$$\alpha_{r_c,w_c,r,w'} := \delta_{r_c,r} \cdot \text{sim}(w_c, w') = \begin{cases} \text{sim}(w_c, w') & \text{if } r_c = r \\ 0 & \text{else} \end{cases}$$

Here, we generalize over the surface context and license all words w' that are semantically similar to the context word w_c.

While any measure of semantic similarity can be employed, in the experiments reported below we compute the similarity between w_c and w' as the cosine of the angle between their basic vector representations $\mathbf{v}(w_c)$ and $\mathbf{v}(w')$.

Of course, we want to take into account more than a single context word for a given occurrence of w. Given context words $w_1, \ldots, w_n$ and corresponding syntactic relations $r_1, \ldots, r_n$, we obtain a contextualized vector of w by superimposing the vectors $\mathbf{v}_{r_i,w_i}$ $(1 \leq i \leq n)$ through vector addition:

$$\mathbf{v}_{r_1,w_1,\ldots,r_n,w_n}(w) := \sum_{i=1}^{n} \mathbf{v}_{r_i,w_i}(w)$$

The resulting vector $\mathbf{v}_{r_1,w_1,\ldots,r_n,w_n}(w)$ is our completely contextualized representation for the word w that contains information about all context words.

4 Ranking Paraphrases

In this section, we evaluate to what extent our model supports the choice of contextually appropriate paraphrases for different uses of a target word. We follow previous work (Thater et al., 2010; Erk and Padó, 2010; Dinu and Lapata, 2010) and consider the following task: We are given a target word w in a sentential context and a set of reference words $w_1, \ldots, w_k$, where each w_i is a lexical paraphrase of w in one of w's senses. The task is to rank the candidate words w_i according to their appropriateness as paraphrases of *w in the given context*. Ideally, the model will rank, for instance, *levy* higher than *recharge* as a paraphrase of *charge* in *charge a fee*, and lower in *charge the battery.*

4.1 Experimental Set-up

Gold standard. We derive our gold standard from the SemEval 2007 lexical substitution task dataset (McCarthy and Navigli, 2007). The original dataset contains 10 instances for each of 201 target words (nouns, verbs, adjectives and adverbs) in different sentential contexts. For each instance, five subjects were asked to name appropriate paraphrases. Table 1 shows an example of three instances of *charge* together with their gold standard paraphrases. Each paraphrase comes with a weight, which corresponds to the number of times it was chosen by the different subjects.

The original task addresses two subtasks: identifying paraphrase candidates and ranking them according to the context. Here, we restrict ourselves to the second subtask. Following previous work, we pool all annotated gold-standard paraphrases of a target word w across all contexts into a set of *paraphrase candidates* for w, which our model is supposed to rank with respect to contextual appropriateness for the individual instances of w. We do not extract multi-word expressions, for which our model cannot compute vector representations, and obtain a dataset consisting of 1986 instances for 197 different words. In our derived dataset, each word type has an average of 17 paraphrases, 3.5 of which are correct (on average) for individual instances of the word.

Vector space. We draw on dependency trees obtained by parsing the English Gigaword corpus (LDC2003T05) to build our vector space model. The corpus consists of news from several newswire services, and contains over four million documents. We used the Stanford parser (de Marneffe et al., 2006) to parse the corpus. The resulting dependency trees were modified in a post-processing step by folding prepositions into edge labels to make the relation between a head word and the head noun of a prepositional phrase explicit. Furthermore, we collapsed particle verb constructions into single nodes. To facilitate processing and reduce noise, we excluded all dependency triples that occurred less than 3 times or had a PMI score below 0, which resulted in a corpus of about 888 million dependency triples accounting for 28 million triple types.

To further reduce computational costs, we set higher frequency and PMI thresholds for the computation of the similarity scores used in the contextualization of vectors: in the experiments reported

Sentence	Substitution candidates
Annual fees are *charged* on a pro-rata basis [...]	levy 2; require 1; impose 1; demand 1
Plug in you h 10 in the usb outlet and it will *charge* without the plug in adaptor.	recharge 2; supply electricity 1; charge up 1
Pauline Gilmore, 32, was *charged* with possessing a blast bomb.	indict 3; accuse of 2; accuse 1

Table 1: Three examples from the lexical substitution task data set for the target word *charge*.

below, we consider only (vectors based on) dependency triples that occur at least 5 times and have a PMI score of at least 2. Note that these thresholds are used only to speed up processing. The effect on the overall performance is minimal: an experiment on a randomly chosen 10% subset of the test set shows that we obtain almost identical scores, but runtime is reduced by a factor of more than 35.

Scoring. We rank the paraphrase candidates for a target word in context by the similarity of their basic vectors to the contextualized vector of the target. Contextualizing both the target and the paraphrase candidate has been observed to reduce performance (Thater et al., 2010; Dinu and Lapata, 2010). Similarity is measured in terms of the dot product of the vectors. In cases where the Stanford parser produced dependency trees that are inconsistent with the information about the target word in the gold standard, or where the contextualized vector is zero, we use the basic vector of the target as a fallback. This fallback method applies to 7% of all instances in the dataset.

Evaluation method. Following previous work (Thater et al., 2010; Erk and Padó, 2010), we use *Generalized Average Precision* (Kishida, 2005) to compare the ranking predicted by our model with the gold standard. GAP takes values between 1.0 and 0.0, where a value of 1.0 indicates that all correct items are ranked before all incorrect ones, and that higher-weighted items are ranked before lower-weighted ones. Statistical significance of differences in performance are computed by approximate randomization (Chinchor et al., 1993).

4.2 Results

Table 2 shows results for three versions of our model, corresponding to the three definitions of the weighting factors that were detailed in Section 3:

(a) No contextualization

POS	Random	No context	Strict	Sim.-based
Verb	27.4	38.4	41.6	48.8
Noun	30.1	45.2	47.3	52.9
Adj	28.4	42.2	45.8	51.1
Adv	36.4	51.6	50.6	55.3
All	30.0	43.7	46.0	51.7

Table 2: Results for our model using different contextualization methods, compared to a random baseline.

(b) Strict contextualization

(c) Similarity-based contextualization

In addition, we show the performance of a baseline that ranks paraphrase candidates randomly.

We observe that similarity-based contextualization is very effective, improving performance by 8% compared to the "no context" variant, and still by almost 6% compared to the strict variant that uses surface context only. The differences are statistically significant ($p < 0.001$).

Figure 2 provides a different view on system performance. It shows how often the k first candidates in the ranking contain at least one gold standard paraphrase. In particular, we can observe that similarity-based contextualization predicts a good top-ranked candidate in 55% of the cases; the top three contain a correct paraphrases in more than 80% of the cases.

Table 3 compares our model to previous models that have been evaluated using the Lexical Substitution Task (LST) dataset. Our model outperforms all previously proposed methods. Although all models have been evaluated on test-sets derived from the LST dataset in essentially the same way, the datasets differ slightly due to technical details, so strictly speaking the results cannot be compared directly. However, since all authors report similar

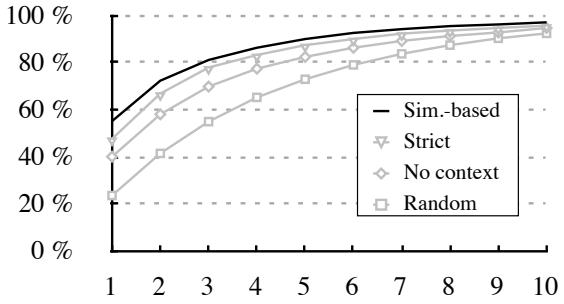

Figure 2: The figure shows how often the k first candidates in the ranking contain at least one gold standard paraphrase (for $k \leq 10$).

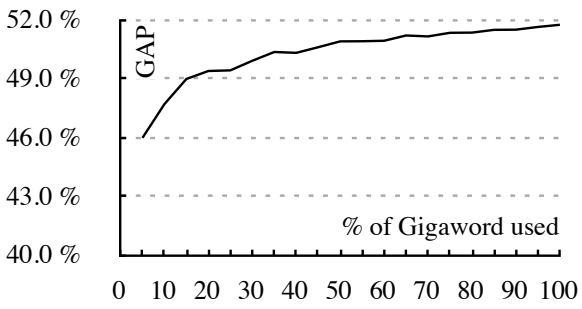

Figure 3: Learning curve: GAP with varying corpus size.

Model	GAP	Random
Erk and Padó (2008)	27.4†	N/A

‡ Evaluated on nouns, verbs, and adjectives (not adv.).

Table 3: Comparison to previous work

scores for the random baselines, we assume that the complexity of the subsets used in previous work is more or less comparable.

Learning curve. The corpus used in our study is much larger than the British National Corpus (BNC) that has been used, for instance, in Erk and Padó's (2008; 2010) models. To assess the contribution of the corpus size to the performance of our model, we randomized the order of dependency trees in the parsed Gigaword corpus and constructed vector space models using increasing subsets of the complete corpus with a step size of 5%. The resulting learning curve is shown in Figure 3. We see that our model performs well even on small subsets of Gigaword. When we use only 5% of the dependency trees, which is roughly two third of the size of BNC, we already obtain a GAP score of 46.0%, which is 5.7% less than our result with full Gigaword, but 7.4% more than the best reported BNC-based model.

Syntactic information. Finally, we investigated the impact of syntactic information by comparing our model against two variants: (i) a "bag of words" variant that does not use syntactic information at all and (ii) a "syntactically filtered" variant similar to Padó and Lapata (2007) that uses syntactic information but does not explicitly represent syntactic role information in the vector representations. Variant (i) is based on co-occurrence statistics on pairs (w, w') of content words within a five-word window; for variant (ii) we consider all pairs (w, w') such that w and w' are linked by some syntactic relation. Technically, we represent these pairs as dependency triples involving some arbitrary fixed syntactic role label.

We observe that syntactic information contributes to the success of our approach both by selecting relevant context words and by characterizing their syntactic relations: In terms of GAP, the "bag of words" variant achieves 48.7%, the "syntactically filtered" variant 50.9%, and our full model 51.7%. The relatively small difference between the two syntactic variants, while maybe surprising at first sight, is explained by the fact that in most cases the syntactic role of a dependency triple is predictable from the words it connects: For more than 88% of all dependency triples in Gigaword, the syntactic role is actually the most frequent one for the respective pair of words. Yet, the difference between the two variants is statistically significant ($p < 0.05$): The model supports correct decisions in those cases where syntactic role information matters.

5 Word Sense Disambiguation

In a second experiment, we applied our model to the task of word-sense disambiguation. For an individual instance of a word, we predict the correct WordNet sense (Fellbaum, 1998) of the target based on its immediate syntactic context, without relying on any manually annotated training data. Our system is *knowledge-based*, according to the classification of WSD approaches proposed in McCarthy

(2009) and Navigli (2009). It is a *knowledge-lean* system, in contrast to many other systems that exploit external resources, since it uses only a small subset of the structural information provided by WordNet – just as much as is required to adapt our contextualization model to the WSD task.

The state of the art in knowledge-based WSD systems not trained on annotated data is defined by the models of Navigli and Velardi (2005), Ponzetto and Navigli (2010) and Li et al. (2010). The former two rely on a rich inventory of additional knowledge resources. Li et al. (2010) restricts itself to WordNet information in a similar way as our approach, and therefore is our natural benchmark.

5.1 Method

We frame the task of choosing the right WordNet sense as a paraphrase ranking task like the one considered in Section 4, with all possible synonyms of the target word constituting the set of (lexical) paraphrase candidates. The basic idea for predicting a sense of the target word is to choose the synset that contains the most similar paraphrase. As the WordNet synsets of the target word are often singletons, just containing the target itself, we additionally include all words from direct hypernym, hyponym, and similar synsets (WordNet relation "similar to"). We ignore multiword expressions since our model does not provide vector representations for them.

While we generally found the richer collection of candidates to improve system performance, the inclusion of hypernyms can have a negative effect on sense discrimination, since different word senses frequently share the same hypernym. To counter this effect, we consider the average similarity scores of the best two paraphrase candidates of each sense rather than relying on the most similar candidate alone. More technically speaking, we collect all relevant sense paraphrases $c_{i,1}, \ldots, c_{i,k_i}$ for each sense s_i of the target word. We compare the contextualized vector of the target word to the basic meaning representations of these candidate words, obtaining a similarity score for each of them. The score of the sense s_i is then defined as the average of the scores of the two top-scoring candidate words, and the sense with the highest such score is predicted. Our model fails to predict a sense for an ambiguous target if the candidate set of any sense is empty, which can happen in cases where all applicable sense paraphrases are multiword expressions.

We will experiment with two instantiations of this model: the basic version described above, and a version that additionally integrates information about prior sense distributions by multiplying the score of each synset with its prior probability, and falls back to the most frequent sense in cases where the basic model fails to make a prediction. Prior probabilities are estimated by using sense frequency information from WordNet.

5.2 Experimental setup

Gold standard. We evaluate our model on the SemEval 2007 Coarse-grained English All-words Task (Navigli et al., 2007) test set. The test set consists of 5,377 words of running text from five documents from different genres. All open-class words in this corpus are annotated with coarse-grained sense labels, which are defined as clusters of WordNet senses and are obtained by mapping WordNet 2.1 senses to the Oxford Dictionary of English (Soanes and Stevenson, 2003). On a subset of 710 instances an inter-annotator agreement of 93.80% was reported, which can be considered the upper bound for any WSD system on the data set.

Predicting coarse-grained senses. The method described in Section 5.1 predicts (fine-grained) WordNet senses. It can be straightforwardly extended to the coarse-grained WSD task by picking the sense cluster containing the top-ranked synset. We achieved slightly better results by applying a different method: We normalize the scores of all synsets so that they sum up to 1, which allows us to interpret them as a probability distribution. We then compute probabilities for each sense cluster by aggregating over its constituent synsets, and predict the most probable one (which need not be the one containing the most probable synset).

Baselines. We compare our model against a random baseline and the most frequent sense (MFS) baseline that always predicts the sense with the highest sense frequency according to WordNet.

5.3 Results

Table 4 summarizes results on the test set in terms of precision, and compares them to two baselines and the state-of-the-art system of Li et al. (2010). Except in the case of our basic system (-MFS) without prior information, which cannot use information about most frequent senses as fallback and covers only 74.6% of the test cases, coverage is 100% and therefore precision coincides with recall.

Model	+MFS	-MFS
Random	52.4	52.4
Most frequent sense (MFS)	78.9	—
Li et al. (2010)	81.3‡	78.8‡
Our Model	80.9	78.7†
Combined system	82.2	78.9

† Covers 74.6% of the dataset.

‡ Results reported here are higher than the results reported by Li et al. (2010). Our results are based on the scoring script provided by the organizers of the SemEval 2007 shared task. Differences are due to details such as sensitivity to capitalization when system predictions are compared with the gold standard.

Table 4: Precision of our model on the WSD task, with (+MFS) and without (-MFS) prior knowledge about sense distributions, compared to the state-of-the-art system by Li et al.

We can see that our model's performance is competitive with the state of the art: In both settings our model outperforms the two baselines, and reaches the performance level of the benchmark system of Li et al. (2010).

Interestingly, the strengths of our and Li el al.'s systems are complementary. For example, in the sentence "The *diners* at my table simply lit more Gauloises [...]," our model correctly predicts the sense "person eating a meal" of the target *diners*, based on the leading sense paraphrase *eater*. The system by Li et al. (2010), on the other hand, predicts the sense "passenger car where food is served", which fits the general topic similarly well, but is highly implausible in the given syntactic context. However, in the sentence "The program text, or source, was converted into machine instructions using a special program called a *compiler*," the system by Li et al. (2010) is able to leverage topical clues to correctly predict the software sense of *compiler*, whereas our system ranks the sense paraphrase *author* over *program* and thus incorrectly predicts the sense "person who compiles encyclopedias."

Given this complementary nature of the two systems, we tried to combine them in a straightforward way, by averaging their predicted probability distributions (defaulting to Li et al. for instances not covered by our model). Table 4 shows that the combined system outperforms both individual systems both with and without MFS information. In the former case (with MFS), the improvement of 0.9% is statistically significant ($p < 0.01$) according to McNemar's test.

6 Conclusions and Future Work

We have presented a technically simple and intuitively transparent vector space model of word meaning in context. Contextualization of a vector is realized by reweighting its components, using semantic similarity information about the words occurring in the target's local syntactic context.

We evaluated our method on a paraphrase ranking task derived from the SemEval 2007 Lexical Substitution Task dataset and showed that it substantially outperforms all previous approaches, exceeding the state of the art by almost 6% in terms of generalized average precision. We showed that our model supports a wider range of application by evaluating it on a word sense disambiguation task. The model reaches the performance level of the state-of-the-art benchmark system of Li et al. (2010). The combination of the two systems performs significantly better than either system used in isolation, and outperforms the most-frequent-sense baseline by over 3%.

The contextualization operation takes only the *words* in the targets *local* syntactic context into account. A natural direction for future research is to generalize the contextualization operation so that the context words themselves can be contextualized in a recursive fashion and all words in the target's complete syntactic environment can contribute information.

Our present model incorporates syntactic relations, although semantic information should ideally be expressed in terms of underlying semantic roles. We have seen that the use of syntactically structured vector representations leads to a relatively small, but statistically significant increase in performance, compared to variants of our model that do not represent rich syntactic information. We expect that further progress can be made by integrating semantic role information.

Acknowledgments. We would like to thank Georgiana Dinu and Linlin Li for their support and helpful comments. Abstract

SciPo is a system whose ultimate goal is to support novice writers in producing academic texts in Brazilian Portuguese through presentation of critiques and suggestions. Currently, it focuses on the rhetorical structure of texts, being capable of automatically detecting and criticizing the rhetorical structure of Abstract sections. We describe a system that enhances SciPo's functionality by evaluating aspects of semantic coherence in academic abstracts. This system identifies features of sentences based on semantic similarity measures and rhetorical structure. Different machine learning algorithms were trained and evaluated with these features, resulting in three classifiers capable of detecting specific coherence issues on sentences with regard to a rhetorical structure model for abstracts. Results indicate that the system yields higher performance than the baseline for all classifiers.

1 Introduction

This research has been motivated by a need for advanced discourse analysis capabilities for writing tools such as SciPo (short for Scientific Portuguese). SciPo (Feltrim et al., 2006) is a system whose ultimate goal is to support novice writers in producing academic texts in Brazilian Portuguese. Currently, it focuses on Computer Science academic texts and supports the writing of abstracts and introductions. Its functionalities are based on the use of structure models — in terms of schematic structure, rhetorical strategies and lexical patterns — similar to the ones proposed by Swales (1990) and Weissberg and Buker (1990), and authentic examples organized as case bases. Although SciPo provides feedback with regard to the text rhetorical structure in the form of critiques and suggestions, it does not provide considerations about the text semantics, such as aspects related to its coherence, which is a fundamental characteristic for text legibility and interpretability.

We understand coherence as what makes a group of words or sentences semantically meaningful. We assume that coherence refers to the establishment of a logical sense among different sentences of a text. Thus, it is a principle of interpretability related to the communicational situation and to the capability of the reader in calculating the meaning of the text. Therefore, it is bounded to the text, but it does not depend only on the text (van Dijk, 1981).

Aiming at complementing SciPo's functionalities, we have developed classifiers for the automatic detection of specific semantic relations in academic texts in Portuguese, then it can be used by SciPo for providing feedback referring to text coherence. Based on textual features that can be readily read off the text, the classifiers present indications related to semantic aspects that contribute to a high level of coherence.

We believe that our work brings innovative contributions due to the nature of the analyzed corpus, especially by language and rhetorical structure of the texts, and the kind of application to which we intend to apply coherence analysis. As mentioned by Burstein et al. (2010), there is a small body of work that has investigated the problem of identifying coherence in student essays. None of the work cited by Burstein et al. (2010) is focused on academic writing, but on essays written by English writers that may be native/non-native and have different writing skills. This kind of text tends to present more explicit coherence problems than the ones that may occur on a academic writing corpus, as the one used in this work. Academic texts are usually written by students who have domain, at a certain level, on the language (in our case, Por-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1144–1152,
Chiang Mai, Thailand, November 8 – 13, 2011.

tuguese) and on the genre, which can make structure and coherence problems subtle. The more subtle a problem is, more difficult it is to be automatic treated.

Besides the corpus differences, most of systems presented in the literature that realize coherence analysis are in the context of Automatic Essay Scoring (Lapata and Barzilay, 2005), which is also different from our context of work. We cite three scoring systems which considers aspects of coherence when grading essays: *Criterion* (Burstein et al., 2003; Higgins et al., 2004; Burstein et al., 2010), *Intelligent Essay Assessor* (Landauer et al., 2003), and *Intellimetric* (Elliot, 2003). Unlike these systems, SciPo is a writing support system, which means that we are not interested in to ascribe a score to it, but we want the system to be able to detect a possible structure and coherence issues and give some comprehensible feedback to the writer. The three cited systems employ the Latent Semantic Analysis (Landauer et al., 1998) to extract text features related to coherence aspects, and the results reported by them have motivated their use in our work .

2 Corpus and Annotation

In order to analyze coherence issues that may occur in academic texts written in Portuguese by undergraduate students, we have collected 385 abstracts of monographs written as part of the requirements for achieving a BS degree in Computer Science. The corpus annotation was processed in two distinctive parts: (i) rhetorical structure annotation and (ii) coherence annotation, as following described.

2.1 Rhetorical Structure Annotation and Analysis

Each abstract has the correspondent work's title attached to it. Also, each sentence was previously delimitated with appropriate beginning/ending tags. Then, we used AZPort (Feltrim et al., 2006) to label each sentence accordingly to its rhetorical status (Teufel and Moens, 2002). AZPort is a Naive Bayesian classifier that renders each input sentence a set of six possible categories, namely Background, Gap, Purpose, Methodology, Result, and Conclusion. These categories correspond to the components that make up the rhetorical structure model proposed by Feltrim et al. (2006) to academic abstracts.

We manually revised the resulting annotated corpus and corrected possible mistakes made by AZPort. Thus, the noise from the automatic annotation of rhetorical structure does not interfere in the coherence annotation. A total of 2,293 sentences were automatically annotated and manually revised. The distribution of categories in the annotated corpus is presented in Table 1.

Categories	Sentence (N)	Distribution(%)
Background	808	35.23
Gap	215	09.38
Purpose	426	18.58
Methodology	273	11.90
Result	451	19.67
Conclusion	120	05.24
Total	2,293	100

Table 1: Rhetorical categories distribution.

It can be observed in Table 1 that Background is the most frequent category (34.78% of all sentences). The prevalence of category can be explained by the corpus nature. When writing monographs abstracts, writers usually are not limited to a fixed maximum of words, thus they tend to write more sentences contextualizing the work. This is not true for papers abstracts, which tend to be limited in length and, therefore, leading writers to focus on Purpose and Result (Feltrim et al., 2003). In our corpus, Purpose and Result are also frequent categories, accounting for 19.63% and 19.41% of all sentences, respectively. Methodology, Gap and Conclusion categories were less frequent.

2.2 Coherence Annotation and Analysis

Following Higgins et al. (2004), we have tried to identify and annotate semantic relations among specific rhetorical categories, but taking into consideration that we are dealing with abstract sections of academic texts and that we want to use the resulting information as a resource to formulate useful feedback to SciPo users. We came up with an adaptation of the four dimensions proposed by Higgins et al. (2004), resulting in four kinds of relations that we also called dimensions: (i) Dimension Title, (ii) Dimension Purpose, (iii) Dimension Gap-Background, and (iv) Dimension Linearity-Break. Each dimension is described as follows.

2.2.1 Dimension Title

We assume that the title of an academic text should reveal the main topics treated in it. We also assume that the abstract of an academic text should

inform the reader about these topics, even though in a summarized form. The lack of relationship between the abstract sentences and the title may be an evidence of two possible situations: (i) the title is inappropriate for the abstract or (ii) the abstract has coherence problems.

In order to proceed with the corpus annotation, we have assumed that the abstracts titles were always appropriate and then we verified the semantic similarity between each sentence in the abstract and its title. Each sentence was labeled as *high* if it is strongly related to the title. Otherwise, it was labeled as *low*. We have decided to use a binary scale rather than a finer grained one due to the subjective nature of the task. Even with only two possible labels, the agreement between two human annotators measured by the Kappa statistics over a randomly selected subset of 209 sentences of the corpus and was around 0.6 (see Table 4).

Over a total of 2,293 sentences, 1,050 (46.80%) were ranked as been weakly related to the title (*low* sentences) and 1,243 (54,20%) as been strongly related (*high* sentences). The distribution of *high* and *low* sentences among the six possible rhetorical categories is presented in Table 2.

	Sentences	
Categories	High	Low
Background	364	444
Gap	104	111
Purpose	355	071
Methodology	139	134
Result	220	231
Conclusion	061	059
Total	1,243	1,050

Table 2: Dimension Title annotation.

It can be observed in Table 2 that Purpose sentences tend to have a strong level of relatedness to the title, since 83.33% of such sentences were ranked as *high*. It is much higher than the average of *high* sentences for other categories, which is 48.79%. Background sentences are the less related to the title, having more than half of the total of sentences (54.95%) ranked as *low*. In fact, these are not surprising results. Background sentences usually appears at the beginning of the abstract with the purpose of establishing the context of the research and, therefore, may not be directly related to the main topics of the research being presented. Instead, it may address questions or state facts of a broader area of study, which will prepare the reader to understand the motivations that led to the presented work. Thus, the detection of a weak relationship between the title and a Background sentence cannot be assumed as a coherence problem. On the other hand, Purpose sentences are expected to address directly the main topics treated by the research and then to be strongly related to the title. This is in accordance with the traditional "general — specific — general" model accepted as standard for scientific texts (Swales, 1990; Weissberg and Buker, 1990), especially introduction and abstract sections. Therefore, the existence of a weak relationship between Purpose sentences and the title probably indicates a coherence issue. With respect to the remaining rhetorical categories (Gap, Methodology, Result, and Conclusion), its relatedness to the title is quite balanced, with an average of 50.5% of *low* sentences and 49.5% of *high* sentences over a total of 1,059 sentences. In our observations, the relatedness of these categories of sentences to the title depends on other aspects than coherence, like the very nature of the research being reported. Thus, we cannot assume that the lack of a strong relationship between a sentence of these categories and the title may indicate a coherence problem.

Taking into account these results, we have concluded that the analysis of this dimension can be used as an indicative of a possible coherence problem in the Purpose rhetorical component of the abstract.

2.2.2 Dimension Purpose

The relationship between a rhetorical component and other components dictates the global coherence of the text (Higgins et al., 2004). Therefore, for an abstract to be easy to follow and understand, the rhetorical components must be related. Taking into consideration the rhetorical structure model used for the annotation of the corpus, it is expected the Purpose component to be related to Methodology, Result and Conclusion components. Thus, we understand that the absence of relationship between each of these components and the Purpose component can be an indication of a coherence problem.

For each abstract in the corpus, we have verified the semantic similarity between the sentences labeled as Purpose and the remaining sentences of the abstract. Each non-Purpose sentence was labeled as *high* if it is strongly related to Purpose; otherwise, it was labeled as *low*. The label *n/a* was assigned to sentences of abstracts which do

not have Purpose sentences. We have measured the agreement between two human annotators by the Kappa statistics over a randomly selected subset of 167 sentences of the corpus and was around 0.8 (see Table 6).

Apart from 573 sentences (426 Purpose sentences and 147 *n/a* sentences distributed among the other five categories), 1,720 sentences were labeled as *high/low* for this dimension. Over this total of sentences, 704 (40.93%) were ranked as been weakly related to the Purpose (*low* sentences) and 1,016 (59,07%) as been strongly related to the Purpose (*high* sentences). The distribution of *high* and *low* sentences among the rhetorical categories is presented in Table 3.

	Sentences	
Categories	High	Low
Background	378	380
Gap	129	079
Methodology	171	082
Result	264	135
Conclusion	074	028
Total	1,016	704

Table 3: Dimension Purpose annotation.

As it can be observed in Table 3, the sentences most related to the Purpose indeed are those labeled as Conclusion, Methodology, and Result. The percentages of *high* sentences for these categories are 72.55%, 67.59%, and 66.17%, respectively. It is worth noticing that the percentage of *high* sentences for Methodology, and Result categories could be even higher, as many sentences of these categories restate the content of the Purpose component by the use of anaphoric expressions, which decreases the level of semantic relationship between the sentences.

Once again, the general nature of Background sentences have placed them as the higher percentage of *low* sentences (50.13%). In fact, Background sentences tend to be closely related to Gap sentences then to Purpose ones, so the low level of relationship between Background and Purpose sentences cannot be assumed as a possible coherence problem.

We have concluded that the analysis of the Dimension Purpose for Methodology, Result, and Conclusion sentences can be used to detect possible coherence problems involving these rhetorical components.

2.2.3 Dimension Gap-Background

As noted earlier, Background sentences tend to be closely related to Gap sentences then to Purpose ones. Thus, it is expected that the Gap component is related with at least one sentence of Background. Therefore, we understand that the absence of relationship between these components can be an indication of a coherence problem.

For each abstract with Gap and Background sentences in the corpus, we have verified the semantic relationship between the sentences of these categories. Each Gap sentence was labeled as *yes* if it is strongly related with some Background sentence; otherwise, it was labeled as *no*.

Apart from 32 sentences belonging to abstracts which do not have Gap/Background sentences, 183 sentences were labeled as *yes/no* for this dimension. Over this total of sentences, 74.86% were ranked as *yes* and 24.14% were ranked as *no*. We have measured the agreement between two human annotators by the Kappa statistics over a randomly selected subset of 46 sentences of the corpus and was around 0.7 (see Table 8).

Taking into consideration the annotation results for this dimension, we have concluded that the analysis of the Dimension Gap-Background can be used to detect possible coherence problems involving the relationship between the rhetorical components Gap and Background.

2.2.4 Dimension Linearity-break

This dimension focuses on detecting linearity breaks between adjacent sentences. Unlike to the other dimensions, Linearity-break is independent of the rhetorical structure of the abstract. A human annotator was instructed to label sentences *yes* when there was a difficulty in establishing a logical connection between the current sentence and its previous and/or its following sentence. Otherwise, the annotator was instructed to label sentences *no*.

Over a total of 2,293 sentences, only 153 were ranked as *yes* (7.14%). This indicates that it is relatively rare to find a sentence which is not related to its adjacencies, as 92.86% of all sentences in our corpus were ranked as *no* with respect to this dimension. In fact, the analysis of this dimension indicates very local coherence issues, which we believe to be more frequent in texts with more serious writing problems than the ones observed in the texts of our corpus.

3 Automatic Analysis of Coherence

As previously stated, the purpose of this work is to develop complementary functionalities for the SciPo system to be capable of identifying semantic coherence related aspects in academic abstracts written in Portuguese. The feedback to be provided by the new functionalities proposed in this work aims at highlighting the presence of potential issues related to semantic coherence in academic abstracts, especially the ones related to Dimension Title, Dimension Purpose, and Dimension Gap-Background.

3.1 Development

For performing the automatic analysis of Dimension Title, Purpose and Gap-Background, we developed classifiers induced by machine learning algorithms and based on features extracted from the text surface and from LSA processing.

The first stage is the annotation of the rhetorical structure of the abstract. In our experiments, we have used abstracts whose automatically assigned rhetorical labels were manually revised. As noted earlier, this is necessary so that the noise from the automatic annotation of rhetorical structure does not interfere in predicting coherence judgments. Nevertheless, in a final version of the semantic coherence analysis module we would use the rhetorical labels assigned by AZPort, and further evaluation of the effect of using these automatically assigned labels is necessary.

The next stage for the semantic coherence analysis concerns the LSA processing. Some pre-processing was required and it proceeds in three steps for all sentences in the corpus: (i) case folding (for data standardization), (ii) stop words removal, and (iii) stemming. These three steps contribute to a better performance of the attributes extracted based on LSA. After data pre-processing and build of a significant semantic space, LSA allows to make comparisons between sentences in order to extract features of the texts. The comparisons took in to account the semantic relation between each pair of sentences based on the LSA model, where the level of similarity is given by the frequency of sentences occurring in similar contexts. For each of the 385 abstracts, we performed all possible comparisons between pairs of sentences within a same abstract, including the abstract title sentences.

3.2 Attribute Extraction

We extracted a set of 13 features for each sentence in the corpus. We have used the features proposed by Higgins et al. (2004) as a starting point for our owns. All features were automatically extracted and used in the induction of the classifiers. The complete set of features is:

1. Rhetorical category of the target sentence;
2. Rhetorical category of the sentence that precedes the target sentence;
3. Rhetorical category of the sentence that follows the target sentence;
4. Presence of words that may characterize an anaphoric element;
5. Position of the sentence within the abstract, computed based on the beginning of the abstract;
6. Presence of words that may characterize some kind of transition;
7. Length of the target sentence measured in words;
8. Length of the title measured in words;
9. LSA similarity score of the target sentence with its preceding sentence;
10. LSA similarity score of the target sentence with its following sentence;
11. LSA similarity score of the target sentence with the entire abstract title;
12. LSA similarity score of the target sentence with all the sentences of the abstract classified as Purpose; and
13. Maximum LSA similarity score of the target Gap sentence with some Background sentence of the abstract.

Features 1 to 8 are based on the abstract rhetorical structure and other shallow measures. Features 9 to 13 are based on LSA processing. Features 1 to 10 compose our basic pool of features and were used in the induction of all classifiers. Feature 11 was added to the basic pool of features when inducting Dimension Title classifier. For each sentence in an abstract, Dimension Title classifier uses the extracted features to predict whether it is strongly/weakly related to the title (*high/low* categories). Similarly, feature 12 was added to the basic pool of features for the induction of Dimension Purpose classifier. This classifier uses the extracted features to predict, for each sentence

in an abstract, whether it is strongly/weakly related to the Purpose sentences of the target abstract (also *high/low* categories). Feature 13 is extracted only of Gap sentences in abstracts that also have Background sentences. Thus, Dimension Gap-Background classifier uses the basic pool of features plus feature 13 to predict, for each Gap sentence in an abstract, whether it is related with at least one Background sentence (*yes/no* categories).

4 Evaluation of Classification Models

Based on the extracted features, we generated and evaluated classification models for Dimension Title, Purpose and Gap-Background. For each dimension, we trained and tested 15 different machine learning algorithms using the implementations provided by the WEKA (Witten and Frank, 2005), resulting on a total of 45 classifiers. Among the classes of algorithms that we evaluated are decision trees, rule induction, probabilistic models, support vector machines, linear regression, and others. All the classifiers were inducted using 10-fold stratified cross-validation and the set of features. The performance was measured by comparing the system's prediction with one human annotation. We assumed the annotation performed by one of the subjects in the previous annotation experiment as our "gold standard" and used it as training material. The best model for each dimension was used for further experiments and evaluation.

For each dimension, we also report the performance of a simple baseline measure, which always assigns the prevalent category (*high*/*low* or *yes*/*no*) to every sentence.

4.1 Classification Model for Dimension Title

Among the evaluated learning algorithms for Dimension Title, MultiBoostAB implemented based on Webb (2000) presented the best performance. Using C4.5 (Quinlan, 1993) as the base learning algorithm, MultiBoostAB combines boosting and wagging techniques for forming decision committees. The MultiBoostAB classifier achieved F-measure of 0.811 for the *high* category, and 0.782 for the *low* category. We also evaluated the performance of each of our features for this dimension. As expected, feature 11 (LSA similarity score of the target sentence with the entire abstract title) achieved the best performance.

In order to analyze the performance of the classification model with regard to each rhetorical category, we inducted and evaluated six different classifiers, one for each rhetorical category. Each of these classifiers was trained using the abstracts titles and a set of sentences of the target category. Baselines classifiers were also evaluated for each category. The baseline performance for all the Dimension Title classifiers in terms of Precision, Recall, F-measure, accuracy, and Kappa is presented in Table 4. The performance of each Dimension Title classifier also in terms of Precision, Recall, F-measure, Accuracy, and Kappa is presented in Table 5. The Kappa measure shown in Table 4 refers to the agreement between two human annotators. In Table 5, refers to the agreement among each classifier and our "gold-standard".

As shown by the results reported on Table 4 and Table 5, all our MultiBoostAB classifiers outperform the baseline. The best performance, both in terms of F-measure and Kappa, was achieved by the Purpose classifier. The Kappa above 0.8 indicates high agreement between classifier and human annotator.

Looking at the performance of the classifiers for *high* and *low* sentences, it can be observed that most of them perform better for *high* sentences. We ascribe this to the lower level of ambiguity in assigning a sentence as *high*. In fact, our human annotators have found more difficulties in ranking a sentence as being weakly related to the title (*low* sentences) than in ranking it as strongly related (*high* sentences). They claim the existence of a higher level of ambiguity in *low* sentences than in *high* sentences.

As for the superior performance of the Purpose classifier, we attribute that to the strong relationship between the content of Purpose sentences and the title, as previously discussed, and to the fact that Purpose sentences usually are clear and objective, presenting well defined lexical and syntactic markers. In general, it is possible to say that there is less ambiguity in ranking a Purpose sentence as strongly/weakly related to the title than ranking the relationship of a Background sentence to the title.

Both the evaluation results for the classification model and the semantic content of Purpose sentences leads us to employ the Dimension Title automatic evaluation only to sentences rhetorically categorized as Purpose.

4.2 Classification Model for Dimension Purpose

Among the evaluated learning algorithms for Dimension Purpose, SimpleLogistic, an algorithm of logistic regression implemented based on Sumner et al. (2005), presented the best performance. The SimpleLogistic classifier achieved F-measure of 0.868 for the *high* category, and 0.801 for the *low* category. Once again, the strongest feature was one of the LSA set, feature 12 (LSA similarity score of the target sentence with all the sentences of the abstract classified as Purpose).

In order to analyze the performance of the classification model with regard to each rhetorical category, we inducted and evaluated five different classifiers, one for each rhetorical category except Purpose. Each of these classifiers was trained using Purpose sentences and a set of sentences of the target category. Baselines classifiers were also evaluated for each category. The baseline performance for all the Dimension Purpose classifiers in terms of Precision, Recall, F-measure, Accuracy, and Kappa is presented in Table 6. The performance of each Dimension Purpose classifier also in terms of Precision, Recall, F-measure, Accuracy, and Kappa is presented in Table 7. The Kappa measure shown in Table 6 refers to the agreement between two human annotators. In Table 7, refers to the agreement among each classifier and our "gold-standard".

The results reported on Table 6 and Table 7 show that all our SimpleLogistic classifiers outperform the baseline. The best performance, both in terms of F-measure and Kappa, was achieved by the Gap classifier. The Kappa for this classifier is 0.754, which indicates a good level of agreement between classifier and human annotator. Apart from Background classifier, all four classifiers performed well. As discussed earlier, it is not surprising that the Background classifier present a weaker performance, as the semantic content of Background sentences usually are general, and, therefore, semantically distant from the Purpose.

Taking into account the F-measure values only for *high* sentences, the best performance was achieved by the Conclusion classifier. In most cases, Conclusion sentences that are strongly related to Purpose, reintroduce the topics stated in the Purpose, even if in a broader context. Again, it is accordance with "general—specific—general" model for scientific texts.

It can also be observed on Table 7 that the Methodology classifier presents the second worse performance on this dimension (it outperforms only the Background classifier), despite the strong relationship between the Methodology and Purpose components. We ascribe this to the characteristics of Methodology sentences, which usually introduce new nouns to the abstract, such as names of techniques, metrics, and other. These newly introduced nouns cause a low LSA score between Methodology and Purpose sentences, contradicting the human annotator whose analysis considers more than just the text surface.

	High			Low			Total

Conclusion (N=102)	0.897	0.946	0.921	0.833	0.714	0.769	0.882	0.691
All sentences (N=1,720)	0.852	0.885	0.868	0.824	0.778	0.801	0.841	0.669

Table 7: SimpleLogistc performance on Dimension Purpose.

Both the evaluation results for the classification model and the results from the manual annotation process leads us to employ the Dimension Purpose automatic evaluation to sentences categorized Methodology, Result, and Conclusion.

4.3 Classification Model for Dimension Gap-Background

Considering the evaluated learning algorithms for Dimension Gap-Background, DecisionTable implemented based on Kohavi (1995) presented the best performance. The classifier achieved F-measure of 0.935 for the *yes* category, and 0.795 for the *no* category. We evaluated the performance of each of our features and feature 13 (Maximum LSA similarity score of the target sentence with some Background sentence of the abstract) achieved the best performance. The baseline performance and the DecisionTable classifier in terms of Precision, Recall, F-measure, Accuracy, and Kappa is shown in Table 8.

As shown the Table 8, our classifier outperforms the baseline. Furthermore, the Kappa measured between the classifier and our "gold-standard" was 0.731, which indicates high agreement between the classifier and the human annotator.

Looking at the performance of the classifier, it can be observed that most of them perform better for *yes* sentences. We ascribe this to the presence of anaphoric references in Gap sentences, which decrease the level of semantic relationship. Furthermore, we have a smaller number of sentences ranked as *no* (24.14%).

Evaluation results for the classification model and the results from the manual annotation process encourage us to employ the automatic evaluation of Dimension Gap-Background to sentences rhetorically categorized as Gap in abstracts that have both Background and Gap sentences.

5 Conclusions and Future Work

This work mainly proposes to present four coherence-related dimensions that can be incorporated to the SciPo system. We believe such a proposal to be novel in the context of academic writing, especially in Portuguese.

We also presented how the three dimensions can be automated by using classification models. Dimension Title, Purpose and Gap-Background models present good results and should be incorporated to SciPo as new functionalities. On the other hand, taking into consideration the annotation process, we observed difficulties to label the sentences with regard to the Dimension Linearity-break. Therefore, due to the annotation ambiguity and the low number of examples found, we do not present the classification model for Linearity-break in this work. We believe that such a dimension can be applied to future works in a corpus with can provide more examples of linearity break as, for instance, texts generated by automatic summarizers. In addition, an alternative to be considered in analyzing Dimension Linearity-break is the use of the Entity-grid model proposed by Barzilay and Lapata (2008), which treats local coherence aspects.

Abstract

This paper presents a hierarchical Bayesian model based on latent Dirichlet allocation (LDA), called subjLDA, for sentence-level subjectivity detection, which automatically identifies whether a given sentence expresses opinion or states facts. In contrast to most of the existing methods relying on either labelled corpora for classifier training or linguistic pattern extraction for subjectivity classification, we view the problem as weakly-supervised generative model learning, where the only input to the model is a small set of domain independent subjectivity lexical clues. A mechanism is introduced to incorporate the prior information about the subjectivity lexical clues into model learning by modifying the Dirichlet priors of topic-word distributions. The subjLDA model has been evaluated on the Multi-Perspective Question Answering (MPQA) dataset and promising results have been observed in the preliminary experiments. We have also explored adding neutral words as prior information for model learning. It was found that while incorporating subjectivity clues bearing positive or negative polarity can achieve a significant performance gain, the prior lexical information from neutral words is less effective.

1 Introduction

Subjectivity detection seeks to identify whether the given text expresses opinions (subjective) or reports facts (objective). Such a task of distinguishing subjective information from objective is useful for many natural language processing applications. For instance, sentiment classification often assumes that the input documents are opinionated, and ideally only contain subjective statements. Document summarization systems need to summarize different perspectives and opinions. For question answering systems, extracting and presenting information of the appropriate type, i.e., opinions or facts, is imperative according to the specific question being asked (Yu and Hatzivassiloglou, 2003; Wiebe and Riloff, 2005; Pang and Lee, 2008).

Work on sentence-level subjectivity detection is relatively sparse compared to document-level sentiment classification. Early work used a bootstrapping algorithm to learn subjective (Riloff and Wiebe, 2003) or both subjective and objective (Wiebe and Riloff, 2005) expressions for sentence-level subjectivity detection. In contrast to bootstrapping, there has been some recent attempts exploring various n-gram features and different level of lexical instantiation for detecting subjective utterance from conversation data (Wilson and Raaijmakers, 2008; Raaijmakers et al., 2008; Murray and Carenini, 2009).

However, the aforementioned line of work tackled subjectivity detection either as supervised or semi-supervised learning, requiring labelled data and extensive knowledge which are expensive to acquire. On the other hand, both subjectivity and sentiment are context sensitive and in general quite domain dependent (Pang and Lee, 2008), so that classifiers trained on one domain often fail to produce satisfactory performance when shifted to new domains (Gamon et al., 2005; Blitzer et al., 2007). Moreover, user generated content from web are often massive and evolve rapidly over time, which imposes more challenges to the subjectivity detection task. These observations have thus motivated us to develop a subjectivity detection algorithm that is relatively simple compared to existing methods (e.g., based on bootstrapping or n-gram features), and yet can easily be trans-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1153–1161,
Chiang Mai, Thailand, November 8 – 13, 2011.

ferred between domains through unsupervised or weakly-supervised learning without using any labelled data.

In this paper, we focus on the problem of weakly-supervised sentence-level subjectivity detection. Instead of learning subjective extraction patterns or exploring various n-gram features, we view the problem as generative model learning with the proposed subjectivity detection LDA (subjLDA) model. In this model, the generative process involves: (1) three subjectivity labels for sentences (i.e., sentence expresses subjective opinions as being positive/negative, or states facts as being objective); (2) a sentiment label for each word in the sentence (either positive, negative, or neutral), and (3) the words in the sentences.

We test the subjLDA model on the publicly available Multi-Perspective Question Answering (MPQA) dataset. Two lists of domain independent subjectivity lexicons, namely the subjClue and SentiWordNet lexicons (Esuli and Sebastiani, 2006), were incorporated as prior knowledge for subjLDA model learning. Preliminary results show that the weakly-supervised subjLDA model is able to significantly outperform baseline. Furthermore, it was found that while incorporating subjectivity clues bearing positive or negative polarity can achieve a significant performance gain, the prior lexical information from neutral words is less effective for improving the classification accuracy.

The rest of the paper is organized as follows. Section 2 reviews the previous work on subjectivity classification. Section 3 presents the subjLDA model. Experimental setup and results on the MPQA dataset are discussed in Sections 4 and 5, respectively. Finally, Section 6 concludes the paper and outlines the future work.

2 Related Work

2.1 Subjectivity Detection

While sentiment classification and subjectivity detection are closely related to each other, it has been reported that separating subjective and objective instances from text is more difficult than sentiment classification, and the improvement of subjectivity detection can benefit the latter as well (Mihalcea et al., 2007).

Early work by Riloff and Wiebe (2003) focused on a bootstrapping method for sentence-level subjectivity detection. They started with high-precision subjectivity classifiers which automatically identified subjective and objective sentences in un-annotated texts. The subjective expression patterns were learned from syntactic structure output from the previously labelled high confidence texts. The learned patterns were used to automatically identify additional subjective sentences, which enlarged the training set, and the entire process was then iterated. Wiebe and Riloff (2005) used very similar method for subjectivity detection as Riloff and Wiebe (2003). But they moved one step forward that they also learned objective expressions apart from subjective expressons. As the subjective/objective expression patterns are based on syntactic structures, they are more flexible than single words or n-grams.

Wilson and Raaijmakers (2008) compared the performance of classifiers trained using word n-grams, character n-grams, and phoneme n-grams for recognizing subjective utterances in multiparty conversation. Raaijmakers et al. (2008) extended the work in (Wilson and Raaijmakers, 2008) by further analyzing the performance of detecting subjectivity in meeting speech by combining a variety of multimodal features including additional prosodic features. More recently, Murray and Carenini (2009) proposed to learn subjective expression patterns from both labeled and unlabeled data using n-gram word sequences. Their approach for learning subjective expression patterns is similar to (Raaijmakers et al., 2008) which relies on n-grams, but goes beyond fixed sequences of words by varying levels of lexical instantiation as in (Riloff and Wiebe, 2003).

2.2 Weakly-supervised Sentiment Classification

In this section, we first review some work in sentiment analysis using generative models as it partly inspires our work of viewing subjectivity detection as generative model learning. We then discuss other weakly-supervised sentiment classification approaches which also use prior word knowledge.

Intuitively, sentiment or subjectivity are context dependent. Therefore, modelling topic coupled with sentiment should serve a critical function in sentiment analysis. There has seen several lines of work pursuing this direction. Eguchi and Lavrenko (2006) considered the topic dependence of sentiment and combined sentiment mod-

els with topic models for sentiment retrieval. Mei et al. (2007) proposed the topic-sentiment mixture (TSM) model for capturing mixture of topics and sentiment simultaneously on Weblogs. The multi-aspect sentiment (MAS) model by Titov and McDonald (2008) focused on aggregating sentiment text for sentiment summary of rating aspects.

The more recently proposed joint sentiment-topic (JST) model (Lin and He, 2009; Lin et al., 2010) holds the closest paradigm to the proposed subjLDA model. They targeted document-level sentiment detection with weakly-supervised generative model learning, where the only knowledge being incorporated was from generic sentiment lexicons. In the JST model, topics are assumed to be generated dependent on sentiment distributions and then words are generated conditioned on sentiment-topic pairs. However, there are several intrinsic differences between JST and subjLDA: (1) JST mainly focused on document-level sentiment classification, while, in contrast, subjLDA has a different scope of targeting sentence-level subjectivity detection; (2) in JST the prior knowledge was encoded during the Gibbs sampling by assigning a word with its prior sentiment label if that word appears in the sentiment lexicon. This essentially places hard sentiment label to words and can not resort the situation when words have ambiguous sentiment polarity. Our proposed approach incorporates sentiment prior knowledge in a more principled way, in that we use sentiment lexicons to modify the topic-word Dirichlet priors and essentially create an informed prior distribution for the sentiment labels.

Another common solution to weakly-supervised sentiment classification is to make use of prior word polarity knowledge, where one uses a small number of seed words with known polarity to infer the polarity of a large set of unidentified terms. Turney and Littman (2002) classified the sentiment orientation of other terms in the corpus through mutual information, based on a small set of positive/negative paradigm words. Starting with a single seed word meaning "*good*" and a negation check, Zagibalov and Carroll (2008) derived a classifier through iteratively retraining, and treated sentiment and subjectivity as a continuum rather than distinct classes.

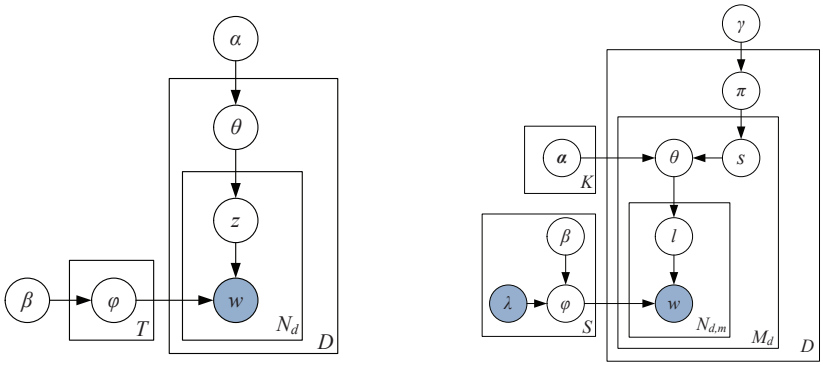
3 The SubjLDA Model

As shown in Figure 1(b), subjLDA is essentially a four-layer Bayesian model. In order to generate a word $w_{d,m,t}$ (i.e., the t^{th} word token of sentence m within document d), one first chooses a subjectivity label[1] $s_{d,m} \in [1, K]$ for each sentence in document d from the per-document subjectivity distribution π_d. Following that, one chooses a sentiment label $l_{d,m,t} \in [1, S]$ for each word in the sentences from the per-sentence sentiment distribution $\theta_{s_{d,m}}$. Finally, one draws a word from the per-corpus word distribution $\varphi_{l_{d,m,t}}$ conditioned on the corresponding sentiment label. The classification of sentence subjectivity in subjLDA is determined directly from the sentence subjectivity label $s_{d,m}$. The formal definition of the subjLDA generative process is as follows:

- For each sentiment label $l \in [1, S]$
  - Draw $\boldsymbol{\varphi}_l \sim \text{Dir}(\boldsymbol{\lambda}_l \times \boldsymbol{\beta}_l^T)$.
- For each document $d \in [1, D]$, choose distributions $\pi_d \sim \text{Dir}(\gamma)$.
- For each sentence $m \in [1, M_d]$ in document d,
  - Sample a subjectivity label $s_{d,m} \sim \text{Mult}(\pi_d)$,
  - Choose a distribution $\theta_{d,m} \sim \text{Dir}(\alpha_{s_{d,m}})$,
  - For each of the $N_{d,m}$ word position,
    - Choose a sentiment label $l_{d,m,t} \sim \text{Mult}(\theta_{s_{d,m}})$,
    - Choose a word $w_{d,m,t} \sim \text{Mult}(\varphi_{l_{d,m,t}})$.

In practice, it is quite intuitive that one classifies a sentence as subjective if it contains one or more strongly subjective clues (Riloff and Wiebe, 2003). However, the criterion for classifying objective sentences could be rather different, because a sentence is likely to be objective if there are no strongly subjective clues. In order to encode this knowledge into the subjLDA model learning, during the model initialization step, we initialized sentence subjectivity label s based on the aforementioned criterion with prior knowledge input from the sentiment lexicon. If a sentence does not match any sentiment words, its subjectivity label will be randomly sampled.

[1] We have conducted another set of experiments modelling only subjective and objective labels. It was found that subjLDA performed slightly better with 3 subjectivity labels than with binary labels. We do not report the binary label results here due to page limit.



(a) (b)

Figure 1: (a) LDA model; (b) subjLDA model.

3.1 Incorporating Model Prior

Compared to the LDA model, besides adding a sentence-level subjectivity label generation layer, we also add an additional dependency link of $\boldsymbol{\varphi}$ on the matrix $\boldsymbol{\lambda}$ of size $S \times V$ which we use to encode word prior sentiment information. The matrix $\boldsymbol{\lambda}$ can be considered as a transformation matrix which modifies the Dirichlet priors $\boldsymbol{\beta}$ so that the word prior sentiment polarity can be captured.

Intuitively, $\boldsymbol{\lambda}$ is firstly initialized as a matrix with all the elements taking a value of 1. Given a sentiment lexicon, for each term $w \in \{1, ..., V\}$ in the corpus vocabulary, if w is found in the sentiment lexicon, then for each $l \in \{1, ..., S\}$, the element λ_{lw} is updated as follows

$$\lambda_{lw} = \begin{cases} 0.9 & \text{if } S(w) = l \\ 0.05 & \text{otherwise} \end{cases}, \qquad (1)$$

where the function $S(w)$ returns the prior sentiment label of w in a sentiment lexicon, i.e., positive, negative or neutral. For example, the word "*excellent*" with index w_t has a positive sentiment polarity. The corresponding row vector λ_{w_t} is $[0.05, 0.9, 0.05]$ with its elements representing neutral, positive, and negative prior polarity. Multiplying $\boldsymbol{\beta}$ with $\boldsymbol{\lambda}$, we can enforce that the word "*excellent*"has much higher probability of being drawn from the positive topic word distributions generated from a Dirichlet distribution with parameter $\beta_{l_{pos}w_t}$.

The previously proposed DiscLDA (Lacoste-Julien et al., 2008) and Labeled LDA (Ramage et al., 2009) also utilize a transformation matrix to modify Dirichlet priors by assuming the availability of document class labels. In contrast, we use word prior sentiment as supervised information to modify the topic-word Dirichlet priors.

3.2 Model Inference

The total probability of the model is

$$P(\boldsymbol{w}, \boldsymbol{l}, \boldsymbol{s}, \boldsymbol{\theta}, \boldsymbol{\varphi}, \boldsymbol{\pi}; \alpha, \beta, \gamma) = \prod_{j=1}^{S} P(\varphi_j; \boldsymbol{\lambda} \times \boldsymbol{\beta}) \cdot \prod_{d=1}^{D} P(\pi_d; \gamma) \prod_{m=1}^{M_d} P(s_{d,m}|\pi_d) P(\theta_{d,m}; \alpha_{s_{d,m}}) \cdot \prod_{t=1}^{N_{d,m}} P(l_{d,m,t}|\theta_{d,m}) P(w_{d,m,t}|\varphi_{l_{d,m,t}}), \qquad (2)$$

where the bold-font variables denote vectors.

We use Gibbs sampling to estimate the posterior of subjLDA by sequentially sampling each variable of interest, $l_{d,m,t}$ and $s_{d,m}$ here, from the distribution over that variable given the current values of all other variables and the data. Letting the index $x = (d, m)$ and the subscript $-x$ denote a quantity that excludes counts in sentence m of document d, the conditional posterior for s_x is

$$P(s_x = k|\boldsymbol{s}_{-x}, \boldsymbol{l}, \boldsymbol{w}, \alpha, \beta, \gamma) \propto \frac{(N_{d,k} + \gamma_k) - 1}{(N_d + \sum_{k=1}^{K} \gamma_k) - 1} \cdot \frac{\prod_{j=1}^{S} \prod_{b=0}^{N_{d,m,j}-1} (b + \alpha_{s_x,j})}{\prod_{b=0}^{N_{d,m}-1} (b + \sum_{j=1}^{3} \alpha_{s_x,j})}, \qquad (3)$$

where $N_{d,k}$ denotes the frequency of sentences assigned to subjectivity label k in document d; N_d is the total number of sentences in document d; $N_{d,m,j}$ is the total number of words in sentence m of document d associated with sentiment label j; $N_{d,m}$ is the total number of words in sentence m of document d.

In terms of the sentiment label, letting the index $y = (d, m, t)$ denote t^{th} word in sentence m of document d and the subscript $-y$ denote a quantity that excludes data from t^{th} word position, the

conditional posterior for l_t is

$$P(l_y = j|\boldsymbol{s}, \boldsymbol{l}_{-y}, \boldsymbol{w}, \alpha, \beta, \gamma) \propto \frac{N_{d,m,j} + \alpha_{s_{d,m},j} - 1}{N_{d,m} + \sum_{j=1}^{S} \alpha_{s_{d,m},j} - 1} \cdot \frac{Y_{j,w_t} + \lambda_{j,w_t}\beta_{j,w_t} - 1}{Y_j + \sum_{r=1}^{V} \lambda_{j,r}\beta_{j,r} - 1}, \quad (4)$$

where Y_{j,w_t} denotes the frequency of word w_t associated with sentiment label j in the document collection; Y_j is the total number of words associated with sentiment label j in the document collection.

Equations 3-4 are the conditional probabilities derived by marginalizing out the random variables π, θ, and φ. Samples obtained from the Markov chain are used to approximate the per-document subjectivity distribution

$$\pi_{d,k} = \frac{N_{d,k} + \gamma_k}{N_d + \sum_{k=1}^{K} \gamma_k}. \quad (5)$$

The approximated per-sentence sentiment distribution is

$$\theta_{d,m,j} = \frac{N_{d,m,j} + \alpha_{s_{d,m},j}}{N_{d,m} + \sum_{j=1}^{S} \alpha_{s_{d,m},j}}. \quad (6)$$

Finally, the per-corpus sentiment-word distribution is

$$\varphi_{j,r} = \frac{Y_{j,r} + \lambda_{j,r}\beta_{j,r}}{Y_j + \sum_{r=1}^{V} \lambda_{j,r}\beta_{j,r}}. \quad (7)$$

4 Experimental Setup

4.1 Dataset

We tested our model on the MPQA dataset[2] version 1.2, which is derived from a variety of foreign news documents. The whole corpus consists of 535 documents with a total number of 6,111 subjective and 5,001 objective sentences. We performed a two-stage preprocessing on the dataset by first removing stop words and non-word characters, followed by standard stemming for reducing vocabulary size and minimizing sparse data problems. After preprocessing, the MPQA dataset contains 131,220 words with 10,511 distinct terms (cf. the original dataset with 264,808 words and a vocabulary size of 31,201 without any preprocessing).

[2] http://www.cs.pitt.edu/mpqa/databaserelease/

4.2 Lexical Prior Knowledge

We explored incorporating two subjectivity lexicons as prior knowledge for subjLDA model learning, namely, the subjClue[3] and SentiWordNet[4] lexicons. We point out that the subjClue lexicon is not related to the MPQA dataset as it was collected from a number of sources, where some were culled from manually developed resources and others were identified automatically using both annotated and unannotated data (Wiebe and Riloff, 2005). We only extract the lexical clues that are considered strongly subjective, with the weakly subjective clues being discarded. The rationale behind the filtering is that while a strongly subjective clue is seldom used without a subjective meaning, weakly subjective clues are ambiguous, often having both subjective and objective uses. After stemming, removing the duplicated lexical terms and retaining those that have appeared in the corpus, we finally obtained a lexicon subset of 477 positive and 917 negative words.

SentiWordNet provides a wide coverage of lexical terms by tagging all the synsets of WordNet with three sentiment labels, i.e., positive, negative and neutral. In our experiment, we only use the neutral words from SentiWordNet for investigating how neutral words would affect the subjLDA model performance. After the same preprocessing as performed on the subjClue lexicon, a total of 193,871 neutral words were extracted. Further mapping the extracted neutral words with the corpus results in 6,457 neutral words.

5 Experimental Results

In this section, we first present the experimental results of sentence-level subjectivity classification on the MPQA dataset, and subsequently evaluate the impact on the classification performance by varying the proportion of prior information being incorporated. All the results reported here are averaged over 5 runs with 800 Gibbs sampling iterations.

5.1 Overall Results

The baseline is calculated by counting the overlap of the prior lexicon with the dataset. We classify a sentence as subjective if it contains one or more positive/negative sentiment words; if there is no matching, the sentence will be classified as

[3] http://www.cs.pitt.edu/mpqa/

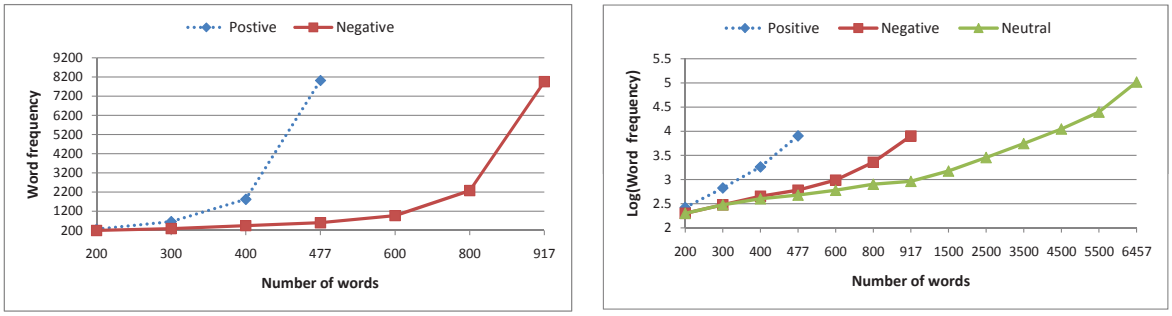
Table 1: Subjectivity classification results. (Boldface indicates the best results.)

Model	Objective (%)			Subjective (%)			Overall (%)
	Recall	Precision	F-measure	Recall	Precision	F-measure	Accuracy
Baseline	46.5	74.1	57.1	76.7	63.7	69.6	63.1
subjLDA	59.7	**71.6**	**65.1**	**80.9**	**71.0**	**75.6**	**71.2**
LDA (Sent.)	**60.5**	65.7	63.0	74.2	69.7	72.0	68.1
LDA (Doc.)	51.4	68.7	58.8	80.6	67.0	73.2	67.6
Wiebe 05	77.6	68.4	72.7	70.6	79.4	74.7	73.8



(a) (b)

Figure 2: (a) Positive and negative lexicon statistics; (b) Positive, negative and neutral lexicon statistics.

objective. The improvement over this baseline will reflect how much subjLDA can learn from data. The LDA model (Blei et al., 2003), as shown in Figure 1(a), has been used as baseline in document-level sentiment classification in previous research (Lin et al., 2010). Thus, we also evaluated LDA on the sentence-level subjectivity detection task by modelling a mixture of three sentiment topics, i.e., positive, negative and neutral. For fair comparison, we encoded prior knowledge of sentiment lexicon into LDA as identical to subjLDA. Thus the LDA model here can be considered as a weakly-supervised version. Moreover, we tested LDA under two different modes, i.e., modelling a normal document vs. treating each individual sentence as a separate document. The sentence sentiment is determined as follows.

(a) LDA in document mode: sentiment of sentence m in document D is calculated using

$$P(l|m) \propto P(m|l)P(l|d) = \prod_{w_t \in \mathrm{m}} P(w_t|l)P(l|d). \quad (8)$$

We define that sentence m is classified as an objective sentence if its probability of neutral label given sentence $P(l = neu.|m)$, is greater than both $P(l = pos.|m)$ and $P(l = neg.|m)$. Otherwise, the sentence is classified as subjective.

(b) LDA in sentence mode: sentence subjectivity is directly determined based on the per-sentence sentiment distribution θ, using identical classification metrics to the document mode.

As can be seen from Table 1, a significant performance gain was observed for both subjLDA and LDA over the baseline. Particularly, more than 8% gain was observed for subjLDA, giving the best overall accuracy of 71.2% which is 3.1% and 3.6% higher than LDA(Sent.) and LDA(Doc.), respectively. In addition, except for objective recall, subjLDA outperforms LDA in both the sentence and document modes for all the other evaluation metrics, with more balanced objective and subjective F-measures being attained compared to the other two models. On the other hand, it was observed that while LDA(Doc.) can achieve a comparable subjective F-measure to LDA(Sent.), its objective F-measure is nearly 5% lower, resulting in worse overall performance. This is probably due to the fact that by treating each individual sentence as a document, LDA(Sent.) can avoid inferencing global sentiment topics and thus capture more accurate sentiment information from local topics. We measured the overall accuracy significance with paired t-Test (critical P=0.01). Results show that the improvements of subjLDA over both LDA(sent.) and LDA(doc.) are highly statistically significant. Thus, we conclude that subjLDA is superior than LDA in the subjectivity detection task.

When compared to the previous proposed boot-

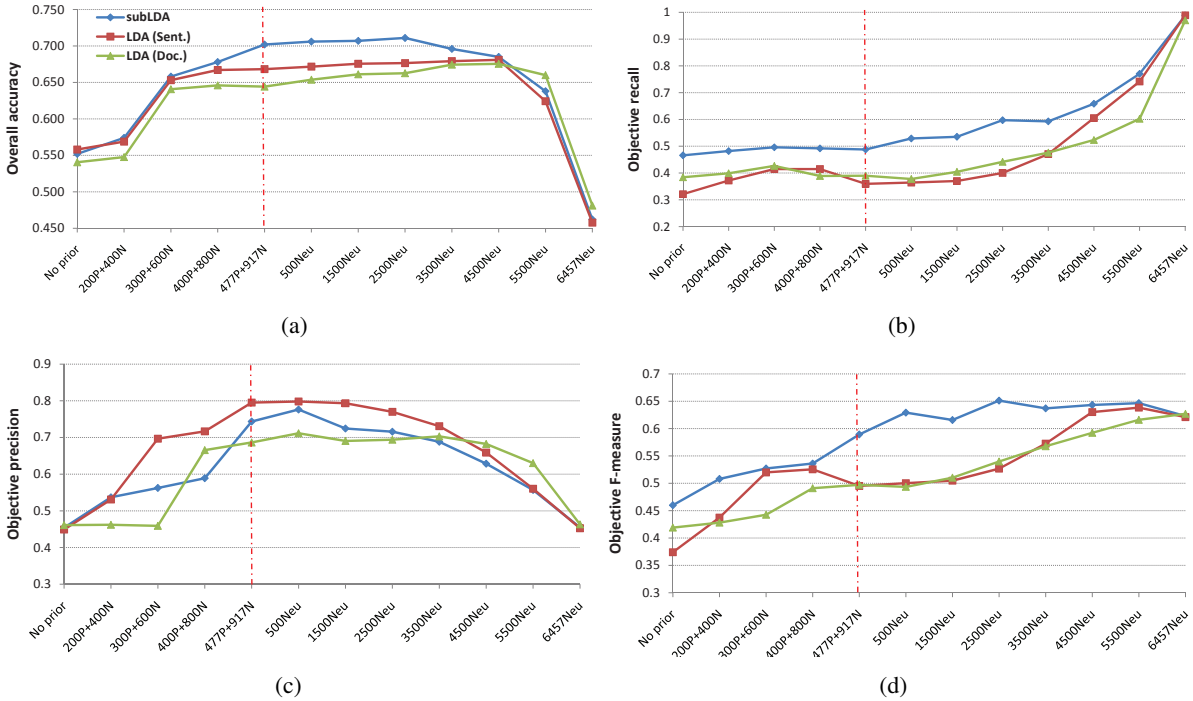


Figure 3: Subjectivity classification performance vs. different prior information by gradually adding the subjective and neutral words. The vertical dashed line denotes the point where all the positive and negative words have been incorporated into the model; 200P+400N denotes adding the least frequent 200 positive and 400 negative words; 500Neu denotes adding the least frequent 500 neutral words in addition to all the positive and negative words.

strapping approach (Wiebe and Riloff, 2005), subjLDA is about 2% lower in terms of overall accuracy. However, it should be noted that, their approach used a much larger training set for self-training which consists of more than 100,000 sentences. Moreover, apart from subjectivity clues, they also used additional features such as subjective/obejctive pattern and POS for the Naive Bayes sentence classifier training. In contrast, the proposed subjLDA model is relatively simple with only a small set of subjectivity clues being incorporated as prior knowledge.

5.2 Classification Results with Different Priors

While positive/negative sentiment lexicon is commonly used in lexical approaches to sentiment classification, the impact of incorporating neutral words remains relatively unexplored. In this experiment, we investigated the impact on the model performance by incorporating additional knowledge from neutral words. We started by first considering the positive and negative words only and gradually increased the number of words starting with the lowest frequency words. After all the positive and negative words have been incorporated, we then gradually added additional neutral words into the model also from the lowest frequency to the highest. Figure 2 shows the lexicon statistics of all the positive, negative and neutral words, where the value on the x-axis represents the number of words sorted by word frequency and the corresponding y-axis value indicates the total number of times those words appear in the corpus. For instance, the 400 least frequent positive words appear a total of 1,826 times in the corpus as shown in Figure 2(a).

Figure 3 depicts the subjectivity classification results of subjLDA and LDA by varying the proportion of lexical terms being incorporated. It is quite obvious from the overall accuracy shown in the figure that both subjLDA and LDA benefit from incorporating the information of subjective words, and in general, the more lexical items the better the results. Without using any neutral words, all the three models achieved the best results when all the subjective words were incorporated. It was noted that subjLDA performed similar to LDA when only a small number of low frequency subjective words were used. However,

with more higher frequency subjective words being incorporated, subjLDA shows stronger performance boosting over LDA and gives the best accuracy of 70.2% when all the subjective words were incorporated, being 3.4% and 5.8% better than LDA(Sent.) and LDA(Doc.), respectively, as indicated by the vertical dashed line in the figure.

On the other hand, adding neutral words is also beneficial, where performance gain was observed for all the 3 models in addition to the best results using subjective words only (i.e., subjLDA by 1%, LDA(Sent.) by 1.6% and LDA(Doc.) by 2.9%). Analyzing the objective recall and precision shown in Figure 3(b) and 3(c) reveals that, while incorporating the 4,500 least frequent neutral words considerably increases the objective recall, the objective precision does not drop much which eventually leads to the overall improvement of all the three models.

However, compared to the subjective words, the classification improvements by incorporating additional neutral words are less significant. This is probably due to the fact that while the presence of positive/negative words conveys clear subjective meanings, neutral words are relatively vague which could bear objective or subjective sense under different contexts. Furthermore, all three models experience a significant performance drop after the point of (4500Neu). Examining Figure 2 reveals that, while the 4,500 least frequent neutral words appear 11,142 times in the corpus, the 1,957 most frequent words (i.e., from 4500 to 6457) appear 93,036 times, nearly 10 times as much as the former. Thus, the high frequency neutral words become dominant in the model and result in severe classification bias towards the objective class. Therefore, appropriate filtering of neutral words is necessary in order to avoid introducing bias into model learning.

5.3 Sentiment Topics

In subjLDA, we model three topics in the per-corpus word distribution, each of which corresponds to neutral, positive and negative sentiment. Figure 4 shows the top 15 topic words of the sentiment topics extracted from the MPQA dataset by subjLDA. It can be easily observed that while the positive and negative sentiment topics consist of clear sentiment bearing words, the neutral topic contains mostly theme words with no sentiment, which illustrates the effectiveness of subjLDA in extracting sentiment bearing topics from text.

Sentiment topics		
Neutral	Positive	Negative
countri	state	terror
presid	right	opposit
unit	support	concern
govern	gener	evil
intern	want	critic
bush	interest	question

6 Conclusions and Future Work

This paper presents the subjectivity detection LDA Model (subjLDA) for sentence-level subjectivity classification. In contrast to most of the existing approaches requiring labelled corpora or linguistic pattern extraction, we view this problem as weakly-supervised generative model learning where the only input to the model is a small amount of domain independent subjective/neutral words. The subjLDA model has been evaluated on the MPQA dataset. Preliminary results show that except slightly lower in objective recall, subjLDA outperformed LDA over all other evaluation metrics, and is comparable to the previously proposed bootstrapping approach using a much larger training set. Moreover, it was found that while incorporating more subjective words can generally yield better results, the performance gain by employing extra neutral words is less significant.

There are several directions we would like to pursue in the future. While word lexical prior information is incorporated by modifying the Dirichlet prior for topic-word distributions here, it is also possible to explore other mechanisms to define expectation or posterior constraints. In addition, the current subjLDA model only models bag-of-words features, another future step would be extending subjLDA to include higher order information such as bigrams for improving model performance.

Opinion Expression Mining by Exploiting Keyphrase Extraction

Gábor Berend
Department of Informatics,
University of Szeged
2. Árpád tér, H-6720, Szeged, Hungary
berendg@inf.u-szeged.hu

Abstract

In this paper, we shall introduce a system for extracting the keyphrases for the reason of authors' opinion from product reviews. The datasets for two fairly different product review domains related to movies and mobile phones were constructed semi-automatically based on the pros and cons entered by the authors. The system illustrates that the classic supervised keyphrase extraction approach – mostly used for scientific genre previously – could be adapted for opinion-related keyphrases. Besides adapting the original framework to this special task through defining novel, task-specific features, an efficient way of representing keyphrase candidates will be demonstrated as well. The paper also provides a comparison of the effectiveness of the standard keyphrase extraction features and that of the system designed for the special task of opinion expression mining.

1 Introduction

The amount of community-generated contents on the Web has been steadily growing and most of the end-user contents (e.g. blogs and customer reviews) are likely to deal with the author's emotions and opinions towards some subject. The automatic analysis of such material is useful for both companies and consumers. Companies can easily get an overview of what people think of their products and services and what their most important strengths and weaknesses are while users can have access to information from the Web before purchasing some product.

In this paper we will introduce a system which assigns pro and con keyphrases (free-text annotation) to product reviews. When dealing with product reviews, our definition of keyphrases is the set of phrases that make the opinion-holder feel negative or positive towards a given product, i.e. they should be the reason why the author likes or dislikes the product in question (e.g. *cheap price*, *convenient user interface*). Here, we adapted the general keyphrase extraction procedure from the scientific publications domain (Witten et al., 1999; Turney, 2003) to the extraction of opinion-reasoning features. However, our task is rather different since we aim at identifying the reasons for opinions, instead of keyphrases that represent the content of the whole document.

The supervised keyphrase extractor to be introduced here was trained on the pros and cons assigned to the reviews by their authors on the `epinions.com` site. These pros and cons are ill-structured free-text annotations and their length, depth and style are extremely heterogeneous. In order to have clean gold-standard corpora, we manually revised the segmentation and the contents of the pros and cons, and obtained sets of tag-like keyphrases.

2 Related work

There have been many studies on opinion mining (Turney, 2002; Pang et al., 2002; Titov and McDonald, 2008; Liu and Seneff, 2009). Our approach relates to previous work on the extraction of reasons for opinions. Most of these papers treat the task of mining reasons from product reviews as one of identifying sentences that express the author's negative or positive feelings (Hu and Liu, 2004a; Popescu and Etzioni, 2005). This paper is clearly distinguishable from them as our goal is to find the reasons for opinions expressed by phrases and we aim the task of phrase extraction instead of sentence recognition.

This work differs in important aspects even from the frequent pattern mining-based approach of (Hu and Liu, 2004b) since they regarded the main task of mining opinion features with respect

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1162–1170,
Chiang Mai, Thailand, November 8 – 13, 2011.

to a group of products, not individually at review-level as we did. Even if an opinion feature phrase is feasible for a given product-type, it is not necessary that all of its occurrence are accompanied with sentiments expressed towards it (e.g. *The phone comes in red and black colors*, where *color* could be an appropriate product feature, but not an opinion-forming phrase).

A similar task to pro and con extraction gathers the key aspects from document sets, which has also gained interest recently (Sullivan, 2008; Branavan et al., 2008; Liu and Seneff, 2009). Existing aspect extraction systems first identify a number of aspects throughout the whole review set, then they automatically assign items from this pre-recognized set of aspects to each unseen review. Hence, they work at the corpus level and restrict themselves to using only a pre-defined number of aspects.

The approach presented here differs from these studies in the sense that it looks for the reason phrases themselves review by review, instead of multi-labeling some aspects. These approaches are intended for applications used by companies who would like to obtain a general overview about a product or would like to monitor the polarity relating to their products in a particular community. In contrast, we introduce here a keyphrase extraction-based approach which works at the document level as it extracts keyphrases from reviews which are handled independently of each other. This approach is more appropriate for the consumers, who would like to be informed before purchasing some product.

The work of Kim and Hovy (2006) lies probably the closest to our one. They addressed the task of extracting con and pro sentences, i.e. the sentences on why the reviewers liked or disliked the product. They also note that such pro and con expressions can differ from positive and negative opinion expressions as factual sentences can also be reason sentences (e.g. *Video drains battery.*). Here the difference is that they extracted sentences, but we targeted phrase extraction.

Most of the keyphrase extraction approaches (Witten et al., 1999; Turney, 2003; Medelyan et al., 2009; Kim et al., 2010) work on the scientific domain and extract phrases from one document that are the most characteristic of its content. In these supervised approaches keyphrase extraction is regarded as a classification task, in which certain n-grams of a specific document function as keyphrase candidates, and the task is to classify them as proper or improper keyphrases. Here, our task formalization of keyphrase extraction is adapted from this line of research for opinion mining and we focus on the extraction of phrases from product reviews that also bear subjectivity and induce sentiments in its author. As community generated pros and cons can provide abundant training samples and our goal is to extract the users' own words, here we also follow this supervised keyphrase extraction procedure.

3 Opinion Phrase Extraction Framework

Here, we employed a supervised machine learning approach for the extraction of reason keyphrases from a given review. Candidate terms were extracted from the text of the review and those present in the extracted set of pros and cons were regarded as positive examples during training and evaluation. Maximum Entropy classifiers were trained and the keyphrase candidates with the highest posteriori probabilities were selected to be keyphrases for a review of a test document in question. In the following subsections we will describe how keyphrase candidates and the feature space representing them were constructed.

3.1 Candidate term generation

One key aspect in keyphrase extraction is the way keyphrase candidates are selected and represented. As usually the number of potentially extracted n-grams and that of genuine keyphrases among them show high imbalancedness, keyphrase candidates are worth to be filtered, instead of using any successive n-grams. For this reason we limited the maximal length of the extracted phrases to at most 4 tokens and also required that the phrases should begin with either a non-stopword adjective, verb or noun and should end to either a non-stopword noun or adjective.

As for the filtration of the candidate set, a new step is introduced here, which omits normalized phrases that had only such occurrences which contained stopwords. This simple step proved effective in excluding many non-proper opinion phrases (i.e. increasing the maximal precision achievable) at the cost of discarding only a small proportion of proper phrases (i.e. slightly decreasing the best recall achievable).

Once we had the keyphrase candidates, they had

to be brought to a normalized form. The normalization of an n-gram consisted of lowercasing and Porter-stemming each of the lemmatized forms of its tokens, then putting these stems into alphabetical order (while omitting the stems of stopword tokens). With this kind of representation it was then possible to handle two orthographically different, but semantically equivalent phrases, such as '*the screen is tiny*' and '*TINY screen*' in the same way.

Previous works on keyphrase extraction also usually carry out this step of normalization, however, here we did it in such a manner that a mapping to each of the original orthographic forms of a normalized form and its corresponding context (i.e. the sentences containing it) was preserved at the same time and that could be successfully utilized at later processing steps.

To provide an alternative way of normalizing phrases, experiments relying on the usage of WordNet (Fellbaum, 1998) were also conducted. In these settings the normalized form of a single token was determined by first searching for all its synsets (in the case of verbs, these were such noun synsets that were in derivative relation with the synsets of the verb word form). Then instead of Porter-stemming the original token, its most frequent word form was stemmed, based on the estimated frequencies of WordNet for all the word forms of the synsets of the original token. In this way two – originally differently stemmed – word forms, such as *decide* and *decision* could be stemmed to the same root forms. Another advantage of this procedure is that it is able to handle semantic similarity to some extent.

The remaining parts of the normalization procedure were left unchanged (i.e. lowercasing and alphabetical ordering of the normalized forms of the individual tokens). Later, in the Results section, the effect of this kind of normalization will be shown.

Candidate terms were handled at the review level instead of occurrence level. This means that each normalized occurrence of a keyphrase candidate was gathered from the document and the feature values for the candidate term aggregate over its occurrences.

3.2 Feature representation

We constructed a rich feature set to represent the review-level keyphrase candidates. The feature space incorporates features calculated on the basis of the normalized phrases themselves, but more importantly, thanks to the mapping between the normalized phrase forms and their original occurrences, new contextual and orthographic features were possible to incorporate.

Features that could be generally used for any kind of keyphrase extracting task (e.g. that makes use of multiword expressions or character suffixes in a special way) and ones designed especially for the novel task of opinion phrase extraction (e.g. that uses SentiWordNet to determine polarity) as well as the standard features of keyphrase extraction are both introduced in the following.

Standard Features Since we assumed that the underlying principles of extracting opinionated phrases are quite similar to that of extracting standard (most of the time scientific) keyphrases, features of the standard setting were applied in this task as well. The most common ones, introduced by KEA (Witten et al., 1999) are the **Tf-idf** value and the **relative position** of the first occurrence of a candidate phrase within a document. We should note that KEA is primarily designed for keyphrase extraction from scientific publications and whereas the position of the first occurrence might be indicative in research papers, product reviews usually do not contain a summarizing "abstract" at the beginning. For these reasons we chose these features as the ones which form our baseline system. **Phrase length** is also a common feature, which was defined here as the number of the non-stopword tokens of an opinion phrase candidate.

Linguistic and orthographic features Since certain POS-codes are more frequent than others among genuine keyphrases, features generated by POS-codes belonging to an occurrence of a normalized phrase were applied. As **POS-code** sequences seem to be more informative, instead of simply indicating which POS-codes were assigned to any orthographic alternation of a normalized keyphrase candidate, it would be desirable to store the POS-code sequences in their full length as well. However, doing so might affect dimensionality in a negative way (especially when having few training data), i.e. the number of all the possible POS-code sequences ranging from lengths of 1 to 4 is too much. To overcome this issue, positional information was added to the POS-code features derived from the tokens of an n-gram. Features

of POS-codes that were assigned to a token being itself a 1-token long keyphrase candidate, at the beginning, at the end, in between an n-gram, got a prefix `S-`, `B-`, `E-` and `I-`, respectively. For instance, the phrase *cheap/JJ phone/NN* induces the features {*B-JJ*, *E-NN*}, whereas the 1-token-long phrase *cheap/JJ* induces the feature {*S-JJ*}. Finally, numeric values for a normalized candidate phrase were assigned based on the distribution of the different POS-related features of all the running-text forms of a normalized phrase.

We introduced features exploiting the syntactic context of a candidate with parse trees. For an n-gram with respect to all the sentences it was contained in a given document, this feature stored the average and the minimal depths of those **NP-rooted trees** that contained the whole n-gram in its yield. These features are intended to express the "noun phraseness" of the phrase.

Features generated from the **character suffixes** of the individual tokens of the occurrences of a normalized keyphrase candidate were also employed. Character suffix features also incorporated positional information, similarly as it was done in the case of POS features. The suffixes themselves came from the last 2 and 3 characters of the tokens constructing an n-gram. For instance, the features induced by (and thus assigned with true value) for the phrase *ch**eap** ph**one*** are {*B-eap*, *B-ap*, *E-one*, *E-ne*}.

Opinionated phrases often bear special orthographic characteristics, e.g. in the case of *so sl**ooo**w* or *CHEAP*. Due to the fact that the original forms of the phrases are stored in our representation, it was possible to construct two features for this phenomenon: the first feature is responsible for **character run**s (i.e. more than 2 of the same consecutive characters), and an other is responsible for **strange capitalization** (i.e. the presence of uppercase characters besides the initial one). The S-,B-,E-,I- prefixes were applied here as well, just like in the case of the **Named Entity** feature, which represented if a token was part of NE (with its type as well).

World knowledge-based features Features relying on the outer resources of Wikipedia and SentiWordNet were also exploited during our experiments. They were useful as world knowledge could be incorporated by their means.

Multiword expressions are lexical items that can be decomposed into single words and display idiosyncratic features (Sag et al., 2002), in other words, they are lexical items that contain space.

To measure the added value of MWEs in the task of opinion phrase extraction, a set of features was designed that indicated whether a certain phrase candidate (1) is an MWE on its own (e.g. *ease of use*), (2) can be composed from more MWEs on the list (e.g. *mobile internet access*), or is just the (3) superstring of at least one MWE from the list (e.g. *send text messages*). In order to be able to make such decisions, a wide list of MWEs was constructed from Wikipedia (dump 2011-01-07): all the links and formatted (i.e. bold or italic) text were gathered that were at least two tokens in length, started with lowercase letters and contained only English characters or some punctuation. Finally, an alignment of the elements of the list and the contexts of the reviews of the dataset was carried out (taking care of linguistic alternations and POS-tag matchings).

A more sophisticated surface-based feature used external information as well on the individual tokens of a phrase. It relied on the **sentiment scores** of SentiWordNet (Esuli et al., 2010), a publicly available database that contains a subset of the synsets of the Princeton Wordnet with positivity, negativity and neutrality scores assigned to each one, depending on the use of its sentiment orientation (which can be regarded as the probability of a phrase belonging to a synset being mentioned in a positive, negative or neutral context). These scores were utilized for the calculation of the sentiment orientations of each token of a keyphrase candidate. Surface-based SentiWordnet-calculated feature values for a keyphrase candidate included the *maximal positivity and negativity and subjectivity* scores of the individual tokens and the *total sum* over all the tokens of one phrase.

Sentence-based features were also defined based on SentiWordNet as it was also used to check for the presence of **indicator terms** within the sentences containing a candidate phrase. Those word forms were gathered from SentiWordNet, for which the sum of the average positivity and negativity sentiments scores among all its synsets were above 0.5 (i.e. the ones that are more likely to have some kind of polarity). Then for a given keyphrase candidate of a given document, a true value was assigned to the SentiWordNet-derived indicator features that had at least one

co-occurrence within the same sentence with the keyphrase candidate in the same document.

SentiWordnet was also used to investigate the entire sentences that contained a phrase candidate. This kind of feature calculated the sum of every sentiment score in each sentence where a given phrase candidate was present. Then the mean and the deviation of the sum of the sentiment scores were calculated for each token of the phrase-containing sentences and assigned to the phrase candidate. The mean of the sentiment scores of the individual sentences yielded a general score on the **sentiment orientation** of the sentences containing a candidate phrase, while higher values for the **deviation** was intended to capture cases when a reviewer writes both factual (i.e. uses few opinionated words) and non-factual (i.e. uses more emotional phrases and opinions) sentences about a product.

Finally, Wikipedia was also used to incorporate semantic features from its category hierarchy. (Wikipedia categories form a taxonomy, indicating which article belongs to which (sub)category). In the case of a candidate phrase all the nominal parts of the normalized titles of **Wikipedia categories** for its related Wikipedia articles were added as separate binary features to the feature space. The normalization of the Wikipedia category names was similar to that of keyphrase candidates. For instance, given the candidate phrase '*service quality*' the feature *wiki_control_qual* is set to true since the Wikipedia article named *Service quality* is in the category *Quality control*.

Document and corpus-level features Among document-level features, the **standard deviation of the relative positions** compared to the document length was a measure to be computed. Higher values of the deviation in the position means that the reviewer keeps repeating some phrase from the beginning to the end of the review, which might indicate that this phrase is of higher importance for them.

As verbs often contribute to the sentiment polarity of the noun phrases they accompany (e.g. '*I adore its fancy screen.*' versus '*I bought this phone one year ago.*'), a set of features was introduced to deal with the **indicative verbs** in the context of candidate phrase occurrences within their document. For this feature to be calculated we took those verbs as indicators that occurred at least 100 times in the whole training dataset. When calculating a feature value for an opinionated-phrase candidate, the algorithm matched all of its occurrences in a document against every indicator verb. For the calculation of the feature value for a given phrase candidate – indicator verb pair, a syntactic distance value was first defined. This syntactic distance was equal to the minimal height of the subtree which contained both the keyphrase candidate and the indicator verb itself to the left among all the sentences associated with a document that contained the keyphrase candidate. The feature value was then determined by simply taking the reciprocal of this semantic distance. This way, the feature value was scaled between 0 and 1. (Note that for indicator verbs that were not present in any of the sentences containing a phrase candidate associated with a document, the semantic distance value was defined to be infinity, the limit value of the reciprocal of which is 0.)

Quite general characteristics of reason-expressing phrases can also be captured at the corpus level. Simply using the number of times an argument phrase aspirant was assigned to a review as a proper phrase on the training dataset was also taken into account as a **corpus-level** feature since the same proper opinion phrases can easily reoccur regarding products of the same type.

4 Experiments

Experiments were carried out on two fairly different types of product reviews, namely mobile phones and movies. We use standard keyphrase extraction evaluation metrics and baselines for evaluating our pros and cons extractor system.

4.1 Datasets

In our experiments, we crawled two quite different domains of product reviews, i.e. mobile phone and movie reviews from the review portal `epinions.com`. For both domains, 2000 reviews were crawled from `epinions.com` and an additional of 50 and 75 reviews for measuring inter-annotator agreement, respectively. This corpus is quite noisy (similarly to other user-generated contents); run-on sentences and improper punctuation were common, as well as grammatically incorrect sentences since reviews were often written by non-native English speakers. [1]

[1] All the data used in our experiments are available at `http://rgai.inf.u-szeged.hu/proCon`

	Mobiles	Movies
Number of reviews	2009	1962
Avg. sentence/review	31.9	29.8
Avg. tokens/sentence	16.1	17.0
Avg. keyphrases/review	4.7	3.2
Avg. keyphrase candidates/review	130.38	135.89

Table 1: Size-related statistics of the corpora

The list of pros and cons was inconsistent too in the sense that some reviewers used full sentences to express their opinions, while usually a few token-long phrases were given by others. The segmentation of their elements was marked in various ways among reviews (e.g. comma, semicolon, ampersand or the *and* token) and even differed sometimes within the very same review. There were many general or uninformative pros and cons (like *none* or *everything* as a pro phrase) as well.

In order to have a consistent gold-standard annotation for training and evaluation, we manually refined the pros and cons of the reviews in the corpora. In the first step, the automatic preprocessing of the segmentation of pros and cons was checked by human annotators. Our automatic segmentation method split the lines containing pros and cons along the most frequent separators. This segmentation was corrected by the annotators in 7.5% of the reviews. Then the human annotators also marked the general pros and cons (11.1% of the pro and con phrases) and the reviews without any identified keyphrases were discarded.

4.2 Evaluation issues

Keyphrase extraction systems are traditionally evaluated on the top-n ranked keyphrase candidates for each document by F-score (Kim et al., 2010), which combines the precision and recall of the correct keyphrases' class. Evaluation is carried out in a strict manner as a top-ranked keyphrase candidate is accepted if it has exactly the same standardized form as one of the keyphrases assigned to the review. The ranking of the phrase candidates was based on a probability estimation of a candidate belonging to the positive keyphrase class. Results reported here were obtained using 5-fold cross validation using Maximum Entropy classifier.

As we treated the mining of pros and cons as a supervised keyphrase extraction task, we conducted measurements with KEA (Witten et al., 1999), which is one of the most cited publicly available automatic keyphrase extraction system. However, we should note that due to the fact that our phrase extraction and representation strategy (and even the determination of true positive instances to some extent) slightly differs from that of KEA, the added values of our features should rather be compared to our second Baseline System (BL_{WN}) which uses WordNet for candidate phrase normalization. The baseline systems use our framework, with the feature set of KEA, which consists of tf-idf feature and the relative first occurrence of a keyphrase candidate. The only difference among the two baseline systems is that BL does not apply the WordNet-based normalization of phrase candidates introduced in Section 3.1.

Since we had the same findings as Branavan et al. (2008) that authors often omit several opinion forming aspects from their pros and cons listings that they later include in their review, we decided to determine the complete lists of pros and cons manually, that is, to compose pro and con phrases on the basis of the reviews. Due to the highly subjective nature of sentiments, the determination of sentiment-affecting pro and con phrases was carried out by three linguists, who were asked to annotate a 25-document subset of the mobile phone dataset. Their averaged agreements for the determination of pro phrases are 0.701 and 0.533 for Dice's coefficient and Jaccard index, and 0.69 and 0.526 for cons, respectively.

4.3 Results

In our experiments all the linguistic processing of the product reviews were carried out using Stanford CoreNLP. It uses the Maximum Entropy POS-tagger of Toutanova and Manning (2000) and syntactic parsing works on the basis of Klein and Manning (2003). The ranking of the candidate keyphrases was based on the posteriori probabilities of the MALLET implementation (McCallum, 2002) of Maximum Entropy classifier (le Cessie and van Houwelingen, 1992).

During the fully automatic evaluation, we followed strict evaluation (see 4.2) that is commonly utilized in scientific keyphrase extraction tasks. Table 2 contains the results of the strict evaluation for both domains. However, since strict evaluation is more likely to suit the evaluation of scientific keyphrase extraction better, i.e. semantically equivalent but different word forms are less common at that domain, we conducted human evaluation on the 25-document subset of the mobile

Table 2: Performance using different features in the form of Precision/Recall/F-score obtained. IV, KF, SWN and Orth. stands for indicator verbs, corpus-level keyphrase frequency, SentiWordNet and orthography-driven features, respectively. Symbols §, † and ‡ in the upper index of a result indicates that it is significantly better compared to the baseline system which uses the WordNet based candidate phrase normalization (BL_{WN}) at confidence levels of 0.1, 0.05 and 0.01, based on Student's t-test, respectively. As it was only the KF feature which did not yield any significant improvement at all, the combined system (COMB) incorporated all the features but KF.

phone domain. The results of the manual evaluation is shown in 3.

4.4 Discussion

The fact that the highest F-scores for keyphrases are achieved when the number of extracted phrases is around the average number of pro and con phrases per reviews (i.e. between 3 and 5) suggests that our ordering of keyphrase candidates is quite effective (since once we find the number of keyphrases a document has, performance cannot really grow anymore).

Comparing the nature of the task of extracting keyphrases from scientific publications and that of product reviews, we shall take two observations: firstly, keyphrases of scientific documents are more universal, i.e. once we have the knowledge that the expression *distributed computing* was a good keyphrase for one scientific document, we can be more confident about it being a proper keyphrase for other documents within the same domain as well, whereas in the case of opinion phrases such as *pink color* can easily be mentioned in either opinionated and non-opinionated contexts. Secondly, besides scientific keyphrases being more ***universal***, they are more ***deterministic*** in the sense that there are fewer ways to express good keyphrases, e.g. suppose *simulated annealing* is a proper keyphrase for a scientific document, it is unlikely that an automatic system would extract *imitated annealing*, whereas in the case of product review the gold standard keyphrases often differ from their mention in the text (e.g. *tiny keys* and *small keys*).

The above mentioned examples suggest that opinion phrase extraction is more difficult to be performed and evaluated compared to scientific keyphrase extraction. We should note that the best performing system at SemEval-2010 (Kim et al., 2010) that dealt with the much simpler task of scientific keyphrase extraction achieved an F-score of 19.3 when evaluated against author keywords at the top-15 level.

It should be also added here, that among the keyphrases regarded as false positives in our evaluations, there were many near misses due to synonymy, e.g. *tiny keys* and *small keys* or *slow Web* and *slow WAP*. To overcome the synonymy issue to some extent the WordNet-based rewriting of tokens was introduced, which brought improvement in the case of the baseline systems for both domains (so it was employed in the later experiments as well). Another source of false positive classifications was due to the incompleteness of the opinion aspect entered by the user, i.e. not all the important aspects are necessarily listed among the

	Top-5			Top-10			Top-15

$\cup$	72.8	20.63	32.14	66.8	33.54	44.66	63.47	46.88	53.92
$\cap$	46.4	27.81	34.77	41.6	44.92	43.2	37.07	56.68	44.82
Author	34.4	22.29	27.05	31.6	35.43	33.4	28.8	45.14	35.17

Table 3: Results of the human evaluation. $\cup$, $\cap$ and Author means when the automatic keyphrases were matched against the union, intersection of the keyphrases of three independent annotators and the keyphrases of the original author, respectively.

pros and cons section, as described earlier. On the other side, many of the author-entered keyphrases were absent in the contents of a review in their same form: only 34,8% and 23,9% of gold standard keyphrases could be found in the texts having the same normalized form for the mobile phone and the movie domains, respectively, setting an upper bound for the recall values when evaluating based on strict matching.

To overcome all the previously mentioned shortcoming during automatic evaluation, human evaluation was performed and it showed that real life application of opinion phrase extraction could be of much higher utility than strict evaluation would suggest. This is due to the fact that human annotators had access to common sense knowledge and during the inspection of keyphrases they could resolve such cases that were impossible during automatic evaluation.

All the features were effective in the sense that expanding the baseline feature set by them separately resulted in better results. Moreover, in the majority of the cases improvements were of high significance (see Table 2). The added value of Wikipedia features (that are likely to work well in other domains as well) should be highlighted as well as the relatively poor effect of keyphrase frequency feature which normally works better in the case of standard scientific keyphrase extraction tasks. A possible reason for keyphrase frequency feature not being that effective in the opinion domain is that in the case of opinionated keyphrases, the presence of such a phrase that was marked as positive in one document is not necessarily marked the same way in other documents, e.g. because one author may write about the feature objectively while the other may write his strong opinions about the very same feature, using similar wording.

5 Conclusions

In this paper, we presented a pros and cons extraction system by pointing out the parallelism between the keyphrases of scientific papers – given by their author – and the pros and cons phrases – given by product reviewers. The WordNet-based phrase normalization and an extended stopword-based filtration of keyphrase candidates introduced here could be of possible use for any kind of phrase extraction tasks. Besides demonstrating their similarity, the main differences of the two tasks were also highlighted, and several ways to adopt to the specialties of opinion phrase extraction have been suggested by introducing a rich feature set, some of which could also be widely used (e.g. Wikipedia-based ones), and others are specifically designed to the special task of opinion phrase extraction (e.g. SentiWordNet-related ones).

Among the most important differences of opinion phrase extraction from scientific keyphrase extraction we should note that for product reviews the pure occurrence of a single phrase is less deterministic to be a keyphrase, i.e. some emotional context is necessary to treat them as genuine ones. Also, the language of reviews is more special since it tends to contain elements that are not present in other genres of documents, such as irony and sarcasm and offers more possibility to express identical things in different ways. In total, our results are competitive with those of other standard keyphrase extraction tasks even when applying strict normalized form matching evaluation. Moreover, human evaluation showed that when semantics are involved into the evaluation, results are significantly better than it is suggested by automatic evaluations.

Abstract

Existing research on sentiment analysis mainly uses sentiment words and phrases to determine sentiments expressed in documents and sentences. Techniques have also been developed to find such words and phrases using dictionaries and domain corpora. However, there are still other types of words and phrases that do not bear sentiments on their own, but when they appear in some particular contexts, they imply positive or negative opinions. One class of such words or phrases is those that express resources such as water, electricity, gas, etc. For example, "*this washer uses a lot of electricity*" is negative but "*this washer uses little water*" is positive. Extracting such resource words and phrases are important for sentiment analysis. This paper formulates the problem based on a bipartite graph and proposes a novel iterative algorithm to solve the problem. Experimental results using diverse real-life sentiment corpora show good results.

1 Introduction

Sentiment analysis or opinion mining has been an active research area in recent years (e.g., Pang and Lee 2008; Turney, 2002; Wiebe *et al*. 2004; Hu and Liu, 2004; Kim and Eduard, 2004; Wilson *et al*. 2005; Popescu and Etzioni, 2005; Riloff *et al*. 2006; Esuli and Fabrizio, 2006; Mei et al, 2007; Stoyanov and Cardie; 2008). Researchers have studied the problem at the document level, sentence level and aspect level to determine the sentiment polarity expressed in a document, in a sentence and on an aspect of an entity (see the surveys (Pang and Lee, 2008) and (Liu, 2010)). One type of key information used in almost all existing sentiment analysis techniques is a list of sentiment words (or opinion words). Positive sentiment words are words expressing desired states or qualities, e.g., *good*, *amazing*, and *excellent*, and negative sentiment words are words expressing undesirable states or qualities, e.g., *bad*, *crappy*, and *ugly*.

A key characteristic of these words is that they themselves bear sentiments. They are frequently used in sentiment analysis tasks. However, it is also important to recognize that sentiment analysis based only on these words (or phrases) is far from sufficient. There are still many other types of expressions that do not bear sentiments on their own, but when they appear in some particular contexts, they imply sentiments. In (Liu, 2010), several such expressions and their corresponding opinion/sentiment rules are introduced. We believe that all these expressions have to be extracted and associated problems solved before sentiment analysis can achieve the next level of accuracy. One such type of expressions involves resources, which occur frequently in many application domains. For example, *money* is a resource in probably every domain ("*this phone costs a lot of money*"), *gas* is a resource in the car domain, and *ink* is a resource in the printer domain. If a device consumes a large quantity of resource, it is undesirable. If a device consumes little resource, it is desirable. For example, the sentences, "*This laptop needs a lot of battery power*" and "*This car uses a lot of gas*" imply negative sentiments on the laptop and the car. Here, "gas" and "battery power" are resources, and we call these words *resource terms* (which cover both *words* and *phrases*).

In terms of sentiments involving resources, the rules in Figure 1 are applicable (Liu, 2010). Rules 1 and 3 represent normal sentences that involve resources and imply sentiments, while rules 2 and 4 represent comparative sentences that involve resources and also imply sentiments, e.g., "*this washer uses much less water than my*

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1171–1179,
Chiang Mai, Thailand, November 8 – 13, 2011.

1. Positive ← consume no or little resource
2. | consume less resource
3. Negative ← consume a large quantity of resource
4. | consume more resource

Figure 1: Sentiment polarity of statements involving resources.

old GE washer". To the best of our knowledge, there is no reported algorithm that extracts resource terms. In this paper, we propose an iterative algorithm to extract them from a domain corpus, e.g., a set of product reviews. In the above example sentence, we want to extract "*water*" as a resource term.

The most related work to ours is the product aspect/feature extraction (e.g., Hu and Liu, 2004, Popescu and Etzioni, 2005, Kobayashi *et al*. 2007, Scaffidi *et al*. 2007, Titov and McDonald, 2008, Stoyanov and Cardie. 2008, Wong *et al*., 2008, Zhao *et al*., 2010). A resource in a domain is often an aspect or implies an aspect. For example, in "*this camera uses a lot of battery power*", "battery power" clearly indicates *battery life*, which is an aspect of the camera entity. However, there are some important differences between resources and other types of aspects. The key difference is that resource terms often contribute directly to sentiments (e.g., based on the quantity that is consumed), while other aspects may not. e.g., "picture quality" in "*the picture quality of this camera is great*," where "great" solely determines the sentiment of the sentence. Thus, resource terms require special treatments in sentiment analysis. In this paper, we focus on identifying and extracting resource terms.

This paper models the extraction problem with a bipartite graph and proposes a novel circular definition to reflect a special reinforcement relationship between *resource usage verbs* (e.g., *consume*) and resources (e.g., *water*) for resource extraction. We call the proposed method MRE (*M*utual *R*einforcement based on *E*xpected values). Based on the definition, the problem is solved using an iterative algorithm. To initialize the iterative computation, some global *seed resources* are employed to find and to score some strong resource usage verbs. These scores are applied as initialization for the iterative computation in the bipartite graph for any application domain. When the algorithm converges, we obtain a ranked list of candidate resource terms. Our experimental results based on 7 real-life data sets show the effectiveness of the proposed method. It outperforms 5 strong baselines.

2 Related work

As we discussed in the introduction, this work is mainly related to product aspect extraction. Hu and Liu (2004) proposed a technique based on association rule mining to extract frequent nouns and noun phrases as product aspects. They also introduced the idea of using sentiment words to find additional (infrequent) aspects. Popescu and Etzioni (2005) improved the precision of this method by determining whether a noun/noun phrase is indeed a product aspect by computing the pointwise mutual information (PMI) score between the phrase and class discriminators, e.g., "*xx has*", "*xx comes with*", etc., where *xx* is a product class word, and using Web search.

A dependency based method is proposed in (Zhuang *et al*., 2006) to extract aspects for a movie review application. Dependency relations are also used in (Qiu *et al*. 2011) to extract both aspects and sentiment words. Zhang *et al*. (2010) augmented this method by introducing aspect ranking. Wang and Wang (2008) proposed a similar bootstrapping method but not based on dependencies. In (Kobayashi *et al*. 2007), a pattern mining method was proposed to find extraction patterns. Statistics from the corpus are employed to determine the extraction confidence.

Other works on aspect extraction use topic modeling and probabilistic modeling to capture and group aspects at the same time (e.g., Mei *et al*., 2007; Titov and McDonald, 2008; Lu *et al*. 2009; Zhao *et al*., 2010; Wang *et al.* 2010; Jo and Oh, 2011). In (Su *et al*., 2008), a clustering method was also proposed with mutual reinforcement to identify aspects.

However, all these existing works focused on extracting aspects in general. They do not specifically identify resource terms, which are a special type of aspects, and need additional techniques to recognize them.

Our work is also related to the general information extraction problem. There are two main approaches to information extraction: rule-based and statistical. Early extraction systems are mainly based on rules (e.g., Riloff, 1993). In statistical methods, the most popular models are Hidden Markov Models (HMM) (Rabiner, 1989;

Jin *et al*., 2009), and Conditional Random Fields (CRF) (Lafferty *et al*., 2001). CRF has been used in extracting aspects and topics (e.g., Stoyanov *et al*., 2008, Jakob and Gurevych, 2010). However, a limitation of CRF is that it only captures local patterns rather than long range patterns. Also, CRF is a supervised method, but our method is a bootstrapping method which needs no supervision but only a few initial global resource seeds.

Our proposed method is also related to the Web page ranking algorithm HITS (Kleinberg, 1999), which finds hub and authority pages based on the hyperlink structure of the Web pages. However, our method is quite different as we have a different formulation. We will discuss the details in Section 3. HITS is also one of the baseline methods that will be compared with the proposed MRE technique in the evaluation section. Our method outperforms HITS considerably.

3 The Proposed Method

In this section, we present the proposed technique. Let us use the following two example sentences to develop the idea and the algorithm:

1. *This car uses a lot of gas*.
2. *This car uses less gas than Honda Civic*.

We call the first sentence a *normal sentence*, and the second sentence a *comparative sentence*.

From these two sentences, we can make the following observation:

Observation: The sentiment expressed in a sentence about resource usage is often determined by the triple,

(verb, quantifier, noun_term),

where *noun_term* is a noun or a noun phrase

In the first sentence, "uses" is the main verb, "a lot of" is a quantifier phrase, and "gas" is a noun representing a resource. In the second sentence, "uses" is also the main verb, "less" is a comparative quantifier, and "gas" is again a resource as a noun. We want to use such triples to help identify resources in a domain.

We notice that using only a pair,

(verb, noun_term), or
(quantifier, noun_term)

is not sufficient. The pair (verb, noun_term) is unsafe because such pairs are very common since subject-verb-object (SVO) is the most common English sentence structure, and the object is usually a noun term. Using (quantifier, noun_term) is also unsafe as the meaning of the noun terms following quantifiers can be diverse.

By no means do we say that any above triple implies the last noun term is a resource. For example, "colors" is not a resource in "*this car got many colors*". The triples only find candidate resources, which need to be further analyzed (see Section 3.2).

Since it is unsafe to use the pair (verb, noun_term) or (quantifier, noun_term), we use only triples for candidate resource extraction. Due to the fact that it is easy to compile the main expressions of quantifiers, we just need to extract verbs and noun terms to discover candidate resources which are the noun terms. The quantifiers that we use in this work are listed in Table 1.

Quantifiers
some, several, numerous, many, much, more, most, less, least a large/huge/small/tiny number of a large/huge/small/tiny quantity/amount of lot/lots/tons/ton/plenty/deal/load/loads of [a] few/little

Table 1: A list of quantifiers

3.1 Extract Triples and Build a Graph

Since our algorithm is based on triples, we now discuss how to extract them. To extract triples from a corpus, part-of-speech (POS) tagging is first performed on each sentence. Verbs and nouns are then identified based on their POS tags. Verbs are words tagged as VB, VBD, VBZ, VBG, VBN, and VBP. Nouns are words tagged as NN and NNS. In addition, we regard a phrase with continuous POS tags of NN and NNS as a noun phrase, e.g., "spray/NN gel/NN" is seen as a single noun phrase "spray gel". In English grammar, quantifiers usually precede and modify noun terms. Thus, after locating a quantifier in a sentence, we extract its associated noun term, which directly follows the quantifier. After obtaining the noun term, we further exploit the dependency relation to find the associated verb in the sentence, since there is an assumed *verb-object* relationship between the verb and the noun. The relationship can be determined by a dependency parser. In our work, we approximate the dependency by making use of a text window in the sentence. It works quite well. Thus we did not use a dependency parser, which tends to be inefficient. We choose the closest verb in a text window (e.g., 10 words) before the noun as the

verb part of the triple. Note that verbs such as "*is*", "*was*", "*am*" "*are*", "*were*" "*have*", "*has*", and "*had*" are not used since they usually do not express resource usages. Finally, we lemmatize both the verb and the noun and store them only in the lemmatized format in a triple.

With all extracted triples, we build a bipartite graph based on the verb set V, the noun set N, and the set of links L between V and N. A link (i, j) is in L if there is a triple involving a verb $i \in V$ and a noun term $j \in N$. Note that in this graph, we do not use quantifiers, which are only used to identify candidate verbs and nouns.

3.2 The Proposed Algorithm

We now present the proposed algorithm, which relies on the bipartite graph to encode a special kind of mutual enforcement relationship between resource usage verbs and resource terms. Before diving into the details of the algorithm, we define the following concepts.

Definition (Resource Term): A resource term represents a physical or virtual entity that can be consumed or obtained in order to benefit from it.

Some resources are general, which exist in many different application domains, i.e., "money" in "*this TV costs me a lot of money*". Other resources are more domain-specific, e.g., "onboard memory" in "*the phone uses more onboard memory*".

Definition (Resource Usage Verb): A resource usage verb (or *resource verb* for short) is a verb that can express resource usage.

Likewise, some resource verbs are general and can modify many different resource terms, e.g., "uses" in "*this car uses much more gas*", "*this washer uses a lot of water*", and "*this program uses a lot of memory*." Many others are more resource-specific, and tend to frequently co-occur with specific resources, e.g., "*spent*" in "*I spent too much money to buy the car*".

It seems that we can solve the problem of extracting resource terms using a simple graph propagation strategy. That is, given an application domain corpus, the user first provides a few seed resource terms. Using the bipartite graph, we can identify some resource verbs by following the links of the graph. The newly identified resource verbs are then used to identify new resource terms. The process continues until no more resource terms or verbs can be found.

However, this simple strategy has some major problems. First, as many resource verbs and terms are domain-specific, asking the user to provide some seeds for each domain is non-trivial. Second, many nouns (or verbs) in the triples may not be resources (or resource usage verbs), e.g., "*this car comes with many colors*." Any error resulted in the propagation can generate more errors subsequently.

With these concerns in mind, we propose a more sophisticated iterative algorithm. To solve the first problem above, we take a global approach. Instead of asking the user to provide some seed resources for each domain, we simply provide some global resource seeds, e.g., *water*, *money*, and *electricity*. Then in each application, the user does not need to do anything. Using these global resource seeds, we want to identify some good resource usage verbs. These verbs act as the initialization for the discovery of additional resource terms in each domain based on the domain corpus. The proposed method thus consists of two main stages. The first stage is only done once and the results are used for individual application domains as the initialization.

Stage 1: *Identifying Global Resource Verbs*

Global resource verbs are those verbs that can express resource usage of many different resources, e.g., *use* and *consume*. We can use a bipartite graph constructed from a large data set to find them. The following observations help us formulate the solution:

1. A global resource verb has links to many different resource terms. The more diverse the resource terms that a verb can modify, the more likely it is a good global resource verb.
2. Conversely, the more global resource verbs a resource term is associated with, the more likely it is a genuine resource term.

These two observations indicate that the global resource verbs and the resource terms have a mutual enforcement relationship, which can be modeled by the Web page ranking algorithm HITS exactly. We give a brief introduction to the HITS algorithm (Kleinberg, 1999) below.

The objective of HITS (Hyperlink-induced topic search) is to find Web pages that are authorities and hubs. A good authority page is a page pointed to by many pages, and a good hub is a page that points to many pages. There is a mutual reinforcement relationship between authority pages and hub pages.

Given a set of Web pages S, HITS computes an *authority score* and a *hub score* for each page

in S. Let the number of pages to be studied be n. We use $G = (S, E)$ to denote the (directed) link graph of S, where E is the set of directed edges (or links) among the pages in S. We use M to denote the adjacency matrix of the graph.

$$M_{ij} = \begin{cases} 1 & if\ (i, j) \in E \\ 0 & otherwise \end{cases} \quad (1)$$

Let the authority score of page i be $A(i)$, and the hub score of page i be $H(i)$. The mutual reinforcing relationship in HITS is defined as follows:

$$A(i) = \sum_{(j,i)\in E} H(j) \quad (2)$$

$$H(i) = \sum_{(i,j)\in E} A(j) \quad (3)$$

We can write them in a matrix form. We use $\mathbf{A}$ to denote the column vector with all authority scores, and use $\mathbf{H}$ to denote the column vector with all hub scores:

$$\mathbf{A} = M^T\mathbf{H} \quad (4)$$

$$\mathbf{H} = M\mathbf{A} \quad (5)$$

To solve the equations, the widely used method is power iteration, which starts with some random values for the vectors, e.g., $\mathbf{A}^0 = \mathbf{H}^0 = (1, 1, \ldots 1)^T$. It then continues to compute iteratively till convergence. Note that the initial values do not generally affect the final ranking of authorities and hubs.

In our scenario, global resource verbs act as hubs and resource terms act as authorities. We provided a list of common resources (seeds) (see Section 4). Using these seeds, we extract triples from the corpus and produce a link graph as discussed in Section 3.1. The noun term set N consists of only these seed resource terms, and the V set consists of only those verbs which form triples with the N set. HITS is then applied on the graph. After HITS converges, each candidate resource verb has a hub score. We normalize them to the 0-1 interval. The resulting values are used to initialize the system for discovering resource terms from each application domain. That is, we do not need to execute stage 1 anymore.

Stage 2: *Discovering Resource Terms in a Domain Corpus*

Given the global resource verb values from stage 1 and a domain corpus, the stage 2 system identifies resource terms from the domain corpus.

In this stage, we still start with a bipartite graph as in the first stage. The graph can be constructed as discussed in Section 3.1 by extracting triples from the domain corpus. On one side of the bipartite graph, it is the set of candidate resource terms N (noun terms) and on the other side, it is the set of candidate resource (usage) verbs V. For each $i \in V$, we want to compute its likelihood of being a resource verb, denoted by $u(i)$, and for each noun term $j \in N$, we want to compute its likelihood of being a resource term, denoted by $r(j)$. If i and j are in a triple, a link (i, j) is in the link set L.

An obvious question is: Can we use HITS here as in stage 1? The answer is no. Unlike stage 1, the N set here is no longer a set of true resources, but only a list of noun terms, which are just candidate resources. A verb modifying multiple noun terms does not necessarily indicate that the verb is a resource usage verb. For example, it could be a general verb like "get". Also, as mentioned earlier, it is not always the case that if a noun term is modified by many verbs, it is a resource term. For example, it could be a topic word like "car" for the car domain. Applying the simple reinforcement relation in HITS is ineffective as we will see in the experiment section. To introduce the proposed technique, we make the following observations:

1. If a noun term is *frequently* associated with a verb (including quantifiers), the noun term is more likely to be a genuine resource term.
2. If a verb is *frequently* associated with a noun term (including quantifiers), it is more likely to be a genuine resource verb.

These two observations indicate that we should take verb and noun term co-occurrence frequency into consideration, which cannot be used in HITS. To consider frequency, we turn the frequency into a probability and make use of the expected value to compute scores for the verbs and noun terms, rather than summation in HITS.

In probability, given a random variable X, its *expected value* is defined as

$$E[X] = \sum_i p_i x_i \quad (6)$$

where x_i is a possible outcome of the random variable X and p_i is the probability of x_i.

For our case, we have the following definitions for $u(i)$ and $r(j)$.

$$u(i) = \sum_{(i,j)\in L} p_{ji} r(j) \quad (7)$$

$$r(j) = \sum_{(i,j)\in L} p_{ij} u(i) \quad (8)$$

where

$$p_{ij} = \frac{c(i,j)}{\sum_{(k,j)\in L} c(k,j)} \text{ and}$$

$$p_{ji} = \frac{c(i,j)}{\sum_{(i,k)\in L} c(i,k)}$$

$c(i, j)$ is the frequency count of the link (i, j) in our corpus. p_{ij} is thus the probability of link (i, j) among all links from different verbs i to a noun j. p_{ji} is the probability of link (i, j) among all links from different nouns j to a verb i. We called this proposed algorithm MRE (*M*utual *R*einforcement based on *E*xpected values)

Smoothing the Probabilities

Although the idea is reasonable, we found an important issue when computing expected values. If a noun term j occurs only once, and it is connected with a strong resource verb i, its ranking value becomes very high. Due to its low frequency, the expected value of $r(j)$ is just the value of $u(i)$. In many cases, the value may be even higher than some frequent noun terms, whose value may be reduced by being associated with some non-resource verbs. This situation is not desirable. Since for sentiment analysis application, we should rank those frequent resource terms at the top instead of the terms which only occur once in the corpus.

The problem is that the probabilities of verbs or nouns are not reliable due to limited data. In order to handle infrequent verbs or noun terms, we smooth the probabilities to avoid probabilities of 0 or 1. The standard way of doing this is to augment the count of each distinctive verb/term with a small quantity λ ($0 \le \lambda \le 1$) or a fraction of a verb or noun term in both the numerator and denominator. Thus any verb and noun term will have a smoothed probability as follows.

$$p_{ij} = \frac{\lambda + c(i,j)}{\lambda |N| + \sum_{(k,j)\in L} N(k,j)} \quad (9)$$

$$p_{ji} = \frac{\lambda + c(i,j)}{\lambda |V| + \sum_{(i,k)\in L} N(i,k)} \quad (10)$$

This is called the *Lidstone smoothing* (Lidstone's law of succession) (Lidstone, 1920). We use λ to 0.01, which performs well. In the equations, $|V|$ is the total number of verbs and $|N|$ is the total number of noun terms in the graph.

Algorithm: MRE (Q, G)
Input: A global resource verb set Q with their hub scores computed from HITS in stage 1, and G is the bipartite graph
Output: a ranked list of candidate resource terms

1. $u^0(i) \leftarrow H(i)$ of verb i, if *verb* $i \in Q$
2. $u^0(i) \leftarrow \arg\min_{r\in Q}\{H(r)\}$, if *verb* $i \notin Q$
3. **Repeat** till convergence
4. $r^{n+1}(j) = \sum_{(i,j)\in L} p_{ij} u^n(i)$
5. $u^{n+1}(i) = \sum_{(i,j)\in L} p_{ji} r^n(j)$
6. normalize $r(j)$ and $u(i)$
7. Output the ranked candidate resource terms based on their $r(j)$ score values.

Figure 2: The proposed MRE algorithm

Note that with smoothing, the original bipartite graph becomes a complete bipartite graph. Each added link is given a very small probability as computed using Equations (9) and (10).

The Computation Algorithm

The computation algorithm for the proposed method MRE is given in Figure 2. Q is the set of verbs from stage 1, and G is the bipartite graph. To initialize the iterative computation, we assign the hub score from stage 1 to each verb $i \in V$ as its initial score $u^0(i)$ if i is in Q (line 1). If i is not in Q, $u^0(i)$ is given the minimum value of the hub scores of all verbs in Q (line 2).

After this initialization, the algorithm proceeds iteratively until convergence. We will describe the convergence characteristic of the algorithm in Section 4.5.

Finally, we note that unlike HITS, which converges to the same hub and authority (steady-state) scores regardless the initialization. For MRE, the initialization makes a big difference as we will see in the evaluation section.

4 Evaluation

We now evaluate the proposed MRE method. We first describe the data sets, evaluation metrics, and then the experimental results. We also compare MRE with 5 baseline methods.

4.1 Data Sets and Global Resource Seeds

We used seven (7) diverse data sets to evaluate our technique. These data sets were crawled from the Web. Table 2 shows the domains (based on their names) and the number of sentences in each

Data sets	Car	Washer	Paint	Printer	Haircare	Mobile	TV

data set ("Sent." means the sentence). Each data set contains a mixture of reviews, blogs, and forum discussions about one type of product. We split each posting into sentences and the sentences are POS-tagged using the Brill's tagger (Brill, 1995). The tagged sentences are the input to our system MRE.

The global resource terms (resource seeds) used in the first stage of our method are: "gas", "water", "electricity", "money", "ink", "shampoo", "detergent", "room" "fabric softener", and "soap". In stage 1 of our algorithm, we used the combined data set of those in Table 2 to compute the hub scores for global resources usage verbs found to be associated with the resource seeds through some quantifiers.

4.2 Evaluation Metrics

We adopt the rank precision, also called **precision@N** metric for the experimental evaluation. It gives the percentage of correct resource terms (precision) at different rank positions. This is a popular method used in search ranking evaluation because one does not know all the relevant pages. This is also the case in our work as we do not know how many resource terms have been mentioned in each of the data set.

4.3 Baseline Methods

TF (Triple Frequency): This method finds all triples of the form (verb, quantifier, noun_term), and then ranks them according to their frequency counts. This basically corresponds to the methods used in (Hu and Liu 2004; Popescu and Oren, 2005; Zhuang *et al*. 2006; Qiu *et al*. 2011) as it combines the frequency and dependency patterns of the triples. This method is reasonable because many triples are indeed resource usage descriptions, and those more frequent ones (ranked high) are more likely to be genuine ones.

TFR (Triple Frequency Ratio): This method is similar to the above method but it divides TF by the number of pairs (verb, noun_term) with the same verb and the same noun term as in the triple. The reason for doing so is that such pairs are very common because **subject-verb-object** (**SVO**) is the most common English sentence structure, and object is usually a noun term. If the ratio of the occurrences of

the triple is small, it may not be a resource usage description and then should be ranked low because sentences containing resources are usually talking about resource usages.

HITS: This method simply runs the HITS algorithm in the second stage for each data set. In this case, the global initialization is not useful as HITS will reach a steady state regardless of the initialization.

MRE-NI: Our MRE method without initialization by the global resource usage verbs.

MRE-NS: Our MRE method without the probability smoothing.

4.4 Results and Discussions

Tables 3-5 give the precision results for top 5, top 10, and top 20 ranked candidate resource terms. Each value in the last column gives the average precision for the corresponding row. We note that in Table 5, there are no results for "Paint" and "Printer" because no resources were found by any algorithm beyond top 10 as there are not many resources in these domains. It is also important to note that those resources that have been used as global seeds in stage 1 of our algorithm are not counted in the precision computation for the results in the tables. In other words, the discovered resource terms are all new. From the tables, we can make the following observations:

1. TF and TRF perform poorly. We believe the reason is that frequent triples or frequent triple ratio do not strongly indicate resource usages.
2. The performance of the HITS algorithm is also inferior. For only two data sets (out of 7), it performs similarly to MRE for the top 5 results. Its average results are all much worse than those of MRE.
3. Global resource verbs are very useful. As we can see, without using them (MRE-NI), the results are dramatically worse.
5. Probability smoothing also helps significantly. Without it, MRE-NS produces worse results consistently compared with MRE.
6. MRE is the best method overall. On average, it consistently outperforms every baseline method. Moreover, it does better than the 5 baseline methods on every data set at every rank position except for the data set "Printer" for the top 10 results, for which HITS is better.

From these observations, we can conclude that our proposed MRE algorithm is highly effective and it outperforms all 5 baseline methods.

4.5 Algorithm Convergence

In this sub-section, we show the convergence characteristic of the proposed MRE algorithm.

Figure 3 shows the convergence behavior of MRE for the car data set, where the *x*-axis is the number of iterations, and the *y*-axis is the difference of the average 1-norm values of the vector r and vector u in two consecutive iterations. We can see that the algorithm converges quite fast, i.e., in about 8 iterations. For other data sets, they behave similarly. All of them converge within 6-9 iterations. In all experiments, the algorithm stops when the 1-norm difference is less than 0.01.

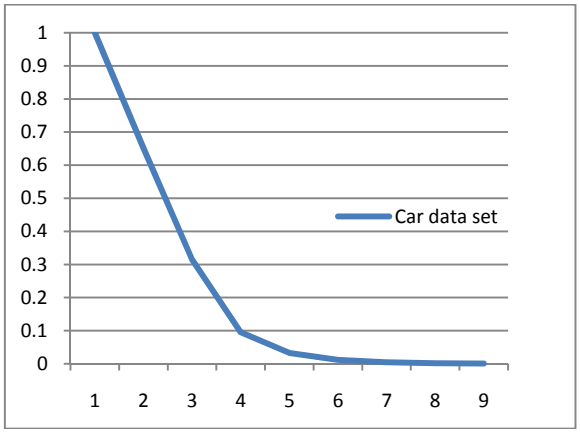

Figure 3: Convergent rate for car data

5 Conclusion

This paper proposed the problem of extracting resource words and phrases in opinion documents. They are a class of terms that are important for sentiment analysis. As we explained in the introduction section, when such resource terms appear with certain verbs and quantifiers, they often imply positive or negative sentiments or opinions. To the best of our knowledge, this work is the first attempt to discover such words and phrases. A novel iterative algorithm based on a circular definition of resource words and their corresponding verbs has been proposed. It was modeled on a bipartite graph and a special reinforcement relationship between resource usage verbs and resource terms. Experimental results based on 7 real-world opinion data sets showed that the proposed MRE method was effective. It outperformed 5 baseline methods. In our future work, we plan to improve the algorithm to make it more accurate, and also study sentiment analysis involving resource words or phrases

Abstract

We propose a new subjectivity classification at the segment level that is more appropriate for discourse-based sentiment analysis. Our approach automatically distinguish between subjective non-evaluative and objective segments and between implicit and explicit opinions, by using local and global context features.

1 Introduction

Subjectivity and polarity classification is one of the most studied research area in opinion analysis (Pang and Lee, 2004; Wiebe and Riloff, 2005; Wilson et al., 2009). The first task generally distinguish between objective and subjective statements. Polarity classification is then performed in order to extract positive, negative and possibly neutral statements. These two tasks are co-dependent, since subjectivity analysis filters out statements that contain no opinion.

A common approach in these tasks is to rely on the prior polarity of words and expressions as encoded in external lexical resources. However, as (Polanyi and Zaenen, 2006) stated, identifying prior polarity alone may not suffice to improve sentiment analysis at a finer grain, we need both *local* and *global* context. Context provided *locally* can help in two ways. First, it can be used in subjectivity word sense disambiguation (SWSD) in order to determine if a given word has a subjective or an objective sense (Akkaya et al., 2009). It can also be used to identify valence shifters (viz. negations, modalities and intensifiers) that strengthen, weaken or reverse the prior polarity of a word or an expression (Kennedy and Inkpen, 2006; Wilson et al., 2009). *Global* context on the other hand can be used to identify implicit opinions and to improve the recognition of the overall stance.

Few research efforts have been undertaken on using discourse as features for sentence / clause-based opinion analysis. Among them, (Pang and Lee, 2004) assume that subjective and objective sentences are more likely to appear together, (Asher et al., 2008) have developed an annotation schema for a fine-grained contextual opinion analysis using discourse relations, (Taboada et al., 2008) have used a Rhetorical Structure Theory discourse parser in order to calculate semantic orientation by weighting the nuclei more heavily, and finally, (Somasundaran, 2010) has proposed a discourse-level treatment to improve sentence-based polarity classification and to recognize the overall stance. More recently, (Zhou et al., 2011) proposed an unsupervised method to recognize RST-based discourse relations for eliminating intra-sentence polarity ambiguities. However, no work has investigated so far how discourse structure can be used to enhance subjectivity analysis (SA).

Using discourse for SA raises new issues: *Is sentence/clause subjectivity-based analysis appropriate? Is binary subjective vs. objective classification enough for capturing how opinions are expressed within discourse?* and finally, *how can rhetorical relations help to correctly identify subjective orientation at a finer-grained level?* In this paper, we aim to answer these questions.

2 Context-Based SA: New Challenges

2.1 Segment-Based SA

The sentence level is not appropriate for context-based SA, since, in addition to objective clauses, a single sentence may contain several opinion

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1180–1188,
Chiang Mai, Thailand, November 8 – 13, 2011.

clauses that can be connected by rhetorical relations. Moving to the clause level is also not appropriate, since several opinion expressions can be discursively related as in *The movie is great but too long* where we have a *Contrast* relation or as in *Mr. Dupont, a rich business man, has been savagely killed* where we have an *Elaboration* because the appositive gives further information about the eventuality introduced in the main clause. Therefore, we need to move to a finer-grained analysis, at the segment level. (Somasundaran et al., 2007) have used a similar level to detect the presence of sentiment and arguing in dialogues. However, segment annotations were provided by their corpus, whereas in our case, segments are defined according to the Segmented Discourse Representation Theory (SDRT) (Asher and Lascarides, 2003) and are automatically detected.

2.2 Beyond Binary Classification

SA can not be simply reduced to binary subjective vs. objective classification. The following examples extracted from our corpus of French movie reviews illustrate this (they are translated in English and discourse segments are between []):

(1) [The movie is not bad,]$_a$ [although some persons left the auditorium]$_b$
(2) [Laborious]$_a$ [and copy/paste of the first part.]$_b$
(3) [This movie is poignant,]$_a$ [and the actors excellent.]$_b$ [It will remain in your DVD closet.]$_c$
(4) [I suppose]$_a$ [that the government policy failed]$_b$

Segments (1.a), (2.a), (3.a), (3.b) and (4.b) are *explicit opinions*. (1.b), (2.b) and (3.c) convey *implicit opinions* and (4.a) is *subjective*, but *non-evaluative*. (Wiebe et al., 2005) have already proposed an expression-level annotation scheme that distinguishes between explicit mentions of private states, speech events expressing private states, and expressive subjective elements. (Liu, 2010) has also observed that subjective sentences and opinionated sentences (which are objective or subjective sentences that express implicit positive or negative opinions) are not the same, even though opinionated sentences are often a subset of subjective sentences. We follow the same observations and we propose a new subjectivity classification at the segment level that is more appropriate for discourse-based sentiment analysis. We automatically classify each segment into four classes, namely *S*, *OO*, *O* and *SN*, as defined below.

Definition 1. *S segments* are segments that contain explicitly lexicalized *subjective and evaluative* expressions. Their polarity can be positive (as in (1.a)), negative (as in (2.a)) or neutral in the sense that their positivity/negativity depends on the context (as in (3.a)).

Definition 2. *OO segments* are positive or negative opinions implied in an objective segment. They do not contain any explicit subjective clues and are objective out of context [1].

Definition 3. *O segments* do not contain any lexicalized subjective term, neither do an implied opinion.

Definition 4. *SN segments* are subjective, but non-evaluative segments that are used to introduce opinions. In general, these segments contain verbs that are used to report the speech and opinions of others. It is important to note that *SN* does not cover the cases of neutral opinion.

These classes have several advantages over standard binary classification. First, they allow us to distinguish between purely subjective expressions (*S*) and implicit subjective expressions (*OO*). Secondly, our classes can be used to enhance polarity classification, since they allow for the removal of the *O* and *SN* segments, which do not convey any positive, negative or neutral opinion. Finally, our classes can also be used to enhance the overall opinion strength assessment. *SN* segments, especially in news articles, can play an important role since they convey the degree of veracity of the information and the degree of the commitment of the author and of the writer.

Recently, some efforts have been done on the automatic identification of implicit sentiments. For example, (Greene and Resnik, 2009) used lexical semantics and syntax. (Muşat and Trăuşan-Matu, 2010) investigated the influence of valence shifters on the identification of implicit sentiment in economic texts. However, to our knowledge, as yet no work proposed to automatically distinguish between evaluative and non-evaluative segments on the one hand, and between implicit and explicit opinions on the other hand, by using contextual features.

2.3 Rhetorical relations and SA

Using SDRT as a formal framework, we have the following discourse relations: *Contrast*(a,b) in (1) marked by *although*, *Continuation*(a,b) in

[1] This definition does not take into account implicit opinions conveyed in subjective segments, such as metaphors.

(2) marked by *and*, and *Attribution*(a,b) in (4).We observe in our corpus that segments related by a *Contrast* or *Continuation* relation often share the same subjective orientation (about 80 %). However, discourse connectors are not the only indicator for deciding whether a segment is opinionated or not. Indeed, some connectors can introduce several discourse relations. In addition, relations are not always explicitly marked, as in (3) where the implicit opinion conveyed in segment c is linked to the subjective segments a and b by a *Result* relation. Another problem is how segments are attached within the discourse structure. In (3), we have *Continuation*(a,b) and *Result*([a,b], c) where [a,b] is a complex segment. Therefore, the subjectivity of segment c depends on [a,b].

Using discourse in opinion analysis is thus a complex task. As a preliminary step, we propose to study the influence of contextual features using mostly lexically-marked discourse relations, and, crucially, without relying on any existing discourse relation annotated corpora. We do not use complex segments and we assume that each segment is only attached to the nearby segment on the left or on the right. In the next sections, we first present the data and our subjective lexicon. Sections 5 and 6 detail respectively the segmentation algorithm and the classification strategies. Section 7 presents the experiments we carried out and discusses the results.

3 Data and Annotations

Our corpus is composed of 136 French movie reviews extracted from the Allô Ciné web site (115 are used for development (our gold) and 21 for test). Three judges performed a two step annotation: first segmentation and then segment classification. Segmentation consists in finding elementary discourse units (EDUs). EDUs typically correspond to verbal clauses, but also to other syntactic units describing eventualities, adjuncts (like appositions or frame adverbials), non-restrictive relatives and appositions (for embedded EDUs). In case of *S* EDUs, we observe that several opinion expressions (often conjoined NPs or APs clauses) can be related by discourse relations.We resegment such EDUs into separate clauses – for instance [*the film is beautiful and powerful*] is taken to express two segments: [*the film is beautiful*][*and powerful*]. For segment annotation, we rely on an already existing annotation guide elaborated during the ANNODIS project (Afantenos et al., 2010) that shows that segmentation is a relatively easy task even for naives. In order to avoid errors in determining the basic units, segmentation relies on annotation consensus.

For segment classification, we elaborated a specific annotation guide where we ask the judges to annotate each EDU into *S*, *OO*, *O* and *SN* according to the definitions given in Section 2.2. First, the judges were trained to the task and discussed while annotating the same documents (10 reviews that were subsequently discarded from the gold). Then, they separately doubly-annotated each review. This yielded an average Cohens kappa of 0.7 for *S*, 0.72 for *O*, 0.61 for *SN* and 0.54 for *OO*. The latter two are moderate agreements and figure, we believe, an artifact of the length of the texts. Indeed, the longer a text is, the higher difficulty for human subjects is in detecting discourse context in longer texts. However, the study of this hypothesis falls out of the scope of this paper and is therefore left for future work. Nonetheless, these figures are well in the range of state-of-the-art research reports in distinguishing between explicit and implicit opinions (Toprak et al., 2010). For our experiments, the conflicting cases were resolved through discussion between annotators.

4 Subjective Lexicon

Our lexicon is composed of 270 verbs, 632 adjectives, 296 nouns, 594 adverbs, 51 interjections, 178 opinion expressions, with 95 modalities among all these. Since there is no existing free subjective lexicon for French, we have manually built our own lexicon from the study of a wide variety of corpora.Following the opinion categorization described in (Asher et al., 2008), each entry (except for adverbs) is associated to four high-level semantic categories (namely *reporting*, *judgement*, *sentiment* and *advice*) and to 24 subcategories. For adverbs, we use additional categories: *negation, affirmation, doubt, intensifier* and *manner*. Only adverbs of manner express opinions, the other adverbs are used as valence shifters.

We manage both polarity and sense ambiguities. We do not fix the polarity of entries that may have context-dependent polarity orientations. Instead, we list all possible orientations (for example, the entry *long* has both a positive and a negative polarity). In order to detect if a subjective entry from

our lexicon is employed in an objective sense, we coupled our lexicon to an external French dictionary D that manually encodes the senses of more than 77 678 words and expressions depending on syntactic configurations For example, the French adjective "*noble*" (noble) has three senses: (a) "noblesse" (pertaining to the aristocracy), (b) "précieux" (precious) and (c) "élevé" (lofty). For each entry E_L in our lexicon, we manually look for its corresponding senses in D as follows: if $E_L \in D$ then if $SubjSense_{E_L} \subseteq Sense_{E_L}$ then add to our lexicon the set $SubjSense_{E_L}$. Thus, for *noble* we only retain (b) and (c) as subjective senses. This dictionary is used by the Cordial syntactic parser (Laurent et al., 2009) in order to perform SWSD. If the identified sense found by the parser is encoded in our lexicon, then the word has a subjective sense; otherwise, it has an objective sense.

5 Automatic Discourse Segmentation

The segmentation is carried out using a set of lexical and syntactic features as described in (Afantenos et al., 2010). These features include the distance from sentence boundaries, the dependency path, and the chunk start/end. Since we used a different syntactic parser, we modified certain features accordingly, and discarded others. We performed a two-level segmentation. First, we constructed a feature vector for each word token, which is classified into: R (Right) for words starting an EDU, L (Left) for tokens ending an EDU, N (Nothing) for words completely inside its EDUs, and B (Both) for tokens which constitute the only word of an EDU.

In the second step, the EDUs which contain at least one token that belongs to our subjective lexicon were retained for a further segmentation. The latter is easier than the segmentation performed at the first level, because we do not encounter embedded segments. Thus, the second-level segmentation of EDUs comes down to searching for one or more "cut points" therein. Since the proportion of EDUs that need to be resegmented is relatively low (about 12 % in the gold standard), we carried out this step by using symbolic rules. These are mainly based on discourse markers.

We performed a supervised learning by using the MegaM software package[2], based on the Maximum Entropy model (Berger et al., 1996) in order to classify each segment into the R, L, Nothing or Both classes, as described above. We carried out a 10-fold cross-validation on our gold standard and an evaluation on the Test data. Table 1 shows first-level EDUs segmentation results for the Right, the Left and Nothing boundaries. For the symbolic segmentation, we evaluated our results (i) on the gold and (ii) on the Test data. The F-measures for boundary recognition are 97.88 % in (i) and 98.65 % in (ii); for the internal-boundaries, we have 84.17 % in (i) and 84.68 % in (ii). Finally, for the new EDU recognition we obtain 77.23 % in (i) and 76.31 % in (ii).

[2] http://www.cs.utah.edu/~hal/megam/

6 Classifiers

The classes, *S*, *O*, *SN* and *OO* are unbalanced in the development corpus. Besides, getting the *OO* segments right is far from obvious, sometimes even for humans. This is why we have defined two orthogonal binary sets of classes:

(a) S_NC vs. O_NC where S_NC = $S \cup SN$ and O_NC = $O \cup OO$ which distinguish between *subjective non-contextual* segments, which are intrinsically subjective, irrespective of their context of occurrence and *objective non-contextual* segments, which, in the absence of any context, are intrinsically objective.

(b) Eval_Op vs. Non_EvalOp where Eval_Op = $S \cup OO$ and Non_EvalOp = $O \cup SN$ which distinguish between *evaluative* and *opinionated* segments, which, given the appropriate context, contain an explicit or an implicit opinion and *non-evaluative* and *non-opinionated* segments, which, irrespective to the context, are not evaluative.

On the gold standard, this grouping yields 919 S_NC EDUs, 511 O_NC EDUs and 1083 Eval_Op EDUs, 347 Non_EvalOp EDUs. Two binary classifiers are constructed, one for each of the two binary sets of classes, defined above: an "S" classifier for **(a)** and an "Op" classifier for **(b)**. Given that the binary sets of classes represent two mutually independent re-partitionings of the segment space, the classifiers are independent of one another. Hence, they can be run in parallel. Then, their outputs are used, via a simple set of four rules, to yield the original four EDU classes. The rules are:

- IF an EDU is S_NC AND Eval_Op, then it is *S*;
- IF an EDU is S_NC AND Non_EvalOp, then it is *SN*;
- IF an EDU is O_NC AND Eval_Op, then it is *OO*;
- IF an EDU is O_NC AND Non_EvalOp, then it is *O*.

The two orthogonal classifiers introduced above

	Precision			Recall			F-measure		
	R	**L**	**Nothing**	**R**	**L**	**Nothing**	**R**	**L**	**Nothing**
Gold	94.97	93.80	97.88	93.41	94.14	98.10	94.18	93.97	97.99
Test	92.61	93.47	94.05	81.79	78.69	98.15	86.86	85.45	96.06

Table 1: First-level EDU segmentation results (in percents)

operate on the same input text. Hence, to get the class of each EDU in the input text, it suffices to perform a fusion of the results of these classifiers, via the four rules shown above. Each classifier is based on SVMs ("Support Vector Machines") (Burges, 1998). From each EDU a distinct feature vector is computed for each classifiers.

6.1 Feature Set

The features used are described in Table 2. They have been grouped in "Local" and "Contextual" features, according to whether they rely on adjacent EDUs or not. All the features are binary.

Local Features. They have been grouped in "Lexical", "Stylistic" and "Syntactic", according to whether they rely on lexical information only, on stylistic or on syntactic information. We have three lexical features. The first one concerns the presence in an EDU of a noun, adjective, adverb of manner, verb, expression or interjection that belongs to the lexicon, excluding entries expressing modalities and negations. The second feature refines the previous one by taking into account only those lexical entries that have subjective senses as described in section 4. The last lexical feature checks the presence of modals in the lexicon.

"Stylistic" features look for emoticons, words in capital letters and for specific punctuation marks. For emoticons, we rely on a dictionary of 79 emoticons. Capitalization is extracted by taking care to filter out certain standard acronyms, such as DVD. For punctuations, we look for sequences of punctuation marks, such as "??", "!!", "?!", or "!?".

We have five "syntactic" features. The first one looks for comparatives and relative superlatives using a set of manually-built French language-specific comparative and superlative patterns. The second one checks the presence of verbs in the "reporting" category, or in the "advice" category that do not have prior polarity, and by seeing whether the arguments the verbs are in the EDUs or not. The next feature gets the scoping of the modals via a syntactic (dependence) analysis of the EDU. The fourth local syntactic feature is extracted by using a set of manually-built typical French syntactic patterns that bear a subjective meaning. These patterns also allow for some flexibility since other words might be intercalated. The last feature is also detected via a syntactic analysis of the text in order to check if an EDU is left-detached place or time (circumstantial) complement (CC) since these EDUs are mainly objective.

Contextual Features. These features have been grouped in two subtypes, "Non-discursive" and "Discursive". Non-discursive features test the presence of a reporting or non-polar advice verband we test it on the EDU that occurs *before* (i.e., to the left of) the current EDU. The second group of contextual features refer to discourse constraints. The first one checks for the *unmarked Commentary* relation between the current EDU and the next one, when the latter contains an emoticon. If this happens, then that previous EDU is Eval_Op. The next feature checks for the simultaneous presence of two marked SDRT rhetorical relations, in the set {*Continuation*, *Parallel*, *Contrast*, *Alternation*}, one between the current EDU and the previous one, and the other between the current EDU and the next one, with the previous and the next EDUs being in the Eval_Op class. In order to determine the presence of these rhetorical relations, we rely on a French lexicon of discourse connectors, developed with the SDRT rhetorical relations in mind (Roze et al., 2010). The feature that follows is a relaxation of the previous one, in that it applies when at least one marked rhetorical relation is found, between the previous EDU and the current one, or between the latter and the next one. The last feature is based on the empirically-motivated intuition that, in general, in reviews, the last EDU tends to be the second argument of a *Result* relation between (some EDUs in) the rest of the document and itself. As such, this last EDU tends to be in the Eval_Op class.

6.2 Getting the Discursive Features

For computing the two discursive features in a current EDU that are based on discourse markers (henceforth, "DFM"), we rely on an already

Scope	Type	Description	S	Op

Table 2: Features for the two classifiers: S and Op

available Op classification of the previous and/or next EDUs. Of course, for a raw input text, such a classification is not available. Hence, we have devised an iterative procedure for the Op classifier, which first starts with an Op classification by using all the features in Table 2, except for DFM. This provides a first Op classification of the input EDUs, which is used for *bootstrapping* a second iterative Op classification of the EDUs, this time by using all the features in Table 2.

In order to guarantee the convergence of the procedure, we rely on the idea that the goal of the Op classification is mainly to detect *OO* EDUs among intrinsically *O* EDUs. Thus, from the perspective of the Op partitioning of the EDU space, the classification is supposed to start with all the input EDUs as Non_EvalOp, and then to move the appropriate ones into the Eval_Op class. This boils down to imposing a constraint on the second Op classification in the iterative procedure, namely, that it does not alter the class of the EDUs which had already been classified as Eval_Op. The stopping criterion consists in the stabilization of the F-measure of the classifier with respect to the initial test data. The procedure assumes that both classifiers (the bootstrapping one and the iterative one) have been trained on the same data, except that the feature vectors are defined as appropriate for each classifier; the DFM features are determined, in the training phase, by relying on the gold annotation of the training EDUs.

The procedure goes as described below, where $bootstrp\_vs$ is the set of bootstrapping feature vectors, and $curr\_vs(i)$ is the set of input feature vectors at iteration i. $preds(i)$ are the predicted class labels of the respective SVM classifier, at iteration i; $\leftarrow$ is the assignment operator; $F\_score(A, B)$ is the F-measure between the class labellings of a list of feature vectors, A, and a list of class labels, B, both lists having the same length. $\oplus$ is an operator that takes the same types of arguments as F_score, A and B, and implements the filter on the Eval_Op EDUs ensuring the convergence of the iterative procedure ($length(A)$ is the number of elements in list A). It is defined as:

$A \oplus B ::=$ for i from 0 to $length(A)$:
if $class(A[i])$ = Non_EvalOp:
$class(A[i]) \leftarrow B[i]$.

We call ϵ the "convergence factor", a threshold of the F-measure variation from one iteration to another. MAX_ITER is the maximum number of iterations if convergence is not achieved before. The procedure is:

for an input test document $test$:

1. compute $bootstrp\_vs$, with all features except for DFM;
2. apply the bootstrapping classifier on $bootstrp\_vs$; obtain thus $preds(0)$ and $F\_score(0) \leftarrow F\_score(bootstrp\_vs, preds(0))$;
3. compute DFM by using $preds(0)$; obtain thus $curr\_vs(0)$;
4. for n from 1 to MAX_ITER:
   4.1 $curr\_vs(n) \leftarrow curr\_vs(n-1) \oplus preds(n-1)$
   4.2 apply the iterative classifier on $curr\_vs(n)$; obtain thus $preds(n)$ and $F\_score(n)$ $\leftarrow$

$F\_score(curr\_vs(n), preds(n))$;

4.3 if $||F\_score(n) - F\_score(n-1)|| \leq \epsilon$:

STOP

5. compute $F\_score(preds(n), test)$.

7 Experiments and Results

Several experiments were performed for testing the validity of our subjectivity classification approach, and especially of the contextual features. Thus, first the two classifiers are assessed in a 10-fold cross-validation on the development corpus. Secondly, the two classifiers are evaluated on the 21-document test corpus, with the entire development corpus used for training. For both setups, we have used the SVM-light software package[3]. Due to the fact that the feature vector spaces were found to be non-linearly-separable for both the S and Op classifiers, training was performed by using polynomial kernels. The Op classifier is evaluated in two manners when DFM features are used: first, the values of these features are drawn from the class annotation of the EDUs as given in the manually annotated corpus. Secondly, the iterative approach has been used, in order to test the approach in the real-life scenario when the contextual features cannot be detected by relying on a prior annotation of the input data. In all situations, the four rules introduced in Section 6 are used on the results of the two classifiers for inferring the finer-grained class of each EDU.

7.1 Evaluation of the Classifiers

We first present, in Table 3 the results of both classifiers, both in 10-fold cross-validation on the development corpus ("Gold"), and on the test data ("Test"). We first start with baseline feature sets, to which several features are progressively added; this is marked by the "+" sign. The best performances are marked in boldface. For the S classifier, our baseline considers only emoticons, all entries from the lexicon, except adverbs of manner or negation as well as modalities, along with the presence of a reporting verb with no argument. We observe that when adverbs of manner are added, all the performance figures improve, on both Gold and Test data (although a slight loss in precision is noticed on the new data). We also observe that adding SWSD yields the best performance figures for S.

For the Op classifier, our baseline uses local and syntactic features which rely on our lexicon: the presence of a subjective word or an emoticon or a modal or a word in the scope of a modal. Adding stylistic features provides a slight improvement of all the performance figures on the Gold but a slight degradation on the Test data. This might be due to a less regular way of using punctuation marks. The use of the feature referring to the presence of comparative and superlative patterns in the Gold slightly degrades precision, but provides the best recall of all the feature combinations for the Op classifier. On the Test data, no change in the measures is recorded. When syntactic patterns are added the recall slightly degrades but the accuracy and precision improve, thus providing the best F-score of all the feature combinations on the Gold. However, on the Test data all performance figures slightly degrade. Adding SWSD degrades the recall and, slightly, the F-measure but improves the accuracy and precision; this is true for the Gold and for the Test data. Adding contextual features that do not rely on a prior classification of the context slightly degrades accuracy and precision in the Gold, but provides a more significant improvement in the recall and yields a slightly higher F-score than without these features.

On the Test data, contextual features detect more subjective (explicit or implicit) EDUs than without them. Adding contextual features that rely on a prior classification of the EDUs, provides the best accuracy and precision of all our feature sets which shows their added value. The recall however, worsens on both the Gold and on the Test data (and so does the F-measure), because of the sparseness of the discourse markers in our corpus. Indeed, these last contextual features rely on surface cues which mark only a slight proportion of the discourse relations considered (cf. Section 2.3). This shows that although discourse information seems to be useful in detecting (mostly implicit) subjective EDUs that cannot be detected by other surface means, providing a good coverage is a caveat that could be solved, we believe, through a deeper level of analysis (for example lexical semantic). Finally, adding syntactic information pertaining the EDU being a left-detached CC, and to the presence of a reporting or non-polar advice verb without argument, yields only an improvement of the recall and F-measure, but the accuracy and precision worsen.

In the iterative Op classifier, for the convergence factor $\epsilon = 0.01$, the iterative procedure stops af-

Best S / best iterative (contextual) Op	81.45	73.03	97.64	93.03	79.21	74.54	77.88	70.9

Table 4: Accuracies (in percents) for the four-class classification

ter at most 2 iterations on the Gold data, and at most 3 iterations on the Test data. As expected, the accuracies and precisions worsen slightly (by around 1 %) on the Test data, since the classes of the adjacent EDUs are not provided beforehand by the gold standard. However, on the Test data the accuracy (but not the precision) very slightly improves (by less than 0.5 %). The recall increases slightly as well on both data sets (by around 1 % as well), which means that the imperfections of the iteratively-obtained classification of the adjacent EDUs somewhat compensates for the limits of these two features themselves.

7.2 Evaluation of the Four Classes

We now show the results of the classification of the EDUs in the four classes *S*, *OO*, *SN* and *O*, obtained by applying the four rules described in Section 6 on the outputs of the S and Op classifiers with the feature sets providing the best performance figures, according to the boldface results in Table 3. For the contextual Op configuration we analyze both the non-iterative (non-iter. Op) and iterative (iter. Op) performance effects on the four classes. The accuracies are synthesized in Table 4. We observe that adding contextual features improves the performance figures, except for the *SN* class, where they degrade by 0.01 % for the non-iterative contextual Op, and, only on the Test data, for the *O* class, where they degrade by 0.21 %. We especially notice the dramatic improvements, on both the Gold and the Test data, for the *OO* class, of implicit subjective EDUs. We thus see that the contextual features provide an improvement of around 5–6 % for the accuracy. The improvements are, as expected, less marked in iter. Op. However, the degradation is rather slight: less than 2 % for the *OO* class and even less for the other classes. Nonetheless, even with the iter. Op, the performance figures remain higher than with the non-contextual Op classifier. Interestingly, in iter. Op, performance figures for the *S* (on the Gold only) and *SN* classes slightly improve.

8 Conclusion and Further Work

In this paper, we have assessed a discourse-based approach to SA. We have proposed a method to distinguish between four types of discourse units, by using both local and global context features. In the future, we plan to annotate opinion documents with SDRT-inspired relations, in order to learn them automatically from several cues other than discourse markers. We believe that the real strength of the discourse-based approach to opinion analysis appears when assessing the global polarity of documents.

Abstract

There is serious data sparseness problem in Chinese dictionary stored in a double-array trie. This paper proposes six compression methods by code mapping and code dividing to make it more compact, and a metric called Resource Consumption Ratio is proposed to evaluate these methods. Under the proposed criteria, five of the six methods are better than the baseline. The best method maps the character code into its frequency order, and then divides it into two jump codes. It achieves a space usage reduction of 39.88% and takes only 0.20% time of the baseline on the construction while it takes 13.21% more time on the retrieval. As preprocessing methods, these methods can be used to reduce more space by combining to other compression method which improves the double-array structure itself.

1 Introduction

In many applications of processing strings, a trie search is very useful because it enables fast retrieval and longest prefix matching with a small dictionary (Fredkin, 1960). Tries are used in a broad range of applications to represent a set of strings in fields such as information retrieval systems (Brain and Tharp, 1994; Nelson, 1997; Okada et al., 2001), lexical analyses (Aho et al., 2007; Lesk, 1975), morphological analyses (Aoe et al., 1996), natural language processing (Baeza-Yates and Gonnet, 1996; Peterson, 1980), bibliographic search (Aho et al., 1975), pattern matching (Flajolet and Puech, 1986), for IP address routing tables (Fu et al., 2007; Nilsson and Karlsson, 1999; Pao and Li, 2003), and text indexing (Navarro, 2004).

Double-array is a trie implementation which is proposed by (Aoe, 1989), and it is widely used in many applications at present because it combines the fast access of a matrix form with the compactness of a list form. However, there is a serious data sparseness problem when the double-array is used to store Chinese dictionary (Chinese double-array, hereafter, and similarly, English double-array for English dictionary). For a typical English dictionary with 45,373 words, the compression ratio of the double-array reaches 94.48%, but for a Chinese dictionary with 343,103 words, it's only 43.95%. In this paper, we analyze the reasons which lead to the data sparseness, and propose several methods to reduce the space usage of the Chinese double-array.

This paper is organized as follows: Section 2 introduces related work. Section 3 describes the outline of the double-array. In Section 4, we analyze the reasons resulting in the data sparseness. In Section 5, we give a baseline double-array, and propose six methods to make the double-array more compact. We propose the evaluation metric in Section 6. We make experiment and evaluate the six methods in Section 7. Section 8 concludes this paper.

2 Related work

Aoe (1989) presented an efficient digital search algorithm by introducing the structure called a double-array, which combines the fast access of a matrix form with the compactness of a list form.

Aoe (1992) proposed an implementation of the double-array which stores only as much of the pre-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1189–1197,
Chiang Mai, Thailand, November 8 – 13, 2011.

fix in the trie as is necessary to disambiguate the key, and the tail of the key is stored in a string array, denoted as TAIL. This structure is called a minimal prefix (MP) double-array.

Andersson and Nilsson (1993) introduced level-compressed (LC) trie to compress parts of the trie that are densely populated (Nilsson and Karlsson, 1999). A recent improvement in the LC trie is proposed by Fu et al. (2007).

Bentley and Sedgewick (1997) first presented the Ternary Search Tree (TST). TST combines the attributes of binary search trees and digital search tries.

Heinz (2002) proposed the burst trie, which is a collection of "containers" that are accessed via a conventional trie. It achieves high space efficiency by selectively collapsing chains of trie nodes into small containers of strings that share a common prefix. Askitis and Sinha (2007) proposed an improvement of burst trie called the HAT-trie which uses cache-conscious hash tables. Compared with a TST, the burst trie is 25% faster and uses only 50% of the memory, though it was found to be slower than TST with genomic data (Heinz et al., 2002).

Oono (2003) presented a method of dividing a key into several parts and defining link information between keys. It turned out that the double-array is 30% smaller than old method.

Wang (2006) proposed an improved strategy for the double-array. The node with most child nodes is inserted firstly while constructing, which reduces the data sparseness and keeps the search efficiency. Li (2006) designed and implemented a Chinese dictionary based on the double-array. Wang et al. (2009) introduced the idea of Sherwood random thoughts and mutation of genetic algorithms to improve the performance of the method proposed by Wang (2006) to avoid catching the trap of local optimal solution.

Yata (2007) presented two compaction methods for a static MP double-array, an element compaction and a trie compaction. The element compaction reduces the size of each element. The trie compaction reduces the number of nodes (a descended trie) and the length of the array keeping suffixes. The space usage for the new double-array is under the half of that for the original one, but the compaction methods little degrade the retrieval speed of the double-array.

Dorji (2010) presented three methods to compress the MP double-array. The first two methods accommodate short suffixes inside the leaf nodes, and prune leaf nodes corresponding to the end marker symbol. They achieve size reduction of up to 20%, making insertion and deletion faster at the same time while keeping the retrieval time of $O(1)$. The third method eliminates empty spaces in the array that holds suffixes, and improves the size reduction further by about 5% at the cost of increased insertion time. Compared to a TST, the key retrieval of the compressed double-array is 50% faster and its size is 3-5 times smaller.

All the compression methods are focusing on the corresponding trie or the double-array structure itself. However, the space usage of a double-array is very relevant to the content which is stored in it. We will compress the double-array by preprocessing the content.

3 Outline of double-array

A double-array is an array form of a trie (Aoe, 1989). It uses two one-dimensional arrays, named BASE and CHECK, to represent a trie. An element of the trie consists of the two array units with the same index in BASE and CHECK. Every element corresponds to a node of the trie, except empty elements, and we will also take the nonempty element as a node in this paper. For a certain node, the unit in BASE indicates the offset to child nodes, while the unit in CHECK normally stores the index of the parent node.

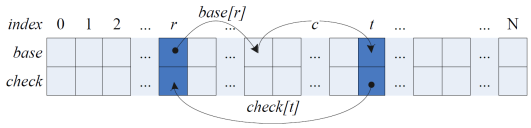

Figure 1: Relation between a node t and its parent node r in the double-array

As shown in Figure 1, in a double-array, a node t is a child of another node r, if and only if there is a relation between the two nodes.

$$\begin{cases} BASE[r] + c & = t \\ CHECK[t] & = r \end{cases} \quad (1)$$

where c is a numerical value corresponding to a character in a key, which we call "jump code" because it leads to a jump (state transition) from a node to its child node.

The retrieval of a key is just a walk from the root node to a leaf node, which is done fast by array operations in the double-array. The time complexity

for a state transition from node r to its child node t is $O(1)$ in the double-array, thus the time complexity for retrieving a key is $O(k)$ for the length k of that key.

4 Data sparseness problem analysis

Unlike alphabetic writing script, Chinese is an ideographic script which has a large character set. There are more than 70,000 coded Chinese characters in Unicode 6.0. Although most of them are historic characters, there are still a large amount of characters that are frequently used. As in the Chinese dictionary mentioned above, there are more than 14,000 characters used.

The data sparseness problem of Chinese double-array mainly results from the large character set. First, jump codes vary in a large interval. In Unicode 6.0, the code of Chinese character varies from 3400 to 9FCB, and there are still a large amount of characters out of the range because they are out of the basic multilingual plane and should be represented by surrogate pairs which are in the interval from D800 to DFFF. But, not all of the characters are used in the dictionary. As a result, there are many empty elements between the most left child node and the most right one from the same parent in the double-array while inserting, although some of them may be used to store other nodes soon after. Second, a node has much more child nodes in Chinese trie than in English. In the Chinese dictionary, there are more than 800 words which begin with the same character "" meaning "one", which indicates that the corresponding node will have more than 800 children. However, in an English trie, the number of child nodes for any node doesn't exceed 52 for there are only 26 letters in the alphabet. More child nodes lead to more collision, which results in more empty elements indirectly.

5 Compression of Chinese double-array

In this section, we first present a baseline double-array, and then propose six methods of compaction. For each method, we only focus on the space usage, and compare it with the baseline from node count (NC), array length (AL), auxiliary space and compression ratio (CR). CR is the ratio of the number of non-empty elements to the total number of elements in the double-array. It represents the compactness of the double-array. We will use it to estimate how much room there is to apply compression method to reduce the space usage. We evaluate each method by calculating the space reduction rate (SRR), which is the ratio of the total space usage of each method to that of the baseline.

5.1 Baseline

Simply, we take the double-array proposed by (Aoe, 1989) which uses directly the code of a character as the as the baseline. Generally, there is an array called TAIL (Aoe et al., 1992) which stores suffix strings in the MP double-array. But we use the original double-array which store all the whole keys rather than only the minimal prefixes as the baseline to compute the space usage conveniently. As each unit in the array is an integer which takes up 4 bytes memory, the total space usage can be calculated as follow: $8bytes \times len$, where len is the length of the double-array.

We use the character code as the jump code in the baseline. For the key set K={"中国", "中国象棋", "中间", "上海", "上浮"} in which it means "China", "Chinese chess", "middle", "Shanghai" (a city of China), "floating upward" respectively, the corresponding trie is as shown in Figure 2. Note that a node with two concentric circles corresponds to an acceptance state which indicates the end of a word.

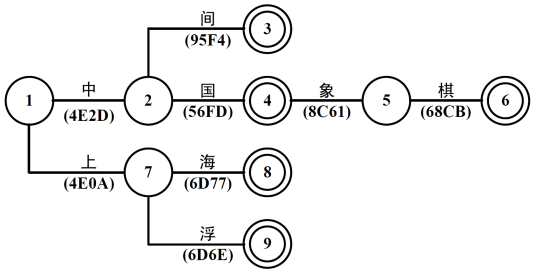

Figure 2: The trie of the key set K.

Based on the trie shown in Figure 2, a Chinese double-array is built to store the Chinese dictionary. As it will be represented by a surrogate pair if a character is out of the basic multilingual plane, we will take it as two characters for convenience. The baseline takes 1,714,339 units for the BASE and CHECK respectively, in which only 753,412 units are not empty, and the CR is 43.95%. As we analyzed in the former section, the first method we can think out is mapping the jump codes into a small interval.

5.2 Code mapping methods

As shown in Figure 3, this method maps the codes of all characters used in the dictionary into a small continuous interval. BASE stores the offsets from each node to its child nodes, and different start points only lead to different offsets, which hardly affect the space usage. So the start point of the interval is not very important. In this paper, we take 80 (hex) as the start point to make it compatible with English script. The mapping just changes the value of each jump code, while the trie keeps unchanged.

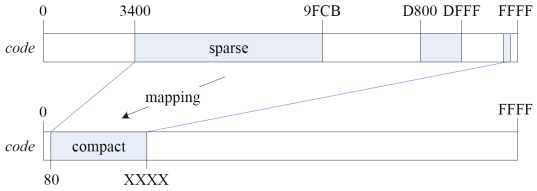

Figure 3: Code mapping.

We have to use another array to store the mapping table. Each unit takes 2 bytes, and 65536 (10000 in hex) units are needed to include all codes in basic multilingual plane. The auxiliary space is: $2\ bytes \times 65536 = 131072\ bytes$.

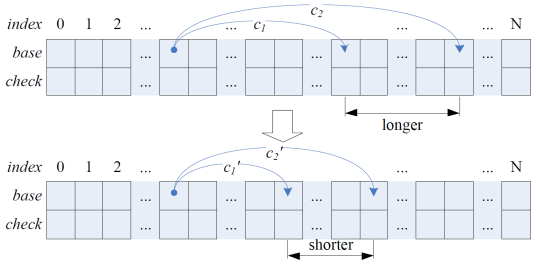

Figure 4: Double-arrays before and after applying code mapping method.

As shown intuitively in Figure 4, before applying code mapping method, for every node in the trie, there is a long distance between the most left child node and the most right one. After apply the method, the distance becomes much shorter. The number of child nodes keeps the same, data is more compact for the parent node, and the collision is controlled in a small range in the double-array while inserting other nodes. As child nodes for every intermediate node are arranged more compactly, it alleviates the data sparseness problem more or less.

Based on code mapping, we introduce the following two methods:

Method 1: Mapping each character code to its original order number in Unicode. The method takes the order number as the jump code for each character used in the dictionary, and keeps their original codes for others during the retrieval process. The relation between the target jump code c' and the original jump code c can be represented by the following formula:

$$c' = order(c) + C \tag{2}$$

where $order(c)$ is the order number of c among all the Chinese characters used in the dictionary when they are sorted in ascending order by code, and C is a constant which indicates the start point of the target interval. We set C equal to 80 (hex).

This method is already used by many people (Aoe, 1989; Aoe et al., 1992; Wang et al., 2006; Li et al., 2006; Dorji et al., 2010). Wang (2006) and Li (2006) used this method in their dictionary, but they just simply map the Chinese characters coded in the Chinese standard GB 2312 to 1∼6763.

As shown in Table 1, after the mapping, the CR is improved to 47.49%, and it reduces the space usage of the double-array by 6.51% in total considering the auxiliary space. As the CR is still very low, there is much room for improvement.

	NC	AL	AS (bytes)	CR	SRR
Baseline	753412	1714339	0	43.95%	
Method 1	753412	1586337	131072	47.49%	6.51%

Table 1: Space usage of Method 1 compared with the baseline.

In Method 1, we make code mapping according to their original order in Unicode. However, different characters have different frequencies in the dictionary, then what will happen if we map two characters with the same frequency to two target jump codes of which the numerical difference is as small as possible?

Method 2: Mapping the jump codes to their frequency orders. Then, all high frequency characters will be mapped into a small interval. If two characters leading to state transitions from the same node to its two child nodes are both frequency used in the dictionary, then the distance between the two child nodes will be shorter than in Method 1. The relation between the target jump code c' and the original one c is represented by the following formula:

$$c' = freqorder(c) + C \tag{3}$$

where $freqorder(c)$ is the order number of c among all the Chinese characters used in the dic-

tionary when they are sorted by frequency in descending order.

As shown in Table 2, after the mapping, the CR is improved to 58.56%, and it reduces the space usage of the double-array by 23.99% in total.

	NC	AL	AS (bytes)	CR	SRR
Baseline	753412	1714339	0	43.95%	
Method 2	753412	1286622	131072	58.56%	23.99%

Table 2: Space usage of Method 2 compared with the baseline.

Compared with Method 1, Method 2 makes a significant improvement, but there is still room for improvement.

5.3 Code dividing methods

We make all jump codes varying in a small interval by code mapping, but the interval is still much larger than that in the English double-array. It spreads from 80 (hex) to 3730 (hex), for there are more than 14,000 Chinese characters are used in the dictionary. However, in a English double-array, the jump codes vary in a much smaller interval, which is from 41 (hex of letter "A") to 7A (hex of letter "z") originally. To compress the interval equivalent to that of English, we divide each original jump code into two or more jump codes to break a long jump in the original double-array into two much shorter jumps.

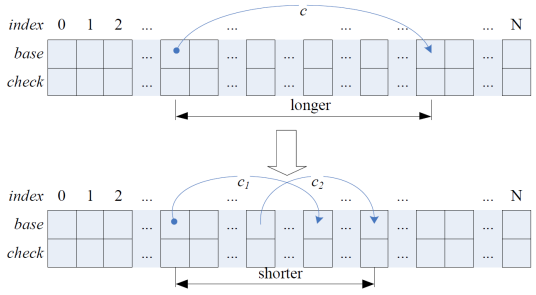

Figure 5: Double-arrays before and after applying code dividing methods.

As shown in Figure 5, every original jump code is divided into two jump codes. A state transition in the original double-array becomes two state transitions in the new double-array. The node (state) count increases. But it becomes more compact, it's still possible to reduce the space usage.

Method 3: Divide the code of a Chinese character into two small codes. To ensure that the two codes vary in equivalent interval, we take the high byte of the code as the first target code, and the low byte as the second. To make it compatible with English, we also change the start point of the interval to 80 (hex) as we do in Method 1. The relation between the two target jump codes c1, c2 and the original jump code c can be represented by Formula 4.Note that in the formula, $(c \gg 8)$ and $(c\&FF)$ are just the high/low byte of the c.

$$\begin{cases} c1 &= (c \gg 8) &+ C \\ c2 &= (c \,\&\, FF) &+ C \end{cases} \tag{4}$$

Generally, the sum of c1 and c2 is much smaller than c. For example, for a certain Chinese character "一", $c = 4E00$, then $c1 = CE(hex), c2 = 80(hex)$, and $c1 + c2 = 014E(hex)$, which is much smaller than c1. It results in shorter distance between a parent node and its child nodes, and shorter distance between different child nodes from the same parent.

As every original jump code is divided into two jump codes, the corresponding trie changes. For the key set K, the corresponding trie is shown in Figure 6. Although each jump code is divided into two, the total node count is smaller than the twice of the original trie's, because some nodes are shared, just like the nodes 2 in Figure 6 because "中" and "上" have the same high byte. It's similar to node 13.

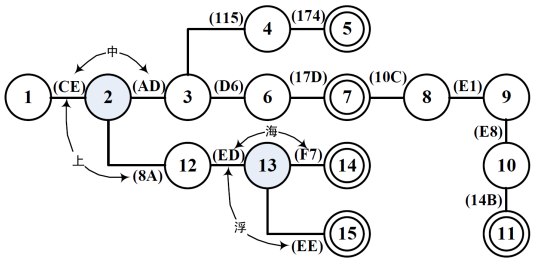

Figure 6: The new trie of key set K.

	NC	AL	AS (bytes)	CR	SRR
Baseline	753412	1714339	0	43.95%	
Method 3	998995	1043342	0	95.75%	39.14%

Table 3: Space usage of Method 3 compared with the baseline.

As shown in Table 3,every original code is divided into two codes, the node count of the double-array increases by 32.60% from 753412, but the CR is improved to 95.75%, which is similar to English double-array. So the length of the double-array is still smaller than the baseline. Meanwhile, Method 3 doesn't use a mapping table. It needs no auxiliary space. Thus, the space reducing rate reaches 39.14% in total.

Then what will happen if we divide the original code into 3 or more codes?

Method 4: Take the UTF-8 sequence of Chinese character as the corresponding jump codes.

	NC	AL	AS (bytes)	CR	SRR
Baseline	753412	1714339	0	43.95%	
Method 3	998995	1043342	0	95.75%	39.14%
Method 4	1200403	1264949	0	94.90%	26.21%

Table 4: Space usage of Method 3 and Method 4 compared with the baseline.

As shown in Table 4, after applying Method 4, the node count increases nearly 60% compared with the baseline, which leads to more space usage than Method 3. The CR of Method 4 is a little smaller than that of Method 3. The space usage reduction rate is only 26.21%, which is much smaller than Method 3. In a word, Method 3 is better than Method 4.

5.4 Combined methods

Then, what will happen if we combine methods of code mapping and code dividing? Let's have a try. Combining Method 3 to each of the code mapping methods, we get Method 5 and Method 6. Method 4 is worse than Method 3. We won't try to combine it to the code mapping methods.

Method 5 (Method 1 + Method 3): First, map the original character to its order number, and then divide it into two target jump codes. The corresponding formula of Method 5 is as follow:

$$\begin{cases} c1 &= (order(c) \gg 7) &+ C \\ c2 &= (order(c) \,\&\, 7F) &+ C \end{cases} \tag{5}$$

Method 6 (Method 2 + Method 3): First, map the original character to its frequency order number, and then divide it into two jump codes. The corresponding formula of Method 6 is as follow:

$$\begin{cases} c1 &= (freqorder(c) \gg 7) &+ C \\ c2 &= (freqorder(c) \,\&\, 7F) &+ C \end{cases} \tag{6}$$

Note that we don't shift by 8 bits any longer like in Method 3 and Method 4, because the total number of characters used in the dictionary is about 14 thousand, and so it needs only 14 valid bits to represent all the order numbers.

As shown in Table 5, Method 5 and Method 6 both need auxiliary space to store the mapping table like in Method 1 and Method 2. They both achieve a CR larger than 95% and reduce the space usage by a percentage near or even larger than 40%, which is similar to Method 3. However, Method 6 is slightly better than Method 5 from the aspect of space usage, just like Method 2 is slightly better than Method 1.

	NC	AL	AS (bytes)	CR	SRR
Baseline	753412	1714339	0	43.95%	
Method 5	972703	1014204	131072	95.91%	39.88%
Method 6	925643	962857	131072	96.14%	42.88%

Table 5: Space usage of Method 5 and Method 6 compared with the baseline.

Now, we don't think there is still much room for improvement because the CR is close to 100% and neither combined method makes big improvement compared with Method 3.

6 Evaluation metric

If we evaluate several methods or systems from n aspects of resources consumption such as space usage and time cost, and then we denote the value on the ith aspect by V_{Ai} and the normalized weight of the ith aspect by w_i. We define the resource consumption ratio (RCR) of two methods A and B as follow:

$$RCR(A,B) = \prod_{i=1}^{n} \left(\frac{V_{Ai}}{V_{Bi}} \right)^{w_i} \tag{7}$$

RCR has the following properties:

- $RCR(A,A) = 1.0$, if a method A is compared with itself;
- $RCR(A,B) = 1.0$ means the two methods A and B are equally good or bad;
- $RCR(A,B) > 1.0$ means the method A is worse than the reference method B, because it consumes more resources.
- $RCR(A,B) < 1.0$ means the method A is better than the reference method B because it consumes fewer resources.

7 Experiment and Evaluation

In this section, We evaluate the six methods from the following aspects:

1. Total space usage (TSU), including the space for the double-array and the mapping table.
2. Construction time (CT), including the time spent on making the code mapping or the code dividing.

3. Retrieval time (RT) on searching all words in the dictionary.

7.1 Experiment

The dictionary used in this paper is the Modern Chinese Dictionary in Traditional Chinese.

Normally, a double-array allocates space many times to extend space to accommodate newly inserted nodes during the construction. As different methods have different space usage, they may need different times of space allocation, and thus need different time cost. We simply allocate a large enough space in advance for the double-array before the construction to eliminate the difference of time cost on space allocation.

It takes a short time to retrieve all words in the dictionary once. If we execute the experiment twice, the time costs will be very different from each other if it is interfered by some accidental factors. We do the retrieval 1000 times to alleviate the problem mostly and keep the time costs comparable.

The experiment is performed on a computer with an 8-core 2.80GHz Intel Core i7 CPU and 2.96GB memory. The experimental data is shown in Table 6. Note that SUR, CTR, RTR is the ratio of TSU, CT, RT in each method to that in the baseline respectively.

7.2 Evaluation

	Baseline	Method 1	Method 2	Method 3	Method 4	Method 5	Method 6
NC	753412	753412	753412	998995	1200403	972703	925643
AL	1714339	1586337	1286622	1043342	1264949	1014204	962857

Figure 7: Node count and array length.

As we see from Figure 7 and Figure 8, Method 1 and Method 2 achieve space usage reduction of 6.51% and 23.99% respectively, but they take too much time on the construction. Method 3 achieves a space usage reduction of 39.14% while it takes very short time on the construction. It takes a little longer time on the retrieval than the baseline. Method 4 also takes very short time on the construction, but much more time on the retrieval and it only achieves a space usage reduction of

	Baseline	Method 1	Method 2	Method 3	Method 4	Method 5	Method 6
CR	43.95%	47.49%	58.56%	95.75%	94.90%	95.91%	96.14%
SRR	0.00%	6.51%	23.99%	39.14%	26.21%	39.88%	42.88%
SUR	1.0000	0.9349	0.7601	0.6086	0.7379	0.6012	0.5712
CTR	1.0000	0.9284	1.1127	0.0023	0.0020	0.0020	0.0029
RTR	1.0000	1.2522	1.2664	1.1443	1.4673	1.1321	1.2360

Figure 8: Comparison of the six methods.

26.21%. Method 5 achieves a better space usage reduction, short time cost both on construction and retrieval than Method 3. Method 6 achieves the best space usage reduction by 42.88%, but it takes longer time cost on the construction and retrieval than Method 5. Method 3∼6 have more nodes because they have divided original codes into two or more codes, but they makes the double-array more compact, so every one of them has a CR close to 97%. Method 6 takes more time on the construction than Method 5, which is similar to Method 2 and Method 1, because it has to spend time to sort the characters by frequency. All the methods take more retrieval time, but result from different reasons. Method 1 and Method 2 have to make the code mapping while Method 3∼6 have to make the code dividing and visit more nodes while searching a key.

Now, we evaluate the six methods with the metric proposed in the former section from three aspects: space usage, construction time, retrieval time. We assign the three aspects with weights (9/20, 1/10, 9/20) respectively. The construction is only performed once but the retrieval is performed many times for a double-array, so the construction time is assigned a smaller weight, and the space usage has an equal weight to retrieval time because we can't decide which is more important roughly without any application scenarios. We compare each method A with the baseline to calculate each RCR:

$$\begin{aligned} RCR(A) &= RCR(A, baseline) \\ &= SUR^{\frac{9}{20}} \times CTR^{\frac{1}{10}} \times RTR^{\frac{9}{20}} \end{aligned} \tag{8}$$

We calculate the RCR of each method with the

	NC	AL	CR	SRR	TSU(byte)	SUR	CT(ms)	CTR	RT(ms)	RTR	RCR
Baseline	753412	1714339	43.95%	0.00%	13714712	1.0000	504437	1.0000	23172	1.0000	1.0000
Method 1	753412	1586337	47.49%	6.51%	12821768	0.9349	468328	0.9284	29015	1.2522	1.0655
Method 2	753412	1286622	58.56%	23.99%	10424048	0.7601	561265	1.1127	29344	1.2664	0.9935
Method 3	998995	1043342	95.75%	39.14%	8346736	0.6086	1140	0.0023	26516	1.1443	0.4621
Method 4	1200403	1264949	94.90%	26.21%	10119592	0.7379	1015	0.0020	34000	1.4673	0.5570
Method 5	972703	1014204	95.91%	39.88%	8244704	0.6012	984	0.0020	26234	1.1321	0.4506
Method 6	925643	962857	96.14%	42.88%	7833928	0.5712	1484	0.0029	28641	1.2360	0.4773

Table 6: Comparison of the six methods and the baseline.

values collected from the experiment, and the results are shown in Figure 9.

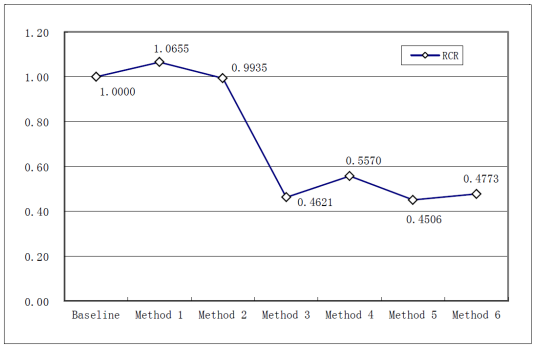

Figure 9: RCRs of the six methods.

As we see in Figure 9, most of the six methods are better than the baseline except Method 1, whose RCR is slightly larger than 1.0. Method 5 has the smallest RCR and it outperforms others.

8 Conclusion

We propose six methods to reduce the space usage of Chinese double-array. Method 1 and Method 2 achieve space usage reduction of 6.51% and 23.99% by code mapping into the order number or frequency order number respectively, but they take too much time on the construction. Method 3 achieves a space usage reduction of 39.14% by dividing each original jump code into two codes while it takes very short time on the construction. It takes a little longer time on the retrieval than the baseline. Method 4 divides the original jump code into three codes. It also takes very short time on the construction, but much more time on the retrieval and it only achieves a space usage reduction of 26.21%. Method 5 and Method 6 are the combinations of Method 3 with Method 1 and Method 2 respectively. Method 5 achieves a better space usage reduction, short time cost both on construction and retrieval than Method 3. Method 6 achieves the best space usage reduction by 42.88%, but it takes longer time cost on the construction and retrieval than Method 5.

Also, an approach is proposed to evaluate those methods by a metric called Resource Consumption Ratio (RCR) which compares the total resource consumption of two methods such as space usage and time cost. Under the proposed criteria, five of the six methods are better than the baseline, and the best one (Method 5) achieves a space usage reduction by 39.88% and takes only 0.20% time of the baseline on the construction, while it takes 13.21% more time on the retrieval. As preprocessing methods, these methods can be used to reduce more space by combining to other compression method which improves the double-array structure itself.

Functional Elements and POS Categories

Abstract

We propose a bootstrapping algorithm which successfully resolves two fundamental tasks: morphology acquisition and the acquisition of a subset of functional words. Given the outputs of these fundamental tasks, we build a nearly state-of-art morphology analyzer performing with a F1-score of 80.94%; also, we can improve the baseline model for acquiring functional words by an absolute error reduction of 26%. Furthermore, with these acquisition outputs, a minimally supervised tagging system proposed before can be turned into a totally unsupervised one, achieving a tagging accuracy of 85.26% for open-class words.

1 Introduction

Studies of child language acquisition have shown that functional elements as distinctive categories are available to the child from very early on. These include both functional words (closed class items) such as determiners (Valian et al., 2009), and functional bound morphemes such as verbal inflections (Yang, 2002). Motivated by such studies, we propose that functional categories, including both functional words and functional morphemes, should be identified first in the process of acquiring syntactic categories automatically from language input. Further motivation comes from the experimental results of the minimally supervised tagging system in (Zhao and Marcus, 2009)[1], which, given only seven functional features, including four contextual features, whether modal verbs or determiners are left or right neighbours, and three specific morphological features, whether *'-ing', '-ed'*, or *'-s'* are observed as endings, performs clustering in order to generate the two fundamental open class categories, verbal vs. nominal. This work suggests that functional elements are highly useful in further classification of open class items.

This is quite different from most other POS induction systems in the Natural Language Processing (NLP) field for inducing Part-of-Speech (POS) tags, which, instead of generating clusters complying with the common understanding of 'syntactic' categories, such as distinct clusters of determiners, nouns or inflections of verbs, tend to output scattered clusters consisting words of interesting similarities on many different dimensions (Christodoulopoulos et al., 2010). This is because, in these clustering-based systems, a vector space over the words is spanned by lexical features and suffix/prefix features, so that the generated clusters mix semantic and syntactic similarities (Clark, 2000).

In this work, we explore an alternative 'top-down' view of deriving categories, as opposed to the 'bottom-up' view adopted by these earlier distributional clustering methods. Here, we report on experiments which acquire functional elements first and integrate the acquisition output into a full unsupervised POS tagging system later. Since we are not aware of previous work to acquire functional elements, we approach the problem by seeking answers for the following two questions: 1) What are the special properties of the distribution of functional elements that enables the child to distinguish them easily from other categories at a very early stage of acquisition? 2) What might the acquisition processes of the two forms of functional elements (bound vs. free) have in common, reflecting some deeper distributional property of functional elements in general?

[1]The tagging system in (Zhao and Marcus, 2009) was referred to as 'unsupervised' in their paper, because back then, a lexicon was a common input to so-called unsupervised POS tagging systems. We classify their system as minimally supervised here, so as to differentiate it from this work which requires only raw text as input.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1198–1206,
Chiang Mai, Thailand, November 8 – 13, 2011.

We believe that answers to these questions begins to emerge from the success of a single bootstrapping algorithm proposed here to the acquisition of both bound and free functional elements, i.e. closed class words and bound morphemes. This bootstrapping algorithm explores a particular simple contextual property of functional elements, which we call the *diversity property*, and resolves both fundamental acquisition tasks without any input beyond raw written text:

> 1) **Bound morphemes** Separating functional elements in the form of bound morphemes from contentful elements. As for English, the two output sets are a list of productive endings such as *'-ed'*, and *'-s'*, and a list of base stems such as *'consist-'* and *'bootstrapp-'*.
>
> 2) **Free morphemes** Separating 'first-order' functional elements in form of free morphemes (words) from contentful elements. As for English, the two output sets are a list of modal verbs and determiners (in a general sense[2]), and a list of nominal elements as well as verbs in bare forms.

The bootstrapping algorithm we propose here operates by iteratively generating two complementary sets, (e.g. base stems and productive endings for the bound morpheme task); in these way, it reflects the intuition behind co-training (Abney, 2004), but in a greatly reduced form and requiring no seeds for initialization. For both tasks, the bootstrapping algorithm generates highly reliable outputs, with barely any errors and requires no task-specific parameter settings. For example, it discovers 26 modal verbs and determiners (in a general sense) from raw text of WSJ Treebank (Marcus et al., 1993) with only a single noisy term.

We validate these outputs on a range of useful applications. Given the two sets output by the bound morpheme task, we can straightforwardly build an unsupervised morphology analyzer which achieves an F1-score of 80.94 evaluated on the CELEX corpus, comparable to a state-of-art morph analyzer (Lignos, 2010) which achieves 82.21 F1 on the same task. Next, given this new morphology analyzer and the two output sets from the free morpheme task, we give a new very simple algorithm for acquiring the full set of functional/closed class words, improving on a reasonable baseline model for acquiring functional/closed-class words by an absolute error reduction of 26%, from 63% to 89% type accuracy as evaluated on the WSJ Treebank[3]. Finally, we plug this newly acquired closed-class lexicon into a minimally supervised tagging system, (Zhao and Marcus, 2009), which requires as input exactly such a lexicon. The resulting system, now completely unsupervised, achieves a tagging accuracy of 85.26% for tagging open-class words as evaluated on the whole WSJ Treebank. Although the evaluation is done over 6 open-class tags only, and thus is not directly comparable to related works, the tagging performance reported here is still satisfying given that recently reported unsupervised tagging accuracy vary among 50%-70% e.g. (Abend et al., 2010), (Reichart et al., 2010) and (Moon et al., 2010).

2 Acquiring Functional Elements

Functional elements are those elements that provide structural clues in expressions, which form a complementary set to the contentful elements that provide semantic content of the expressions. Two forms of elements in languages come into our attention, bound morphemes and free morphemes (words). As for English, functional elements of bound morphemes are inflectional endings or derivational endings/prefixes, for example, in a word *'runs'* the contentful part *'run-'* provides us with some contentful information, whereas, the functional part *'-s'* provide us with some grammatical specification which are specially important when the word is used in context. On the other hand, functional elements of free morphemes, generally refer to those closed-class words that don't fall into lexical categories, i.e. those words that are not nouns, verbs, adjectives or adverbs; however, the functional roles these closed-class words play in context are more complicated.

The algorithm described in section 2.2 solves two tasks on acquiring functional elements: 1) identifying productive endings/prefixes vs. base stems (the contentful parts of words), and 2) identifying determiners (possessive determiners and

[2]In this paper, we refer to determiners in a general sense which includes determiners, possessive determiners and demonstratives.

[3]Given the lack of previously reported results, the baseline model we compare against is to select the most frequent words in the corpus as closed-class items.

demonstratives as well) and modal verbs vs. nouns and verbs. Given these acquisition outputs, we can acquire a full set of closed-class words, falling in all functional categories, with a simple extra step. The subset of functional words that are acquirable by the bootstrapping algorithm is referred as 'first-order' functional words in this work, since they include determiners and modal verbs only which don't project to other functional words.

Before introducing the bootstrapping algorithm in section 2.2, we discuss the diversity property of functional elements first, in section 2.1, which is an important concept to be explored in the algorithm.

2.1 Diversity Property

Our algorithm is built upon a distributional property of functional elements well-known to linguists: they occur in diverse contexts. For example, determiner *'the'* in English is observed everywhere in text and inflectional ending *'-ed'* can be concatenated to most verbs to derive past forms. As discussed above, functional elements provide structural clues to compose expressions and are basically independent to the meanings conveyed by the expressions; therefore, they are not bound to co-occur with specific contentful elements and are natively expected to occur in diverse contexts.

In the NLP field, a more popular property known for distinguishing functional elements is that they occur more often. Although frequency can be used to approximate 'diversity', the high frequency of functional elements is only a reflection of their high degree of contextual diversity, which, following the definition, is more accurately approximated by the types of contexts that an element occurs in.

There are few previous works that quantitatively demonstrate that 'contextual' diversity is a better diversity measurement than frequency regarding experimental results. In this work, we are going to explicitly compare these two options for measuring diversity within the bootstrapping algorithm. As shown in all applications (section 3), measuring contextual diversity for diversity brought in a consistent improvement as compared to measuring frequency.

Proper Contexts

We haven't define in what occurrences two elements may form a contextual relationship, and let's consider the case for bound morphemes first. Given a type of word, e.g. *'laughing'*, several ways of dividing it can yield a pair of possible morphemes with either one being *as/in*-context of the other morpheme: for the division *'laugh-ing'*, *'laugh-'* can be considered *in*-context of *'-ing'* and *'-ing'* considered *as*-context of *'laugh-'* or vice verse; or for the division *'laughin-g'*, *'laughin-'* *in*-context of *'-g'* and *'-g'* *as*-context of *'laughin-'*, or vice verse.

For words, ideal scopes to define contextual relationships should be phrases/phases, from a linguistic point of view, such as N(ominal)P, V(erbal)P and so on. However, it is not easy to detect boundaries of phases in unannotated input; therefore, we only consider contextual relationships between two words in adjacency. For the sake of coherence, we consider the preceding word *as*-context of the following word and the following word *in*-context of the preceding one, however, it could also be vice verse, though with worse experimental results.

As one may have noticed, without any further constraints on the concept of contexts, the top 3 bound morphemes with the highest contextual diversity will be *'-d'*, *'-e'* and *'-t'*, which do not comply with our understanding of functional morphemes in English. In other words, for acquiring inflectional or derivational suffix/prefixes, we want to compute contextual diversity of bound morphemes according to properly justified contextual relations only, instead of from all arbitrary divisions of words. The most simple way of justifying one element as proper contexts for other elements is to check whether it can serve *as*-context of more than one type of element, by which criteria *'laughin-'* is not justified, since it cannot be concatenated by other suffixes than *'-g'* to form a legal word. It is first noticed in (Chan, 2008) that morphological transformations should be discovered with respect to 'base forms', i.e. properly justified contentful stems; and we generalize this idea for a better measurement of diversity to acquire both forms of functional elements in this work.

Suppose that we are given a set of properly justified contexts of bound morphemes including *'laugh-'* but not *'b-'*, the diversity measurement of *'-ing'* will increase by one given the existence of word *'laughing'* but not given word *'bing'*. For the case of words, if only nouns are justified to be proper contexts, then the top words of highest

diversity should be determiners. More formally, given a set $\mathbb{B}$ of justified contexts, we can define two measurements of diversity for an element e, frequency or contextual diversity as discussed above:

$$tokenC(e, \mathbb{B}) = \sum_{e' \in \mathbb{B}} \text{\# occur. of } e' \textit{ in}\text{-context of } e$$

$$typeC(e, \mathbb{B}) = \sum_{e' \in \mathbb{B}} \text{\# occur. of } e' \textit{ in}\text{-context of } e > 0$$

2.2 The Bootstrapping Algorithm

The proposed bootstrapping algorithm in Algorithm 1 generates two complementary sets during the bootstrapping process, both of which justify proper contexts for each other. As the two sets updated during bootstrapping, the diversity measurement of the other set is expected to be more and more accurate. This strategy reflects the intuition behind co-training (Abney, 2004), but in a greatly reduced form and requiring no seeds for initialization.

Given a specific form of elements (bound or free morphemes), inputs to this algorithm are a dataset $\mathbb{S}$[4] containing all the elements of this form in some corpus and a choice of diversity measurement, $tokenC$ or $typeC$ as defined in section 2.1.

Assuming that functional elements can be distinguished by higher diversity degree, as discussed in section 2.1, we explicitly let a set $\mathbb{F}$ contain the most diverse elements as computed by the diversity measurement function with respect to its complementary set $\mathbb{B}$; and at each bootstrapping iteration, we increase the size of $\mathbb{F}$ by one.

On the other hand, set $\mathbb{B}$, which is generated to provide proper contexts for $\mathbb{F}$, contain those elements of a diversity degree greater than one with respect to $\mathbb{F}$, implementing our understanding of properly justified contexts in section 2.1. Since the order of diversity ranking of elements in $\mathbb{S}$ varies over iterations with respect to $\mathbb{B}$, which is also updated at each iteration according to current $\mathbb{F}$, an element classified into $\mathbb{F}$ at some iteration is not guaranteed to show up in $\mathbb{F}$ in the following iterations.

In addition to the update of $\mathbb{F}$ and $\mathbb{B}$, we also introduce a special 'filtering' step to prevent those elements that are ever seen *as/in*-context of elements in $\mathbb{F}$ from being classified into $\mathbb{F}$. This filtering idea is implemented through a set $\mathbb{R}$ containing elements to be excluded from $\mathbb{F}$, which is also updated at each iteration after the update of $\mathbb{F}$. This filtering step guarantees that there is no element in $\mathbb{F}$ ever occurring *as/in*-context of any other element in $\mathbb{F}$. We will explain more about the linguistic motivation behind this filtering step in section 4.

[4]For each element e in $\mathbb{S}$, the number of its occurrences *in/as*-context of other elements are also provided.

2.3 The Acquisition Output

We run the bootstrapping algorithm introduced in Section 2.2 for two acquisition tasks: acquiring functional morphemes and acquiring 'first-order' functional words. The outputs of both tasks, which are done separately, are depicted in Table 1 and 2 respectively. For each task, we experiment with two options of diversity measurement: $tokenC$ or $typeC$ as defined in section 2.1. If any element classified to be functional is of a diversity degree lower than a threshold, the bootstrapping process stops.

First of all, as clearly shown by the quality of acquisition outputs, this algorithm is sensitive to the choice of diversity measurement, and $typeC$, which measures the contextual diversity of an element in proper contexts, is always a better option compared to $tokenC$, which measures the frequency of an element in proper contexts. *tokenC* produces better outputs in the sense that fewer noisy elements are acquired and if acquired, they are acquired later in the bootstrapping process.

In both Table 1 and 2, functional elements are shown ordered by diversity in the second column, which order varies over the bootstrapping iterations, corresponding to the update of its complementary set, which is shown at the last column.

For the case of acquiring words, it is worth wondering about why, at the first few iterations, there were only determiners generated as functional, but at later iterations, modal verbs also show up. This fact seems to contradict our intuition that modal verbs are not of high diversity with respect to a complementary set containing nominal words only, which are generated according to determiners. However, we know that, at least in English, words are of ambiguous categories; therefore, those words of both nominal and verbal senses, such as *'consider'* and *'help'*, are classified to the complementary set by determiners according to their nominal sense, but their existence in the complementary set also enlarges the diversity of modal verbs due to their verbal sense.

While measuring the diversity by $typeC$, the

Table 2: The acquisition outputs at each iteration of the bootstrapping algorithm running for morphemes.

notable noisy item for acquiring functional words is *'york'*, which is classified as functional because 1) we lowercase all texts and 2) in WSJ articles, there are a lot complex NPs composed of *'York'*, i.e *'York'* is seen in many occurrences followed by nominal elements that may have already been classified as contentful during the bootstrapping process. On the other hand, with the diversity measurement $tokenC$, *'York'* has showed up as noisy much earlier in the bootstrapping process, as well as other noisy items.

It is even clearer in table 2 that the contextual diversity is a better measurement to distinguish functional elements than frequency. While measuring the diversity by $tokenC$, there are two noisy items show up as early as 15th iteration, *'-t'* and *'-n'*, which are successfully excluded from the output with diversity measurement $typeC$. While measuring the diversity by $typeC$, a possibly noisy item is *'-ers'*, which can be decomposed into *'-er'* and *'-s'*.

3 Applications

As shown above, the proposed bootstrapping algorithm generates outputs of high accuracy for both acquisition tasks: acquiring productive endings and acquiring 'first-order' functional words. In addition to the functional elements, this algorithm also generates complementary sets of contentful elements, which are base stems of words when acquiring morphemes and nouns plus verbs when acquiring words. Given these acquisition outputs, we can immediately accomplish the following two tasks, using very straightforward strategies only: 1) building a morph analyzer (section 3.1) ; and 2) acquiring the full set of functional categories, not just the first-order ones (section 3.2). Finally, we can plug the acquired list of closed-class words into a minimally supervised tagging system, (Zhao and Marcus, 2009), which requires the input of such a lexicon only. The resulting tagging system is then totally unsupervised and performs with satisfying accuracy as a totally unsupervised POS

tagger for open-class words (section 3.3). The bootstrapping algorithm runs over the WSJ Treebank, which contains 1173766 words, with raw text input only for both tasks. And all experiments described below are trained over the same corpus.

3.1 Morphological Analysis

Those syntactic related morphological features, such as *'ended with -ed'* or *'ended with -ing'* have already been proven useful in syntactic related tasks such as POS tagging, parsing and so on; therefore, accomplishing such a morph analysis in an unsupervised way is meaningful for related unsupervised works.

Given an acquired set $\mathbb{B}$ of base stems, e.g. $\mathbb{B} = \{$ *'laugh-'*, *'analyz-'* and *'-define'*$\}$, and a set $\mathbb{F}$ of functional morphemes , e.g. $\mathbb{F} = \{$*'-ed'*, *'-s'* and *'pre-'*$\}$, we can divide a word w into morphemes b- and -e where $b+e == w$, if b- in $\mathbb{B}$ and -e in $\mathbb{F}$; or if vice verse, i.e. b- in $\mathbb{F}$ and -e in $\mathbb{B}$. If such a division $b+e$ can be successfully performed on the word w with -e in $\mathbb{F}$, we specify that w has a morph feature *'ended with -e'*. For instance, given the above examples of $\mathbb{B}$ and $\mathbb{F}$, *'laughed'* has an ending *'-ed'* but not ending *'-ing'*, and *'analyzed'* has an ending *'-ed'*, but *'red'* doesn't have such an ending *'-ed'* as its morph feature. Overall, given two lists of morphemes, we can build a morph analyzer implementing this constrained stemming strategy for detecting morph features of interest.

For evaluating the morph analyzer composed by our acquisition outputs from WSJ Treebank, we use the CELEX corpus (Baayen et al., 1996) providing gold annotations of 6 syntactic related morphological features: {*'-s'*, *'-es'*, *'-ed'*, *'-ing'*, *'-er'*, and *'-est'*}. Among the 20058 types of words seen in both WSJ and CELEX corpus, 8789 types are annotated with these features. The precision number reported in Table 3 is the percentage of correct predictions out of all predictions the analyzer makes about the 6 morph features; and the recall is calculated by the percentage of correctly-predicted featured words out of all types of words with these features (8789).

We report the performance of two morph analyzers: one is composed by the acquired outputs with the diversity measurement $tokenC$; and the other one acquired with $typeC$. We also compare our results against a state-of-art morphology analyzer, (Lignos, 2010), which is adapted for this experiment. As shown in Table 3, our general bootstrapping algorithm, which is designed for various applications, is able to generate useful outputs for building a morph analyzer that performs comparably well as the stat-of-art achievements.

Algorithm	Precision	Recall	F-score
bootstrap-$tokenC$	77.89	82.38	80.07
bootstrap-$typeC$	78.71	83.31	80.94
(Lignos, 2010)	80.16	84.37	82.21

Table 3: The performance of morph analyzers evaluated for syntactic related morphological features.

3.2 Acquiring Closed-class Words

The bootstrapping algorithm is not designed to generate closed-class words falling in all functional categories, instead, it acquires those 'first-order' functional words, including only determiners and modal verbs. Given this acquired subset of closed-class words and the morph analyzer built in section 3.1, it is only a step away from acquiring all closed-class words falling in various functional categories.

We are not aware of previous work that acquires closed-class words in an automatic process, and in the NLP field, they are often approximated by the most frequent words. In other words, as a baseline model, we can acquire closed-class words by selecting k top words of the highest diversity measured by $tokenC$. Given discussion of diversity measurement in section 2.1, we also experiment with another baseline model, which acquires closed-class words by selecting k top words of the highest diversity measured by $typeC$. As shown in Table 4, with a better approximation of diversity, the type accuracy of predicting closed-class words is improved by an absolute error reduction of 11%, from 63% to 74% (k=100).

Moreover, as discussed in section 2, we know that those 'first-order' functional words, which can be generated by the bootstrapping algorithm with high accuracy, don't project onto other functional words. Therefore, after running the bootstrapping algorithm for words, we have already obtained a list of words that can be used for filtering the output of the baseline models. More specifically, given a set of 'first-order' functional words, those words that occur relatively often *in-*context of them should not be output as closed-class words. For example, two common noisy

top k *words*	20	40	80	100
baseline-$tokenC$	90.00	80.00	68.75	63.00
baseline-$typeC$	100.0	90.00	76.25	74.00
bootstrap-$tokenC$	95.00	95.00	90.00	86.00
bootstrap-$typeC$	**100.0**	**97.50**	**93.75**	**89.00**

Table 4: The percentage of correctly predicted closed-class word types out of k predictions

items in the output of the baseline models, *'billion'* and *'say'*, can be successfully filtered by the output set shown in Table 1.

In addition, since we have already built an unsupervised morph analyzer as described in section 3.1, which is acquired by the same bootstrapping algorithm, we would like to make use of them as well, in a straightforward way: as long as a word can be analyzed by the acquired morph analyzer, it should not be output as closed-class items.

Models 'bootstrap-$tokenC$' and 'bootstrap-$typeC$' implement the above idea using diversity measurement $tokenC$ and $typeC$ respectively. For example, the model 'bootstrap-$typeC$' uses the diversity measurement $typeC$ to both acquire the morph analyzer and to acquire the set of 'first-order' functional words, and it uses these acquisition outputs to filter the baseline model that uses $typeC$ as diversity measurement as well. The gold lexicon we use to evaluate the acquired list contains 288 closed-class words as described in (Zhao and Marcus, 2009).

With the help of acquisition outputs by a single algorithm running for different tasks, we can significantly improve the baseline model for acquiring closed-class words. As shown in Table 4, the performance of the baseline models drops rapidly as the size k grows; however, by taking acquired categories as constraints, we achieve quite reliable models. For example, 'bootstrap-$typeC$' improves 'baseline-$tokenC$' by an absolute error reduction of 26% (k=100), from 63% to 89%. So as to show how the models perform as k keeps growing, we provide more results in Figure 1, which plots the percentage of correctly predicted closed-class word types out of k predictions.

3.3 Unsupervised POS Tagging

Finally, to demonstrate the value of such a highly pure list of closed-class words, which previously could not be acquired through unsupervised learning, we plug the acquired list into a previously existing minimally supervised tagging system, (Zhao and Marcus, 2009), which only requires a closed-class lexicon for tagging all words. The resulting system now provides a totally unsupervised system for tagging open-class words, inducing both the categorical information itself and also the disambiguation rules for tagging open-class words.

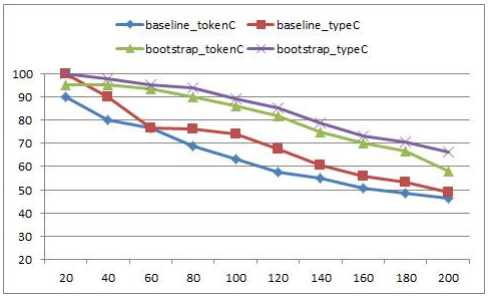

Figure 1: The percentage of correctly predicted closed-class word types out of k predictions

Following (Zhao and Marcus, 2009), the six open-class POS categories to be predicted are verbs, nouns, past participles, present participles and numbers. The tagging predictions for open-class words (any word not in the closed-class list) are evaluated by the percentage of correct predictions on all tokens in the open-class set. Although all tagging experiments are done over the whole WSJ Treebank, the total number of tagging predictions may vary according to different input closed-class lists.

We experiment with four lists of closed-class words of the top 200 words acquired by the 'baseline-$typeC$', 'baseline-$tokenC$', 'bootstrap-$typeC$' and 'bootstrap-$tokenC$' respectively, as introduced in section 3.2. We evaluate against a gold-standard closed-class lexicon containing 288 words, also used for evaluation in section 3.2.

closed-class input	accuracy	totally tagged
baseline-$tokenC$	81.68	536535
baseline-$typeC$	75.51	554012
bootstrap-$tokenC$	77.30	627803
bootstrap-$typeC$	**85.26**	612997
gold lexicon	*91.03*	*611028*

Table 5: The percentage of correctly tagged tokens out of all predictions. The system tags open-class words only and distinguishes 6 POS categories.

As shown in Table 5, the tagging system using the closed-class set acquired by 'bootstrap-$typeC$' tags 612997 open-class tokens, which accounts for

more than half of all the tokens in the WSJ Treebank, with an accuracy of 85.26%. In recent work on unsupervised tagging, tagging accuracys are reported in the range of 50-70%, e.g. (Abend et al., 2010), (Reichart et al., 2010), (Moon et al., 2010) and so on. Compared to these results, the tagging performance reported here, even though only on open-class words for six categories, is quite promising.

Because most previous work distinguishes between more categories than we do here, our results may be misleading, in that we appear to be reporting on a simpler task. However, these previous systems operate by clustering over a vector space of lexical features and suffix/prefix features, resulting in a large number of scattered clusters with similarities on different semantic and syntactic dimensions. As a result, it has proven difficult for them to use further agglomerative processing to induce simple distinct syntactic categories which map to POS tags naturally (Christodoulopoulos et al., 2010), and thus operating in a mode which achieves a higher tagging accuracy with coarser categories is not available to those systems at all. Therefore, achieving high accuracy with a smaller tag set is the harder, not easier, task for those systems.

4 Discussion

We propose a bootstrapping algorithm which successfully resolves two fundamental acquisition tasks: acquiring functional morphemes and acquiring 'first-order' functional words. We have shown that the outputs of these two fundamental acquisition tasks are very useful for more generalized tasks: they can be directly used to built a nearly state-of-art morph analyzer and they can be used to acquire a full set of closed-class words with high accuracy. Furthermore, the acquired list of closed-class words allows us to turn a minimally supervised tagging system into a totally unsupervised tagger for tagging open-class words. As a completely unsupervised tagger, the resulting system performs at a satisfying tagging accuracy above 85%.

The bootstrapping algorithm proposed here also gives us cause to think about the connection between functional categories in two forms: bound morphemes and words. As shown in this work, identically the same computational process that acquires functional morphemes also can be used to acquire the subset of functional words that includes modal verbs and determiners. All these elements share the property that, from the point of view of modern generative grammar, they only project locally, in other words, the elements that are acquired by this algorithm project to contentful elements *directly* most of the time but not through any other functional elements. Since all productive bound morphemes project mainly locally, they can all be acquired by the algorithm; in contrast, those functional words that project in larger scopes quite often, rather than in local contexts (i.e. not determiners and modal verbs), will not be acquired by this algorithm directly. This understanding of viewing local contexts as first-order functional projections motivates the filtering step in the bootstrapping algorithm. This overall understanding was motivated for us by the strict locality constraints assumed in phase theory (Chomsky, 2006).

Abstract

In this paper, we first carry out an investigation on two existing pivot strategies for statistical machine transliteration, namely *system*-based and *model*-based strategies, to figure out the reason why the previous model-based strategy performs much worse than the system-based one. We then propose a joint alignment algorithm to optimize transliteration alignments jointly across source, pivot and target languages to improve the performance of the model-based strategy. In addition, we further propose a novel *synthetic data*-based strategy, which artificially generates source-target data using pivot language. Experimental results on benchmarking data show that the proposed joint alignment optimization algorithm significantly improves the accuracy of model-based strategy and the proposed synthetic data-based strategy is very effective for pivot-based machine transliteration.

1 Introduction

Machine transliteration refers to the phonetic translation of names across languages by computer. With the rapid growth of the Internet data and the dramatic changes in the user demographics especially among the non-English speaking parts of the world, machine transliteration is important in many cross-lingual NLP, MT and CLIR applications as their performances have been shown to positively correlate with the correct conversion of names between the languages in several studies (Demner-Fushman and Oard, 2002; Mandl and Womser-Hacker, 2005; Hermjakob *et al.*, 2008; Udupa *et al.*, 2009). However, the traditional source for name equivalence, the bilingual dictionaries — whether handcrafted or statistical built — offer only limited support because new names always emerge.

All of the above points to the critical need for high-performance machine transliteration technology. Much research effort has been made to address this issue in the research community (Knight and Graehl, 1998; Meng *et al.*, 2001; Al-Onaizan and Knight, 2002; Oh and Choi, 2002; Klementiev and Roth, 2006; Sproat, 2006; Zelenko and Aone, 2006; Li *et al.*, 2004, 2009a, 2009b; Sherif and Kondrak, 2007; Bertoldi *et al.*, 2008; Goldwasser and Roth, 2008). These previous work falls into three categories, i.e., grapheme-based, phoneme-based and hybrid methods (Li *et al.*, 2009a, 2009b). The report of the first machine transliteration shared task NEWS 2009 (Li *et al.*, 2009a, 2009b) provides common benchmarking data in diverse language pairs and systematically evaluate the state-of-the-art technologies using their provided data.

Although promising results have been reported, one of major issues is that the current transliteration methods rely heavily on significant amount of source-target parallel data to learn transliteration model. However, such corpora are not always available and the amounts of the currently available corpora, even for language pairs with English involved, are far from enough for training, letting alone many low-density language pairs. Indeed, transliteration corpora for most language pairs without English involved are unavailable and are usually rather expensive to manually construct (Khapra *et al.*, 2010; Zhang *et al.*, 2010). To date, only two previous works (Khapra *et al.*, 2010; Zhang *et al.*, 2010) touch this issue of transliterating names across low-density language pairs. Both of them resort to pivot language-based approaches to address this issue.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1207–1215,
Chiang Mai, Thailand, November 8 – 13, 2011.

Khapra *et al.* (2010) proposes the system-based pivot strategy for machine transliteration, which learns a source-pivot model from source-pivot data and a pivot-target model from pivot-target data, respectively. In decoding, it first transliterates a source name to *N*-best pivot names and then transliterates each pivot name to target names which are finally re-ranked using the combined two individual transliteration scores. Zhang *et al.* (2010) verifies the system-based strategy together with joint source-channel model (Li *et al.*, 2004) on Chinese, English, Korean and Japanese data (Li *et al.*, 2009a, 2009b) and they further proposes a model-based strategy, which learns a direct source-target transliteration model from two independent [1] source-pivot and pivot-target name pair corpora, and does direct source-target decoding without relying on pivot languages. However, it was reported that the model-based strategy performed much worse than the system-based one (Zhang *et al.*, 2010).

This paper investigates the reason why previous model-based strategy performs worse than system-based one and then proposes a joint alignment algorithm to solve the alignment unit inconsistent issue, which is the main reason of leading to the worse performance of model-based strategy. The key point of the proposed joint alignment algorithm is to jointly optimize transliteration unit alignments among source, pivot and target languages. In addition, the paper further proposes a novel synthetic data-based strategy for pivot-based machine transliteration. It automatically constructs source-target data using source-pivot and pivot-target data, and then trains a direct source-target transliteration model using the synthetic data. We verify the proposed methods using the benchmarking data released at NEWS2009 (Li *et al.*, 2009a, 2009b). Experiential results show that our proposed joint alignment optimization algorithm is able to effectively solve the transliteration unit mismatching issue and the proposed synthetic data-based strategy is very effective, achieving the best-reported performance.

The rest of the paper is organized as follows. Section 2 introduces the direct transliteration model. Section 3 discusses our proposed joint alignment algorithm and synthetic data-based strategy. Experimental results are reported at section 4. Finally, we conclude the paper in section 5.

2 The Transliteration Model: JSCM

To make our study language-independent, we select joint source-channel model (JSCM, also named as *n*-gram transliteration model) (Li *et al.*, 2004) under grapheme-based framework as our transliteration model due to its state-of-the-art performance and using orthographical information only (Li *et al.*, 2009a). In addition, unlike other feature-based methods, such as CRFs (Lafferty *et al.*, 2001), MaxEnt (Berger *et al.*, 1996) or SVM (Vapnik, 1995), the JSCM model directly computes model probabilities using maximum likelihood estimation (Dempster *et al.*, 1977). This property facilitates the implementation of the model-based strategy.

JSCM directly models how both source and target names can be generated simultaneously. Given a source name *S* and a target name *T*, it estimates the joint probability of *S* and *T* as follows:

$$\begin{aligned} P(S,T) &= P(s_1 \dots s_i \dots s_K, t_1 \dots t_i \dots t_K) \\ &= P(< s_1,t_1 >, \dots, < s_i,t_i >, \\ &\qquad \dots, < s_K,t_K >) \\ &= P(< s,t >_1, \dots, < s,t >_i, \\ &\qquad \dots < s,t >_K) \\ &= \prod_{k=1}^{K} P\left(< s,t >_k \mid < s,t >_1^{k-1}\right) \\ &\approx \prod_{k=1}^{K} P\left(< s,t >_k \mid < s,t >_{k-n+1}^{k-1}\right) \quad (1) \end{aligned}$$

where s_i and t_i is an aligned transliteration unit[2] pair, and *n* is the *n*-gram order.

In our implementation, we compare different unsupervised transliteration alignment methods, including Giza++ (Och and Ney, 2003), JSCM-based EM algorithm (Li *et al.*, 2004), edit distance-based EM algorithm (Pervouchine *et al.*, 2009) and Oh et al.'s alignment tool (Oh *et al.*, 2009). Based on the aligned transliteration corpus, we learn the transliteration model using maximum likelihood estimation (Dempster *et al.*, 1977) and decode the transliteration result $T^* = \text{argmax}_T P(S,T)$ using stack decoder (Schwartz and Chow, 1990).

[1] Here "independent" means the source-pivot and pivot-target data are not from the same English name source.

[2] Transliteration unit is language dependent. It can be a Chinese character, a sub-string of English words, a Korean Hangual or a Japanese Kanji or several Japanese Katakanas.

3 Joint Alignment and Synthetic Data-based Strategy

In this section, we elaborate our proposed joint alignment algorithm and synthetic data-based strategy for pivot-based machine transliteration.

3.1 System-based Strategy

Given a source name *S*, a target name *T* and let *Z* be the n-best transliterations of *S* in a pivot language Ź [3], the system-based transliteration strategy under JSCM can be formulized as follows:

$$\begin{aligned} P(S,T) &= \sum_{Z} P(S,Z,T) \\ &= \sum_{Z} P(T|S,Z) * P(S,Z) \\ &\approx \textstyle\sum_{Z} P(T|Z) * P(S,Z) \\ &\approx \sum_{Z} \frac{P(S,Z) * P(T,Z)}{P(Z)} \end{aligned} \quad (2)$$

where $P(S,Z)$ and $P(T,Z)$ can be computed using JSCM as formalized at Eq. (1). Eq. (2) assumes that T is independent of S when given Z because the parallel name corpus between *S* and *T* is not available under the pivot transliteration framework. The n-best transliterations in pivot language are expected to be able to carry enough information of the source name *S*. Following the nature of JSCM, Eq. (2) directly models how the source name *S* and pivot name *Z* and how the pivot name *Z* and the target name *T* are generated simultaneously. Since *Z* is considered twice in $P(S,Z)$ and $P(T,Z)$, the duplicated impact of *Z* is removed by being divided by $P(Z)$.

3.2 Joint Alignment Algorithm for Model-based Strategy

Rather than combining the transitive transliteration results at system level, the model-based strategy aims to learn a direct model $P(S,T)$ by combining the two individual models of $P(S,Z)$ and $P(T,Z)$. Here we use bigram as an example to illustrate how to learn the JSCM transliteration model $P(S,T) = \prod_{k=1}^{K} P(< s,t >_k \mid < s,t>k-1$ using the model-based strategy.

$$P(< s,t >_k \mid < s,t >_{k-1}) = \frac{P(< s,t >_k, < s,t >_{k-1})}{P(< s,t >_{k-1})} \quad (3)$$

where,

$$\begin{aligned} &P(< s,t >_k, < s,t >_{k-1}) \\ &\quad = P(s_k, s_{k-1}, t_k, t_{k-1}) \\ &\quad = \sum_{z_k, z_{k-1}} P(s_k, s_{k-1}, t_k, t_{k-1}, z_k, z_{k-1}) \\ &\quad = \sum_{z_k, z_{k-1}} P(t_k, t_{k-1} | s_k, s_{k-1}, z_k, z_{k-1}) \\ &\qquad\qquad * P(s_k, s_{k-1}, z_k, z_{k-1}) \\ &\quad \approx \sum_{z_k, z_{k-1}} P(t_k, t_{k-1} | z_k, z_{k-1}) \\ &\quad * \qquad\qquad P(s_k, s_{k-1}, z_k, z_{k-1}) \\ &\quad \approx \sum_{z_k, z_{k-1}} P(t_k, t_{k-1}, z_k, z_{k-1}) \\ &\qquad\qquad * P(s_k, s_{k-1}, z_k, z_{k-1}) \\ &\qquad\qquad / P(z_k, z_{k-1}) \end{aligned} \quad (4)$$

$$P(< s,t >_{k-1}) = \sum_{<s,t>_k} P(< s,t >_k, < s,t\ >_{k-1}) \quad (5)$$

where $P(t_i, t_{i-1}, z_i, z_{i-1})$, $P(s_i, s_{i-1}, z_i, z_{i-1})$ and $P(z_i, z_{i-1})$ can be directly estimated at training corpus.

In summary, eq. (2) formalizes the system-based strategy while eq. (3) formalizes the model-based strategy, where we can find that eq. (2) involves the pivot language *Z* in modeling and decoding while eq. (3) does not (its model parameters are pre-computed using eq. (4) and (5) during training).

In previous work (Zhang *et al.*, 2010), the model-based strategy was reported to perform much worse than the system-based. We find that the main reason is due to the size inconsistence of transliteration unit of pivot language in the source-pivot and pivot-target alignments during training. As shown at eq. (4), the source-target model is calculated using the source-pivot el$P(s_k, s_{k-1}, z_k, z_{k-1})$and the pivot-target model $P(t_k, t_{k-1}, z_k, z_{k-1})$ directly. This requests that the pivot transliteration unit z_k, z_{k-1} must be consistent in the two individual modes. Thus, all the source-pivot and pivot-target model parameters $P(*_k, *_{k-1}, z_k, z_{k-1})$ are of no use if their involved pivot unit z_k, z_{k-1} can only be found at either source-pivot or pivot-target model. Unfortunately in the only previous work (Zhang *et al.*, 2010), the source-pivot model and pivot-target

[3] There can be multiple pivot languages used. However, same as Khapra *et al.* (2010) and Zhang *et al.* (2010), without loss of generality, we only use one pivot language to facilitate our discussion. It is straightforward to extend one pivot language to multiple ones by considering all the pivot transliterations in all pivot languages.

model are trained separately, i.e., their object function is to maximize $P(S,Z)$and $P(T,Z)$ independently. This results in serious pivot transliteration unit inconsistent issue for some language pairs. For example, in our experiment (Chinese→English→ Japanese) with English as pivot language, we find that the English transliteration unit size in Chinese→English model is much larger than that in English→Japanese model. This is because from phonetic viewpoint, in Chinese→English model, the English unit is at syllable level (corresponding one Chinese character) while in English→Japanese model, the English unit is at sub-syllable level (consonant or vowel or syllable, corresponding one Japanese Katakana). Following example excerpted from our training corpus illustrates the pivot transliteration unit mismatching issue, where the English word "Aachen" is segmented into "Aa" and "chen" in Chinese-English model while it is segmented into "A", "a", "che" and "n" in English-Japanese model. This trilingual pair is then of no use in model-based strategy.

To solve the mismatching issue, this paper proposes a joint alignment algorithm to jointly optimize transliteration unit alignments among source, pivot and target languages for model-based strategy. To facilitate discussion, we base on the task of using English as pivot language for Chinese-Japanese transliteration (see Table 1) to present our proposed algorithm. The core idea of this algorithm is to use Chinese-English alignments as a constraint to do English-Japanese alignment. The algorithm consists of the following 6 steps:

Algorithm 1. Joint Alignment

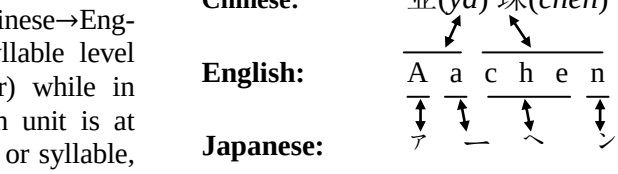
Inputs:

Chinese-English Name List (CE).
English-Japanese Name List (EJ).

Outputs:

More consistent CE and EJ alignments at Chinese syllable level and a direct Chinese-Japanese (CJ) JSCM.

1. Align the CE names at Chinese syllable level using the JSCM-based EM algorithm (Li *et al.*, 2004).
2. Train a transliteration unit-based English bi-gram LM with the transliteration unit-segmented (at step 1) English side names of CE using SRILM toolkits (Stolcke, 2002). Note that here the English transliteration units are corresponding to Chinese syllable level.
3. Align the Chinese-English-Japanese (CEJ) names that are the intersection of the entire CE and EJ names (with the same English names).
   a. CE part of CEJ has been aligned at Step 1.
   b. Align the CJ part of CEJ at Chinese syllable level using the JSCM-based EM algorithm (Li *et al.*, 2004).
   c. Construct the CEJ name alignments by merging the CE and CJ alignments.



4. Align EJ names at Chinese syllable level.
   a. The intersection part of EJ with CJ (*i*EJ) has already been aligned at Chinese syllable level at step 3.
   b. Align the remaining non-intersection part of EJ name pairs (*ni*EJ) using Algorithm 2 with the help of the aligned intersection part done at step 4.a and the transliteration unit-based English bi-gram LM learned at step 2.
   c. Merge the above two parts.
5. Train two individual JSCMs using the Chinese syllable level-aligned CE and EJ name corpus, respectively.
6. Train a direct CJ JSCM using the two individual JSCMs learned at step 5 by the model-based pivot strategy as formulated at eqs. (3), (4) and (5).

Algorithm 2. Constrained EM-based Alignment

Inputs:

1. Non-intersection part of EJ name pairs (*ni*EJ).
2. Intersection part of EJ name pairs (*i*EJ) aligned at Chinese syllable level and the initial JSCM (named as iJSCM) learned from this corpus (step 3.d of Algorithm 1).
3. The transliteration unit-based English bi-gram LM (named as eLM, step 2 of Algorithm 1).

Output:

English-Japanese name pairs aligned at Chinese syllable level.

1. Bootstrap initial alignment of the *ni*EJ name using the initial model iJSCM.

2. **Expectation**: re-train iJSCM using both the input *i*EJ name alignments and the updated *ni*EJ name alignments.
3. **Maximization**: Apply the re-trained iJSCM and the input eLM to obtain new alignments of the *ni*EJ names. Note that different from previous EM-based transliteration alignment algorithm (Li *et al.*, 2004) that only maximizes the JSCM probabilities, here we maximize two kinds of probabilities:

$$A^* = \underset{A}{\operatorname{argmax}} P(E,J,A) * P(E,A) \quad (6)$$

where E refers to English and J refers to Japanese; A is an alignment which defining the transliteration unit segmentations of E and J, and their mappings; $P(E,J,A)$ is the JSCM probability of E and J under A; and $P(E,A)$ is the eLM transliteration unit bigram probability of E segmented by A.
4. Go to step 2 until the alignment converges.
5. Output the *ni*EJ name alignments.

The motivation of the joint alignment algorithm (Algorithm 1 and 2) is to address the English transliteration unit mismatching issue by aligning the EJ at Chinese syllable level with the help of CE alignment. While the mismatching issue in the intersection part of the data is easy to solve by step 3 of Algorithm 1, it is more complicated at the non-intersection part. As illustrated at step 3 of Algorithm 2, the core idea is to use English segmentation learned from CE alignment (step 2 of Algorithm 1) and already-aligned intersection part of EJ (*i*EJ, step 3 of Algorithm 1) to constrain the EM alignment process. Therefore, the English bigram LM and the aligned intersection part (*i*EJ) keep unchanged during all the EM iterations. But in E step (step 2 of Algorithm 2), the iJSCM model is updated at each iteration using the entire EJ data while in M step (step 3 of Algorithm 2), the alignments are decoded out using both the iJSCM and the English bi-gram LM. Indeed, in our implementation, we introduce more knowledge sources, including transliteration unit insertion penalty and Japanese LM, into the M step by simply considering these two features at eq. (6).

Given the jointly optimized CE and EJ aligned name corpus, we can easily learn a direct CJ model using the pivot-based strategy (steps 5 and 6 of Algorithm 1).

3.3 Synthetic Data-based Strategy

Different from previous two strategies, the synthetic data-based strategy automatically constructs source-target data using source-pivot and pivot-target data, and then trains a direct source-target transliteration model using the synthetic and any other available source-target data. The philosophy of this strategy is straightforward while the key is how to generate "good" data. Next, we also use Chinese-English-Japanese as example to elaborate this strategy.

Algorithm 3. Artificial Data Generation

Inputs:

Chinese-English Name List (CE).
English-Japanese Name List (EJ).

Outputs:

Synthetic Chinese-Japanese name pairs.

1. Directly output those CJ names (*i*CJ), which are the intersection of the entire CE and EJ names (with the same English names).
2. Transliterate those Chinese names which are not in *i*CJ to Japanese using either the system-based or model-based strategy. To maintain the transliteration quality, we consider both forward and backward transliteration probabilities as well as the information whether the original Chinese can be recovered from a transliterated Japanese name. The process is formalized as follows:

$$J^* = \underset{J}{\operatorname{argmax}} P(J|C) * P(\acute{C}|J) * I(\acute{C},C) * P(J) \quad (7)$$

where $P(J|C)$ is the forward transliteration probability, $P(\acute{C}|J)$ is the backward transliteration probability, and $I(\acute{C},C)$ is a penalty function to penalize those cases where $\acute{C}$ is not equal to C, i.e., C fails to be covered from J. $P(J)$ is a Japanese Katakana language model.
3. Translate those Japanese names which are not in *i*CJ to Chinese in the similar way as step 2.

$$C^* = \underset{C}{\operatorname{argmax}} P(C|J) * P(\acute{J}|C) * I(\acute{J},J) * P(C) \quad (8)$$

Note that the outputs of step 2 and 3 do not overlap with each other. $P(C)$ is a Chinese character-based language model.
4. Merge the results of step 1, 2 and 3. Given the merged data, we can easily train a direct Chinese-Japanese transliteration model.

The core idea of Algorithm 3 lies in eqs. (7) and (8). Among the three strategies (system-based, model-based and synthetic data-based), the first and the third ones are transliteration model independent while the second one is not.

3.4 Comparison with Previous Work

Almost all previous work on machine transliteration focuses on direct transliteration or transliteration system combination. Only two recent work (Khapra *et al.*, 2010; Zhang *et al.*, 2010) touches on the issue of pivot transliteration. Khapra *et al*. (2010) proposes the system-based strategy and does extensively empirical study together with CRF model on Indic/Slavic/Semetic languages and English. Zhang *et al*. (2010) proposes the model-based strategy, but reporting very bad performance. To address the low performance issue of the model-based strategy, this paper proposes the joint alignment algorithm to optimize the source-pivot-target alignment directly, resulting in significant performance improvement. Moreover, the paper proposes a new synthetic data-based strategy for pivot-based machine transliteration.

Machine translation carries out similar pivot-based translation studies. Bertoldi *et al.* (2008) studies two pivot approaches for phrase-based statistical machine translation. One is at system level and one is to re-construct source-target data and alignments through pivot data. Cohn and Lapata (2007) explores how to utilize multilingual parallel data (rather than pivot data) to improve translation performance. Wu and Wang (2007, 2009) study the model-level pivot approach and explore how to leverage on rule-based translation results in pivot language to improve translation performance. Utiyama and Isahara (2007) compare different pivot approaches for phrase-based statistical machine translation. All of the previous work on machine translation works on phrase-based statistical machine translation. Therefore, their translation model is to calculate phrase-based conditional probabilities at unigram level ($P(t_k|s_k)$) while our transliteration model is to calculate joint transliteration unit-based conditional probabilities at bigram level ($P(< s,t >_k | < s,t >_{k-1})$). This is the fundamental difference.

4 Experimental Results

4.1 Experimental Settings

Language Pair	Training	Test
Chinese-English (CE)	31,961	2,896
English-Japanese (EJ)	23,225	1,489
Chinese-English-Japanese (CEJ, the intersection part of CE and EJ)	10,071	1,030

Table 1. Statistics on the data set

We use the NEWS 2009 Chinese-English and English-Japanese benchmark data as our experimental data (Li *et al.*, 2009a). All of the names originate from Western names, i.e., no native Chinese and Japanese names are involved in this experiment. Considering the fact that those language pairs with English involved have the most training data, it is reasonable to select English as pivot language. Table 1 reports the statistics of all the experimental data. The Chinese-English-Japanese data is the intersection of the Chinese-English and English-Japanese data.

We compare different alignment algorithms on the DEV set (Li *et al.*, 2009a). Finally we use Pervouchine *et al.* (2009)'s alignment algorithm for Chinese-Japanese and Li *et al.* (2004)'s for Chinese-English and English-Japanese. Given the aligned corpora, we directly learn each individual JSCM model (i.e., *n*-gram transliteration model) using SRILM toolkits (Stolcke, 2002). We also use SRILM toolkits to do decoding. For the system-based strategy, we output top-10 pivot transliteration results. For the evaluation matrix, to save space, we only use top-1 accuracy (ACC) (Li *et al.*, 2009a) to measure transliteration performance since other five evaluation matrix used at Li *et al*. (2009a) are reported to have great correlation with ACC.

4.2 Experimental Results

4.2.1 Results of Direct Transliteration

Language Pair	ACC
English-Chinese	0.681049
English-Japanese	0.456755
Chinese-English	0.394490
Japanese-English	0.314970
Chinese-Japanese	0.288022
Japanese-Chinese	0.366559

Table 2. Performance of direct transliterations

Table 2 reports the performance of direct transliteration. The first two experiments (line 1-2) are part of the NEWS 2009 share tasks and the others are our additional experiments for our pivot studies. Comparison of the first two experimental results and the results reported at NEWS 2009 shows that we achieve comparable performance with their best-reported systems under the same conditions of using single system and orthographic features only. This indicates that our baseline represents the state-of-the-art performance. In

Methods	Chinese-English-Japanese	Japanese-English-Chinese
Baseline 1: Independent alignment of Chinese-English and English-Japanese (Zhang *et al.*, 2010)	0.065949 (5816/16989)	0.043011(5816/16989)
Baseline 2: Linguistically heuristic-based re-construction of Chinese-English and English-Japanese alignment (Zhang *et al.*, 2010)	0.282638 (26351/34812)	0.378299 (26351/34812)
Method 1: Joint alignment on intersection part of Chinese-English and English-Japanese data (Ours)	0.287360 (26432/34920)	0.378796 (26432/34920)
Method 2: Joint alignment on entire data set (Ours)	**0.325367 (37437/48590)**	**0.440782 (37437/48590)**

Table 4. Performance of model-based strategy (in ACC/# of unigram/# of bigram of the different transliteration models learned y the model-based strategy)

addition, we find that the backward transliteration (line 3-4) consistently performs worse than its corresponding forward transliteration (line 1-2). This observation is consistent with what reported at previous work (Li *et al.*, 2004; Zhang *et al.*, 2004). The main reason is because English has much more transliteration units than foreign C/J languages. This makes the transliteration from English to C/J a many-to-few mapping issue and backward transliteration a few-to-many mapping issue. Therefore backward transliteration has more ambiguities and thus is more difficult. Moreover, due to the less available training data for the language pairs without English involved (Chinese/Japanese), the lowest two experiments (line 5-6) performs worse than the case with English involved . This observation motivates us the study using pivot language for machine transliteration.

4.2.2 Results of System-based Strategy

Language Pair	ACC
Chinese-English-Japanese (**System**)	0.324361
Chinese-English (**Direct**)	0.394490
English-Japanese (**Direct**)	0.456755
Chinese-Japanese (**Direct**)	0.288022
Japanese-English-Chinese (**System**)	0.445748
Japanese-English (**Direct**)	0.314970
English-Chinese (**Direct**)	0.681049
Japanese-Chinese (**Direct**)	0.366559

Table 3. Performance of system-based strategy

Table 3 reports the experimental results of system-based strategy. It confirms the previous observations (Khapra *et al.*, 2010; Zhang *et al.*, 2010).

- The system-based pivot strategy is very effective, achieving significant performance improvement over direct transliteration.
- Different from other pipeline methodologies, system-based pivot strategy does not suffer from the error propagation issue. Its ACC is significantly better than the product of the ACCs of the two individual systems.

The main reasons of the good performance reported at the above observations are due to the following reasons:

- The pivot approach is able to use large amount of source-pivot and pivot-target data.
- The nature of transliteration is a phonetic translation process. Therefore a little bit variation in orthography may not hurt or even help to improve transliteration performance in some cases as long as the orthographical variations keep the phonetic equivalent information.
- The N-best accuracy of machine transliteration is very high (Li *et al.*, 2004; Zhang *et al.*, 2004). It means that in most cases the correct transliteration in pivot language can be found in the top-10 results and the other 9 results hold the similar pronunciations with the correct one, which can serve as alternative "quasi-correct" inputs to the

second stage transliterations and thus largely improve the overall accuracy.

4.2.3 Results of Model-based Strategy

Table 4 reports the performance of model-based strategy with different alignment refinements, where we can find:

- Baseline 1 clearly shows that the model-based strategy performs extremely worse than the other three settings if we align the Chinese-English and English-Japanese data independently. The major reason attributes to the size mismatching of the English transliteration units between the two data sets (syllable level *vs*. phoneme or syllable level).
- The other three experiments demonstrate the effectiveness of the alignment refinements. However Baseline 2 is more heuristic while ours are more mathematically principled.
- Method 1 performs comparably with Baseline 2 even utilizing fewer training data.
- Method 2 achieves the best performance. It convincingly shows the effectiveness of the proposed joint optimization algorithm.
- Among all the models, Method 2 has the largest amounts of model parameters (# of unigram and bigram). From modeling viewpoint, it indicates that this model is more powerful than others. This is due to the contribution of the more consistent English transliteration units.
- Comparing Tables 4 and Table 3, we can see that the model-based strategy performs as well as the system-based strategy. This clearly demonstrates the effectiveness of our proposed joint alignment algorithm.

4.2.4 Results of Synthetic Data-based Strategy

Language Pair	ACC
Japanese-Chinese (**Synthetic Data**)	0.465648
Japanese-Chinese (**System**)	0.445748
Japanese-Chinese (**Model**)	0.440782
Japanese-Chinese (**Direct**)	0.366559
Chinese-Japanese (**Synthetic Data**)	0.338930
Chinese-Japanese (**System**)	0.324361
Chinese-Japanese (**Model**)	0.325367
Chinese-Japanese (**Direct**)	0.288022

Table 5. Performance comparison of the three pivot strategies

Table 5 shows the advantage of synthetic data-based strategy over the other methods.

- The synthetic data-based strategy significantly outperforms the direct one. This clearly shows the effectiveness of the additional synthetic data.
- Using the same amount of data, the synthetic data-based strategy significantly outperforms the model-based one. This is not surprising since model-based strategy suffers from the transliteration unit mismatching issue and its performance is also compromised by the independent assumption of eq. (4) while the synthetic data-based directly learns the model from bilingual data without suffering from the above two issues.
- Using the same amount of data, the synthetic data-based strategy significantly outperforms the system-based one. This is because the synthetic data-based strategy directly learns a source-target transliteration model while system-based method utilizes two indirect models and has to bear with the independent assumption of eq. (2).
- It is worth noting the transliteration performance of the synthetic data-based strategy highly depends on the quality of the artificially generated data. Table 5 reports the performance using the default setting of eq. (7) and (8) at Algorithm 3. We expect that the synthetic data-based strategy has the potential to further improve its performance by simply introducing more features into eq. (7) and (8).

5 Conclusions

A big challenge to statistical-based machine transliteration is the lack of the training data, esp. to those low-density language pairs without English involved. To address the above issue, this paper propose a simple, but very effective solution, namely synthetic data-based strategy, to artificially generate direct source-target training data using pivot language. Experimental results on NEWS 2009 data shows that the proposed strategy is very useful, achieving the best-reported performance. The paper also proposes a joint alignment algorithm to jointly optimize the alignments between source, pivot and target data. Experimental results show that the joint alignment algorithm is able to largely boost the performance of model-based strategy.

The system-based and the proposed synthetic-based strategy are transliteration model-independent while model-based strategy is not. However, the three strategies and the proposed joint alignment algorithm are not limited to the machine transliteration task. They can be applied to those tasks which possess the similar "transitive" property as machine transliteration, such as paraphrasing, domain adaptation and some multilingual tasks.

Abstract

We address the problem of joint part-of-speech (POS) tagging and dependency parsing in Chinese. In Chinese, some POS tags are often hard to disambiguate without considering long-range syntactic information. Also, the traditional pipeline approach to POS tagging and dependency parsing may suffer from the problem of error propagation. In this paper, we propose the first incremental approach to the task of joint POS tagging and dependency parsing, which is built upon a shift-reduce parsing framework with dynamic programming. Although the incremental approach encounters difficulties with underspecified POS tags of look-ahead words, we overcome this issue by introducing so-called *delayed features*. Our joint approach achieved substantial improvements over the pipeline and baseline systems in both POS tagging and dependency parsing task, achieving the new state-of-the-art performance on this joint task.

1 Introduction

The tasks of part-of-speech (POS) tagging and dependency parsing have been widely investigated since the early stages of NLP research. Among mainstream approaches to dependency parsing, an incremental parsing framework is commonly used (e.g. Nivre (2008); Huang and Sagae (2010)), mainly because it achieves state-of-the-art accuracy while retaining linear-time computational complexity, and is also considered to reflect how humans process natural language sentences (Frazier and Rayner, 1982).

However, although some of the Chinese POS tags require long-range syntactic information in order to be disambiguated, to the extent of our knowledge, none of the previous approaches have addressed the joint modeling of these two tasks in an incremental framework. Also, since POS tagging is a preliminary step for dependency parsing, the traditional pipeline approach may suffer from the problem of error propagation.

In the example sentence in Figure 1, 的 has POS ambiguity between DEG (a genitive marker), which connect two noun phrases as "'s" in English, and DEC (a complementizer), which introduces a relative clause. Since both can take the form of NP-的-NP (NP: noun phrase), it is hard to distinguish these two tags only by considering local context. Based only on local context, a standard n-gram tagger is likely to assign the wrong tag DEG to 的, which inevitably makes the following parsing step fail to process the sentence correctly. However, knowing that the NP preceding 的 is the object of 沟通/VV (VV: verb), we can assume that 的 is a complementizer because 的/DEG is unlikely to follow a verb phrase.

In this paper, we propose the first incremental approach to the task of joint POS tagging and dependency parsing. Given a segmented sentence, our model simultaneously considers possible POS tags and dependency relations within the given beam, and outputs the best parse along with POS tags. However, the combined model raises two challenges: First, since the combined search space is huge, efficient decoding is difficult while the naïve use of beam is likely to degrade the search quality. Second, since the proposed model performs joint POS tagging and dependency parsing in a left-to-right manner, the model cannot exploit look-ahead POS tags to determine the next action.

To deal with the increased search space, we adopt a recently-proposed dynamic programming (DP) extension to shift-reduce parsing (Huang and Sagae, 2010), which enables the model to pack equivalent parser states, improving both speed and accuracy. Also, we overcome the lack of look-ahead POS information by introducing a concept of *delayed features*. The delayed features are those features that include underspecified POS tags, and shall be evaluated at the step when the look-ahead tags are determined. Based on experiments on the Chinese Penn Treebank (CTB) 5, we show that our joint models substantially improve over the

$C_n(w_j)$	*(if $C_n(w_j)$ equals to $C_{n+1}(w_j)$)*

1) if $len(w_{j+1}) < 3$; 2) if $len(w_j) < 3$; 3) if $len(w_j) = 1$.

Table 1: Feature templates for the baseline POS tagger, where t_i is the tag assigned to the i-th word w_i, $B(w)$ and $E(w)$ is the beginning and the ending character of word w, $C_n(w)$ is the n-th character of w, $P(c)$ is the set of tags associated with the single-character word c based on the dictionary.

pipeline and baseline systems in both POS tagging and dependency parsing accuracy. We also present some discussion on the results and error analysis. Although we specifically focus on Chinese in this work, our joint model is applicable to any languages for which a projective shift-reduce parser works well.

2 Baseline Models

First of all, we describe our baseline POS tagger and dependency parsers. These models will later be combined into pipelined models, which are then used as the baseline models in Section 4.

2.1 Baseline POS Tagger

We build a baseline POS tagger, which uses the same POS-tagging features as those used in the state-of-the-art joint word segmentation and POS tagging model for Chinese (Zhang and Clark, 2008a). The list of features are shown in Table 1. We train the model with the averaged perceptron (Collins, 2002), and the decoding is performed using the Viterbi algorithm with beam search.

Following Zhang and Clark (2008a), we use a tag dictionary and closed-set tags, which lead to improvement in both speed and accuracy. During training, the model stores all word–tag pairs into a tag dictionary, and for each word occurring more than N times in the training data, the decoder only assigns one of the tags that have been seen in the training data. For words that do not exist in the dictionary, the decoder still considers every possible tag. We also construct a dictionary for the closed-set tags (Xia, 2000), and allow the decoder to assign these tags only to the words listed in the dictionary.

2.2 Baseline Parsers

For the baseline parsers for experiments, we build two dependency parsers: a reimplementation of the parser by Huang and Sagae (2010) (hereinafter *Parser-HS*), which is a shift-reduce dependency parser enhanced with dynamic programming (DP) using graph-structured stack (GSS; Tomita (1991)), and our extension of Parser-HS by incorporating a richer set of features taken from Zhang and Nivre (2011) (hereinafter *Parser-ZN*), which is originally a non-DP arc-eager dependency parser and achieves the current state-of-the-art performance for Chinese dependency parsing. In this section, we briefly describe these models since the features and DP formalism serve as a basis for the joint models described in Section 3.

2.2.1 Shift-reduce parsing

Shift-reduce dependency parsing algorithms incrementally process an input sentence from left to right. In the framework known as "arc-standard" (Nivre, 2008), the parser performs one of the following three actions at each step:

- SHIFT (SH): move the first word in the input queue, q_0, onto the stack
- REDUCE-RIGHT (RR): combine the top two trees on the stack, (s_0, s_1), into a subtree $s_0^{\curvearrowleft} s_1$
- REDUCE-LEFT (RL): combine the top two trees on the stack, (s_0, s_1), into a subtree $s_0^{\curvearrowright} s_1$

where $S = (\ldots, s_1, s_0)$ is a stack of trees and $Q = (q_0, q_1, \ldots, q_{n-j-1}) = (w_j, w_{j+1}, \ldots, w_{n-1})$ is an input queue where j is the index of the first word in the queue Q and n is the number of words in the input sentence. Note that $s_0^{\curvearrowright} s_1$ denotes a combined tree where s_1 is a child of s_0.

To deal with conflicts between more than one of these actions, each action is associated with a score, and the score of a parser state is the total score of the actions that have been applied. To train the model, we adopt the averaged perceptron algorithm (Collins, 2002) with early update (Collins and Roark, 2004), following Huang and Sagae (2010). With the early update, whenever the gold action sequence falls off from the beam, the parameters are immediately updated with the rest of the sentence neglected.

2.2.2 Merging equivalent states

Dynamic programming is enabled by merging *equivalent states*: if two states produce the same feature vector, they are merged into one state. Formally, a parser state (or configuration) ψ is described by $\langle \ell, i, j, S \rangle$, where ℓ is the current step, $[i \dots j]$ is the span of the top tree s_0 in the stack $S = (s_{d-1}, \dots, s_0)$, where d is the depth of the stack. The equivalence of two states $\psi : \langle \ell, i, j, S \rangle$ and $\psi' : \langle \ell', i', j', S' \rangle$ is then defined as

$$\psi \sim \psi' \;\; \textit{iff} \;\; j = j' \wedge \vec{f}(j, S) = \vec{f}(j', S'), \quad (1)$$

where $\vec{f}(j, S)$ is the feature vector of the state $\langle \ell, i, j, S \rangle$. In practice, just remembering a minimal set of features called *kernel features* $\tilde{\vec{f}}(j, S)$ suffices to evaluate the equivalence of states:

$$\tilde{\vec{f}}(j, S) = \tilde{\vec{f}}(j', S') \Rightarrow \langle \ell, i, j, S \rangle \sim \langle \ell', i', j', S' \rangle. \quad (2)$$

By merging equivalent states based on this condition, we only need to remember relevant information from the top d ($d = 3$ in our models) trees on the stack to evaluate the score of the next actions. However, since the stack shrinks when a REDUCE-LEFT/RIGHT action is applied, you often need to recover the last element of the stack from the history. Following Huang and Sagae (2010), we use a concept of *predictor states* $\Pi(\psi)$ to retain the links to multiple different histories.

2.2.3 Features

The feature templates used in the baseline parser Parser-HS are listed in Table 2 (a), where $s.w$ and $s.t$ are the form and tag of the root word of tree s, $s.\mathrm{rc}$ and $s.\mathrm{lc}$ are the right- and left-most children of s, and $\circ$ denotes conjunction of features. Note that these features can be constructed by only using 13 kernel features listed in Table 2 (c). The baseline parser Parser-ZN$^-$ additionally utilizes features in Table 2 (b), where d denotes the distance between the root nodes of s_0 and s_1, $s.v_r$ and $s.v_l$ are the numbers of the right and left modifiers of s, $s.\mathrm{rc}_2$ and $s.\mathrm{lc}_2$ are the second right- and left-most children of s. Note that some of the features described in Zhang and Nivre (2011), which are associated with dependency labels and head information of stack elements, are not included since our framework is based on unlabeled dependencies and the arc-standard strategy. The additional features for Parser-ZN$^-$ require the features in Table 2 (d) to be added into the set of kernel features.

2.2.4 Beam search with DP

In the shift-reduce parsing with dynamic programming, we cannot simply apply beam search as in a non-DP shift-reduce parsing, because each state does not have a unique score any more. To decide the ordering of states within the beam, the concept of *prefix score* and *inside score* (Stolcke, 1995) is adopted. The prefix score ξ is the total score of the best action sequence from the initial state to the current state, while the inside score η

is the score of the tree on the top of the stack. With these scores and a set of predictor states $\Pi(\psi)$ of state ψ, the full description of state ψ takes the form $\psi : \langle \ell, i, j, S; \xi, \eta, \Pi \rangle$. The calculation of the prefix and inside scores is described in Huang and Sagae (2010). By using these scores, the ordering of states is defined as

$$\langle \ell, \ldots; \xi, \eta, \_ \rangle \prec \langle \ell, \ldots; \xi', \eta', \_ \rangle \\ \textit{iff } \xi < \xi' \vee (\xi = \xi' \wedge \eta < \eta'),$$

where "_" denotes "match anything".

3 Joint POS Tagging and Parsing Model

In this section, we describe our models that jointly solve POS tagging and dependency parsing, which are based on the shift-reduce parsers described in Section 2.2. Corresponding to the two baseline parsers Parser-HS and Parser-ZN$^-$, we investigate two joint models: Joint-HS$^+$ and Joint-ZN$^-$. Although the latter uses a richer set of features, the formers can take more advantage of DP because a compact representation of features results in more frequent state packing.

3.1 POS Tagging with Modified Shift Action

Our joint parsers incorporate POS tagging during the course of shift-reduce parsing, by modifying the SHIFT action so that it assigns a tag to the word when it is shifted:

- SHIFT(t) (SH(t)): move the head of the queue, q_0, onto the stack, and assign tag t to it.

Along with REDUCE-LEFT/RIGHT actions, our joint model utilizes a total of $n+2$ actions, where n is the number of tags in the given dataset ($n = 33$ for the CTB-5 tag set (Xia, 2000)). A trace of an example joint parsing is illustrated in Figure 2.

3.2 Training and Decoding

We formulate the task of POS tagging and dependency parsing in a joint framework: given an input segmented sentence x, the model tries to find the best output y that satisfies:

$$\tilde{y} = \underset{y \in \mathcal{Y}(x)}{\operatorname{argmax}} \vec{w} \cdot \vec{\theta}(y),$$

where $\mathcal{Y}(x)$ is a set of possible outputs for x, $\vec{w}$ is the global feature vector, and $\vec{\theta}(y)$ is the feature vector of y. As in the baseline parsers, we train our models with the averaged perceptron; the beam search and early update strategy is almost the same except that the update is now caused by an error in POS tagging as well as by an error in dependency parsing. Similarly to the baseline tagger, we use the tag dictionary and closed-set tags to prune unlikely tags during decoding.

(a)	$q_0.t$ $q_0.w \circ q_0.t$	$s_0.t \circ q_0.t$
	$s_0.t \circ q_0.t \circ q_1.t$	$s_1.t \circ s_0.t \circ q_0.t$
	$s_0.w \circ q_0.t \circ q_1.t$	$s_1.t \circ s_0.w \circ q_0.t$
(b)	$t \circ s_0.w$	$t \circ s_0.t$
	$t \circ s_0.w \circ q_0.w$	$t \circ s_0.t \circ q_0.w$
	$t \circ B(s_0.w) \circ q_0.w$	$t \circ E(s_0.w) \circ q_0.w$
	$t \circ s_0.t \circ s_0.\text{rc}.t$	$t \circ s_0.t \circ s_0.\text{lc}.t$
	$t \circ s_0.w \circ s_0.t \circ s_0.\text{rc}.t$	$t \circ s_0.w \circ s_0.t \circ s_0.\text{lc}.t$
(c)	j $s_2.t$ $q_0.w$	$q_{-1}.t$ $q_{-2}.t$
	$s_1.w$ $s_1.t$	$s_1.\text{rc}.w$ $s_1.\text{lc}.t$
	$s_0.w$ $s_0.t$	$s_0.\text{rc}.w$ $s_0.\text{lc}.t$

Table 3: (a) List of delayed features for the joint parsers. (b) Syntactic features for the joint parsers, where t is the POS tag to be assigned to q_0. (c) Kernel features for the joint parser Joint-HS$^+$.

3.3 Features

For the features of the models, we incorporate the union of the features in the baseline tagger and the baseline parsers; features from Parser-HS are used for Joint-HS, and features from Parser-ZN$^-$ for Joint-ZN$^-$. Furthermore, we additionally incorporate a set of *syntactic features* for POS tagging that capture dependencies between syntactic elements in the stack and the POS to be tagged (described in Section 3.3.1).

The features for the baseline tagger (shown in Table 1) and Parser-ZN$^-$ (shown in Table 2 (b)) can be used *in situ*, because they do not rely on look-ahead POS tags (i.e. POS tags of the words in the queue). However, it is not straightforward to incorporate the features for Parser-HS: in the joint framework, since the look-ahead POS tags are unavailable when the model tries to determine the next action, we cannot easily incorporate those features that include look-ahead POS (listed in Table 3 (a)). In order to deal with this issue, we introduce a concept of *delayed features*, which enables the model to incorporate the look-ahead information by delayed evaluation of feature scores (described in Section 3.3.2).

Note that the features from the baseline parsers are used for all actions (i.e. SHIFT(t) and REDUCE-LEFT/RIGHT) while the features from the tagger are only used for SHIFT(t) actions in the joint models. The addition of the tagging features requires a few new elements to be added into the set of kernel features; the new set of kernel features for Joint-HS$^+$ is shown in Table 3 (c).

step	action	stack S	queue Q	translation
0	-	ϕ	我/? 想/? 把/? ...	
1	SH(PN)	我/PN	想/? 把/? 这/? ...	我: "I"
2	SH(VV)	我/PN 想/VV	把/? 这/? 个/? ...	想: "want"
3	SH(BA)	我/PN 想/VV 把/BA	这/? 个/? 句子/? ...	把: *object marker*
4	SH(DT)	我/PN 想/VV 把/BA 这/DT	个/? 句子/? 翻译/? ...	这: "this"
5	SH(M)	我/PN 想/VV 把/BA 这/DT 个/M	句子/? 翻译/? 成/? ...	个: *quantifier*
6	RL	我/PN 想/VV 把/BA 这/DT⌢[个/M]	句子/? 翻译/? 成/? ...	
7	SH(NN)	我/PN 想/VV 把/BA 这/DT⌢[个/M] 句子/NN	翻译/? 成/? 英语/?	句子: "sentence"
8	RR	我/PN 想/VV 把/BA [这/DT⌢[...]]⌢句子/NN	翻译/? 成/? 英语/?	
9	RL	我/PN 想/VV 把/BA⌢[[...]⌢句子/NN]	翻译/? 成/? 英语/?	
10	SH(VV)	我/PN 想/VV 把/BA⌢[[...]⌢句子/NN] 翻译/VV	成/? 英语/?	翻译: "translate"

Figure 2: A trace of joint shift-reduce parsing for "我想把这个句子翻译成英语" ("*I want to translate this sentence into English.*"), where grandchildren of stack elements are omitted.

Specifically, $q_{-1}.t$ and $q_{-2}.t$ are added in order to accommodate some of the tagging features, while $q_0.t$ and $q_1.t$ are removed because the look-ahead POS tags are not available when the equivalence of the states are evaluated. Joint-ZN$^-$ additionally requires kernel features in Table 2 (d).

3.3.1 Syntactic Features

Since our joint framework performs tagging and parsing simultaneously, we can think of incorporating a combined feature of the next tag (to be assigned to q_0) with syntactic information from stack elements, which cannot be used in an n-gram POS tagger. Specifically, we propose to use the features shown in Table 3 (b). Intuitively, these features try to capture dependencies between the POS to be assigned and syntactic structure encoded in the trees being built in the stack. For example, at step 9 in Figure 2, the next word 翻译 can be either a noun or a verb. In determining the tag of this word to be VV, the existence of the preceding phrase "把/BA [...]" on the top of the stack plays an important role, because the phrase headed by 把 represents an object for the following verb; in contrast, in an n-gram POS tagger, capturing this information is not easy because 把/BA is located at a distance of four words. Note that the addition of those syntactic features does not require the addition of any elements to the set of kernel features.

3.3.2 Delayed Features

A challenge in the incremental joint approach is that since the shift-reduce model processes an input sentence in a left-to-right manner, it cannot exploit look-ahead POS tags, which a pipeline shift-reduce parser can consider, to determine the next action. In our experiment with Parser-HS, the ablation of the features including look-ahead POS results in 0.67% decrease in parsing performance on the development set, suggesting that the look-ahead POS information is indispensable to achieve the state-of-the-art performance. In order to relieve this problem, we introduce a concept of *delayed features*, which are a set of features that are evaluated later when certain information becomes available. In our model, the parser features that require look-ahead POS information are defined as the delayed features, and shall later be evaluated at the step when the look-ahead POS are determined.

Let us see an example in Figure 2. At step 2, a parser encounters a shift-reduce conflict: the next action can be any of REDUCE-LEFT/RIGHT and SHIFT(t). If this were a (non-joint) shift-reduce parser, the model can utilize the look-ahead POS information by features such as

$$(s_0.t = \text{VV}) \circ (s_1.t = \text{PN}) \circ (q_0.t = \text{BA}),$$

to determine the next action, because the POS of all words in the sentence are already given. However, in the joint parser, the POS of the first word in the queue, 把, remains undetermined until the word is shifted. To deal with this, we define a *delayed feature* that takes look-ahead POS tag(s) as argument(s), as in

$$(s_0.t = \text{VV}) \circ (s_1.t = \text{PN}) \circ (q_0.t = \lambda_1), \lambda_1 = w_2.t.$$

At step 3, after SHIFT(BA) is performed, the delayed features from the previous step becomes a non-delayed feature

$$(s_0.t = \text{VV}) \circ (s_1.t = \text{PN}) \circ (q_0.t = \text{BA}),$$

which can be evaluated in the same way as normal (non-delayed) features.

More formally, each state carries with it a set of delayed feature vectors $\langle \vec{d}_1, \vec{d}_2 \rangle$, where $\vec{d}_n$ is the n-th order delayed feature vector, which has n ar-

guments to be filled in[1]. At each step, a REDUCE-LEFT/RIGHT action a adds a set of delayed features to the delayed feature vectors of state ψ:

$$\langle \vec{d}_1, \vec{d}_2 \rangle \leftarrow \langle \vec{d}_1 + \vec{\Phi}_1(\psi, a), \vec{d}_2 + \vec{\Phi}_2(\psi, a) \rangle,$$

where $\vec{\Phi}_1(\psi, a)$ and $\vec{\Phi}_2(\psi, a)$ are the first-/second-order delayed features generated by action a being applied to ψ. When a SHIFT(t) action is performed, the model fills in the argument in the delayed features with the newly-assigned tag t, as well as adding new delayed features it generates:

$$\langle \vec{d}_1, \vec{d}_2 \rangle \leftarrow \langle \vec{\Phi}_1(\psi, \text{SH}(t)) + \mathcal{T}(t, \vec{d}_2), \vec{\Phi}_2(\psi, \text{SH}(t)) \rangle,$$

where $\mathcal{T}(t, \vec{d}_2)$ is the resulting feature vector after tag t is filled in to the first argument of the features in $\vec{d}_2$. Note that action SH(t) also adds $\vec{d}_0 = \mathcal{T}(t, \vec{d}_1)$ to its (non-delayed) feature vector.

Note that the above formulation with the delayed features is equivalent to the model with full look-ahead features if the exact decoding is performed. Although the approximate search with beam takes the risk of the gold derivation falling off the beam before delayed features are evaluated, we show in Section 4 that the current solution works well in practice.

3.4 Deduction System with DP

With the delayed features, a parser state ψ takes the form of $\langle \ell, i, j, S, \vec{d}_1, \vec{d}_2; \xi, \eta, \Pi \rangle$. Now, if two equivalent states are still merged according to Eq. (1), one state might have multiple sets of delayed feature vectors depending on the previous action sequences. In order to make the joint model still tractable with the DP formalism, we modify the equivalence condition in Eq. (1): in addition to the condition in Eq. (1), two states now need to share the same delayed feature vectors in order for them to be merged:

$$j = j' \wedge \vec{f}(j, S) = \vec{f}(j', S') \wedge \vec{d}_1 = \vec{d}'_1 \wedge \vec{d}_2 = \vec{d}'_2.$$

This guarantees that a parser state has only one unique set of delayed feature vectors.

We can prove by induction that the *correctness* (i.e. the optimality of the deductive system) is still assured (proof omitted due to limited space) even with the delayed features incorporated. However, because any number of REDUCE-LEFT/RIGHT actions can occur between two SHIFT actions, the delayed features might need to refer to unboundedly deep elements from stack trees; therefore, the *boundedness* (see Huang and Sagae (2010)) of the kernel features no longer holds and the worst-case polynomial complexity is not assured. Nonetheless, we show that our models work sufficiently well in practice, with the aid of beam search.

[1] In our joint models, the use of only the first- and second-order delayed vectors suffices, because the feature templates refer to the tags of the first two words in the queue at most.

4 Experiment

4.1 Experimental Settings

We evaluate the performance of our joint parsers and baseline models on the Chinese Penn Treebank (CTB) 5 dataset. We use the standard split of CTB-5 described in Duan et al. (2007) and the head-finding rules in Zhang and Clark (2008b).

We iteratively train each of the models and choose the best model, in terms of the tagging accuracy (for tagger) or word-level dependency accuracy (for parsers and joint parsers) on the development set, to use in the final evaluation. When building a tag dictionary, we discarded instances that appear less than three times (tuned on the development set) in the training data. An Intel Core-i7 950 3.2GHz machine is used for evaluation.

4.2 Baseline Performance

First of all, we evaluate the performance of our baseline tagger and parsers described in Section 2. Based on our preliminary experiments, we set the beam size to 16 for the baseline tagger and Parser-HS, and to 32 for Parser-ZN$^-$. Our baseline tagger achieved a tagging accuracy of 94.15% on the development set, and 93.82% on the test set. Since most recent works on Chinese POS tagging (e.g. Kruengkrai et al. (2009); Sun (2011)) are joint approaches integrating word segmentation, the only directly-comparable work we could find is Li et al. (2011), where they built a perceptron-based POS tagger with the same feature set as we used (Zhang and Clark, 2008a). They reported 93.51% accuracy on test set, which is slightly lower than ours.

The upper part of Table 7 shows the performance of our baseline parsers with a comparison to other state-of-the-art parsers, where (unlabeled) attachment accuracies of word, root, and complete match are shown (with punctuations excluded). Our reimplementation of Huang and Sagae (2010) has reproduced almost the same accuracy. Interestingly, Parser-ZN$^-$ also has comparable performance to that of Zhang and Nivre (2011) even though we could not use some of their features (as described in Section 3.3).

beam	Joint-HS$^+$			Joint-ZN$^-$		
	tag	dep	speed	tag	dep	speed
4	94.37	79.98	37.5	94.26	80.55	25.4
8	94.57	80.56	19.3	94.64	81.47	13.5
16	94.56	80.97	10.1	94.48	81.50	7.0
32	94.66	80.72	4.7	94.40	81.68	3.3
64	94.50	81.09	2.0	94.50	81.88	1.5
128	-	-	-	94.43	81.89	0.69

Table 4: Tagging and word-level dependency accuracies and parsing speed (in sentence/second) on the development set with respect to beam size.

Model	tag	word	non-root	root	compl.
Parser-HS	(100)	85.15	85.61	75.76	34.50
Parser-ZN$^-$		85.77	86.18	77.46	34.99
Pipeline-HS	94.15	78.10	78.49	70.03	26.77
Pipeline-ZN$^-$		78.67	78.92	73.32	27.90
Joint-HS$^+$	94.56*	80.97*	81.32	73.64	29.51
Joint-ZN$^-$	94.50*	81.88*	82.21	74.94	30.26

Table 5: Development result of the proposed models. Joint-HS$^+$/ZN$^-$ perform better than Pipeline-HS/ZN$^-$ in terms of both tagging and word-level dependency accuracies, with statistical significance of $p < 0.05$ (denoted by *) by MeNemar's test.

4.3 Development Results

Table 4 shows the tagging and word-level dependency accuracies of the joint models with respect to the beam size, where "tag" and "dep" show the tagging and word-level dependency accuracies, and "speed" is the joint parsing speed (in sentence per second). Based on this experiment, we use the beam size of 16 for Joint-HS$^+$ and 64 for Joint-ZN$^-$ in the following experiments.[2] The best dependency accuracies are achieved after 36-th and 31-st iterations, respectively.

Table 5 shows the performance of the baseline and joint models on the development set, where "Pipeline-HS" and "Pipeline-ZN$^+$" are the pipeline combinations of the baseline tagger with Parser-HS and Parser-ZN$^+$, respectively. Joint-HS$^+$ and JointZN$^-$ have 0.35–0.41% (tagging) and 2.87–3.21% (word-level dependency) higher accuracies than the pipeline models.

Table 6 shows feature ablation results on the development set, where "wo/delay", "wo/dp", and "wo/syn" correspond to the models that do not use the delayed features, dynamic programming, and syntactic features, respectively. Overall, the tagging accuracies are only slightly affected by the ablation of these features (with differences no larger than 0.10%), while the parsing accuracies decreased in most settings. The ablation of the delayed features resulted in 0.26% and 0.16% decreases of word-level dependency accuracies for Joint-HS$^+$ and Joint-ZN$^-$, showing the effectiveness of these features. The contribution of the dynamic programming is clearly shown for Joint-HS$^+$ with 0.22% improvement in dependency accuracy, although no meaningful effect for Joint-ZN$^-$ is confirmed; this is probably because the use of richer features results in less frequent packing of states. Lastly, the ablation of the syntactic features results in as much as 0.60% and 0.23% decreases of dependency accuracies for Joint-HS$^+$ and Joint-ZN$^-$. As opposed to our first expectation, the syntactic features made little effect on the tagging accuracies; on the contrary, the result suggests that capturing the dependencies between the stack elements and the next word's tag is quite effective to improve parsing accuracy.

[2]Due to limited time, the beam size of 32 is used for Joint-ZN$^-$ for the feature ablation experiment shown in Table 6.

Model		default	wo/delay	wo/dp	wo/syn
Joint-HS$^+$	tag	94.56	$\pm$0.00	$-$0.06	$+$0.04
	dep	80.97	$-$0.26	$-$0.22	$-$0.60
Joint-ZN$^-$	tag	94.40	$+$0.10	$+$0.05	$-$0.07
	dep	81.68	$-$0.16	$-$0.01	$-$0.23

Table 6: Feature ablation results for the joint models on the development set.

Model	tag	word	root	compl.	speed
Huang+ '10		85.20	78.32	33.72	-

4.4 Final Results

Table 7 shows the final result of the proposed models compared to the baseline models. "Li-

error pattern	#↓	total	error pattern	#↑	total
NN → VV	61	169	VV → NN	29	128
DEC → DEG	35	65	NN → NR	16	64
DEG → DEC	19	72	JJ → NN	14	62
NN → JJ	11	59	VA → VV	8	12
P → CC	8	13	JJ → NR	6	2
P → VV	8	18	NR → JJ	6	4

Table 8: POS tagging error patterns that decrease (left side) and increase (right side) by joint decoding (on dev. set). The numbers of errors made by the baseline tagger ("total") and the increases and decreases by Joint-ZN$^+$ (#↓ and #↑) are shown.

11(. . .)" shows the graph-based models by Li et al. (2011), where v1/2 and 2nd/3rdcorrespond to their version 1/2 and second-/third-order models. The joint models Joint-HS$^+$ and Joint-ZN$^-$ achieve improvements of 0.19% and 0.12% in tagging accuracy over the baseline tagger, and 2.70% and 3.29% improvements in word-level dependency accuracy over the pipeline models, showing the effectiveness of the joint approach. Furthermore, the tagging and parsing accuracies of Joint-ZN$^-$ surpass the graph-based models by Li et al. (2011), achieving the new state-of-the-art performance on this joint task. Since our framework is at least comparable in speed to their models, these results suggest that our incremental framework is suitable to this joint task.

4.5 Discussion and Analysis

Table 8 shows the increase and decrease of error patterns of Joint-ZN$^-$ over the baseline tagger. Notably, the joint model has a clear advantage in the disambiguation of DEC and DEG and the discrimination of NN from VV. While these tags are those that critically influence the overall syntactic structure, the increased error patterns include those tags that are considered less important[3] in deciding the syntactic structure (e.g. NN/NR: general/proper nouns); this observation is largely similar to those reported by Li et al. (2011).

It is noteworthy that we obtained the first positive result that the joint decoding does improve POS tagging, while, in contrast, Li et al. (2011) have reported that the joint decoding has negative effect on the tagging accuracy: their third-order models have 0.6–0.7% lower tagging accuracies than their baseline tagger. When comparing our error patterns with those of their model, although the overall increase and decrease of the error patterns look largely similar, our model has a relatively smaller number of increased error patterns than the decreased ones. Therefore, by selectively improving syntactically-important tags, our joint model is considered to have improved the POS tagging accuracy over the baseline tagger.

[3]although VV → NN errors look like an exceptional case

5 Related Works

In recent years, joint segmentation and tagging have been widely investigated (e.g. Zhang and Clark (2010); Kruengkrai et al. (2009); Zhang and Clark (2008a); Jiang et al. (2008a); Jiang et al. (2008b)). Particularly, our framework of using a single perceptron to solve the joint problem is motivated by Zhang and Clark (2008a). Also, our joint parsing framework is an extension of Huang and Sagae (2010)'s framework, which is described in detail in Section 2.2. In constituency parsing, the parsing naturally involves the POS tagging since the non-terminal symbols are commonly associated with POS tags (e.g. Klein and Manning (2003)). Rush et al. (2010) proposed to use dual composition to combine a constituency parser and a trigram POS tagger, showing the effectiveness of taking advantage of these two systems.

In dependency parsing, Lee et al. (2011) recently proposed a discriminative graphical model that solves morphological disambiguation and dependency parsing jointly. However, their main focus was to capture interaction between morphology and syntax in morphologically-rich, highly-inflected languages (such as Latin and Ancient Greek), which are unlike Chinese. More recently, Li et al. (2011) proposed the first joint model for Chinese POS tagging and dependency parsing in a graph-based parsing framework, which is one of our baseline systems. On the other hand, our work is the first incremental approach to this joint task.

6 Conclusion

In this paper, we have presented the first joint approach that successfully solves POS tagging and dependency parsing on an incremental framework. The proposed joint models outperform the pipeline models in terms of both tagging and dependency parsing accuracies, and our best model achieved the new state-of-the-art performance on this joint task, while retaining competitive parsing speed. Although we mainly focused on Chinese in this work, our framework is generally applicable to other languages including English; for future work, we hope to further investigate the effectiveness of our joint approach in those languages.

Abstract

This paper presents work on extending the adverbial entries of *LGLex*, a NLP oriented syntactic resource for French. Adverbs were extracted from the Lexicon-Grammar tables of both simple adverbs ending in *–ment* '–ly' (Molinier and Levrier, 2000) and compound adverbs (Gross, 1986; 1990). This work relies on the exploitation of fine-grained linguistic information provided in existing resources. Various features are encoded in both LG tables and they haven't been exploited yet. They describe the relations of deleting, permuting, intensifying and paraphrasing that associate, on the one hand, the simple and compound adverbs and, on the other hand, different types of compound adverbs. The resulting syntactic resource is manually evaluated and freely available under the LGPL-LR license.

1 Introduction

Recognising adverbs such as *extrêmement* 'extremely' and *à long terme* 'in the long run' in texts is likely to be useful for information retrieval and extraction because of the information that some of these adverbials convey.

Adverbs, or more generally circumstantial complements, have often been overlooked in the compilation of lexical resources (Nølke, 1990: 3). Several reasons explain this lack of interest. Firstly, adverbials are usually felt as less useful than nouns for information retrieval and extraction. Secondly, compound adverbs in particular are difficult to distinguish from prepositional phrases assuming other syntactic functions, such as arguments or noun modifiers: the distinction is hardly correlated to any material markers in texts and lies in complex linguistic notions (Villavicencio, 2002; Merlo, 2003).

The availability of large-coverage lexicons providing lexical, syntactic and semantic information is essential in order to gain insight on the recognition of adverbs, including the dual problems of variability and ambiguity. In addition, it is likely to help solving prepositional phrase attachment during shallow or deep parsing (Agirre *et al.*, 2008).

In this paper, we present work on extending the adverbial entries of *LGLex*, a NLP oriented syntactic resource for French. These adverbs were extracted from the Lexicon-Grammar tables (hereafter LG tables) of both simple adverbs ending in *–ment* '–ly' (Molinier and Levrier, 2000) and compound adverbs (Gross, 1986; 1990).

The paper is organized as follows. In section 2, we provide an overview of the three resources used in our work. In section 3, we describe how we enhanced *LGLex* thanks to various features that are encoded in LG tables. In section 4, we present results and discuss the manual evaluation process. Finally, we conclude in section 5 by pointing out several possible extensions and issues for future research.

2 Resources

Lexicon-Grammar tables (hereafter LG tables) are currently one of the major sources of lexical syntactic information for the French language; several LG tables exist for other languages (see section 2.1). Their development was initiated as early as the 1970s by Maurice Gross, at the LADL (Gross, 1975; 1994), and then at the LIGM, University Paris-Est (Boons *et al.*, 1976; Guillet and Leclère, 1992).

Lexical information is represented in the form of tables. Each table puts together elements of a given lexical-grammatical category (for a given language) that share a certain number of defining features, which usually concern subcategorization information. These elements form a class. These tables are represented as matrices (see section 2.1.2): each row corresponds to a lexical item of the corresponding class; each column lists all features that may be valid or not for the different members of the class; at the intersection

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1225–1233,
Chiang Mai, Thailand, November 8 – 13, 2011.

of a row and a column, the symbol + (resp. –) indicates that the feature corresponding to the column is valid (resp. not valid) for the lexical entry corresponding to the row.

The resources described in this paper correspond to the LG tables of both simple and compound adverbs, in which previously implicit features have been made explicit[1] for more convenient use in NLP. All tables are fully available[2] under a free license (LGPL-LR).

2.1 The LG tables of adverbs

LG tables of adverbs are available in several languages, notably in English (Gross, 1986), German (Seelbach, 1990), Spanish (Blanco and Català, 1998/1999), Italian (De Gioia, 2001), Portuguese (Baptista, 2003), Korean (Jung, 2005) and Modern Greek (Voyatzi, 2006).

In French, there are two resources of adverbs that follow different principles both in classification and in representation within the Lexicon-Grammar framework. That is, firstly, tables of simple adverbs ending in *–ment* '–ly' (Moliner, 1984; Molinier and Lévrier, 2000), which are mainly derived from adjectives and, secondly, tables of compound adverbs (Gross, 1986; 1990). In this section, we describe briefly the different classes, morphosyntactic structures and features provided in the tables of both types of adverbs.

2.1.1 The LG tables of simple adverbs

According to Molinier and Levrier (2000), adverbs ending in *–ment* '–ly' form a large class of French adverbs. Moreover, as opposed to other types of adverbs, they form a quite open class.

These adverbs constitute a morphologically homogeneous class, since most of them are created according to the pattern `adjective + -ment '-ly'`. In total, there are 3,203 simple adverbial entries which are represented in sixteen LG tables.

The first partition has been established between sentential adverbs and adverbs integrated into the sentence; that means attached to the predicate or any other component of the sentence.

Three major classes of sentential adverbs are worth mentioning: conjuncts, style disjuncts (or utterance-level adverbs) and attitude disjuncts (or statement adverbs). The latter are divided into four classes: evaluative adverbs, e.g. *curieusement* 'curiously', adverbs of habit, e.g. *habituellement* 'usually', modal adverbs, e.g. *certainement* 'certainly', and subject oriented attitude adverbs, e.g. *bêtement* 'foolishly'.

On the other hand, there are six major classes of adverbs integrated into the sentence:

(i) adverbs of subject oriented manner, e.g. *gentiment* 'kindly', *Max traite les gens gentiment = Max est gentil dans la (façon + manière) dont il traite les gens* 'Max treats people kindly = Max is kind in the way he treats people';
(ii) adverbs of verbal manner, e.g. *démocratiquement* 'democratically', *Ce parti est arrivé au pouvoir démocratiquement = C'est démocratiquement que ce parti est arrivé au pouvoir* 'This party came to power democratically = It is democratically that this party came to power';
(iii) adverbs of quantity (including intensifiers), e.g. *excessivement* 'excessively';
(iv) adverbs of time expressing time, e.g. *actuellement* 'actually', duration, e.g. *temporairement* 'temporarily' or frequency, e.g. *régulièrement* 'regularly';
(v) viewpoint adverbs, e.g. *linguistiquement = d'un point de vue linguistique* 'linguistically = from a linguistic point of view';
(vi) focus adverbs, e.g. *essentiellement* 'essentially'.

Features included in the LG tables can be organized into four main groups: distributional features (e.g. the possibility for an adverb to occur at the beginning of a negative clause), local syntactic features (e.g. the possibility for an adverb to have a function as an indefinite determiner), semantic features (e.g. knowing what type of interrogative adverb corresponds to an adverb allows it to be categorized semantically), and paraphrasing features (e.g. *Adv, Pindicatif = C'est Adj que Psubjonctif =: Bizarrement, Marie n'est pas venue à la soirée = C'est bizarre que Marie ne soit pas venue à la soirée* ' Oddly, Mary did not come to the party = It is odd that Mary did not come to the party').

2.1.2 The LG tables of compound adverbs

The scope of the LG tables of compound adverbs is delimited by the intersection of two criteria: (i) multiword expressions and (ii) adverbial func-

[1] In order to make previous implicit features explicit, a table of classes has been created (Tolone, 2009; 2011). Its role is to assign features when their value is constant over a class, e.g. class definition features. Each row stands for a class and each column stands for a feature. Each cell corresponds to the validity of a feature in a class. In particular, the table of French adverb classes is composed of 32 different classes and 163 features.

[2] http://infolingu.univ-mlv.fr/english > Language Resources > Lexicon-Grammar > Download.

tion. As Laporte and Voyatzi (2008) state "a phrase composed of several words is considered to be a multiword expression if some or all of its components are tied together, that is, if their combination does not obey productive rules of syntactic and semantic compositionality". This criterion ensures a complementarity between lexicon and grammar. In other words, it tends to ensure that any combination of linguistic elements which is correct in the language, but is not represented in common syntactic-semantic grammars, should be stored in lexicons.

In terms of the adverbial function, LG tables of compound adverbs deal only with circumstantial complements, namely, complements that modify the predicate or any other element of the sentence in which they occur. Sentential adverbs modify or enhance the entire sentence. They are identified through criteria (Gross, 1986; 1990) involving the fact that they are optional, they combine freely with a wide range of predicates and some of them typically answer questions such as *comment?* 'how?', *où?* 'where?', *quand?* 'when?', etc. The compound adverbs described in LG tables (Gross, 1986; 1990) take several morphosyntactic forms: unsuffixed adverbs, e.g. *demain*[3] 'tomorrow', suffixed adverbs, e.g. *nuitamment*[4] 'by night', prepositional phrases, e.g. *à la dernière minute* 'at the last minute', noun phrases, e.g. *le cas échéant* 'if necessary' or adverbial clauses, e.g. *jusqu'à ce que mort s'ensuive* 'until death comes'.

These compound adverbs are classified according to their internal morphosyntactic structure which is described at the elementary level of sequences of parts of speech. The classification is based mainly on the number, type and position of the fixed and variable lexical components of adverbs. These classificatory morphosyntactic structures have a three-fold aim: first, they are intended as an aid to organize the heterogeneous compound adverbs in an electronic lexicon; second, they are intended as an aid to identify the compound adverbs in a parser; finally, they have impact on the syntactic-semantic subcategorization of compound adverbs. For instance, most of the adverbial clauses represented in table PF are interpolated clauses, e.g. *si ma mémoire est bonne* 'if my memory serves me well".

Table 1 illustrates the sixteen formal classes, together with their defining internal morphosyntactic structure, an illustrative example[5] and the number of entries listed:

Identifier	Morphosyntactic structure	Example	Size
PADV	C	enfin	520
PC	Prép C	par exemple	664
PDETC	Prép Det C	de nos jours	848
PAC	Prép Det Adj C	à la dernière minute	776
PCA	Prép Det C Modif pré-adj Adj	à la nuit tombante	840
PCDC	Prép Det1 C1 de Det2 C2	dans la limite du possible	750
PCPC	Prép Det1 C1 Prép2 Det2 C2	à cent pour cent	287

PECO	(Adj) comme Det C	(fidèle) comme un chien	305
PVCO	(V) comme Det C	(travailler) comme un chien	338
PPCO	comme Prép Det C	(disparaître) comme par enchantement	50
PJC	Conjc Det C1 Prép C2	mais aussi et surtout	185
		Total	7,283

Table 1. Morphosyntactic structures of French compound adverbs

Compound adverbs are represented in sixteen LG tables[6], one for each of the defining morphosyntactic structures[7]. Unlike simple adverbs, compound adverbs are represented in the tables within a structure of elementary sentence which is composed of a verbal predicate (intransitive in most cases) and its arguments. This representation takes into account the combination of the

[3] According to Gross (1990: 153), *demain* 'tomorrow' is a compound form from an etymological point of view: from the Latin expression *de mane* which means literally "in the morning". But, it is now regarded as a simple form since it is represented by a single word. These forms are derived from noun or prepositional noun phrases previously analyzed that were tied at various times.

[4] According to Gross (1986: 2), *nuitamment* 'by night' can also be considered as an idiomatic compound, though not constituted of words but of a word and a suffix. Lack of compositionality stems from the observation that *quotidiennement* 'daily', *mensuellement* 'monthly', etc. which are derived adverbs of the same formal type have a regular formation, in the sense that their interpretation is homogeneous. Thus, *nuitamment* 'by night' is an isolated case, as opposed to an open series of identical forms with a different interpretation.

[5] It is possible that one or more of the components defined in a morphosyntactic structure are absent. For instance, in the adverb *à cent pour cent* 'one hundred percent', which is assigned the structure PCPC, `Dét1` and `Dét2` are empty.

[6] The LG tables of adverbs described in this paper have been updated by the members of LIGM, so that previously implicit linguistic information becomes explicit and convenient for NLP applications. Tolone (2009; 2011) and Tolone *et al*. (2010) give a thorough account of this work.

[7] Symbols with obvious interpretation are used such as: `Prép` (preposition), `Det` (determiner), `Adj` (adjective), `Modif pré-adj` (pre-adjectival modifier), `N` (noun), `V` (verb), `Conj` (conjunction), and `C` (noun tied with the rest of the adverbial).

adverb with a structure of elementary sentence, and, thus provides precise information about various types of constraints occurring between compound adverbs and the predicate they modify. An example of time constraint is given below:

*Les tablettes (remplaceront + *ont remplacé + *remplacent) les PC dans un avenir proche*

'Ipads (will replace + *replaced + *replace) desktop PC in a near future'

The LG tables of French compound adverbs contain 7,283 entries. Table 2 displays a sample of the table PCA which is defined by the morphosyntactic structure `Preposition, Determiner, Constrained noun, Pre-adjectival Modifier, Adjective`:

N0 =: Nhum	N0 =: N-hum	Neg obl	Ppv	Prédicat type	<ENT>Prép	<ENT>Det	<ENT>C	<ENT>Modif pré-adj	<ENT>Adj	Prép Det C	Prép Det Modif pré-adj Adj C	Prép Modif pré-adj Adj C	Conjonction
-	+	-	:se	produire	dans	le	cas	<E>	contraire	-	-	-	+
-	+	-	:se	produire	<E>	le	cas	<E>	échéant	-	-	-	-
-	+	-	:se	produire	à	le	cas	<E>	où	-	-	-	-
-	+	-	:se	produire	dans	le	cas	qui	préoccupe ":Nhum"	-	-	-	-
-	+	-	:se	produire	dans	le	cas	<E>	présent	-	+	-	+
-	+	-	:se	produire	dans	un	cas	<E>	semblable	-	+	-	+

Table 2. Compound adverbs of table PCA

In this table, each row corresponds to a lexical item with adverbial function, and each column corresponds to:

- one of the components in the morphosyntactic structure of the items, i.e. features with identifiers `Prép`, `Det`, `C`, `Modif pré-adj`, and `Adj`;

- a syntactic feature holding binary values, for example: `Prép Det Modif pré-adj Adj C` describes the possible permutation (without loss of information) of the adjectival phrase represented in this table as `Modif pré-adj Adj`; moreover, `Neg obl` encodes the constraint that the adverbial occurs obligatorily in a negative clause;

- a semantic feature holding binary values, for instance, `Conjonction` points out whether the compound adverb has a connector function in discourse, i.e. it links the clause in which it occurs with the previous clause as, for example, *dans le cas contraire* 'otherwise';

- an item of information provided as an aid to help human readers find examples of sentences containing the compound adverb: features with identifiers `Ppv` and `Prédicat type` give an example of a verbal predicate that combines commonly with the adverb.

Unlike simple adverbs, the sixteen classes of compound adverbs, represented in sixteen LG tables, are both syntactically and semantically heterogeneous. For instance, the table PAC encodes adverbs that are defined by the morphosyntactic structure `Prép Det Adj C`, but belong to different syntactic and semantic classes of Molinier and Lévrier (2000): conjuncts, e.g. *dans un premier temps* 'initially', disjuncts, e.g. *à Posss0 humble avis* 'in Poss0 humble opinion', adverbs of time, e.g. *depuis cent sept ans* 'one hundred and seven years since', adverbs of verbal manner, e.g. *n'importe comment* 'no matter how', etc.

Despite their differences, both types of adverbs are often related by productive and regular relations such as, for example, paraphrasing relations allowing the creation of pairs of synonyms, as shown in Table 3:

Adverbs encoded in LG tables of simple adverbs	Adverbs encoded in LG tables of compound adverbs
pratiquement (ADVPS) 'practically'	*en pratique* (PC) 'in practice'
franchement (ADVPS) 'frankly'	*à franchement parler* (PV) 'frankly speaking'
sincèrement (ADVMS) 'sincerely'	*de (E+une) (manière+façon) sincère* (PCA) 'in a sincere way'
politiquement (ADVMP) 'politically'	*du point de vue politique* (PCA) 'from a political point of view'

Table 3. Paraphrasing relations between simple and compound adverbs

2.2 The syntactic lexicon *LGLex*

The current version of the French LG tables has to consider the use of these lexical data in NLP tools (Tolone, 2009). Therefore, the tables have been converted into an interchange format, based on the same linguistic concepts as those handled in the tables. This conversion is based on *LGExtract*: a generic tool for generating a syntactic lexicon for NLP from the LG tables (Constant and Tolone, 2010). It relies, first, on a global table of classes in which we added the missing features and, second, on a single extraction script

including all operations related to each feature to be performed for all tables.

Thanks to *LGExtract*, a French lexicon for NLP has been generated from all LG tables and for most lexical-grammatical categories: verbs, predicative nouns, idioms and adverbs. This syntactic lexicon is named *LGLex* (Constant and Tolone, 2010; Tolone, 2011) and it is freely available[8] under the LGPL-LR license in both plain text format and XML.

LGLex is currently composed of 13,867 verbal entries (from 67 tables), 12,696 nominal entries (from 78 tables), 39,628 idioms (from 69 tables) and 10,487 adverbial entries (from 32 tables) of which 3,203 are simple adverbs (from 16 tables) and 7,284 are compound adverbs (from 16 tables).

3 Extending the LGLex

Each entry of the lexicon includes three sections:

(i) section `Lexical information` identifies the lexical entry, for instance, the adverb *jusqu'à la fin des* (=de les) *temps* 'until the end of time' which is encoded in table PCDC, and also gives the category of each lexical component. We added the information of `paraphrases`, `other structures` and `other entries with intensification` (see section 3.2);

(ii) section `Arguments` gives information about the arguments of the predicate: for instance, the subject argument `N0`, assigned to the predicate that can be modified by the adverb *jusqu'à la fin des temps* 'until the end of time' is a non human noun phrase, represented by `N0 = N-hum`;

(iii) section `Constructions` enumerates the identifiers of all constructions of the lexical entry (e.g. `N0 V Adv W` or `Adv parlant, P`) and of all internal morphosyntactic structures, that is `Adv` for all simple adverbs or `Prép1 Det1 C1 Prép2 Det2 C2` for compound adverbs like *jusqu'à la fin des temps* 'until the end of time', but also `Prép1 Det1 C1` for its variant without prepositional noun phrase modifier, e.g. *jusqu'à la fin* 'until the end'.

So, we first extended *LGLex* with respect to adverbial entries by using various types of features that are encoded in the tables of both simple and compound adverbs. We added 11,328 entries (+108%), so the lexicon is now composed of 21,815 adverbial entries in total.

[8] http://infolingu.univ-mlv.fr/english > Language Resources > Lexicon-Grammar > Download.

3.1 Using the paraphrasing features

The viewpoint adverb *linguistiquement* 'linguistically' accepts the following paraphrasing constructions (Sekine, 2005) that are encoded in the table ADVMP by means of binary features:

linguistiquement 'linguistically'
= *(du+d'un+au) point de vue linguistique*
'from a linguistic point of view'
= *du point de vue de la linguistique*
'from the point of view of linguistics'
= *au niveau linguistique*
'at the linguistic level'
= *(au+sur le) plan linguistique*
'on the linguistic level'
= *en linguistique*
'in linguistics'
= *linguistiquement parlant*
'linguistically speaking'.

For this work, we first dealt with paraphrasing constructions that are described directly in the LG tables through explicit features, as it is shown in Table 4:

Paraphrasing features encoded in the LG tables	Lexical values of the paraphrasing features in the script
`Adj-ment = avec Adj-n`	`"avec @Adj-n@"`
`Adj-ment = (du+d'un) point de vue Adj`	`"d'un point de vue @Adj@", "du point de vue @Adj@"`
`Adj-ment = du point de vue de Ddef Ndomaine`	`"du point de vue de Ddef @Ndomaine@"`
`Adj-ment = au niveau Adj`	`"au niveau @Adj@"`
`Adj-ment = au point de vue Adj`	`"au point de vue @Adj@"`
`Adj-ment = au plan Adj`	`"au plan @Adj@"`
`Adj-ment = sur le plan Adj`	`"sur le plan @Adj@"`
`Adj-ment = de source Adj`	`"de source @Adj@"`
`Adj-ment = en Adj-n`	`"en @Adj-n@"`
`Adj-ment = en Ndomaine`	`"en @Ndomaine@"`
`Adj-ment = en termes Adj`	`"en termes @Adj@"`
`Adj-ment = en toute Adj-n`	`"en toute @Adj-n@"`

Table 4. Paraphrasing features encoded directly in LG tables

The notation @...@ specifies the lexical value of a lexical feature which is encoded systematically in a LG table. For instance, when @Adj@ refers to table ADVMP, it can take the following values: *linguistique* 'linguistic', *politique* 'political', *informatique* 'computational', etc .

Thanks to these features, we added to *LGLex* 2,084 adverbial entries (+20%).

However, a certain number of paraphrases are part of construction features, and thus need to be extracted from them. Construction features are encoded in LG tables by means of binary features, as it is shown in Table 5:

Construction features encoded in the LG tables	Lexical values of the paraphrasing features in the script
Adv parlant, P	"@<ENT>Adv@ parlant"
N0 V W C-a-ment	"@C-a-ment@"
N0 V W avec Adj-n	"avec @Adj-n@"
N0 V W de (E+une) (façon + manière) C-a	"de façon @C-a@", "de manière @C-a@", "d'une façon @C-a@", "d'une manière @C-a@"
N0 V W de (E+une) (façon + manière) Adj	"de façon @Adj@", "de manière @Adj@", "d'une façon @Adj@", "d'une manière @Adj@"
N0hum V W avec Adj-n	"avec @Adj-n@"
N0hum V W de (E+une) (façon + manière) Adj	"de façon @Adj@", "de manière @Adj@", "d'une façon @Adj@", "d'une manière @Adj@"
à Adv parler, P	"à @<ENT>Adv@ parler"

Table 5. Paraphrasing features embedded in construction features

Using this type of features, we enhanced *LGLex* with 7,125 adverbial entries (+68%). Using both types of paraphrasing features, the number of adverbial entries in *LGLex* raised from 10,487 to 19,695 (+88%).

3.2 Other structures

Within the other structures, we distinguish three types of features: deletion, permutation and transformation. They are all described in the following sections.

3.2.1 Using the deletion features

The adverb *jusqu'à la fin des* (=de les) *temps* 'until the end of time' is defined by the morphosyntactic structure Prép1 Det1 C1 Prép2 Det2 C2. It accepts also the substructure *jusqu'à la fin* 'until the end', which is obtained after deletion of the prepositional noun phrase modifier *des* (=de les) *temps* 'of time', and without loss of information. The new adverb has the structure Prép1 Det1 C1. Table 6 displays the deletion features present in LG tables of adverbs:

Deletion features encoded in the LG tables	Lexical value of the deletion features in script
ConjC Det1 C1 Prép2 C2 = Det1 C1 Prép2 C2	"@<ENT>Det1@ @<ENT>C1@ @<ENT>Prép2@ @<ENT>C2@"
Prép Det C	"@<ENT>Prép@ @<ENT>Det@ @<ENT>C@"
Prép1 Det1 C1	"@<ENT>Prép1@ @<ENT>Det1@ @<ENT>C1@"

Table 6. Deletion features encoded in LG tables

The notation @<ENT>...@ specifies the lexical value of an entry described in a LG table. In the case of compound adverbs, an entry is composed by two or more lexical components.

Thanks to the deletion features, we added to *LGLex* 1,519 adverbial entries (+14%).

3.2.2 Using the permutation features

The adverb *dans un avenir proche* 'in a near future', which is defined by the morphosyntactic structure Prép Det C Modif pré-adj Adj, can also take the form *dans un proche avenir* due to the permutation of the adjectival phrase *proche* 'near'. The new adverb has the structure Prép Det Modif pré-adj Adj C, as it is shown in the Table 7:

Permutation features encoded in the LG tables	Lexical value of the permutation features in the script
Prép Det Modif pré-adj Adj C	"@<ENT>Prép@ @<ENT>Det@ @<ENT>Modif@ @<ENT>pré-adj@ @<ENT>Adj@ @<ENT>C@"
Prép Modif pré-adj Adj C	"@<ENT>Prép@ @<ENT>Modif@ @<ENT>pré-adj@ @<ENT>Adj@ @<ENT>C@"

Table 7. Permutation features encoded in LG tables

Let us consider now the compound adverb *dans les délais les plus brefs* 'as soon as possible', which is defined by the morphosyntactic structure `Prép Det C Modif pré-adj Adj`. Although it accepts the permutation of the adjectival phrase *les plus brefs* 'the shortest', it produces an agrammatical entry ***dans les les plus brefs délais***. This happens only when `Modif pré-adj` corresponds to a complex unit, that is, in our example, the superlative determiner *les plus* 'the most'. To remedy this situation, we added to table PCA a specific feature enabling both the deletion and permutation of certain components without loss of information, i.e. the feature `Prép Modif pré-adj Adj C`.

This kind of problem is rather widespread since multiword units raise specific difficulties as regards their representation[9] in an electronic resource. Semantically, by definition, compound adverbs cannot be decomposed into simple units. In other words, the resulting overall meaning of the compound adverb cannot usually be deduced from the sum of the meaning of its component elements. Consequently, the various lexical components of compound adverbs are sometimes represented in the tables in an ambiguous or even arbitrary way. This is due, of course, to their irregular syntax and internal word combination constraints.

By means of the permutation features, we enhanced *LGLex* with 103 adverbial entries (+1%).

3.2.3 Using transformational features

Finally, `other structures` can result from general transformations applied to the free prepositional noun phrase modifier *de N* 'of N', which is part of semi-fixed adverbial expressions. For instance, the adverb *pour le bénéfice* 'for the benefit', defined by the morphosyntactic structure `Prép1 Det1 C1 de N2`, can take the following two forms: *pour le bénéfice général* 'for the general benefit' and *pour son benefice* 'for his benefit'. Table 8 displays the transformational features that are encoded in the corresponding LG tables:

Transformation features encoded in the LG tables	Lexical value of the transformational features in the script
`Prép1 Det1 C1 de N2 = Prép1 Det1 C1 général`	`"@Prép1@ @Det1@ @C1@ général"`
`Prép1 Det1 C1 de N2 = Prép1 Poss2 C1`	`"@Prép1@ Poss2 @C1@"`

Table 8. Transformational features encoded in LG tables

Thanks to these features, we added to *LGLex* 288 adverbial entries (+3%).

Taking into account the three different types of features included in `other structures`, the number of adverbial entries in *LGLex* increased from 10,487 to 12,397 (+18%).

3.2.4 Using the intensifying features

The focus adverb *particulièrement* 'particularly' can be modified by two specific intensifiers conveying a greater emphasis to its meaning, and thus produce the two following entries: *tout particulièrement* 'quite particularly' and *plus particulièrement* 'more particularly'. Intensifying features are represented in LG tables as shown in Table 9:

Intensifying features encoded in the LG tables	Lexical value of the intensifying features in the script
`bien Adv`	`"bien @<ENT>Adv@"`
`fort Adv`	`"fort @<ENT>Adv@"`
`plus Adv`	`"plus @<ENT>Adv@"`
`tout Adv`	`"tout @<ENT>Adv@"`
`très Adv`	`"très @<ENT>Adv@"`
`(plus+moins) Adv`	`"plus @<ENT>Adv@", "moins @<ENT>Adv@"`

Table 9. Intensifying features encoded in LG tables

Thanks to these features, the number of adverbial entries in *LGLex* augmented from 10,487 to 10,697 (+2%).

4 Evaluation of the extended *LGLex*

The Table 10 shows the number of the initial adverbial entries in *LGLex* and the detail of the 11,328 new entries:

[9] According to Gross (1986: 1), the unit of representation in a linear lexicon is roughly the word, defined as a sequence of letters separated from neighboring sequences by boundary blanks or other kind of separators, e.g. apostrophe. As a consequence, multiword units cannot be put directly into a lexicon the way simple words are. An identification procedure is needed for their occurrences in texts, and this procedure will make use of the various simple lexical components included in the multiword unit (and described in the LG tables at the elementary level of sequences of parts-of-speech). Hence, the formal linguistic properties of multiword units will determine both the procedure of identification in texts and the type of storage they require.

Initial entries	10,487
Paraphrases	9,208
Other structures	1,910
Intensifying features	210
Final entries	21,815

Table 10. Number of entries in *LGLex*

The results are quite satisfactory as we obtain more than double, precisely 108% new entries in the lexicon, only by exploiting precise linguistic information of high coverage, which is freely available in existing resources.

We manually evaluated the new entries of the lexicon in order to detect errors.

Indeed, a manual validation was necessary when the generated entries corresponded to one single word. For example, the adverb *pourboire compris* 'tip included', which is defined by the morphosyntactic structure `Prép Det C Modif pré-adj Adj`, accepted the deletion of the participial phrase modifier *compris* 'included', but produced a non-adverbial entry ***pourboire* 'tip'.

Then, we mention the problem of duplicates that may be produced once the generation of new adverbial entries completed. They concern a few pairs of tables, notably, the pairs PCDC and PCDN, PCA and PAC or PDETC. For example, *ces temps derniers* 'recently', defined by the morphosyntactic structure `Prép Det C Modif pré-adj Adj` and encoded in table PCA, can also take the form *ces derniers temps* due to the permutation of the adjective *derniers* 'recent'. This latter is already encoded in table PAC.

We can also evoke the case of the deleting relation that associates the adverbs of table PCDC with those of table PCDN. For example, *en l'état actuel des choses* 'in the current state of things' accepts also the substructure *en l'état actuel*[10] 'in the current state', which is obtained after deletion of the prepositional noun phrase modifier *des choses* 'of things', and without loss of information. The generated substructure is already an entry of table PCDN. In a similar manner, *en l'état actuel des connaissances* 'in the current state of knowledge' produces the same substructure. Moreover, the adverbs *dans l'état actuel des choses* 'in the current state of things' and *dans l'état actuel des connaissances* 'in the current state of knowledge', which are both encoded in table PCDC, accept the substructure *dans l'état actuel* 'in the current state'.

In fact, each substructure provides information about the corresponding entry, and the generated substructures can be filtered automatically to easily delete duplicates.

Last, errors in the new entries are sometimes due to the way initial adverbial entries are encoded in tables. Considering the adverb *à cette heure-ci* 'at the present time' represented in table PCA: the noun component *heure* 'time' is encoded together with the hyphen, and thus form an amalgam that is automatically reproduced in the substructure *à cette heure-* 'at this time'.

5 Conclusion and future work

At a time when the lack of large scale lexical syntactic resources for French impedes on NLP research, we showed the interest of using fine-grained linguistic information, which is provided in existing resources, in order to enrich or diversify their content. This work led to an increase of 108% of the adverbial entries in *LGLex*.

These encouraging results confirm it is worthwhile exploiting features such as paraphrases. Therefore, we plan to complete the LG tables in that direction, starting, for example, with the table of verbal manner adverbs:

Adj-ment = en tout Nabstrait =:
amicalement = en toute amitié
'friendly' 'in all friendship'

Adj-ment = par Nmoyen_communication =:
téléphoniquement = par téléphone
'by telephone' 'by telephone'

Furthermore, we plan to convert the new adverbial entries into the Le*fff* format (Sagot, 2010), in order to integrate them into a parser, following similar work by Tolone and Sagot (2011) and Tolone (2011).

Besides, the new adverbial entries will be added to the French morphological lexicon DELA, which will enable us to evaluate their accuracy by means of both a corpus' annotation practice and a detailed comparison with related work by Laporte *et al.* (2008).

Finally, we can also consider enhancing the French Wordnet with respect to adverbial entries (Sagot *et al.*, 2009).

Abstract

Treebanks are valuable resources for natural language processing (NLP). There is much work in NLP which converts treebanks from one representation (e.g., phrase structure) to another (e.g., dependency) before applying machine learning. This paper provides a framework in which to think about the question of when such a conversion is possible.

1 Introduction

There has been much interest in converting treebanks from one representation to another; for instance, from phrase structure to dependency structure (e.g., motivated by the recent surge in interest in dependency parsing), or from phrase structure to other grammatical frameworks such as LTAG, HPSG, CCG, or LFG. While there has been much work on converting between treebank representations (Collins et al., 1999; Xia and Palmer, 2001; Cahill et al., 2002; Nivre, 2003; Hockenmaier and Steedman, 2007), there has not been a general yet precise discussion of what conditions are necessary for such conversion to happen.

In this paper, we provide an analytical framework for determining how difficult it would be to convert representations under one set of annotation guidelines M_1 to representations under another set of guidelines M_2. We are only interested in cases where annotation guidelines are available for both levels of representation, since it is not clear how one would interpret an undocumented representation, and thus it would not be clear how to evaluate the conversion results. Given two sets of guidelines and a particular linguistic phenomenon, there are three possible scenarios: (1) the phenomenon is represented only on one side; (2) the phenomenon is represented on both sides with incompatible analyses; (3) the phenomenon is represented on both sides with compatible analyses. We give a formal definition of *compatibility* and a procedure for distinguishing these three scenarios. We also discuss how each scenario will affect automatic conversion. Using this framework, researchers can determine the difficulty of a conversion task between existing guidelines, or they can design guidelines for new treebanks so automatic conversion to other representations can be as smooth as possible.

Note that we are not addressing general questions such as "In general, is it easier to convert dependency to phrase structure or *vice versa*?" We believe that such general questions cannot be answered. One needs to examine what information is being represented before the issue of conversion can be addressed, i.e., we must first study the guidelines of the two levels of representation.

While we propose a general approach to analyzing syntactic representations, throughout the paper we will use examples based on converting dependency structures to phrase structures. Specifically, we will use as a source of examples the Hindi/Urdu Treebank (HUTB) (Palmer et al., 2009). The HUTB is unusual in that it contains a dependency structure (DS) annotation, a PropBank-style annotation (PB) (Kingsbury et al., 2002) for predicate-argument structure, and an independently motivated phrase-structure (PS) annotation which is automatically derived from DS plus PB. For lack of space, we will not discuss the PropBank layer in this paper and instead draw all examples from PS and DS.

The structure of the paper is as follows. Section 2 introduces some terminology which helps in our analysis. Section 3 discusses the notion of compatibility and syntactic consistency. Section 4 introduces a procedure for comparing two sets of annotation guidelines with respect to conversion. Section 5 discuss examples from the HUTB that fall into the two "harder" scenarios for conversion.

2 Important concepts in a treebank

This study focuses on the relation between DS and PS treebanks. To understand whether an automatic conversion between DS and PS is possible, it is important to distinguish a few concepts in a treebank. Following (Rambow, 2010), we distinguish three concepts: the linguistic phenomena (what he calls "content"), the representation type, and the linguistic theory (what he calls "syntactic theory"). We reinterpret these concepts and extend them, in terms of the HUTB.

2.1 Linguistic phenomena

The **linguistic phenomena** are what we want to represent about the words which make up our treebank: they are the reason for treebanking. If there were no interesting linguistic phenomena, there would be no reason to create treebanks. The task of treebanking consists of identifying which of the phenomena of interest appear in a given sequence of words (a data token) and then to choose the correct representation for these phenomena in the given data token. The types of linguistic phenomena range from general concepts such as recursive constituency (which words in this sentence form phrases?) to types of relations between words or between a word and a phrase (e.g., subjecthood, or temporal modification) to specific constructions (e.g., small clauses). Linguistic phenomena also include finer-grained distinctions within coarser categories (e.g., unergative/unaccusative as two classes of intransitive verbs). For all of these phenomena, while linguists may disagree about the proper representation or whether the phenomenon is present in a particular instance, they typically agree on the fact that the phenomenon exists in the language, or exists in some language.

Consider first the example of syntactic constituency. There is broad agreement among syntacticians that syntax groups words recursively into hierarchies; to our knowledge, no serious syntactic theory uses only flat representations (such as base phrases). Crucially, this is independent of whether the syntactician uses DS or PS: DS also assumes a recursive structure and represents constituency (in a DS, each subtree represents a constituent, headed by its root).[1] It is difficult to assume that a treebank (DS or PS) would not represent syntactic constituency – there would have to be an explicit disclaimer that what looks like constituents (in DS or PS) are in fact not linguistically meaningful units, and are just notationally expedient devices.

Now consider the example of an embedded small clauses, as in the English sentence *Atif considered Seema stupid*, or its Hindi counterpart in (1). This is a particular construction; it is characterized (in both English and Hindi) by the fact that the NP *Seema* is an argument of the predicate *stupid*, but its case and word order is that of an object of the main verb *considered*, not a subject (as can be seen if we replace it with a pronoun, *her*).

(1) Atif-ne Seema-ko bewakuuf samjhaa
Atif-Erg Seema-Acc stupid consider.Pfv
'Atif considered Seema stupid.'

2.2 Representation type

The **representation type** is the type of mathematical object that is used to represent syntactic facts. A DS is a tree in which all nodes are labeled with words or empty strings (e.g., empty categories). A PS is a tree in which all and only the leaf nodes are labeled with words or empty strings, and the internal nodes are labeled with nonterminal symbols (e.g., syntactic labels). In addition, each representation type can decide what more specific representation devices it will employ, such as labels on the arcs of a tree (e.g., dependency type in a DS), or the use of empty nodes, or coindexation between nodes (e.g., to mark syntactic movement).

2.3 Linguistic theory

A **formal linguistic description** explains how linguistic phenomena are represented in the chosen representation type; a formal description is thus tied to a particular representation type. It can be thought of as a mapping from linguistic phenomena to linguistic representations in the chosen representation type. It has two components: a theoretical framework, and linguistic analyses. If, in addition, the analyses provided by a formal description are such that they rule out certain strings in the language and make falsifiable predictions, then we call the formal linguistic description a **linguistic theory**. These notions of "formal linguistic description" and of "linguistic theory" should not be confused with a **theoretical framework**, such as

[1] Of course, PS allows for intermediate projections. These have two functions. First, they distinguish functionally distinct dependents, such as subject from object. Second, an intermediate projection may actually occur as an empirically identifiable constituent, as in VP fronting in English. In both cases, DS can use alternate representational devices. We leave a fuller discussion to future work.

Government and Binding (GB) or LFG. The goal of theoretical framework is not to provide a complete description of a single language, but rather to provide vocabulary and constraints in which linguistic theories can be formulated.

Once a linguistic theory has chosen a theoretical framework such as GB, the next step is to determine how to represent the linguistic phenomena in that framework. For instance, given the Hindi embedded small clause example in (1), there are many possible ways to represent the phenomenon in a PS-based linguistic theory (e.g., the ones in Figure (1a-c)) or in a DS-based linguistic theory (e.g., the ones in Figure (1d-f)). We call them different **analyses** of this phenomenon.

It is important to stress that elements of the representation on their own may have no meaning. For example, the trace **CASE** in (1c) is not meaningful in isolation. Instead, the trace and its coindexed partner, the NP *Seema ko*, along with their structural configuration, together signify the phenomenon (which we are calling embedded small clause) that was identified by the annotator as happening in this particular sentence. The annotator chose this way of representing the phenomenon for this data token because the annotation guidelines say to do so. But the annotation of course also manifests the particular analysis chosen (namely, the raising-to-object analysis of (1c) and (1f)). However, this analysis is *not* specific to this particular data token; rather, for all annotations that use the guidelines, it must be used whenever an embedded small clause is identified by the annotator. The annotator cannot identify an embedded small clause but suddenly change the analysis on his or her own. It is also impossible that annotation guidelines would identify a unified phenomenon and propose two analyses based on arbitrary conditions (say, the first letter of the head noun). Thus, annotators must learn how to represent each phenomenon, and then must decide which phenomena a specific data token exhibits.

2.4 Annotation guidelines

Every treebank requires annotation guidelines, which can be regarded as a formal linguistic description, typically a very detailed and explicit one with descriptions and examples. The guidelines are used to train annotators, for annotators as a reference, and for users of the treebank as a guide to its meaning. Some annotation guidelines may even be linguistic theories (if they can be used to make predictions about ungrammatical sentences in the language, for example), though this is not generally the case.

To create annotation guidelines, the guideline designers need to choose a theoretical framework and a set of linguistic phenomena to be captured. Next, they need to determine a linguistic analysis for each linguistic phenomenon, and demonstrate the analysis with descriptions and examples (e.g., sentences and the corresponding DS or PS trees).

Take the HUTB as an example. Because it contains both representation types, DS and PS, it has two sets of guidelines for syntactic annotation, one for each representation type. The DS annotation guidelines follow the Paninian grammatical model (Bharati et al., 1995; Begum et al., 2008). The PS guidelines are inspired by the Principles-and-Parameters methodology, as instantiated by the theoretical developments starting with Government and Binding Theory (Chomsky, 1981).

3 Compatibility and conversion

As mentioned in the previous section, annotation guidelines provide linguistic analyses for a set of linguistic phenomena, and they are tied to a representation type (DS or PS). Now given two sets of annotation guidelines (one for DS and the other for PS), the central question is whether automatic conversion between DS and PS is possible; that is, is it possible to write a conversion algorithm that takes as input a DS tree annotated according to the DS guidelines, and produces a PS tree that would be correct according to the PS guidelines, or vice versa? In the rest of the paper, we will focus on the DS-to-PS conversion.

The answer to the question depends on the guidelines. If the DS and PS guidelines cover the same set of linguistic phenomena (explicitly or implicitly) and they choose *compatible* analyses for the phenomena, automatic conversion is possible. If these conditions do not hold, automatic conversion would require additional information or mechanism, as explained in Section 5. In this section, we will provide a formal definition of *compatibility*.

3.1 Intuition about compatibility

To define compatibility between linguistic analyses, let us first look at an example. Figure 1 shows several analyses for small clause: three for PS and

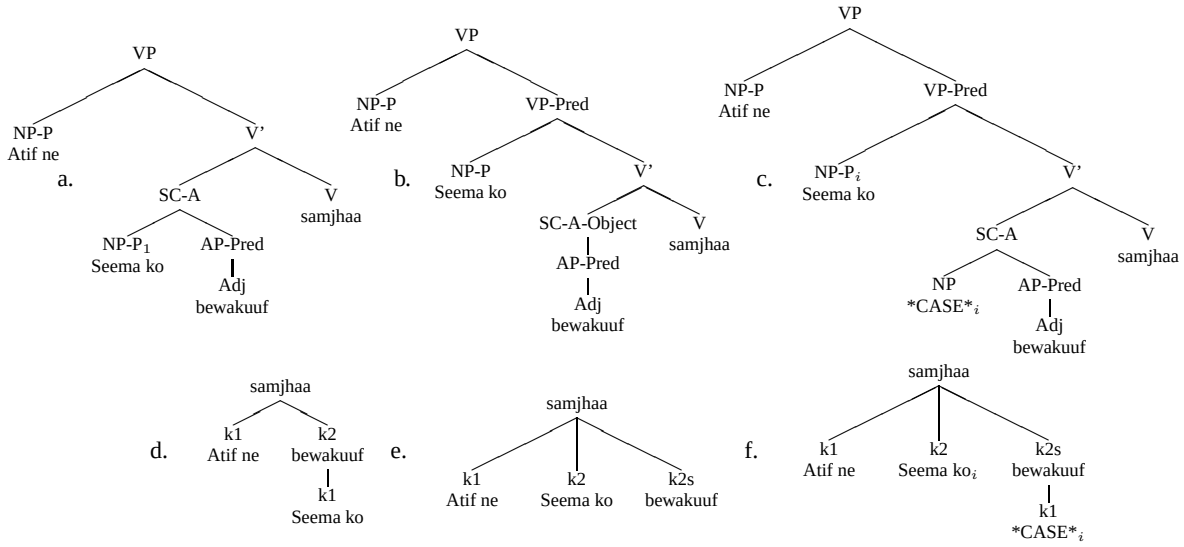

Figure 1: Possible analyses for the Hindi small clause example in Ex (1)

three for DS. It is clear that the analyses in (a) and (d) have something in common (the "exceptional case-marking" analysis), in which the semantic relationship between the adjectival predicated *bewakuuf ('stupid')* and *Seema ko* is seen as primary and the source of the object case marking *ko* on *Seema ko* is not represented explicitly. Similarly, (b) and (e) share an analysis, in which the presence of the object case marking *ko* is seen as primary, and predicate-argument relation between *Seema ko* and *bewakuuf ('stupid')* is deduced only from the label *SC-A-Object* in (b) or *k2s* in (e). Finally, the trees in (c) and (f) share an analysis (the "raising-to-object" analysis), in which a trace is used to indicate that the NP *Seema ko* participates in two relations.

Intuitively, analyses in (a) and (d) are compatible, so are the ones in (b) and (e), and the ones in (c) and (f). The next question is whether we can provide a formal definition of compatibility and write code that automatically checks whether the DS and PS analyses for a linguistic phenomenon is compatible. The answer is affirmative, as we can do that via the definition of *consistency* between (DS, PS) tree pairs, as is explained below.

3.2 Implicit vs. explicit information

Before we define *consistency*, there are two points that are worth mentioning. First, DS and PS, as two representation types, use different representation devices to describe syntactic structure: DS uses edges to represent the dependency or modifier-modifiee relation between words, whereas PS uses internal nodes to mark the spans and types of syntactic constituents. As a result, there are certain aspects of information that DS has to provide *explicitly* but PS does not need to (e.g., DS has to mark the direction of each edge, indicating which node is the head and which node is the dependent). The converse is also true (e.g., each internal node in a PS has to be labeled, indicating the syntactic category of the phrase).

Second, not explicitly providing certain information does not mean that the corresponding concept does not exist in the syntactic theory. For instance, PS does not need to mark the head of an internal node explicitly, but it does not mean that the syntactic theory chosen for PS does not have the concept of *headedness*.

3.3 Syntactic consistency

Our definition of consistency assumes that each phrase in a PS has a special word called *head word* which represents the main properties of the phrase, an assumption shared by all major contemporary syntactic frameworks. A pair (DS, PS) of DS and PS trees for the same sentence is called *consistent* if there is a way to assign a head word to each internal node in the PS so that all the words in the subtree rooted at that internal node are descendants of the head word in the DS. A formal definition is given later, but let us start with an example.

Figure 2 shows a simple PS with two internal nodes and three leaf nodes. Because the head words for the internal nodes are not marked in the PS, there are several possibilities in choosing the

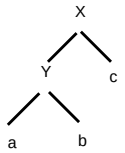

Figure 2: A simple PS: *a*, *b*, and *c* are leaf nodes, *X* and *Y* are internal nodes

head words for the internal nodes: the head word of the Y can be *a* or *b*, and the head word of X can be *c* or the head word of Y, resulting in four possible DSs, as shown in Figure 3. In contrast, no matter which head words we choose for the internal nodes in the PS, the resulting DSs will not be the ones in Figure 4. We call the DSs in Figure 3 *consistent* with the PS, and the DSs in Figure 4 *inconsistent* with the PS.

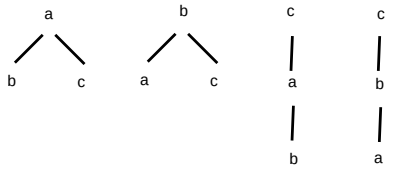

Figure 3: The DSs *consistent* with PS in Fig. 2

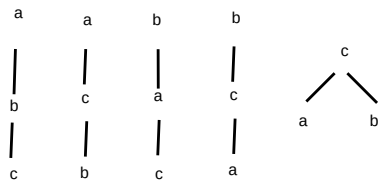

Figure 4: The DSs *inconsistent* with PS in Fig. 2

More formally, let us define two operations on a PS. Given a PS and an assignment of head words for the internal nodes in the PS, a *flatten* operation recursively merges each internal node X with its head child (a head child is a node which has the same head word as its parent). When two nodes, *X* and its head child *h*, are merged, the other children of *X* and the children of *h* (if any) become the children of the new merged node. Then, a *label replacement* operation replaces the label of each internal node with the node's head word. For instance, given the PS in Figure 2 and the assignment where a is the head word of Y and c is the head word of X, the tree after the flatten operation is in Figure 5(ii), and the tree after the label replacement operation is in Figure 5(iii). A PS and a DS are called *consistent* if and only if there exists an assignment of head words for the internal nodes in PS such that after the flatten operation and the label replacement operation, the new PS is identical to the DS.

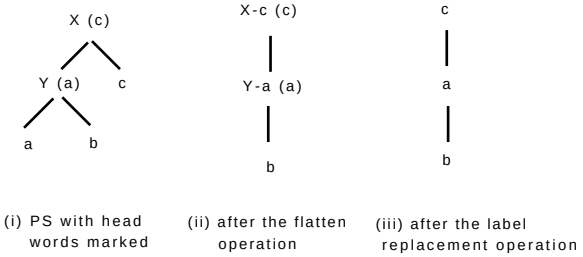

Figure 5: The resulting PS after the flatten and label replacement operations: *X(c)* in (i) means that *c* is the head word of *X*; *X-c* in (ii) means the nodes *X* and *c* are merged.

Given a (DS, PS) pair, one can use the following process to check whether the DS and the PS are consistent. For each edge, ($head$, dep), in the DS, find the nodes for $head$ and dep in the PS and their closest common ancestor $ancest$; for each node on the path between $head$ and $ancest$ (including $ancest$), assign $head$ as its head word; for each node on the path between dep and $ancest$ (excluding $ancest$), assign dep as its head word. The DS and PS are consistent *iff* after all the edges in the DS have been used, each internal node in the PS is assigned exactly one head word.

Now we can define the notion of *compatible analyses*. Given a linguistic phenomenon, let D be the set of (DS, PS) pairs provided in the guidelines for that phenomenon. The analyses in the DS and PS guidelines are *compatible* if and only if every (DS, PS) pair in D is *consistent*.

3.4 Conversion between DS and PS

Given a DS, there are multiple PSs that are consistent with the DS. The reason that a DS-to-PS conversion algorithm could make the right selection is that the (DS,PS) pairs in the annotation guidelines indicate what a PS should look like for a given DS. For instance, Figure 6 shows some patterns in the (DS,PS) pairs: the first pattern says that when a noun depends on a verb with the type *SBJ* in a DS, the corresponding PS should include a *S* node which has two children, an *NP* node that dominates the noun and a *VP* node that dominates the verb. The meaning of the second pattern can be in-

terpreted similarly. Xia et al. (2009) showed that such patterns can be learned from (DS, PS) pairs automatically and with these patterns their conversion algorithm produced good results when tested on the English Penn Treebank.

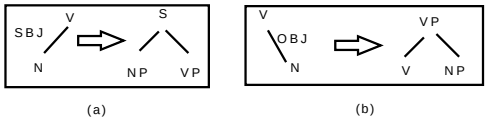

Figure 6: Two patterns that could help a DS-to-PS conversion to produce the correct PS tree as output

4 Analytic Framework for Comparing Treebank Guidelines

We now present our procedure for comparing two sets of treebank guidelines, with the goal of determining whether automatic conversion is possible. The devil is in the details. It is impossible to read the introduction to two sets of annotation guidelines and then to be able to say whether automatic conversion is possible. Instead, it is necessary to look at every single phenomenon: one phenomenon may be easy to convert, while another may be quite hard. We illustrate our procedure assuming we want to transform DS into PS.

For each linguistic phenomenon Φ, we ask two questions: (1) is Φ captured in both DS and PS guidelines? (2) if so, are the analyses in DS and PS guidelines compatible? The answers to the questions lead to three scenarios:

- **The phenomenon is represented by both sides and the analyses are compatible**: automatic conversion can be done using the procedure presented in Section 3, using knowledge which is general to Φ.
- **The phenomenon is represented by both sides but the analyses are incompatible**: automatic conversion is possible but it requires additional mechanisms (e.g., *DS+* as introduced in Section 5.1.2) to bridge the gap in analyses. The knowledge needed is general to Φ.
- **The phenomena is represented only on one side**: If it is represented in the DS only, the conversion algorithm can simply ignore it when creating PS. If it is represented on the PS side only, automatic conversion will require additional information which is not general to Φ, but which provides information specific to each **instance** of Φ (for example, a list of unaccusative verbs, as used in Section 5.2.1).

Of course, establishing the range of phenomena to be considered may not be entirely trivial. It includes not only the set of all constructions in a narrow sense, but also which constituents are represented, which empty arguments are included, what types of dependencies are represented, and so on. We discuss some examples in the following section.

5 Preliminary results in HUTB

As a case study, we compared the PS and DS guidelines of the HUTB with the process outlined in Section 4. The guidelines currently include 209 sentences where both DS and PS trees are provided. Each sentence has a sentence id, which indicates the linguistic phenomenon the sentence intends to represent. We ran the consistency check algorithm on the (DS, PS) pairs and found that 162 out of 209 pairs are consistent.

We then used the consistency results to group the corresponding phenomena into one of the three categories in Section 4. It turns out that most phenomena belong to the first category. For the other two categories, we present one example below and discuss how that will affect conversion.

5.1 Phenomena represented on both sides but differently

This category comprises several constructions in the HUTB: long scrambling and extraposition (which are non-projective), small clauses, local scrambling, and support verb constructions. We discuss small clauses in detail as a typical case.

5.1.1 Small clause

In HUTB, both the DS and the PS analysis represent the sharing aspect of small clauses, but they do so differently, which leads to incompatibility. In the PS analysis, as in Figure (1c), *Seema* is interpreted as the argument of the predicate *bewakuuf* ('stupid') and hence, given the theoretical assumptions adopted by the PS guidelines, it must combine with this predicate. But it gets case from the matrix predicate and hence also has a relationship with the matrix predicate. As a result, *Seema-ko* corresponds to two positions in the PS tree: a lower position (the empty category

CASE) as the subject of the lower predicate and a higher position as the object of the higher predicate. The two positions and the coindexation between them indicate the movement of *Seema-ko* from the lower position to the higher position to acquire case.

In contrast, the DS analysis, as shown in Figure (1e), does not represent the relationship between *Seema* and *bewakuuf ('stupid')* structurally: *Seema* is not a dependent on *bewakuuf*; Instead both *Seema* and *bewakuuf* are dependents of the matrix predicate *samjhaa ('consider')*. The relationship between *Seema* and *bewakuuf* is encoded into their dependency labels: *Seema* has the label *k2* and *bewakuuf* the label *k2s*. The (*k2*, *k2s*) pair indicates that semantically the *k2* node is dependent on the *k2s* node and the dependency relation between them is *k1*.

5.1.2 Handling incompatibility by introducing DS+

When a linguistic phenomenon (e.g., argument sharing in an embedded small clause) is represented in both DS and PS but in different ways, the automatic DS-to-PS conversion is still possible if we can automatically create a new DS, let us call it DS+, which is derived from the original DS but is consistent with the PS. That is, DS+ and PS represent that phenomenon in the same way. For instance, the DS in Figure (1e) is not consistent with the PS in Figure (1c), but the DS in Figure (1f) is because it encodes the sharing aspect of small clause as two coindexed nodes just like in the PS. Furthermore, from the meaning of the (*k2*, *k2s*) pair, it is easy to write an *ad-hoc* procedure that generates the DS in Figure (1f) from the DS in Figure (1e) automatically.

Therefore, the incompatibility due to representation difference can be handled by introducing a DS+, and the DS-to-PS conversion can be done in two steps: first, given a DS, DS+ is created automatically from the DS; second, a PS is generated from DS+ by applying a conversion algorithm. Determining the shape of DS+ and writing the DS-to-DS+ procedure require good understanding of the difference between the DS and PS analyses. But note that the DS-to-DS+ procedure is entirely independent of the data tokens we are trying to convert; we only need to understand the different representations for the type of phenomenon.

5.2 Phenomena represented only in one side

The DS and PS guidelines are formal linguistic descriptions, but they need not be a complete description of the language. The designers of the treebank may choose not to represent certain linguistic information for practical reasons. For example, the English Penn Treebank does not represent the syntactic structure of prenominal nominal and adjectival modifiers, even though it is generally assumed that such structure exists. Consequently, there could be certain phenomena that are represented in either the DS or PS analyses, but not in both. In the HUTB, one such case is the phenomenon of the unaccusativity/unergativity distinction.

5.2.1 Unaccusativity/unergativity

The unaccusativity/unergativity distinction refers to the fact that intransitive verbs cross-linguistically do not form a unified class - they break down into two classes: unaccusative verbs in which, roughly speaking, the sole argument is semantically a patient (e.g., *open, break*), and unergative verbs in which the sole argument is semantically an agent (e.g., *dance, laugh*). Two examples in Hindi are given in (2) and (3). This meaning difference correlates with a number of syntactic differences and many linguistic theories appeal to the unaccusative/unergative distinction to explain these differences. Other linguistic theories, however, do not make a distinction between these two classes.

(2) Unaccusatives:

darwaazaa khul rahaa hai
door.M open Prog.MSg be.Prs.Sg

'The door is opening.'

(3) Unergatives:

Ravi naac rahaa hai
Ravi.M dance Prog.MSg be.Prs.Sg

'Ravi is dancing.'

In the HUTB, the DS guidelines do not make the distinction and the sole argument of both unaccusative and unergative verbs is annotated as *k1*, as shown in Figure 7.

The PS guidelines assume that particular semantic relations (such as patient) are associated with designated structural configurations. Hence, the sole argument of an unaccusative verb needs to combine with the verb in the same position as canonical objects would (as a sister of V). But

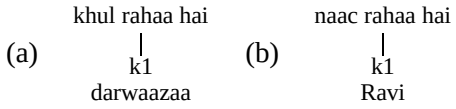

Figure 7: DS for the sentences in (2) and (3)

since the argument also functions as the subject, it must also occupy the position occupied by canonical subjects (sister of V'). This is accomplished in the PS by inserting a special trace in the object position (**CASE**), representing the fact that semantically, the constituent in subject position originates in the object position. The PS analysis follows the standard analysis of unaccusativity as articulated in (Burzio, 1986), and the tree for (2) is shown in Figure 8. In contrast, the sole argument of an unergative verb semantically behaves like an agent and functions as the subject, so it occupies the subject position, as in Figure 9, and there is no object position or the movement from the object position to the subject position. It is easy to show that the (DS, PS) tree pair for the unergative sentence (3) is consistent, whereas the pair for the unaccusative sentence (2) is not.

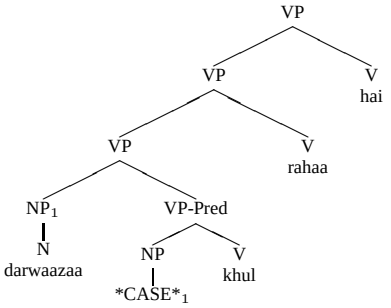

Figure 8: PS for the unaccusative in (2)

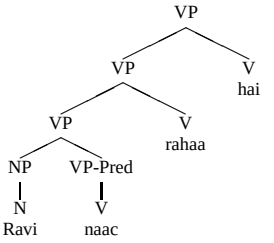

Figure 9: PS for the unergative in (3)

5.2.2 Handling incompatibility requires additional resource

How can we handle the problem that the DS and PS analyses for unergative verbs are compatible, while the ones for unaccusative verbs are not? While one could propose to create a DS+ for unaccusatives like what is done for small clauses, the problem is that this is a property of a data token, and not of the phenomenon of intransitive verbs. We cannot simply use knowledge about this type of phenomenon, since we need to know properties of the particular data token. Because the unaccusative/unergative distinction is not made in the DS, DS+ cannot be created automatically from DS without resorting to an additional resource that will explain the data token. In this case, a list of unergative and unaccusative verbs in Hindi can provide this information, since all instances of a particular intransitive verb are always either unergative or unaccusative. In other words, automatic DS-to-PS conversion is impossible unless an additional resource is provided that allows the conversion mechanism to make the unaccusative/unergative distinction. In the HUTB, the PropBank turns out to be such a resource as it makes the relevant distinction for independent reasons and this allows automatic conversion to proceed.

6 Conclusion

This paper has addressed the issue of when a treebank can be automatically converted to another. We have discussed several important concepts in a treebank and defined compatibility between analyses and consistency between syntactic structures (DS and PS). We have then provided a procedure for comparing treebanks guidelines with respect to conversion. Specifically, we have argued that the conversion from one treebank to another must be examined on a phenomenon-by-phenomenon basis, and that for each phenomenon, there are three scenarios that may arise: the two guidelines have compatible analyses; they have incompatible analyses; and one represents the phenomenon but the other does not. In the first case, automatic conversion is fairly direct; in the second case, we need to study the phenomenon and the analyses proposed for it and provide an intermediate representation to bring the gap; in the third case, we need additional information to achieve the conversion.

Abstract

A method for deriving an approximately labeled dependency treebank from the Thai Categorial Grammar Treebank has been implemented. The method involves a lexical dictionary for assigning dependency directions to the CG types associated with the grammatical entities in the CG bank, falling back on a generic mapping of CG types in case of unknown words. Currently, all but a handful of the trees in the Thai CG bank can unambiguously be transformed into directed dependency trees. Dependency labels can optionally be assigned with a learned classifier, which in a preliminary evaluation with a very small training set achieves 76.5% label accuracy. In the process, a number of annotation errors in the CG bank were identified and corrected. Although rather limited in its coverage, excluding e.g. long-distance dependencies, topicalisations and longer sentences, the resulting treebank is believed to be sound in terms of structural annotational consistency and a valuable complement to the scarce Thai language resources in existence.

1 Introduction

Syntactic resources play an essential role for the majority of NLP applications, but for the Thai language, openly available syntactic resources are few in number: So far, the only reported resources are the CG treebank [Ruangrajitpakorn et al., 2009] and the NAiST dependency bank [Wacharamanotham et al., 2007, Sudprasert, 2008]. Others are either unpublished or minuscule in size. Rather than relying exclusively on labor-intensive manual annotation for further expanding the resources, it would be economically sound to leverage existing efforts and transform an existing treebank in one formalism into another.

1.1 Categorial grammar

Categorial grammar (CG) is a lexicalised theory in natural language syntax motivated by the principle of constitutionality and organised according to the syntactic elements [Steedman, 2000, Ajdukiewicz, 1935], and forms the theoretical basis for the Thai CG treebank. The resource building effort has been very fruitful, but there remains phenomena of Thai language, including long-distance dependencies and topicalisation [Warotamasikkhadit, 1997], which are unhandled by the instantiation of CG currently in use.

Additionally, although the Thai language belongs to a fixed word order typology, Thai spoken language exhibits some flexibility in word order, due to the occasional preference of Thai language users for correspondence in rhyme. As an example, consider the following sentence[1]:

อังกฤษ คิดค้น อย่าง หนัก วัคซีน ป้องกันเชื้อ ไวรัส ไข้หวัดนก

(**Lit**: England/NE invent/V "-ly"/ADVPFX heavy/ADJ vaccine/N protect/V virus/N avian_flu/NP)

"The British are strenuously developing an Avian Flu vaccine."

The adverbial compound formed by **อย่าง หนัก** ("strenuously") conventionally occurs after the direct object, but is in this sentence, it is realised in the pre-direct object position[2] in order for the last syllable [nak^L] of **อย่าง หนัก** to rhyme with the first syllable [wak^H] of **วัคซีน** ("vaccine"). To some degree, this phenomenon from spoken language shines through in written language, especially in the domains of news and recent politics, and is causing a challenge for the employment of CG grammar.

[1] The Thai adverbialising prefix **อย่าง** can be likened to the English "-ly" suffix, which produces an adverbial form from an adjective. Artificial word boundaries are inserted for clarity.

[2] When language users exploit this flexibility in word order to produce aesthetically pleasing sound patterns, it results in a marked form, but the phenomenon is nonetheless productive, and encountered frequently enough to necessitate handling in NLP applications.

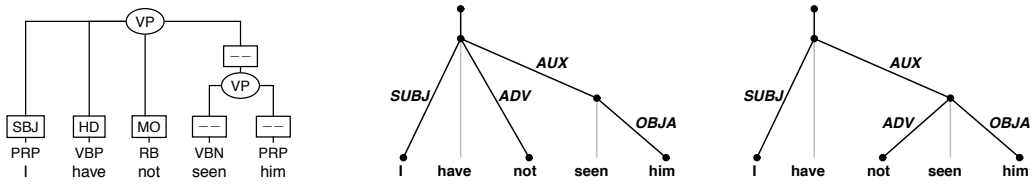

Figure 1: Example of ambiguity arising only in dependency representation [Daum et al., 2004]

1.2 Dependency representation

In recent years, dependency grammar has seen a dramatic increase in interest, likely due to a number of appealing properties of the representation. In comparison to phrase structure grammar, dependency structures provide a relatively direct encoding of predicate-argument structure, which is relevant to subsequent analyses [Nivre, 2005]. Dependency representation is arguably better suited for languages with flexible word order. Additionally, having no non-terminal nodes, dependency structures are often perceived as leaving room for less ambiguity as well as being more computationally manageable.

Certainly, dependency representation has drawbacks of its own in terms of ambiguity, some of which are specific to dependency representation. In particular, Figure 1 shows a construction with an unambiguous constituent structure, which in dependency space is ambiguous with respect to the attachment of the adverb [Daum et al., 2004].

Furthermore, dependency structure allows for a number of ways to represent coordinated phrases, some having the *coordinating conjunction as head* (CCH) of the coordinate structure, and a special dependency label *CJT* that does not describe the grammatical function of the conjuncts (Figure 2a). Another option is having the *coordinating conjunction as dependent* (CCD) of one of the conjuncts, thus allowing one conjunct to occur with a dependency label denoting its grammatical function (Figure 2b). McDonald and Nivre [2007] offer a thorough review of these and other candidate analyses in use. Unfortunately, none of the conceivable representations are unproblematic from a linguistic perspective [Daum et al., 2004], or offer the same transparency as the coordination rules of CCG do [Boonkwan, 2009].

Nonetheless, given the availability of generally applicable, trainable dependency parsers, and reports of beneficial applications of dependency analysis in tasks such as word-alignment [Ma et al., 2008] and reordering [Chang et al., 2009] for statistical machine translation, a dependency treebank of good quality is a highly desirable resource.

1.3 Outline

The rest of the paper is organised as follows. In Section 2 we briefly review other works dealing with similar transformations, before presenting the approach taken in this work in Section 3. Section 4 describes the experimental setting and results. A discussion follows in Section 5, and conclusions in Section 6 .

2 Related work

In preparation for the CoNLL-X shared task on dependency parsing [Buchholz and Marsi, 2006], a number dependency trees were derived from a number of constituency-based phrase structure treebanks, most of which have grammatical function (e.g. "subject" and "object") as part of the annotation. The conversion process for such treebanks would involve a *head table* with rules of the form

- "the head child of a VP/clause is the child with the HD/predicator/hd/Head function" and
- "[the dependency label] for a token is the function of the biggest constituent of which this token is the lexical head".

The case of the Thai CG bank is different, as it does not directly contain any grammatical functions. On the other hand, identifying head tokens

is relatively straight-forward when augmenting the CG annotation with dependency directions.

Chanev et al. [2006] faced a similar situation in their transformation of the BulTreeBank to dependency representation. Heads were first identified from explicitly stated rules in a head table. Lacking explicit grammatical functions in the source treebank, they explored a heuristic rule-based approach for the labeling with a *dependency table,* containing rules based on parent constituents. Although good results are achieved, they report of errors like mistaken subjects and objects.

3 Methodology

The situation with the Thai CG bank is a little different. Together with a set of combinatory grammar rules, the CG type tags and bracketing present in the treebank unambiguously specify the constituent structure of the treebank sentences. When the CG type tags are augmented with dependency directions, a dependency tree can be derived with relative ease from the CG-based constituents. Grammatical functions, however, are not immediately evident from the CG trees.

We first describe a relatively straight-forward method for deriving the dependency trees, and next consider the more daunting task of assigning functional labels to the dependency arcs. Figure 3 shows a schematical overview of the proposed method.

3.1 Terminology

For any given CG type t, we use the *arity* (admittedly a bit sloppily) to denote the ordered list of arguments expected by a type. The arity of the type `s\np/ws/np` is thus `/np`, `/ws` and `\np` — that is,

- a noun phrase from the right, followed by
- a subordinate clause beginning with the Thai word ว่า ("that", subordinate clause marker), and
- another noun phrase from the left.

Complementary, we define the *yield* of t as the set of possible CG types which may result from functional application of a CG rule. The transitive verb type `s\np/np`, for example, yields

- `s\np` and
- `s`

after receiving a `np` to the right, and another `np` to the left, respectively. This is simply the basic combinatory CCG rules:

$$\begin{array}{llll} \text{X/Y} & \text{Y} & \Rightarrow & \text{X} \\ \text{Y} & \text{X\Y} & \Rightarrow & \text{X} \end{array}$$

Algorithm 1 Pseudo-code for propagating dependency directions to non-terminal nodes.

```
def propagateDirections(node):
  for child in node.children:
    propagateDirections(child)
  if node.hasDependencyDirection:
    return
  for child in node.children:
    if child.yields(node.type):
      node.depDirs = child.depDirs
      break
```

3.2 Dependency directions

The first transformation step, which can be regarded as a preprocessing step before the actual transformation, involves a lexical dictionary for assigning dependency directions to the CG types associated with the grammatical entities in the CG bank, falling back on a generic CG to CDG mapping in case of unknown words.

Note that only terminal nodes will have assigned dependency directions assigned by this procedure. Dependency directions are propagated to non-terminal nodes in a bottom-up fashion by the procedure `propagateDirections` (Algorithm 1). In identifying which child to adopt dependency directions from, the parent node type is checked against the yield of each child node.

3.3 Head finding

Dependency arcs are assigned by a procedure that implements the CDG dependency derivation rules introduced by Boonkwan and Steedman [2011] (motivated by Collins, 1999). The idea is to trace the derivation implied by the CG rules, registering the dependency relations specified by the CDG-augmentation along the way.

The derivation rules handled are as follows. Let $c : d$ signify a CDG type c and a dependency structure d, and the notion $h(\mathrm{d}_1) \rightarrow h(\mathrm{d}_2)$ represent a dependency arc between the head of d_1 and the head of d_2 (with $h(\mathrm{d}_1)$ governing $h(\mathrm{d}_2)$) . Then the derivation rules are:

$$\begin{array}{llll} \text{X/<Y:d}_1 & \text{Y:d}_2 & \Rightarrow & h(\mathrm{d}_1) \leftarrow h(\mathrm{d}_2) \\ \text{X/>Y:d}_1 & \text{Y:d}_2 & \Rightarrow & h(\mathrm{d}_1) \rightarrow h(\mathrm{d}_2) \\ \text{Y:d}_1 & \text{X\<Y:d}_2 & \Rightarrow & h(\mathrm{d}_1) \leftarrow h(\mathrm{d}_2) \\ \text{Y:d}_1 & \text{X\>Y:d}_2 & \Rightarrow & h(\mathrm{d}_1) \rightarrow h(\mathrm{d}_2) \end{array}$$

In a simple example, *Mary*[np] *drinks*[s\ < np/ > np] *fresh*[np/ < np] *milk*[np], *fresh* would combine with *milk*, yielding an `np` and a dependency arc specifying *milk* as head of *fresh.*

In addition to the standard combinatory rules for forward and backward functional application above, the Thai CG bank makes use of a CCG-style *serialisation* rule to handle e.g. serial verb

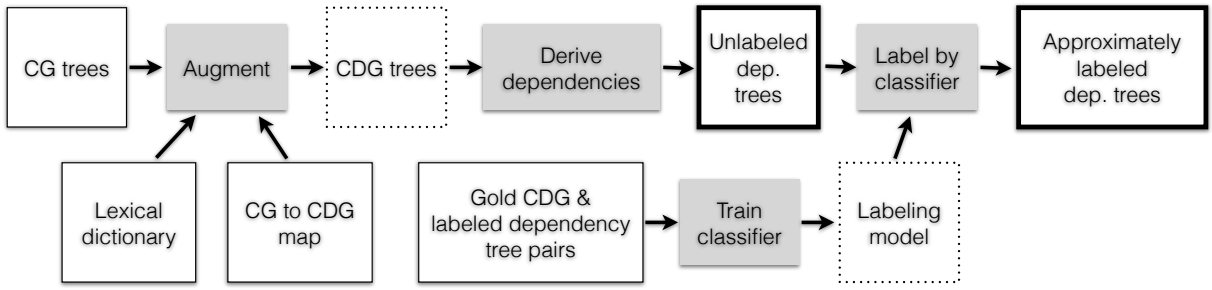

Figure 3: Transformation overview

constructions, which are used in Thai (and Chinese) to express serial or consecutive events. As Boonkwan [2009], we take the notion of a *serial verb construction* to mean a series of verbs or verb phrases without explicit connectives marked with (or understood to have) the same grammatical categories, and sharing at least one common argument, typically a subject.

As an example, the verbs **ตรวจ** ("examine") and **พบ** ("find") occur serially in the following sentence[3] from the CG bank, indicating a resultative course of events [Thepkanjana and Uehara, 2009]:

> **นักวิชาการ ตรวจ พบ ไวรัส โคโรน่า ใน ชะมด**
>
> (**Lit**: scientist/N examine/V find/V virus/N corona/N in/PP civet/N)
>
> "The scientist examined the civet and found coronavirus."

We introduce a generalised derivation rule for serial constructions which simply designates the head of the first dependency structure as governing the head of the following dependency structure:

$$\text{X:d}_1 \;\; \text{X:d}_2 \quad \Rightarrow \quad h(\text{d}_1) \rightarrow h(\text{d}_2)$$

The rule is generalised in the sense that it handles *serial noun constructions* as well as serial verb constructions.

Further CCG-style combinatory rules, such as functional composition and type raising, are not currently in use in the Thai CG bank, and therefore not handled by the transformation.

An outline of the head finding procedure is given as Algorithm 2. Intuitively, the algorithm proceeds by, for each node in turn, beginning at the terminal nodes, identifying sibling nodes which satisfy the arity of the of the node CG type. For each sibling node satisfying an argument, the dependency derivation rule is applied and the sibling is removed.

[3]Artificial word boundaries inserted for clarity.

Algorithm 2 Pseudo-code for the head-finding procedure.

```
def assignHeads(node):
  for c in node.nonterminalChildren:
    assignHeads(c)
  for c in node.terminalChildren:
    assignHeads(c)
  for arg in node.type.arguments:
    if arg.side == 'right':
      sibl = node.rightSiblings.first
    else
      sibl = node.leftSiblings.last
    break unless arg.matches(sibl)
    if arg.side == 'right':
      if arg.dependencyDir == '>':
        registerHead(sibl, node)
      else: # <
        registerHead(node, sibl)
      node.rightSiblings.shift
    else: # left
      if arg.dependencyDir == '>':
        registerHead(node, sibl)
      else: # <
        registerHead(sibl, node)
      node.leftSiblings.pop
```

It is worth noting that while both terminal and non-terminal nodes are involved in this process, we are only interested in assigning dependency arcs to terminal nodes, as non-terminals are absent in the all-terminal dependency structure. This is ensured by an implementation detail of the procedure `registerHead` (omitted from Algorithm 2), in which non-terminal nodes act as proxies for their terminal heads.

3.4 Dependency labeling

Although the CDG-augmentation of the CG treebank implies a dependency structure for each sentence, there are no immediate clues available about the specific grammatical functions of dependency arcs. Obviously, there are some clear-cut cases: When a token with CDG type $((\texttt{s}\backslash <\texttt{np})\backslash >(\texttt{s}\backslash <\texttt{np}))\backslash <\texttt{num}$ modifies a token with CDG type `num`, it must be an application of a *quantifier* (with dependency type "quan"), as exemplified in Figure 4.

Other cases are less obvious. Even when taking

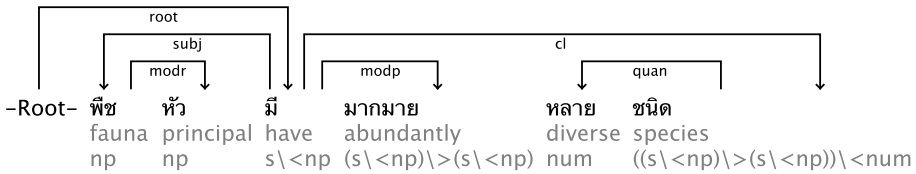

Figure 4: An unmistakable labeling case: Given the CDG types of **หลาย** ("diverse") and **ชนิด** ("species"), the only dependency label supported by the examined data is "quan" (*quantifier*).

dependency direction and argument position into consideration, there are still cases with several possible dependency types, as shown in Figure 5.

While for many practical purposes an unlabeled dependency structure is sufficient, having proper dependency labels is nonetheless desirable. In lack of an exact transformation, the approach explored in this work relies instead on training a classifier to predict the correct dependency label given local features of the tokens involved, as they occur in the dependency structure derived from the CDG tree.

From a related work (manuscript in preparation), we have obtained a number of CDG trees from labeled dependency trees. Such pairs of *labeled* dependency trees and CDG trees can serve as training material for the label classifier.

We evaluate different feature sets for classification task. The basic feature set contains:

- CDG type of token and its head
- # of left siblings
- # of right siblings
- Dependency direction (L/R)
- Concatenations of token/head CDG and # of left siblings

Other feature sets extend the basic set including additional information:

+forms Token and head word form.

+POS(L) Part-of-speech tag for the token, as assigned by a learned part-of-speech tagger[4].

+POS(G) "Gold" part-of-speech tag as found in the labeled dependency tree.

4 Experiments

The Thai CG bank made available for this research contains 1,428 phrases with corresponding CG trees. Trees are mostly medium to low in token count, with 49 single-token trees, and the longest phrase having 9 tokens. Median phrase length is 3

[4]SVMTool [Giménez and Marquez, 2004], trained on the Orchid corpus [Sornlertlamvanich et al., 1997].

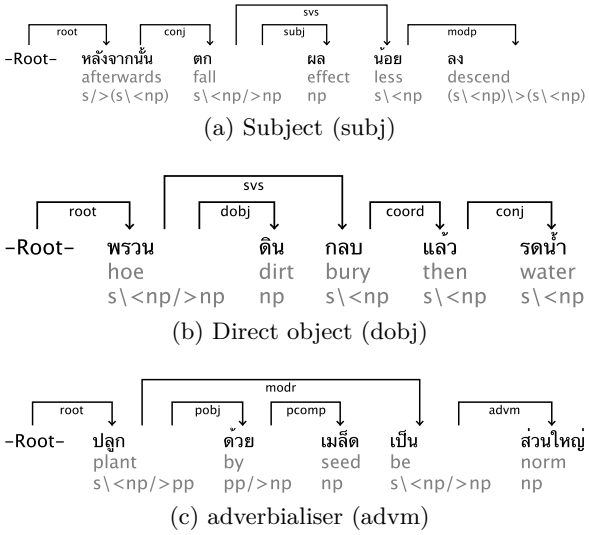

Figure 5: Different labeling of left-pointing dependency arcs with $\mathtt{s}\backslash < \mathtt{np}/ > \mathtt{np}$ as head CDG type and `np` as dependent CDG type. See Figure 6 for depency type abbreviations.

tokens. With a total token count of 5,143 tokens, the arithmetic mean length is 3.60.

As there is no explicit sentence boundary marker in Thai [Satayamas and Kawtrakul, 2004], it is often unclear what constitutes a sentence. Thus, rather than ordinary sentences, the treebank contains phrases of different types, reflecting the partitioning of token sequences made by the treebank annotators for the purpose of treebanking:

- 539 verb phrases or subject-omitted phrases ($\mathtt{s}\backslash\mathtt{np}$),
- 363 sentences (`s`),
- 372 noun phrases (`np`) and
- 4 prepositional phrases (`pp`).

The lexical dictionary used contains possible CDG types for 38.250 word forms, with an average of 2 types listed per word form. For six of the word forms, the dictionary lists several possible dependency directions for a single CG type. These confusable CDG types and the dictionary entries they occur for are listed in Table 1.

An example sentence from the treebank affected by the ambiguous mapping of the adverb **ตอนนี้**

Word form(s)	CG type	Possible CDG equivalents	Interpretation
น่า	(s\np)/(s\np)	(s\ < np)/ > (s\ < np) (s\ < np)/ < (s\ < np)	Adverb "please" Auxiallary verb "should"
ตอนนั้น ("at that time") ตอนนี้ ("at present") ขณะนั้น ("at that moment") ขณะนี้ ("this moment")	s/s	s/ > s s/ < s	Conjunction Adverb of time
กับ	np\np/np	np\ > np/ > np np\ < np/ > np	Preposition "with" Conjunction "and"

Table 1: Entries in the lexical dictionary which are ambiguous with respect to dependency direction

("at present") is [5]:

ตอนนี้ เธอ กำลัง ยุ่ง มาก

(**Lit**: this-moment/ADV she/PRON "-ing"/AUX busy/ADJ very/ADV)

"At this moment she is being very busy."

Examples of the latter two ambiguity classes of the lexical dictionary (Table 1) were not encountered in the treebank — i.e. the affected word forms do not occur with an ambiguous CG type. In dealing with these ambiguous entries in the lexical dictionary, we simply (and naively) choose the first mapping option.

The generic CG to CDG mapping, used in addition to the lexical dictionary as fallback for word forms not found in the lexical dictionary, also exhibits some degree of ambiguity. The seven CG types with multiple possible CDG equivalents are listed in Table 2.

In evaluating the classification-based approach to assigning dependency labels, a sample of 678 labeled dependency edges from the NAiST dependency treebank [Wacharamanotham et al., 2007] was used, along with corresponding CDG trees. The feature sets suggested in section 3.4 on page 4 were evaluated with four different classifiers[6] (see Table 3).

5 Discussion

Transforming CDG-augmented CG trees to unlabeled dependency trees was successful. In this work, the issue of ambiguous CDG types affects only a very small number of trees, but remains an issue to be aware of.

[5]The Thai auxillary verb กำลัง indicates the present participle, meaning "in the act of", similar to the English suffix, "-ing". Articifial word boundaries are inserted for clarity.

[6]Experiments with the learners were done using leave-one-out cross-validation, with the exception of LibSVM, which was run using the standard K-fold cross-validation of the easy.py script [Chang and Lin, 2001].

CG type	Possible CDG equivalents
np\np/np	np\ > np/ > np np\ < np/ > np
s/s	s/ > s s/ < s
s\s	s\ > s s\ < s
(s\np)/(s\np)	(s\ < np)/ > (s\ < np) (s\ < np)/ < (s\ < np)
s/(s\np)	s/ > (s\ < np) s/ < (s\ < np)
s\(s\np)	s\ < (s\ < np) s\ > (s\ < np)
s/(s\np)/np	s/ > (s\np)/ > np s/ < (s\np)/ > np

Table 2: Cases of CD to CDG mappings which are ambigous with respect to dependency direction

For dependency labeling, only a small amount of training data (in the form of sentences with both CDG and labeled dependency analyses) was available for this prelimenary experiment. Using this, dependency labels were not reliably recoverable (76.5% label accuracy). However, it seems hopeful that better recovery of dependency labels can be obtained with this approach once more training material become available.

Head and dependent word forms, as well as part-of-speech tags, were beneficial as added features for the label classifier, resulting in a substantial reduction in error rate — from 0.357 to 0.235 ($\approx$ 34%).

On the other hand, rather than the approximated classfier-based approach to labeling, one could consider settling for an exact but partial labeling by only assigning those dependency labels which unambigously arise from tuples of head and dependent CDG types. However, the dependency labels obtainable with absolute certainty in this way are often of the less interesting kind — e.g. "conj" for a s\ < np governed by a s/ > (s\ < np) — while more useful labels remain ambiguous.

Classifier	Basic	+forms	+POS(L)	+POS(G)	+POS(L) & +forms	+POS(G) & +forms
Random Forest	61.9%	69.6%	66.1%	68.9%	72.9%	71.8%
LibSVM	64.3%	73.9%	66.1%	70.2%	74.5%	**76.5%**
Nearest Neighbors	60.5%	64.8%	62.4%	64.5%	70.5%	70.4%
Naive Bayes	60.6%	63.7%	61.7%	65.8%	63.7%	66.2%

6 Conclusion and future work

In the process, a considerable amount of syntactical and annotational errors in the Thai CG bank were identified and corrected. The authors are of the belief that this work has not only provided a means for continual expansion of resources for Thai natural language processing, but also helped improve the quality the existing CG resource.

As a related work (manuscript in preparation) progresses, more CDG trees for labeled NAiST dependency trees will become available. With this extra training material, the learned classifier used for labeling in this work should become more reliable. Further improvement might also be achievable from an expanded feature set, including for example the argument position (in addition to side) and one or two generations of grandparent nodes.

Further development of the Thai CDG formalism is also expected, in particular for the analysis of sentence-like noun phrases. This will likely need special handling in the dependency representation as well. Currently, the NAiST annotation guidelines do not specify a label for this phenomenon.

Abstract

Existing work shows that lexical dependencies are helpful for constituent tree parsing. However, only first-order lexical dependencies have been employed and investigated in previous work. In this paper, we propose a method to employing higher-order[1] lexical dependencies for constituent tree evaluation. Our method is based on a parse reranking framework, which provides a constrained search space (via *N*-best lists or parse forests) and enables our parser to employ relatively complicated dependency features. We evaluate our models on the Penn Chinese Treebank. The highest F_1 score reaches 85.74%, thus outperforming all previously reported state-of-the-art systems. The dependency accuracy of constituent trees generated by our parser has been significantly improved as well.

1 Introduction

The most commonly used grammar for constituent structure parsing is probabilistic context-free grammar (PCFG). However, as demonstrated in Klein and Manning (2003a), PCFG estimated straightforwardly from Treebank does not perform well. The reason is that the basic PCFG has certain recognized drawbacks: its independence assumption is too strong, and it lacks of lexical conditioning (Jurafsky and Martin, 2008). To address these drawbacks, several variants of PCFG-based models have been proposed (Klein and Manning, 2003a; Matsuzaki et al., 2005; Petrov et al., 2006; Petrov and Klein, 2007). Lexicalized PCFG (LPCFG) (Collins, 1999; Charniak, 2000; Bikel, 2004) is a representative work that tries to ameliorate the deficiency of lexical conditioning. In LPCFG, non-terminals are annotated with lexical heads and the probabilities of CFG rules are estimated conditioned upon these lexical heads. Thus LPCFG becomes sensitive to lexical heads, and its performance is improved. However, the information provided by lexical heads is limited. To obtain higher parsing performance, we must seek additional information. We believe that dependency trees are good candidates because they encode grammatical relations between words and provide much more lexical conditioning than lexical heads for PCFG.

Dependency trees are usually factored into sets of lexical dependency parts for evaluation. The order of a lexical dependency part can be defined according to the number of dependency arcs it contains. For example, in Figure 1, *dependency* is first-order, *sibling* and *grandchild* are second-order and *grand-sibling* and *tri-sibling* are third-order. During the past few years, higher-order[1] lexical dependencies have been successfully used for dependency parsing (McDonald et al., 2005; McDonald and Pereira, 2006; Koo and Collins, 2010). But for constituent tree evaluation, only first-order (bigram) lexical dependencies have been used (Collins, 1996; Klein and Manning, 2003a; Collins and Koo, 2005). However, first-order lexical dependency parts are quite limited and thus lose much of the contextual information within the dependency tree. To improve parsing performance, we propose to evaluate constituent trees with higher-order lexical dependencies.

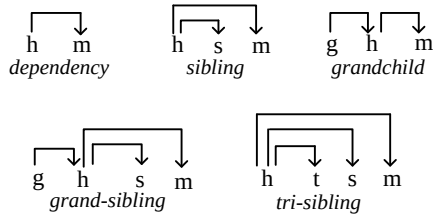

Figure 1. Lexical dependency types. The lowercase letters h, m, s, g are words in a sentence.

In this paper, we propose a method for evaluating constituent trees using higher-order lexical dependencies within a parse reranking framework. We evaluate our method on the Penn Chinese Treebank (CTB). The F_1 score reaches 85.74%, thus outperforming the best previously reported systems. Thanks to the lexical dependencies, the dependency accuracy of the generated constituent trees is improved as well. These experimental results show that higher-order lexi-

[1] Lexical dependency part which contains more than one dependency arcs is called higher-order, e.g., *sibling*, *grandchild* and *grand-sibling* in Figure 1.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1251–1259,
Chiang Mai, Thailand, November 8 – 13, 2011.

cal dependencies are highly beneficial for constituent tree evaluation.

The remainder of this paper is organized as follows: Section 2 briefly reviews related work and proposes our ideas. Section 3 describes our parsing approach. Section 4 describes our parse reranking algorithms based on higher-order lexical dependencies. In Section 5, we describe our training algorithms. We discuss and analyze our experiments in Section 6. Finally, we conclude and mention future work in Section 7.

2 Related Work and Our Ideas

Over the past few years, two kinds of *parse reranking* methods have been proposed. The first is *N*-best reranking (Charniak and Johnson, 2005; Collins and Koo, 2005). In this method, an existing generative parser is used to enumerate *N*-best parse trees for an input sentence, and then a reranking model is used to rescore the *N*-best lists with the help of various sorts of features. However, the *N*-best reranking method suffers from the limited scope of the *N*-best list in that potentially good alternatives may have been ruled out. The second method, called the forest reranking model, was proposed by Huang (2008). In Huang's method, a forest, instead of an *N*-best list, is generated first. Then a beam search algorithm is used to generate *N*-best sub-trees for each node in bottom-up order and the best-first sub-tree of the root node is chosen as the final parse tree.

In recent years, there have been many attempts to use dependency trees for constituent parsing. All these approaches can be classified into three types. The first type is *dependency-driven* constituent parsing (Hall et al., 2007; Hall and Nivre, 2008). Given an input sentence, this approach first parses it into a labeled dependency tree (with complex arc labels, which makes it possible to recover the constituent tree) and then transforms the dependency tree into a constituent tree. The second approach is *dependency-constrained* constituent parsing (Xia and Palmer, 2001; Xia et al., 2008; Wang and Zhang, 2010; Wang and Zong, 2010). In this approach, dependency trees, once generated, are used to constrain the search space of a constituent parser. The third approach is *dependency-based* constituent parsing (Collins, 1996; Klein and Manning, 2003b). In this approach, the constituent tree is evaluated with the help of its corresponding lexical dependencies.

All three existing approaches have certain limitations. In the first approach, the dependency-driven constituent parser is not constrained by the Treebank grammar, so a constituent tree transformed from its corresponding dependency tree may contain context-free productions not seen in the Treebank grammar. Although this limitation may not affect the parsing F_1 score, it often has undesirable effects on applications. For the second approach, if the generated dependency tree includes some erroneous parts, the correct constituent tree may be pruned out directly, leaving no way to recover the correct tree again. The third approach parses sentences making use of first-order lexical dependencies only. As mentioned, first-order lexical dependencies are quite limited, and thus may lose much information about the grammatical relations between words. Consequently, the performance improvement of this approach is limited as well.

To overcome the drawbacks of the existing approaches, we propose to evaluate constituent trees using higher-order lexical dependencies within a parse reranking framework. Our approach has the following advantages: 1) It utilizes the higher-order lexical dependencies, which provide more contextual information within the dependency tree for constituent tree evaluation; 2) the parse reranking method provides high-quality candidates (*N*-best list or parse forest) which yields a small search space, enabling the use of relatively complicated features.

3 Our Approach

For a sentence x, we define constituent parsing as a search for the highest-scoring parse c^* of x:

$$c^* = \arg\max_{c \in GEN(x)} Score(x, c) \qquad (1)$$

Where, $GEN(x)$ is a set of candidate parsers for x, and $Score(x, c)$ evaluates the event that tree c is the parse of sentence x.

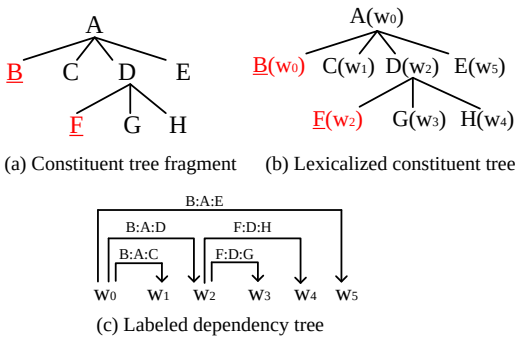
In order to evaluate c with higher-order lexical dependencies, we define:

$$Score(x, c) = \Phi(x, c) \cdot \overline{\alpha} = \sum_i \alpha_i \Phi_i(x, c) \qquad (2)$$

Where, Φ maps each $(x, c) \in X \times C$ to lexical dependency feature vector $\Phi(x, y) \in \Re^d$, and $\overline{\alpha} \in \Re^d$ is the corresponding weight vector.

3.1 Representation of Constituent Tree with Labeled Dependency Tree

The discriminative parsing model in Eq. (1) takes lexical dependencies as features, so we must design a method of representing constituent trees



(a) Constituent tree fragment (b) Lexicalized constituent tree

(c) Labeled dependency tree

Figure 2. Representation of constituent tree with labeled dependency tree

with associated dependency trees. Our method includes the following two steps:

Step 1: ***Lexicalize the constituent tree***, i.e. annotate each node in the constituent tree with its head-word. First, find the head-child of each non-terminal node using a head percolation table (Yamada and Matsumoto, 2003). For example, in Figure 2(a), node B is identified as the head-child of rule A → B C D E. Then the head-words propagate up through the leaf nodes and each parent receives its head-word from its head-child. For example, in Figure 2(b), w_0 is propagated up from node B to A. According to this procedure, we can get the lexicalized constituent tree (shown in Figure 2(b)) for the constituent fragment shown in Figure 2(a).

Step 2: ***Transform the lexicalized tree into a labeled dependency tree***. First, let the head-word of each non-head-child depend on the head-word of the head-child for each rule. For example, in Figure 2(b) for rule A → B C D E, the head words of non-head-child (node C, D and E) which are w_1, w_2 and w_5 should depend on w_0 which is the head word of head-child (node B). In order to encoding the syntactic symbols in the constituent tree into dependency tree, we annotate each dependency arc with a label $N_h : P : N_m$, where N_h is the head-child's syntactic category, P is the parent's syntactic category and N_m is the non-head-child's syntactic category. For example, in Figure 2(c), the dependency arc between w_1 and w_0 is built through rule A → B C D E, where w_0 associates with B, w_1 associates with C and the parent node is A, so we can annotate the dependency arc with B:A:C. According to the procedure, the lexicalized tree in Figure 2(b) can be transformed into the labeled dependency tree shown in Figure 2(c).

3.2 Mapping Higher-Order Lexical Dependencies into Feature Vectors

To map lexical dependencies into feature vectors,

Algorithm 1: Constituent Tree Evaluating

1: **function** Eval(C)
2: **for** $P \in C$ in bottom up topological order **do**
3: EvalSubTree (C_P)
4: **return** $Score(C)$
5:
6: **procedure** EvalSubTree (C_P)
7: ▷ Assume the constituent is $P \rightarrow N_1 \cdots N_n$
8: Find the head-child N_h for P
9: $W_P \leftarrow W_{N_h}$
10: ▷ Building D_P
11: **for** $N_i \in \{N_1, ..., N_n\} \setminus N_h$ **do**
12: Link D_{N_h} and D_{N_i} with a dependency arc
13: Annotate the arc with label $N_h : P : N_i$
14: Make the root of D_{N_h} as D_P 's root
15: Extract all lexical dependencies for P and map them into feature vector $\Phi(P)$
16: $Score(C_P) = \Phi(P) \cdot \bar{\alpha} + \sum_{i=1}^{n} Score(C_{N_i})$

we define certain feature templates, as shown in Table 1. We work with binary indicator features[2] for each lexical dependency. The feature vector $\Phi(x, C)$ of constituent tree C can be calculated through the dependency tree D transformed from C using the follow formula:

$$\Phi(x, C) = \sum_{d \in S(D)} \phi(d) \qquad (3)$$

In this formula $S(D)$ is a set of all the lexical dependencies extracted from D, and d is a lexical dependency in $S(D)$. The function ϕ is used to map each lexical dependency d into feature vector according to the templates in Table 1.

4 Parse Reranking Algorithms

A critical problem when training the discriminative model in Eq. (1) is the extensive training time required, in which we must parse all the sentences in the training set repeatedly. In this paper, we adopt an approximate method: parse reranking. In parse reranking, $GEN(S)$ in Eq. (1) is an N-best list or a parse forest which provides a small and well-formed search space for constituent parsing. Given this small space, we can exploit higher-order lexical dependencies efficiently.

[2] Binary indicator features are defined as follows: if a certain feature is observed in an instance, the value of that feature is 1; otherwise, the value is 0.

h m *dependency*	**Basic Uni-gram Features** h , POS(h), N(h) h , POS(h) h , N(h) m , POS(m), N(m) m , POS(m) m , N(m) **Basic Bi-gram Features** P(m) , h , POS(h), N(h), m), POS(m), N(m) h , POS(h), N(h), m , POS(m), N(m) P(m) ,POS(h), N(h), POS(m), N(m) P(m) , h , N(h), m , N(m) P(m) ,h , POS(h), m , POS(m) P(m) ,h , m P(m) , POS(h),POS(m) P(m) , N(h), N(m) **Surrounding Word POS Features** P(m), N(h), POS(h), N(m), POS(m), POS(h)+1, POS(m)-1 P(m), N(h), POS(h), N(m), POS(m), POS(h)-1, POS(m)-1 P(m), N(h), POS(h), N(m), POS(m), POS(h)+1, POS(m)+1 P(m), N(h), POS(h), N(m), POS(m), POS(h)-1, POS(m)+1	h s m *sibling*	POS(h),N(h),POS(s),N(s),P(s),POS(m),N(m),P(m) POS(h),N(h),N(s),P(s),N(m),P(m) POS(h),N(h),POS(s),P(s),POS(m),P(m) POS(h),N(h),POS(s),N(s),POS(m),N(m) POS(h),POS(s),POS(m) N(h),N(s),N(m) N(h),P(s),P(m)
	g h m *grandchild*	POS(g),N(g),POS(h),N(h),P(h),POS(m),N(m),P(m) POS(g),N(g),N(h),P(h),N(m),P(m) POS(g),N(g),POS(h),P(h),POS(m),P(m) POS(g),N(g),POS(h),N(h),POS(m),N(m) POS(g),POS(h),POS(m) N(g),N(h),N(m) N(g),P(h),P(m)
	g h s m *grand-sibling*	POS(g),POS(h),POS(s),POS(m) N(g),N(h),N(s),N(m) N(g),P(h),P(s),P(m)
	h t s m *tri-sibling*	POS(h),POS(t),POS(s),POS(m) N(h),N(t),N(s),N(m) N(h),P(t),P(s),P(m)

Table 1. Feature templates of various lexical dependency types. The lowercase letters h, m, s, g are words in a sentence. POS(x) is x's POS tag. POS(x)+1 is the POS tag of the word to the right of x. POS(x)-1 is the POS tag of the word to the left of x. P(x), N(x) are syntactic categories of P and N_h (or N_m), which are annotated on dependency arcs (We ignore dependency arc labels in the table for simplicity. More details can be found in section 3.2).

4.1 *N*-best Reranking Based on Higher-Order Lexical Dependencies

The method of sub-section 3.1 determines that each constituent sub-tree must have a corresponding dependency sub-tree. Accordingly, we now describe an efficient algorithm for evaluating constituent trees with higher-order lexical dependencies. We define a quadruple $< C_N, D_N, score(C_N), W_N >$ for each non-terminal node *N*, in which C_N is the constituent sub-tree rooted at *N*; D_N is the dependency sub-tree transformed from C_N ; $score(C_N)$ is the score of C_N evaluated using Eq. (2); and W_N is the head-word of *N* in the tree.

Our algorithm (Algorithm 1) works bottom-up to fill $< C_N, D_N, score(C_N), W_N >$ for each node *N*. For a constituent P in the parse tree, we first find the head-child N_h for P (line 8), then propagate the head-word of N_h to P (line 9). To build D_P , we simply build dependency arcs for current constituent P ; then link D_{N_1} , …, D_{N_n} with these dependency arcs; and then let the root of D_{N_h} be D_P 's root (line 11 to line 14). We extract all the lexical dependencies rooted at *P*'s head-word W_P through D_P . For example, in Figure 2(b), all the lexical dependencies rooted at node A's head-word w_0 can be extracted from the dependency tree in Figure 2(c); and all the lexical dependencies have been shown in Figure 3. Then we map the lexical dependencies into feature vectors and sum over them as the feature vector $\Phi(P)$ for P. Finally, we evaluate the score of C_P using formula (4) below:

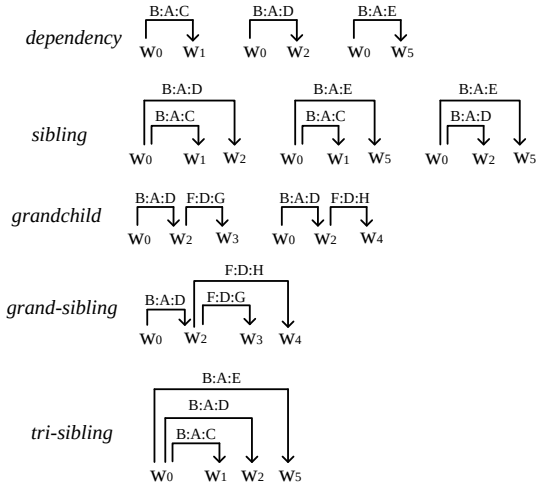


Figure 3. Lexical dependencies for w_0 in Figure 2(c).

$$Score(C_P) = \Phi(P) \cdot \bar{\alpha} + \sum_{i=1}^{n} Score(C_{N_i}) \quad (4)$$

4.2 Forest Reranking Based on Higher-Order Lexical Dependencies

As mentioned, *N*-best reranking suffers from the limited scope of *N*-best list. Forest reranking, by contrast, can rerank a packed forest of exponentially many parses, and thus provides a good way to overcome these limitations. Thus we also use the forest reranking method, based on higher-order lexical dependencies.

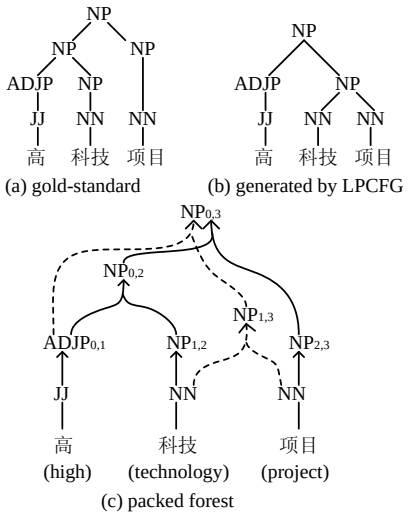

Figure 4. Constituent trees and forest

A forest is a compact representation of many parse trees. Figure 4(c) is a sample forest which is the compact representation of the constituent trees shown in Figures 4(a) and 4(b). To obtain forests, Huang (2008) tried to modify the Charniak parser to output forest directly. Inspired by parser combination methods (Sagae and Lavie, 2006; Fossum and Knight, 2009), we have designed a simple method of building forests starting from *N*-best lists. First, we convert each parse tree in an *N*-best list into context-free productions and label each constituent in each production with its span and syntactic category. Then these converted context-free productions are used to build the forest. For example, in Figure 4, given two candidates (Figure 4(a) and Figure 4(b)), we first convert them into context-free productions, e.g. $NP_{0,3} \rightarrow ADJP_{0,1}\ NP_{1,3}$, $NP_{0,3} \rightarrow NP_{0,2}\ NP_{2,3}$ and so on. Then we combine these productions into the forest shown in Figure 4(c). The recombined forest probably contains some parse trees that are not included in the *N*-best list, as will be shown in sub-section 6.1.

Our algorithm for forest reranking is similar to Algorithm 1. The only difference is that there may be more than one hyperedge for each node in a forest. So we make use of a beam search algorithm (Huang and Chiang, 2005) and store *N*-best sub-trees for each internal node. Finally, we choose the best-first sub-tree of the root node as the result.

5 Training Algorithm

The training task is to tune the parameter weights $\bar{\alpha}$ in Eq. (1) using the training examples as evidence. We employ the online-learning algorithm shown in Algorithm 2 because it has been proven

Algorithm 2:Generic online learning algorithm

1:**Input**: training data (x_t, c_t) for $t = 1 \ldots T$
2: $\bar{\alpha}^{(0)} \leftarrow 0$; $\mathbf{v} \leftarrow 0$; $i \leftarrow 0$ ▷ initial weights
3: **for** *n* in 1…*N* **do** ▷ *N* iterations
4: **for** *t* in 1…*T* **do** ▷ *T* training instances
5: $\bar{\alpha}^{(i+1)} \leftarrow$ update $\bar{\alpha}^{(i)}$ according to (x_t, c_t)
6: $\mathbf{v} \leftarrow \mathbf{v} + \bar{\alpha}^{(i+1)}$
7: $i \leftarrow i + 1$
8: $\bar{\alpha} \leftarrow \mathbf{v}/(N*T)$ ▷ averaging weights
9: **return** $\bar{\alpha}$

to be effective and efficient in many studies (Collins, 2002; Collins and Roark, 2004; McDonald et al., 2005). For Algorithm 2, we define two parameter update strategies (line 5 in Algorithm 2) as follows.

The first strategy is *perceptron updating*. We first obtain the oracle tree c_t^+ that has the highest F_1 score according to the gold-standard tree c_t,

$$c_t^+ = \arg \max_{c \in GEN(x_t)} F_1(c, c_t) \qquad (5)$$

Then we get the highest scoring tree $\hat{c}_t$ with current weights $\bar{\alpha}^{(i)}$,

$$\hat{c}_t = \arg \max_{c \in GEN(x_t)} \Phi(x_t, c) \cdot \bar{\alpha}^{(i)} \qquad (6)$$

If $\hat{c}_t$ is not equal to c_t^+, the weights will be updated through

$$\bar{\alpha}^{(i+1)} \leftarrow \bar{\alpha}^{(i)} + \Phi(c_t^+) - \Phi(\hat{c}_t) \qquad (7)$$

Otherwise, the current weights are kept.

Although the perceptron updating strategy works well, parameter updating must wait until the entire tree has been built. We believe that this strategy probably misses the best opportunity for parameter updating and introduces some noise into the updating procedure. So, inspired by Collins and Roark (2004), we propose an *early updating strategy* for forest reranking. The key idea is to insert the parameter updating procedure into the forest reranking procedure. We parse a forest bottom up with the current parameter $\bar{\alpha}^{(i)}$. When the best-first sub-tree $\hat{s}_N$ for internal node *N* is different from oracle sub-tree s_N^+, we stop the parsing procedure and update the parameters immediately using the following formula:

$$\bar{\alpha}^{(i+1)} \leftarrow \bar{\alpha}^{(i)} + \Phi(s_t^+) - \Phi(\hat{s}_t).$$

Then we continue to parse the current forest with the newer parameters $\bar{\alpha}^{(i+1)}$. Unlike the perceptron updating strategy, this strategy updates parameters at the moment that an error sub-tree is built, and this is why we call it the *early updating* strategy.

6 Experiments and Analysis

We evaluate our method on the Penn Chinese Treebank Version 5.0 with the standard division: Art.301-325 as the development set, Art. 271-300 as the test set and others as the training set. All the F_1 scores are evaluated with EVALB[3].

6.1 To Obtain *N*-best Lists and Forests

We first employ existing parsers to generate *N*-best lists and then recombine the *N*-best lists into forests according to the method described in sub-section 4.2. We split the training set into 20 folds averagely and generate 50-best lists for one fold with both the Berkeley parser[4] and the Charniak parser[5] (trained on the remaining 19 folds) individually. The development set and the test set are parsed with models trained on the entire training set.

	Berkley(50)	Charniak(50)	Comb(100)
Nbest	89.13	89.20	**91.61**
Forest	90.22	90.38	**94.05**

Table 2. Oracle F_1 (%) of *N*-best lists and forests

The oracle F_1 scores of *N*-best lists and forests on test set are listed in Table 2, where 'Berkeley(50)' means the performance of 50-best lists from Berkeley parser; 'Charniak(50)' means the performance of 50-best list from Charniak parser; 'Comb(100)' means the performance of 100-best lists by combining the two 50-best lists; "Nbest" means the oracle F_1 of *N*-best lists; and "Forest" means the oracle F_1 of forests which are evaluated through the Forest Oracle Algorithm proposed in Huang (2008). In Table 2, we can see that the oracle F_1 scores of forests are much better than associated *N*-best lists. This result clearly demonstrates that the approach of obtaining forests by recombining *N*-best lists is effective.

6.2 Parameter Tuning on Development Set

We tuned some parameters manually for our models in the sub-section, including the number of iterations in the training algorithm, and the beam size *k* in the forest reranking algorithm. Models are trained with training set's 100-best lists and evaluated on development set's 100-best lists.

The F_1 score curves varying with iteration times are shown in Figure 5. Although there are some fluctuations, we can see that the F_1 score tends to improve with the incremental iteration times, and that the average model yields additional improvement. To avoid the problem of overfitting to the training set, we fix the iteration times at 10 in the following experiments. Figure 6 shows F_1 score curves varying with beam size. We see that when the beam size exceeds 5, the performance fluctuates slightly, so we fix the beam size at 5 in our experiments. In Figure 6, we can also see that the model trained with the early updating strategy can obtain better performance than with the perceptron updating strategy.

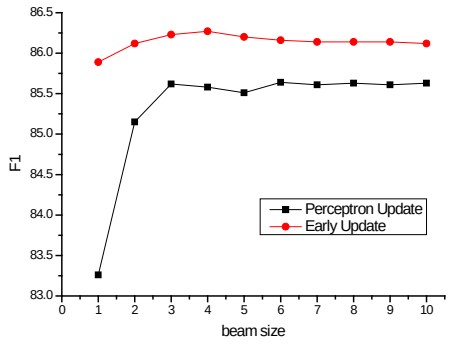

Figure 6. The F1 score curves on the development set varying with beam size in forest reranking.

6.3 Evaluation on Test Set

In this sub-section, we build three parsing systems using the methods described in the previous sections. For brevity, we annotate the *N*-best reranking system trained with the perceptron updating strategy as "NbestRerank"; the forest reranking system trained with the perceptron updating strategy as "ForestRerank"; and the forest reranking system trained with the early updating strategy as "EarlyUpdate". We also employ the Charniak parser (Charniak) and the Berkeley

	Berkeley	Charniak	Combine
Baseline	83.13	82.41	-----
NbestRerank	84.68	83.29	84.68
ForestRerank	84.31	83.11	85.72
EarlyUpdate	**85.06**	**83.32**	**85.74**

Table 3. F1 (%) scores on Test Set. The column headed by "Berkeley" is trained and tested with Berkley parser's 50-best list; the column headed by "Charniak" is trained and tested with Charniak parser's 50-best list; the column headed by "Combine" is trained and tested with 100-best list generated by Berkeley parser and Charniak parser.

Parsers	UA(%)
Charniak	82.31
Berkeley	84.05
NbestRerank	85.89
ForestRerank	85.69
EarlyUpdate	86.26
MST 1-ord (automatic POS)	79.62
MST 2-ord (automatic POS)	80.24
MST 1-ord (gold-standard POS)	85.23
MST 2-ord (gold-standard POS)	86.66

Table 4. Unlabeled dependency accuracy (UA). NbestRerank, ForestRerank and EarlyUpdate are trained and tested with combined 100-best lists

parser (Berkeley) as our baselines.

Using the parameter configuration tuned on development set, we have evaluated all the systems on test set. The F_1 scores are shown in Table 3.We can find that the F_1 scores are improved enormously when we make use of higher-order lexical dependencies. No matter which *N*-best list is used, EarlyUpdate system gets the highest F_1. However, the improved ranges vary with *N*-best list. The improvement is 1.93% for Berkeley parser's 50-best list, while it is 0.91% for Charniak parser's 50-best list. In our opinion, the reason is that Charniak parser has made use of headword information during parsing, so it is less sensitive to lexical dependencies than Berkeley parser. When we use the combined 100-best lists for training and testing, all the three systems are improved. NbestRerank gets 1.55% improvements than Berkeley does, ForestRerank gets 1.04% improvements further than NbestRerank does, and EarlyUpdate makes the final performance up to 85.74%.

Intuitively, since they benefit from the higher-order lexical dependencies, the generated constituent trees should show better dependency accuracy as well. So we convert the generated constituent trees into dependency trees and calculate their unlabeled dependency accuracy (UA)[6].

[6] To compare with dependency parsing systems whose dependency arc labels are different from ours, we simply calculate the UAs.

	F_1(%)
Baseline	84.59
+*dependency* (first-order)	85.46
+*sibling* & *grandchild* (second-order)	86.20
+*grand-sibling* & *tri-sibling* (third-order)	86.37

Table 5. F_1 (%) score on development set of the EarlyUpdate system using different lexical dependency types.

To demonstrate the effectiveness of our systems, we also train a 1-order MSTPaser[7] (MST 1-ord) and a 2-order MSTParser (MST 2-ord), and then use them to parse the test set with gold-standard POS tags and automatically annotated POS tags (accuracy is 95.17%). All of the results are shown in Table 4. We see that the UAs of our systems are much better than those of Charniak and Berkeley. Although our systems employ no gold-standard POS tags during parsing, their UAs exceed those of MST 1-ord, which does employ such tags; and the UA of EarlyUpdate is even comparable with those of MST 2-ord, which also employs such tags.

The figures shown in Table 3 and Table 4 clearly reveal that our parsing approach obtains constituent trees with both better F_1 scores and better UAs.

6.4 Ablation studies

The experimental results above have shown that reranking parses based on higher-order lexical dependencies is effective. To verify the contributions of different lexical dependency types, we further evaluate the development set using the EarlyUpdate system trained with combined forests. First, we reranked forests with first-order (*dependency*) lexical dependencies. Then we added the second-order (*sibling* and *grandchild*) lexical dependencies into our system. Finally, we added the third-order (*grand-sibling* and *tri-sibling*) lexical dependencies. All of the parsing results are shown in Table 5. It is clear that all of the lexical dependency types are helpful for constituent tree evaluation.

6.5 Comparison with State-of-the-art Results

Table 6 compares our best results with that of state-of-the-art parsers. Compared to the

Table 6. F1 (%) scores of state-of-the-art methods compared with ours on the Chinese Treebank.

"Charniak & Johnson Reranker" [8] which is a parse reranking system and exploits various sorts of features including 1-order lexical dependencies (Charniak and Johnson, 2005), our NbestRerank parser, which uses higher-order lexical dependency features, gets a higher F_1. Comparing with the parsers combination system (Zhang et al., 2009) which combines scores evaluated by Berkeley parser and Charniak parser to evaluate a parse tree, our EarlyUpdate system haven't used scores evaluated by first stage parsers and still gets a higher F1 score. Although our EarlyUpdate system uses no resources other than CTB, it still obtains better results than other parsers which have employed extra resources (Burkett and Klein, 2008; Huang and Harper, 2009; Niu et al., 2009). These comparisons allow us to confidently conclude that exploitation of higher-order lexical dependencies is highly beneficial for constituent parsing.

7 Conclusion and Future Work

We have presented a method for evaluating constituent trees using higher-order lexical dependencies. Within a parse reranking framework, our models rerank *N*-best lists and forests based on dependency features. Experimental results show that higher-order lexical dependencies can yield greater improvements in constituent parsing performance than commonly used first-order lexical dependencies. The best results of our models outperformed all previous results on the CTB, and the dependency accuracy of generated constituent trees is significantly improved as well. All of the results demonstrate that exploitation of higher-order lexical dependencies provides significant benefits for constituent tree evaluation.

Although all of our experiments were carried out only on the Chinese Treebank, our method is language independent. It can be adapted to any languages which can represent constituent trees with labeled dependency trees. We will apply our methods to other languages in the future.

[8] The F1 score of Charniak & Johnson Reranker on CTB was reported in Niu et al. (2009).

Abstract

In this paper, we propose a factored parsing model consisting of a lexical and a constituent model. The discriminative lexical model allows the parser to utilize rich contextual features beyond those encoded in the context-free grammar (CFG) in use. Experiment results reveal that our parser achieves statistically significant improvement in both parsing and tagging accuracy on both English and Chinese.

1 Introduction

Part-of-speech (POS) tagging, or tagging for short, is usually considered a front-end preparation for parsing. Folk wisdom holds that accurate tagging result is helpful to alleviate the syntactic ambiguity problem in parsing, motivating a huge amount of research on perfecting tagging techniques.

In the past two decades, most POS tagging systems were based on a sequential classification approach, decomposing a sequence labeling task into a series of classification subtasks. The state of the art of tagging was achieved by virtue of well-developed machine learning methods, e.g. the Maximum Entropy model as in Ratnaparkhi (1996) and the Support Vector Machine as in Gimenez and Marquez (2003). All these techniques boosted the performance of POS tagging significantly. The error rate of the best English POS tagger is less than 3% (Ratnaparkhi, 1996; Toutanova et al., 2003; Shen et al., 2007), very close to the inter-annotator discrepancy of the Penn Treebank (Marcus et al., 1993).

For a long time, however, parsing seems to have been evolving in parallel to tagging without much interaction with each other. Generative parsers (Collins, 1997; Charniak, 2000; Charniak and Johnson, 2005; Petrov and Klein, 2007), owing to their generative nature, all include a lexical probability model in the form $P(w|t)$. The information used to predict the POS tag of a word mainly comes from the word itself and/or the ancestors that derive this word in a tree. Local context, which is proved to be the most useful information source for tagging (Ratnaparkhi, 1996; Toutanova and Manning, 2000), is not efficiently utilized by these parsers. Another noticable fact is that these high-performance parsers cannot do a better job of POS tagging than most of the state-of-the-art taggers (see Section 4 for a comparison). This is quite against our intuition that a parser having access to syntactic and contextual information from all over an input sentence should outperform a tagger that is limited to utilizing only local context and sequential dependency. This is an observation in Charniak et al. (1996). But their explanation is that a parser is built to find phrase markers, not tags. Then an interesting question arises: if a parser cannot tag words better, how can we expect it to do better on phrases?

Driven by this question, our research is intended to explore an approach to integrating parsing with the strength of successful tagging, in the hope of improving both. Firstly, we factor the conventional PCFG-based parsing into a lexical and a constituent model. Then, two candidate lexical models are formulated to incorporate enriched contextual features and sequential dependency into the parsing, with an averaged perceptron algorithm for parameter estimation. Our experiments on English and Chinese treebanks show that this approach achieves a significant performance enhancement in both parsing and tagging over the baseline Berkeley parser.

2 A Factored Parsing Model

2.1 POS Tagging in Parsing

For PCFG-based parsing, the joint probability $\mathcal{P}(T, S)$ for a parse tree T of a sentence S is usu-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1260–1268,
Chiang Mai, Thailand, November 8 – 13, 2011.

ally defined as the product of the probability of every CFG rule $\mathcal{R}$ involved in T:

$$\mathcal{P}(T,S) = \prod_{\mathcal{R}\in T} \mathcal{P}(\mathcal{R})^{|\mathcal{R}|} \quad (1)$$

where $|\mathcal{R}|$ is the number of occurrences of $\mathcal{R}$ in T. In a CFG, such as the one induced from the Penn Treebank, there are usually two types of grammar rules: *lexical rule*, e.g. `NN` $\rightarrow$ `consumer`, to indicate a possible POS-tag for a word, and *constituent rule*, e.g. `PP` $\rightarrow$ `IN NP`, to indicate the composition of a constituent.

Let r denote a lexical rule and R a constituent rule, the probability defined in (1) can be rewritten as

$$\mathcal{P}(T,S) = \prod_{R\in T} \mathcal{P}(R)^{|R|} \prod_{r\in T} \mathcal{P}(r)^{|r|} \quad (2)$$

Accordingly, the parsing model can be decomposed into two factors:

$$\mathcal{P}(T,S) = \mathcal{P}(\mathcal{C},S)\mathcal{P}(\mathcal{L},S) \quad (3)$$

where $\mathcal{P}(\mathcal{C},S) = \prod_{R\in T} \mathcal{P}(R)^{|R|}$ is a constituent model and $\mathcal{P}(\mathcal{L},S) = \prod_{r\in T} \mathcal{P}(r)^{|r|}$ a lexical model. The best parse is then selected by the joint inference with these two submodels. This factored-out lexical model provides the flexibility of integrating various well-developed POS tagging techniques into parsing, and it is also easier for optimization, in contrast to a complex joint model. It is reasonable that a better lexical model is expected to have better effects on parsing.

2.2 Product of Experts

The two separated models may score in different magnitudes, even if they are all properly normalized. Usually, when combining two heterogeneous models, a weighting scheme is needed to balance their unequal effect. For this, we introduce another parameter λ to our factorized parsing model as

$$\mathcal{P}(T,S) = \mathcal{P}(\mathcal{L},S)^{\lambda}\mathcal{P}(\mathcal{C},S) \quad (4)$$

This is known as a product-of-experts (Hinton, 2002; Cohen and Smith, 2007), where a combined distribution is defined by multiplying several component distributions and renormalizing them. The parameter λ can be tuned with the Gold Section Search algorithm (Press et al., 2007) on a development set, using the F-measure of PARSEVAL (Black et al., 1991) as objective function for training.

3 Lexical Model

3.1 Model I

Sequential dependency and local context have shown their strength in tagging disambiguation (Ratnaparkhi, 1996; Toutanova and Manning, 2000; Toutanova et al., 2003). However, in the high-performance PCFG-based parsers (Collins, 1997; Charniak, 2000; Petrov and Klein, 2007), none of these features can be used due to the generative nature of these parsing models.

To address this problem and incorporate the advantages of POS tagging technique into parsing, we propose a discriminative lexicon model following the global linear model (Collins, 2002). Let $\tau = \{t_0, t_1, t_2 ... t_n\}$ be a tag sequence for a sentence $S = \{w_0, w_1, w_2 ... w_n\}$, we define the score of a tagged sequence to be

$$\text{SCORE}(\tau, S) = \theta \cdot \mathbf{f}(\tau, S) = \sum_{i=1}^{n} \theta \cdot f(\tau_i, S) \quad (5)$$

where $\mathbf{f}(\tau, S)$ is a global feature vector and θ a vector of associated weights. A global feature is defined through a collection of local features $f(\tau_i, S)$. We train θ on a treebank using an averaged perceptron algorithm similar to the one presented in Collins and Duffy (2002) and Collins (2002). The number of iterations needed is optimized on the development set.

However, introducing sequential dependency into this lexical model would cause a severe efficiency problem with the joint inference for parsing. When the Viterbi algorithm is used to search for the best parse tree, its efficiency relies heavily on tree structure. The interdependency of adjacent POS tags actually changes the structure of the parse under operation. For example, to determine the best sub-tree for a non-terminal `XP` covering a span of words $[w_i ... w_j]$, we need to calculate the score for w_i's tag, which may largely depend on w_{i-1}'s tag. Unfortunately, such information is not available from the current word span under processing. The inference algorithm thus has to keep all possible sub-trees in memory, resulting in an intractable inference problem.

To deal with this joint inference problem, we approximate the lexical model in a unigram-factored form:

$$\mathcal{P}(\mathcal{L},S) = \mathcal{P}(\mathcal{L}|S)\mathcal{P}(S) \propto \prod_{i\in[0,n]} \mathcal{P}(t_i|S) \quad (6)$$

where $\mathcal{P}(S)$ is the probability of a given input sentence, a constant that can be dropped if search only for the best parse, and t_i a candidate tag for w_i. The conditional distribution $\mathcal{P}(t_i|S)$ can be estimated by

$$\mathcal{P}(t_i|S) = \frac{\sum_{\tau \in \mathbb{T}(t_i)} \exp\left(\text{SCORE}(\tau, S)\right)}{\sum_{\tau' \in \mathbb{T}} \exp\left(\text{SCORE}(\tau', S)\right)} \quad (7)$$

where $\mathbb{T}$ is the set of all possible tag sequences for S, and $\mathbb{T}(t_i)$ a subset of $\mathbb{T}$, consisting of all tag sequences that contain t_i. The numerator is the sum of scores for all possible tag sequences with t_i for w_i. The denominator is the total score of all possible tag sequences of the input sentence. For efficient calculation, we also adopt variants of the forward and backward algorithm, which are similar to those for HMM (Baum and Eagon, 1967; Baum and Sell, 1968). Different from the conventional tagging systems, our lexical model does not generate the best tag sequence for the whole sentence, but a lattice of tags, on which the joint inference with the constituent model can be performed.

In our model, feature functions $f_m(\tau_i, S)$ are primarily binary, each of which maps the local context to 1 if its feature exists, or to 0 otherwise. The only exception is the first one. Using a similar design as in discriminative re-scoring parsing models (Collins, 2000; Charniak and Johnson, 2005; Huang, 2008), we have the first feature f_0 to be the logarithm of the probability of t_i being w_i's tag in S, as proposed in Petrov and Klein (2007), which is $f_0(\tau_i, S) = \log q(t_i, S)$.[1]

Beside $f_0(\tau_i, S)$, all other features are similar to those in the previous works (Ratnaparkhi, 1996; Toutanova et al., 2003; Shen et al., 2007), as listed in Table 1.

The signature features *prefix* and *suffix*, as used in Toutanova et al. (2003), each return a substring of certain length from the current word. In our experiments, this length ranges from 1 to 8. Since these prefix and suffix features are blindly extracted with templates that can be applied to any language, our lexical model is more language-independent than those using a predefined language-specific affix list.

Type	Feature Template	
Word	$[w_i]\ (i = -2, -1, 0, 1, 2)$	$\&[t_0]$
	$[w_{i-2}, w_{i-1}]\ (i = 0, 1, 2)$	$\&[t_0]$
	$[w_{-1}, w_1]$	$\&[t_0]$
	$[w_{i-2}, w_{i-1}, w_i]\ (i = 0, 1, 2)$	$\&[t_0]$
Tag	$[t_i]\ (i = -2, -1, 1, 2)$	$\&[t_0]$
	$[t_{i-2}, t_{i-1}]\ (i = 0, 3)$	$\&[t_0]$
Signature	punctuator	$\&[t_0]$
	digit	$\&[t_0]$
	prefix	$\&[t_0]$
	suffix	$\&[t_0]$

Table 1: Feature templates of lexical model

For feature selection, we also follow other researchers' previous works to use a simply cut-off threshold. During the process to generate features for each word in the training treebank, a feature is not included in the final model if its count falls below a predefined threshold. We set the threshold to 2 for word and tag features, and to 35 for signature features.

3.2 Model II

The lexical model I enables the parsing to utilize a large variety of features other than those encoded in the CFG in use. However, the computation of forward/backward variables is expensive in both time and space. This inefficiency is practically more severe in training, which requires repetitive computation of these values for many times. Lexical model II is proposed as an aggressive approximation of model I, aimed at improving its efficiency at the least cost of performance.

The inefficiency of model I is primarily due to the complexity of the forward/backward procedure. For model II, we propose a lazy procedure as a simple approximation, which calculates the conditional probability $\mathcal{P}'(t_i|S)$ deterministically from left to right. As the procedure proceeds, all features that contain a preceding tag are instantiated with the best predicted tags for those previously processed words. For the features that contain a succeeding tag, we use the tag with the highest score by $f_0(\tau_i, S)$. This lazy procedure traces only one arbitrary best tag sequence. Its time complexity is linear in the length of input sentence.

Accordingly, for lexical model II, the distribu-

[1] In the lexical model, for $t_i = \mathcal{A}$ (a non-terminal symbol), the score $q(t_i, S)$ is calculated by:

$$q(t_i, S) = \frac{\sum_x O(\mathcal{A}_x, i, i+1)\mathcal{P}(\mathcal{A}_x \rightarrow w_i)}{I(ROOT, 0, |S|)} \quad (8)$$

where x is the latent variable (Petrov et al., 2006), and $I(\cdot)$ and $O(\cdot)$ are *inside* and *outside* scores. For more details of $q(t_i, S)$, please refer to Figure 3 in Petrov and Klein (2007).

tion $\mathcal{P}'(t_i|S)$ is estimated as

$$\mathcal{P}'(t_i|S) \propto \frac{\exp\left(\theta \cdot \mathbf{f}(\tau_i^*, S)\right)}{\sum\limits_{\substack{j\in[0,n-1],\\ t_j\in E(S)}} \exp\left(\theta \cdot \mathbf{f}(\tau_j^*, S)\right)} \quad (9)$$

where τ_i^* is the arbitrary best tag sequence and $E(S)$ the collection of all possible POS tags for every word in S. The denominator is introduced for two reasons. Firstly, it is used to map the score of every t_i to the interval $[0, 1]$, so as to make the lexical model to have the similar magnitude as the constituent model. Secondly, we deliberately let it not to be a local normalizer. This allows some confident tags to vote stronger than others in the joint inference.

4 Experiments

We implement a parser for experiments with necessary support from the open source Berkeley parser. To evaluate the performance of this parsing model across languages, we conduct a number of experiments on both English and Chinese treebanks, using the WSJ section of Penn Treebank 3.0 (LDC99T42) and the Chinese Treebank 5.1 (LDC2005T01U01). Since both the constituent and lexical models use the PCFG-LA trained with the Berkeley parser,[2] we take it as the baseline for our evaluation. For comparison purpose, we use exactly the same splits of the treebanks as in Petrov and Klein (2007), as listed in Table 2.

	English	Chinese
Train.	Section 2-21	Art. 1-270,400-1151
Dev.	Section 22	Art. 301-325
Test.	Section 23	Art. 271-300

Table 2: Experiment Setup

As mentioned in Section 3, the parameter estimation for the lexical model requires reparsing the training treebank in use for calculating $q(t_i, S)$ with the PCFG-LA trained with the Berkeley parser. In order to obtain a representative set of training examples, the PCFG-LA is expected to create as much noise as it does in testing. For this, the training set for each language is divided into 20 folds as in Collins (2000) and Charniak and Johnson (2005). Each fold is reparsed with the PCFG-LA trained on the other 19 folds. The number of split-and-merger iterations is set to 6 for the training of all these grammars on the treebanks of both languages.

To examine how much the rich contextual features introduced into the lexical model improve parsing performance, the tagging accuracy of our parser is compared with the state-of-the-art taggers, e.g. the open source Stanford tagger. Although this tagger was developed several years ago, its performance on English is still in the lead according to Spoustová et al. (2009). We train and test this tagger on the same datasets as for parsing, using the default parameter settings for each language.

All parsing results are evaluated with the standard `evalb`. It is noteworthy that the tags are not counted as part of parsing output. The tagging accuracy has to be evaluated with our own program, for `evalb` eliminates some `DELETE LABEL`s when evaluating tagging.

4.1 Tagging Helps Parsing

Table 3 compares the performance of our parser and other baseline systems. When trained on the same data set, the Stanford tagger indeed outperforms the Berkeley parser and the re-scoring parser[3] on POS tagging for both languages. Then, we impose various tagging results into parsing to see how they affect parsing performance. Both the gold POS tags and the output of the Stanford tagger are submitted to the Berkeley parser, using the "`-goldPOS`" option. The results are presented in Table 3, denoted as *Berkeley+GoldTag* and *Berkeley+Stanford* respectively.[4] Surprisingly, however a significant loss of parsing performance is caused by imposing the better yet non-perfect tagging output of the Stanford tagger onto the Berkeley parser. We can see that better tagging does not necessarily improve parsing if the two separate systems work in the conventional "tag then parse" order.

The two lexical models are tested in the other experiments. We use all features as listed in Table

[2]The version released in September, 2009. The option "-Chinese" is not used for parsing Chinese, for it does not give the best parsing performance. All the PCFG-LA mentioned in this paper are trained with this version of the Berkeley parser with default settings.

[3]C&J Parser: the open source re-scoring parser of Charniak and Johnson (2005)

[4]Note that the tagging accuracy of *Berkeley+GoldTag* is not 100%. When some of the gold tags could cause parsing failure, the Berkeley parser will skip them and use its own tagging output.

Table 3: Results on English and Chinese testing sets (all sentences).

1 for English. For Chinese, however, we select a smaller subset of it by removing word trigram templates and all tag templates that contain any tag to the right of the current word.[5] We find that using such tags as features cause a loss of performance, which is consistent with the default setting of the Stanford tagger for Chinese. Another difference in feature design for these two languages is the length of prefix and suffix. The max length of affix is set to 6 for English and 3 for Chinese. This is because the average word length is different in the two languages. And we use no specific Chinese characters for the feature templates of *punctuator* and *digit*, in order to maintain the language independency of our models as much as possible.

As presented in Table 3, our parser with both candidate lexical models performs significantly better than the baseline Berkeley parser.[6] For Chinese, the best labelled F-score 84.59% is 1.3% beyond the baseline 83.22%. For English, our best result 90.02% is even better than 89.88% using gold POS tags. It is evident that our enhanced lexical model can effectively help parsing. With its help, our parser also outperforms both the Berkeley parser and the Stanford tagger on tagging. The observation that the improvement on English looks not as much as that on Chinese could be explained by the fact that the tagging accuracy of English is very close to the inter-annotator discrepancy of the Penn Treebank, leaving a too tiny room for further improvement. According to Dalrymple (2006), parsing ambiguity in about 30% sentences cannot be reduced even by a perfect tagger, implying that improving tagging may only have a limited influence on parsing.

We also examine the effect of different feature set in both lexical models. With only word features, the parser already achieves some improvement on both parsing and tagging, in consistence with the findings in Toutanova et al. (2003). The surrounding words provide most information for the disambiguation for tagging. However, the weight parameter λ seems not as effective as expected for English. This might be caused by the overfitting when it is tuned it on the development set. We also try to remove the feature f_0 from the model (w/o f_0). Then, the performance is still higher than the baseline Berkeley parser, indicating that the effectiveness of our lexical model does not rely on this feature too much. More interestingly, the approximate deterministic lexical model II achieves a similar performance as the complex lexical model I. In practice, model II is a better choice with a lower computational complexity.

Before the joint inference with the constituent model, a lexical model calculates a score for every candidate tag of each word. A choice is to collect the tags with the highest scores as a baseline output of tagging. The tagging accuracy of a lexical model can be compared with this output, as shown in the last column "Lex." for each language in Table 3. Comparing this column with the tagging accuracy of our parser in the second column for each language, we can observe an increase by 0.1-0.3%, indicating that syntactic knowledge as used in our parser does help the disambiguation for tagging.

[5]Specifically, tag templates with $i > 0$ are removed for experiments on Chinese.

[6]All results are tested with Dan Bikel's Randomized Parsing Evaluation Comparator (http://www.cis.upenn.edu/~dbikel/download/compare.pl), resulting in $p < 0.05$.

4.2 Comparison with Previous Work

Table 4 and 5 compare the performance of our parser with other high-performance parsers. Those parsers using self-training or parser combination methods are not included in this comparison, because they use extra resources or more than one parsing model.

For English, our parser outperforms all generative parsers (Collins, 1997; Charniak, 2000). But there is still a gap to the discriminative re-scoring methods (Charniak and Johnson, 2005; Huang, 2008). Given that our parser only improves the lexical model, the re-scoring method using a variety of subtree features indeed has some advantages. For Chinese, our parser has achieved the best performance so far on this data set. It is even better than the one that employs additional knowledge from the Chinese-English Parallel Treebank (Burkett and Klein, 2008).

5 Analysis

The experiments reported in the previous section seems to give a positive answer to the question: whether tagging can help parsing. However, several other questions follow: How does tagging affect paring? Why can this independently optimized lexical model improve parsing? We will look into these issuess in this section.

5.1 Profiling the Improvement of Tagging

We firstly divide the word/tag pairs in the testing data into to two groups: known v.s. unknown, according to the definition in Jin and Chen (2009). The tagging performance of our parser and the two baseline systems are compared in Table 6.

	English		Chinese	
	Known	Unk.	Known	Unk.
Stanford	98.09	77.33	96.47	72.02
Berkeley	97.93	76.13	96.91	59.23
This work	98.09	80.04	97.59	73.81

Table 6: Tagging accuracy (%) for known and unknown word/tag pairs

It is evident that our parser outperforms the Berkeley parser on both groups. The contrast on unknown tags is more significant, especially for Chinese. Since our parser uses the same constituent model as the Berkeley parser, this difference has to be explained by a better lexical model. A similar case can also be observed when our parser is compared against the Stanford tagger. Since our lexical model uses a very similar feature set as the Stanford tagger, the difference in performance should be attributed to the constituent model, which provides more detailed contextual information from the whole sentence to facilitate guessing unknown POS tags.

5.2 Profiling the Improvement of Parsing

In order to profile the parsing errors that can be fixed by better tagging, we count the number of correct constituents in the output of our parser and the other systems for a comparison under a variety of partition schemes, as shown in Table 7 and 8. The span length of a constituent is the number of words in it. Usually, a longer span correlates with a higher position near the root in a parse tree.

Table 7 shows that correct constituents increase in number in almost all types. Without any feature designed for a specific POS tag (such as `IN`), our lexical model brings about a general improvement to the parsing of both languages. Interestingly, however, the comparison in Table 8 presents a different view. The improvement mainly takes place in the constituents of span length ≤ 4, especially those base-level ones of length 1, which are parents of tags, e.g. `NP` $\rightarrow$ `NNS` and `VP` $\rightarrow$ `VBG`. The recognition of these constituents is greatly influenced by a lexical model. This influence tapers off on higher constituents, for the constituent model becomes more dominant when working on larger subtrees. This is also observed on the Chinese side. But the Chinese treebank has many different characteristics from English. According to our

Table 8: Correct constituents by span length

statistics, about 34% of the constituents in the Chinese testing data are base-level ones. This explains why the impact of tagging to parsing for Chinese is much stronger than that for English. Since there are other languages that share similar characteristics with Chinese, our method should be also helpful in parsing these languages.

Currently, tagging and parsing are treated equally in a unified framework of parsing. However, our experiments show that our independently defined and optimized lexical model performs better than the one integrated into the Berkeley parser, especially for the recognition of the base-level constituents mentioned above. This is mostly attributable to the nature of a generative parsing model, for its lexical model can only use the features encoded in the grammar in use, which is never enough for accurate parsing. In fact, the research on POS tagging and chunking shows that the most important information for disambiguation at this level comes from local context (Toutanova et al., 2003), especially the surrounding words. Our current work is an attempt to fill this gap between tagging and parsing, by the way of enabling a parser to use rich contextual features in its lexical model.

6 Related Work

Most successful parsing models are generative models. Therefore, a large portion of previous related work did not change the generative nature of the lexical models involved (Goldberg et al., 2009; Huang and Harper, 2009; Attia et al., 2010). The key idea of these approaches is basically to advance smoothing techniques for the distribution $\mathcal{P}(w|t)$. Goldberg et al. (2009) adopt a trigram HMM tagging model trained on unannotated data to help prediting tags of rare words, but only the emission probabilities are used in parsing. Huang and Harper (2009) propose a better way to smooth the lexical model in a PCFG-LA parser similar to the Berkeley parser. Some morphological features are also used to handle unknown words in Chinese. In their evaluation, however, they exclude all unary rules that cause one of the major difficulties in parsing this language, according to our experiments. Their experiment settings obstruct comparing their results with others'. Attia et al. (2010) head in the same direction extending this method to other languages. Their experiment results are compared with ours in Table 4. The comparison shows that our method is more sophisticated in utilizing the sequential dependency between tags.

A motivation of our current work is that a discriminative lexical model can incorporate rich contextual features. In this respect, Cohen and Smith (2007) combine the strengths of a generative parsing model and a discriminative segmentation-tagging model under the notion of product-of-experts. Here we apply a similar idea to combine parsing and tagging. The discriminative re-scoring method (Charniak and Johnson, 2005; Huang, 2008) is also very successful. It enables a parser to use a large variety of local

and non-local features, so as to boost the performance. Interestingly, however, the comparison in Table 3 shows that the parser of Charniak and Johnson (2005) achieves the highest parsing performance with the lowest tagging accuracy. This parser seems to select the parse trees that contain correct constituents with relatively poor POS tags. This controversial result raises at least two questions: (a) Why correct constituent structures can be built on incorrect POS tags? (b) Does tagging have any effect on parsing? The first question points to the too strong generative capacity of the CFG in use. Note that without semantic and/or pragmatic knowledge as constraints, a CFG induced from a treebank usually can generate many possible but implausible structures for an input sentence. For the second question, the controversial result indeed gives us an impression that tagging has no effect on parsing, strongly against our intuition. Since tagging and parsing are unified into the same framework as a parser, it is reasonable to expect the correct tag sequence for a sentence to appear in the theoretically best parse tree. If a parser has to sacrifice tagging for parsing, it is suspectable that the re-scoring does not help the parser to reach its maximum capacity yet. Besides, the re-scoring method should have subsumed our current work. In fact, incorporating the sequential dependency between adjacent tags into the forest re-scoring model will also cause the efficiency problem in the inference as mentioned in Section 3. Given that no feature for tagging has been adopted in the forest re-scoring method so far, our current work is certainly a complement to this part.

The recent work of Rush et al. (2010) integrates parsing and tagging under the framework of dual-decomposition. This approach has the advantage to combine heterogeneous models, and solves the complex combinatory optimization problem via Lagrangian relaxation. However, it has a inevitable defect of inefficiency, since it requires to parse and tag the input sentence repetitively (usually 10 times for each sentence). Comparatively, our approach is more efficient. Note that lexical model II takes only a linear time in the length of input sentence. Without systematic comparison, however, it is difficult to tell which approach can provide a better performance. We will keep this for our future research.

7 Conclusion

In this work, we have proposed a parsing model which is factored into a lexical and a constituent model, in the hope of enabling the beneficial interaction between tagging and parsing. The relatively independent discriminative lexical model allows our parser to incorporate rich contextual features and even sequential dependency. Our experiments show that our lexical models can help parsing. With access to the syntactic knowledge from all over an input sentence, this parser outperforms the state-of-the-art POS tagging system in terms of tagging accuracy. Moreover, tagging should be an organic part of a parsing model to bring in a mutual positive effect for both parsing and tagging through joint inference. The conventional notion of tagging-parsing pipeline seems to leave no room for this possibility of enhancement.

Finally, individual words in an input sentence are found to be very useful in the disambiguation for POS tagging and even for recognizing base-level constituents. However, the structural parameterization of conventional parsing models cannot incorporate and utilize them effectively. Nevertheless, how to make use of all sorts of information available to enhance parsing is still a challenging research topic.

Models Cascade for Tree-Structured Named Entity Detection

rosset@limsi.fr

Abstract

Named Entity Recognition (NER) is a well-known Natural Language Processing (NLP) task, used as a preliminary processing to provide a semantic level to more complex tasks. In this paper we describe a new set of named entities having a multilevel tree structure, where base entities are combined to define more complex ones. This definition makes the NER task more complex than previous tasks, even more due to the use of noisy data for the annotation: transcriptions of French broadcast data. We propose an original and effective system to tackle this new task, putting together the strengths of solutions for sequence labeling approaches and syntactic parsing via cascading of different models. Our system was evaluated in the 2011 Quaero named entity detection evaluation campaign and ranked first, with results far better than those of the other participating systems.

1 Introduction

Named Entity Detection is a well-known NLP task used to extract semantic information in other more complex tasks such as Relation Extraction (Doddington et al., 2004) or Question Answering (Voorhees, 2001). After its definition in MUC-6 (Grishman and Sundheim, 1996), the NER task evolved increasing its complexity. Current definitions provide a fine-grained semantic information level with a broad coverage (Sekine, 2004). This has increased the interests in developing named entity detection systems.

In this paper we describe a new set of named entities defined recently(Grouin et al., 2011). These named entities have a multilevel tree structure where components are combined to define more complex and general entity structures. This definition increases significantly the complexity of the NER task, even more due to the type of data used for the annotation: manual and automatic transcriptions of French broadcast data.

Given such a definition, it is not possible to tackle the task with traditional sequence labeling approaches. At the same time, solutions able to reconstruct tree structures from flat sequences, like syntactic parsing solutions, may have serious limitations, due to the noisy data used. In order to solve these problems, we studied and implemented a two-stage system that put together the strengths of the two approaches: i) a complex linear-chain Conditional Random Field (CRF) model, integrating a huge number of features, takes the noisy data as input and generates the corresponding sequence of components; ii) a syntactic parsing model based on Probabilistic Context Free Grammar (PCFG) reconstructs the tree-structured named entities.

We describe our solution showing that it is equivalent, in the processing steps, to a syntactic parsing analysis solution, and that it can better handle noisy data. Additionally, given the amount of data used and the relatively slow training time of CRF models when using large amount of data and features, we describe a procedure for incremental CRF model training that solves this particular efficiency problem. The system we propose ranked first at the 2011 Quaero NER evaluation campaign (Galibert et al., 2011), with results far better than those of the other participating systems, though results on automatic transcriptions are largely affected by ASR system errors.

The remainder of the paper is organized as follows: in the next section we describe the new set of named entities defined and the data used for annotation. In section 3 we describe the system we propose, and implemented for the 2011 Quaero Named Entity Recognition evaluation campaign. In section 4 we detail the experimental setup, and

describe and comment the results. Finally in section 5 we draw our conclusions and propose some perspectives for future work.

2 Towards Tree Structured Named Entities

Named Entity Recognition was first defined as recognizing proper names (Coates-Stephens, 1992). Since MUC-6 (Grishman and Sundheim, 1996) named entities are proper names falling into three major classes: persons, locations and organizations. There are some propositions to sub-divide these entities into fine-grained classes. For example, politicians for the person class (Fleischman and Hovy, 2002) or cities for the location class (Fleischman, 2001). Some are sometimes added like product (Bick, 2004; Galliano et al., 2009).

Recently some extensions of named entity have been proposed. For example, (Sekine, 2004) defined a complete hierarchy of named entities containing about 200 types.

A well-known task of named entity detection is the one proposed for the CoNLL shared task 2003, described in (Tjong Kim Sang and De Meulder, 2003), where only four named entities were involved: *Person*, *Organization*, *Location* and *Other*. The latter was used for proper names belonging to any other entity different from the first three types.

After this task, named entity detection has been refined to include other entities, e.g. describing time expressions, events, quantity, currency etc. Current named entity detection tasks provide a fine-grained semantic representation level of the lexical surface form, sometimes comparable to other semantic representations like those used in Semantic Role Labeling (Carreras and Marquez, 2005) or Spoken Language Understanding (De Mori et al., 2008). The increasing complexity of named entities definition reflects the change of needs in computer science activities, that in turn is the consequence of the tremendous growth of the amount of information to deal with nowadays.

The set of named entities used in this work has been recently defined in (Grouin et al., 2011) and presents an important difference with respect to previous sets. Beyond the presence of subtypes, named entities have a tree structure. For example, the *Organization* type can be characterized by the subtypes *administrative* or *enterprise* giving the named entities *org.adm* and *org.ent* starting from the entity *org*. Each entity is composed of at least one component, which trigger in any case an entity type. The component allows to characterize more precisely the semantic content of the entity. For example the entity *pers*, used to describe persons, has, among others, the components *name.first*, for first name, and *name.last*, for last name. The presence of either *name.first* or *name.last* (or both) triggers the entity *pers*. The results of the composition is a tree-structured named entity. Two examples of structured named entities are shown in figure 1. In addition we report a named entity tree in figure 2, where words, corresponding to tree leaves, have been removed to keep readability, and it was generated starting from the sentence:

> **90 personnes** toujours présentes **à Atambua** c'est là qu'**hier matin** ont été tués **3 employés du haut commissariat des Nations unies** aux réfugiés, le **HCR**[1]

Here words realizing entities have been highlighted in bold. More details on the definition of this new set of named entities can be found in (Grouin et al., 2011), where also statistics on inter-annotators agreements are reported.

Given this structured named entities definition, the corresponding NER task is significantly more complex than previous equivalent tasks, where the entity structure was flat. Moreover, the complexity of the task is increased also by the type of data used for the annotation, that is manual and automatic transcriptions of French broadcast data. In

[1] 90 people still present in Atambua is where yesterday morning killed three employees of the United Nations High Commissioner for Refugees UNHCR.

particular the data have been collected not only from French radio channels, but also from a North-African French-speaking radio channel. This aspect introduces complexity due to different expressions used from French non-native speakers as well as to their particular accents and sometimes vocabulary.

The training data are the same used for the ESTER2 evaluation campaign (Galliano et al., 2009). The transcriptions have been re-annotated with the named entities described above.

The corpus will be referred in this work as `Quaero`. Description of training, development and test data are reported in table 1 and 2. In particular the test set is constituted by different kind of data: transcriptions of broadcast news, and broadcast conversations. the merge of the first two types. An interesting point in table 1 and 2 is the Out-of-Vocabulary (OOV) rate of dev and test sets.

3 Tree-Structured Named Entity Detection System

Given the definition of named entities described in previous section, we consider that, even if possible, the best solution cannot be a sequence labeling approach as largely used in standard named entity detection task (Tjong Kim Sang and De Meulder, 2003). In contrast, an approach coming from syntactic parsing would be possible. In that case syntactic parse trees could be replaced by named entity trees like the one shown in figure 2[2].

A first problem with this choice is constituted by the noisy data involved in our task. Indeed, our preliminary evaluations of a classic algorithm used successfully for syntactic parsing, resulted in quite poor results. Note also that most syntactic parsing solutions, are designed to perform parsing using Part-of-Speech (POS) tags, annotated upon words, as tree leaves, instead of words. This solution introduces a good generalization over surface forms, allowing algorithms to deal with relatively noisy data, although the same solutions proved to be much less effective on automatic transcriptions. Moreover, this solution is effective for syntactic parsing, since syntactic constituents are directly related to POS tags, but it would not be reasonable for named entity detection, since the generalization introduced by POS tags over lexical surface forms would make it impossible to discriminate between different entities. Indeed, most of the named entities syntactic heads are known to be nouns. Additionally, since our named entity detection task must be performed also on automatic transcriptions containing ASR mistakes, a solution designed for syntactic parsing and adapted to be applied directly on lexical surface forms would be not robust enough, due to OOV words and ASR mistakes that alter significantly the syntactic structure of the input sentence. Our idea is thus to split the annotation process in two phases:

1. In the first step we use a model robust to noisy input and Out-of-Vocabulary words in order to annotate entity components, i.e. components of named entities that can be annotated directly on words (tree leaves in figure 2).
2. In the second step we use a model for syntactic parsing in order to reconstruct the entire entity trees.

The first step is a sequence segmentation and labeling task, thus any model suitable for this kind of problems can be adopted. Given its characteristics and its success in sequence labeling tasks, we adopt CRF (Lafferty et al., 2001) for the first step. For the second step we adopt a Probabilistic Context-Free Grammar (Booth and Thomson, 1973; Krenn and Samuelsson, 1997). The next two subsections describe these two models.

3.1 Linear-Chain Conditional Random Fields

CRFs have been proposed for the first time for sequence segmentation and labeling tasks in (Lafferty et al., 2001). This model belongs to the family of exponential or log-linear models. Its main characteristics are the possibility to include a huge number of features, like the Maximum Entropy

[2] where words are not shown for readability reason

model, but computing global conditional probabilities normalized at sentence level, instead of position level. In particular this last point results very effective since it solves the label bias problem, as pointed out in (Lafferty et al., 2001).

Given a sequence of N words $W_1^N = w_1, ..., w_N$ and its corresponding sequence of named entities $E_1^N = e_1, ..., e_N$, CRF trains the conditional probabilities

$$P(E_1^N|W_1^N) = \frac{1}{Z}\prod_{n=1}^{N}\exp\left(\sum_{m=1}^{M}\lambda_m \cdot h_m(e_{n-1}, e_n, w_{n-2}^{n+2})\right) \quad (1)$$

where λ_m are the training parameters. $h_m(e_{n-1}, e_n, w_{n-2}^{n+2})$ are the feature functions capturing conditional dependencies of entities and words. Z is a probability normalization factor in order to model well defined probability distribution:

$$Z = \sum_{\tilde{e}_1^N}\prod_{n=1}^{N} H(\tilde{e}_{n-1}, \tilde{e}_n, w_{n-2}^{n+2}) \quad (2)$$

where $\tilde{e}_{n-1}$ and $\tilde{e}_n$ are the entities hypothesized for the previous and current words, $H(\tilde{e}_{n-1}, \tilde{e}_n, w_{n-2}^{n+2})$ is an abbreviation for $\sum_{m=1}^{M}\lambda_m \cdot h_m(e_{n-1}, e_n, w_{n-2}^{n+2})$.

Two particular effective implementations of CRFs have been recently proposed. One is described in (Hahn et al., 2009) and uses a margin based training criteria for probabilities estimation. The other is described in (Lavergne et al., 2010) and has been implemented in the software *wapiti*[3]. The latter solution in particular trains the model using two different regularization parameters at the same time: Gaussian prior, also known as *l2* regularization and used in many software to avoid over fitting; and Laplacian prior, also known as *l1* regularization (Riezler and Vasserman, 2010), which has the effect to filter out features with very low scores. These two regularization parameters are used together in the model implementing the so-called *elastic net* regularization (Zou and Hastie, 2005):

$$l(\lambda) + \rho_1\|\lambda\|_1 + \frac{\rho_2}{2}\|\lambda\|_2^2 \quad (3)$$

λ is the set of parameters of the model introduced in equation 1, $l(\lambda)$ is the minus-logarithm of equation 1, used as loss function for training CRF. $\|\lambda\|_1$ and $\|\lambda\|_2$ are the *l1* and *l2* regularization, respectively, while ρ_1 and ρ_2 are two parameters that can be optimized as usual on development data or with cross validation.

[3]available at `http://wapiti.limsi.fr`

As explained in (Lavergne et al., 2010), using *l1* regularization is an effective way for feature selection in CRF at training time. Note that other approaches have been proposed for feature selection, e.g. in (McCallum, 2003). In this work we refer to the CRF implementation described in (Lavergne et al., 2010).

3.1.1 Incremental CRF Training

Despite the improvements on CRF implementations, this model remains hard to train on large amount of data when using a reasonable amount of features. Using the data described in section 2 and using features as word prefixes and suffixes, capitalization, punctuation and morpho-syntactic features, our CRF model creates more than 2 billions feature functions. Training such a model is infeasible on current machines.

Exploiting the characteristics of the CRF software *wapiti* and the definition of feature functions, we implemented a procedure for incremental training of CRF models that can be used with an arbitrary number of features. Feature functions $h_m(e_{n-1}, e_n, w_{n-2}^{n+2})$ used in our CRF models have the form:

$$h_{w,e}(e_i, w_i) = \delta(w_i^{'}, w_i) \cdot \delta(e_i^{'}, e_i) \quad (4)$$

where $\delta(.,.)$ is the Kronecker function. This particular function fires when the current word $w_i^{'}$ in the sequence matches w_i and the corresponding entity $e_i^{'}$ matches e_i. When using such simple features, there is usually no limitation on the amount of data that can be used for training. Indeed, more accurate models can be trained using complex features, using also words and entities at previous or next positions, i.e. adjacent tokens. For example:

$$\begin{aligned} h_{w,e}(e_i, w_i) \quad = \quad & \delta(w_{i-1}^{'}, w_{i-1}) \cdot \delta(w_i^{'}, w_i) \\ & \cdot\delta(e_{i-1}^{'}, e_{i-1}) \cdot \delta(e_i^{'}, e_i) \end{aligned} \quad (5)$$

This feature function fires if both words and entities at current and previous positions match. The higher accuracy reached with this type of features is paid at training time with the number of feature function generated in situations like the one reported above, and makes direct CRF model training unfeasible. The solution to this limitation is given observing that:

1. The software we use for CRF model training performs an effective feature selection thanks to *l1* regularization and can reload models for further refinements.

2. Feature functions like 5 fire if and only if both words and both entities at previous and current position matches.

The second point means that if a simple feature matching only the word (and/or entity) at current position is filtered away from *l1* regularization, it doesn't make sense to include in the training any complex feature function involving that word (and/or entity). In order to train our model using all the features, we proceed in three different steps:

1. we train a model with simple feature functions like 4
2. we search the model for simple feature functions corresponding to adjacent words (and/or entities), that in turn corresponds to complex features
3. we retrain the model where we added the complex features found at previous step

In the second step, the features kept in the model are some order of magnitude fewer in number than those generated including directly complex features in step 1, like it can be done with less data. As a consequence, the number of complex features is limited. Moreover, the fact that simple feature functions must correspond to adjacent words (and/or entities) is a further constraint for the number of added features. As we will see in section 4.1, training CRF model with this procedure provides the same prediction accuracy than what we could have training the model directly with all features.

3.2 Structured Named Entities Reconstruction

Models described in this section are well-known solutions for syntactic parsing. We report them to provide a self-contained and complet work, our main contribution in this respect is to have implemented and adapted algorithms to our task.

The model we use for entity tree reconstruction is PCFG (Booth and Thomson, 1973; Krenn and Samuelsson, 1997). There are more accurate models for the same purpose, e.g. the one used in (Charniak and Johnson, 2005). In practice, the first annotation step being carried out with CRF, which provide a high robustness on noisy data, there is no need for complex and expensive models. Moreover PCFG are quite accurate and very fast for parsing (Collins and Koo, 2005).

The input of the CRF model described in the previous section is a sentence like the one reported in section 2[4]. The output is the sequence of entities corresponding to the leaves of the tree in Figure 2, i.e. entity tree components. For example the chunk **Nations unies** (*United Nations*) is annotated by CRF as

org.adm-B{**Nations**} *org.adm-I*{**unies**}

where suffixes `-B` and `-I` (for Begin and Inside) are used to have a one-to-one correspondence between words and entities. This makes the NER task a sequence segmentation and labeling problem, without having to deal with alignment issues. From the annotation above it is immediate to reconstruct the annotation

org.adm{**Nations unies**}

Afterwards words are removed and only components are used as input of the PCFG model to reconstruct the entity tree. In our example, the input would then be:

val object name time-modifier val kind name.

PCFG production rules are extracted directly from the trees. For example from the tree in Figure 2 the following set of rules is extracted:

S ⇒ *amount loc.adm.town ... org.adm*
amount ⇒ *val object*
time.date.rel ⇒ *name time-modifier*
object ⇒ *func.coll*
func.coll ⇒ *kind org.adm*
org.adm ⇒ *name*

where the first production as been cut to keep readability and corresponds to the children of the tree root *S*. Once the rules have been generated from all trees in the training set, probabilities are estimated with simple maximum likelihood estimation as the probability of a production given the right-hand side (RHS) of the rule. The parsing algorithm using the PCFG generated from entity trees is the *Cocke-Younger-Kasami* (CYK) described in (Johnson, 1998). In order to use this algorithm production rules must be in Chomsky Normal Form (CNF), i.e. rules must have one of the two forms: i) $X_i \Rightarrow X_j X_k$; ii) $X_i \Rightarrow w$, where X are non-terminal symbols and w are terminal symbols. The corresponding probabilities are

$$p_{i \to j,k} = \frac{P(X_i \Rightarrow X_j, X_k)}{P(X_i)} \quad (6)$$

$$p_{i \to w} = \frac{P(X_i \Rightarrow w)}{P(X_i)} \quad (7)$$

[4] ***90 personnes*** *toujours présentes* ***à Atambua*** *c' est là qu'* ***hier matin*** *ont été tués* ***3 employés du haut commissariat des Nations unies*** *aux réfugiés , le* ***HCR***

There are well-known algorithms to convert a grammar into CNF, e.g. (Krenn and Samuelsson, 1997). Probabilities are then re-estimated using the Expectation Maximization algorithm called *Inside-Outside* (Krenn and Samuelsson, 1997). The latter is equivalent to the *forward-backword* algorithm for HMM (Rabiner, 1989), where *Inside* and *Outside* variables are used instead of *Forward* and *Backward* variables.

Inside variables $I_i^w(s,t)$ store the probability $P(X_i \Rightarrow^* \mathbf{w}_{s,t} \mid X_i)$, that is the probability of producing the sub-sequence $\mathbf{w}_{s,t} = w_s, ..., w_t$ of the string $\mathbf{w}_{1,T} = w_1, ..., w_T$ from the non-terminal symbol X_i, given the non-terminal symbol X_i, in any number of steps ($\Rightarrow^*$ is the closure of the production symbol $\Rightarrow$). *Outside* variables $O_i^w(s,t)$ store the probability $P(S \Rightarrow^* \mathbf{w}_{0,s}, X_i, \mathbf{w}_{t,T} \mid S)$, that is the probability of producing the subsequence $w_0, ..., w_s, X_i, w_t, ..., w_T$ from the root symbol S, given the root symbol S.

Probability re-estimation consists in computing the quantities $P(X_i \Rightarrow X_j, X_k)$, $P(X_i \Rightarrow w)$ and $P(X_i)$ in terms of *Inside* and *Outside* variables. This give a new estimation of rules probabilities that is used to re-compute *Inside* and *Outside* variables. This procedure is repeated until a convergence criterion is met, e.g. the likelihood doesn't increase significantly.

Given the two annotation steps implemented with CRF and PCFG, our system is in principle equivalent to a single system for syntactic parsing performing a "one-shot" annotation. In particular, solutions like (Charniak and Johnson, 2005) and (Collins and Koo, 2005) use POS tags as tree leaves. This has a two-fold benefit: i) introduces a generalization level over surface forms; ii) provide to the parsing algorithm only the essential information, since POS tags are directly related to syntactic constituents and are sufficient to induce the syntactic structure of a sentence. In our system, the role played by POS tags in syntactic parsing is played by entity components, annotated by CRF.In contrast, for named entity annotation it is not true that components are sufficient to induce the entity tree. Nevertheless, as we will see in next section, this solution does not prevent having good results.

4 Experiments and Results

In this section we first describe the experimental setup, and then we discuss the results. As mentioned in section 3.1, the software used for CRF models is *wapiti*.[5] The procedure for incremental training of CRF models is realized with our own software. We didn't optimize parameters ρ_1 and ρ_2 of the elastic net (see section 3.1), default values lead in most cases to very accurate models. We used a wide set of features in CRF models, in a window of [-2,+2] around the target word:

- A set of standard features like word prefixes and suffixes of length from 1 to 5, plus some *Yes/No* features like *"Does the word start with capital letter ?" "Does the word contain non alphanumeric characters ?"*, etc.
- Morpho-syntactic features extracted from the output of the tool *tagger* (Allauzen and Bonneau-Maynard, 2008)
- Features extracted from the output of the tool *WMatch* (Galibert, 2009; Rosset et al., 2008).

The output provided by *WMatch* contains detailed motpho-syntactic information as well as semantic information at the same level of named entities. Concerning the PCFG model, for preliminary studies we used our own implementation, but for this work we used the much faster implementation described in (Johnson, 1998).[6]

Concerning data, for preliminary studies carried out to validate our incremental training procedure, we used the same data used in the ESTER2 named entity detection evaluation campaign, Thus our results can be directly compared with those reported in (Galliano et al., 2009).

The final results of the 2011 Quaero evaluation campaign are obtained on the data described in section 2. The test data contains transcriptions of both broadcast news and broadcast conversation data. Results are provided on both manual and automatic transcriptions. In the last case, three different ASR systems were used in order to study robustness of the named entity detection systems with respect to different ASR errors and accuracies. These systems are referred to as **ASR1**, **ASR2** and **ASR3** and have word error rates of:

- 16.32%, 18.77%, 24.06% on broadcast news
- 23.34%, 22.99%, 29.18% on broadcast conversations
- 20.96%, 21.56%, 27.44% on the whole test data

CRF model training		Incremental procedure	
Model features	SER	**Model features**	SER
Words	27.4%	Words+MS+WM unigrams	24.6%
+ MS	26.3%	–	–
+ WM	22.8%	+ Observation bigrams	20.6%
+ MS + WM	20.0%	+ Label bigrams	20.0%

Table 3: Results of CRF models on ESTER2 task obtained with a "normal" training procedure and our incremental procedure. **MS** are morpho-syntactic features, **WM** are features extracted from *WMatch* output

Model	DEV	TEST
CRF (SER)	24.8%	26.7%
$CYK_{ref.}$ (NER)	6.8%	7.4%
CYK (SER)	30.9%	33.3%

Table 4: Results of preliminary experiments obtained with the CRF model and with PCFG separately

Additionally, since manual transcriptions were provided with punctuation, the **ASR1** output has been automatically annotated with punctuation to try to fit manual transcription conditions.

All results are reported in terms of Slot Error Rate (SER) (Makhoul et al., 1999), which has a similar definition of word error rate for ASR systems, with the difference that correct entity with wrong boundaries and wrong entity with correct boundaries are given half points.

4.1 Results

4.1.1 Evaluation of the incremental procedure

Our incremental procedure was evaluated and results are reported in table 3. We compare two models trained and tested on the ESTER2 data used for the evaluation described in (Galliano et al., 2009). The two models are based on the same features, described in previous section, but use them in two different ways: In the first model, trained with "traditional procedure", the three different type of features (words, features from *tagger* and features from *WMatch*) were integrated in three different steps, using each time unigrams and bigrams on observations and labels. The three steps are mandatory since the total amount of features would not fit into memory.

In the second model, we used directly all type of features, but generating at first only simple features. 3.1.1. In the two other training steps, we added compound features, i.e. bigrams of observations and labels, and we retrained at each step.

As we can see from results in table 3, the two models reach the same final accuracy (a SER of 20.0%), which proves that our incremental training procedure doesn't leave out meaningful features. Additionally, although we don't report training time, we can comment that CRF model training was roughly 10 times faster with our incremental procedure. This is normal since in the second and third steps only compound features corresponding to simple features kept by the first model are added, with the additional constraint that simple features must correspond to adjacent positions. As explained in sub-section 3.1.1, the simple features kept at the end of the training are some orders of magnitude fewer in number than the original features. This limits tremendously the number of compound features added in the other steps. Note also that the results shown in Table 3 are much better than those shown in (Galliano et al., 2009), compared with other solutions.

Table 5: Ranks of average score given by the CRF model to feature types

4.1.2 Features relevance

In order to understand features relevance, we report in table 5 feature types ranked by the average score given by the CRF model. Each type correspond to features at any position with respect to the target word, with label unigrams and bigrams. Unigrams are distinguished from bigrams using suffixes *-1* and *-2* respectively. Feature types *wrd* are words converted to lower case, *Wrd* are words kept with original capitalization. Feature types *Pren* are word prefixes of length n, *Sufn* are word suffixes of length n. Features extracted from *WMatch* output are indexed starting from 1. As we can see from the table, morpho-syntactic features (those marked with *POS*) receive quite low scores, especially POS tags. This point validates our intuition about using POS tags for named entity detection, pointed out in section 3. Note that feature types correspond to different layers of information added upon surface level, from less, like prefixes, to more general, like *WMatch* semantic layer. Thus, although some features may have outlier scores, the average score is a good indicator of the relevance of each feature type.

4.1.3 Models for tree-structured named entities

In table 4 we report an evaluation of the two models composing our system. In the first row we report the SER of the CRF model used in the system, taking into account only components, i.e. base entities annotated directly on words. They can be compared for the test set (TEST) with the 20% SER of table 3. We go from a SER of 20% to 26.7%, but it is important to note that the ESTER2 evaluation campaign was performed using only 17 labels, while 26.7% is obtained using 196 entity components. We can thus be satisfied by that result. In order to evaluate the robustness of the CYK algorithm on our task, we computed the Node Error Rate (NER in table 4) on reference components ($CYK_{ref.}$). The CYK module is applied on the reference components instead of those output by the CRF model. The rate of wrong tree nodes with respect to the reference trees is then computed. The NER being under 10%, we can assume that the PCFG model is robust on unseen data. This also confirms the effectiveness of using components directly, instead of the lexical surface forms. Finally we report the results obtained combining the two approaches (CRF+CYK). Errors of the CYK algorithm are summed to errors of CRF, thus we go from a SER of 24.8% and 26.7% on DEV and TEST (row 1, table 4), to 30.9% and 33.3%.

4.1.4 Official results

We report results of the 2011 Quaero named entity detection evaluation campaign (Galibert et al., 2011) in table 6, where **BN** correspond to broadcast news, **BN** to broadcast conversations and **Mrg** to the merge of these two types. Our system is indicated as *CRF+CYK*. The other two participants, *P1* and *P2*, used a system based on CRF and deep syntactic analysis, respectively.[7]

Looking at results we can see that our system outperforms the others in all cases by several points. Nevertheless error rates are quite high, over 50% on ASR output. The complexity of the task must without a doubt be taken into account. It is indeed the first time that structured named entities are handled with an automatic detection. Also the type of data used for the task, i.e. transcriptions of French broadcast data, contributes to increase the task complexity. Despite these results, our approach seems promising since it worked far better than the others in all cases.

[7]There are not more details on the other participant's systems, since they have not been published yet

Oracles VS Evaluations	**DEV**	**TEST**
CRF+CYK (SER)	30.9%	33.3%
CRF+CYK (OER)	18.6%	21.1%

Table 7: Comparison of Oracle Error Rate (OER) and SER obtained in the evaluation for DEV and TEST sets

We report a comparison of results on manual transcriptions with Oracle Error Rates (OER), i.e. results of our system using the best annotation of CRF among the 10-best hypotheses. This comparison is reported in table 7, and shows that we have a large margin for improvements on our system.

5 Conclusions

In this paper we proposed a system for structured named entity detection. We describe the definition of these structured named entities. The proposed system is based on CRF and syntactic parsing approaches, which combines the effectiveness and robustness of the former with the capability of easily and quickly parsing trees of the latter. Additionally, we proposed an incremental training procedure for CRF model, which showed to be correct and effective and allows to train CRF models with huge number of features. The proposed system participated in the Quaero evaluation campaign and obtained the best results. Although results on ASR output are not satisfactory, taking all results into account the proposed approach seems promising and encourages further studies.

Abstract

This paper investigates clausal data-driven dependency parsing. We first motivate a clause as the minimal parsing unit by correlating inter- and intra-clausal relations with relation type, depth, arc length and non-projectivity. This insight leads to a two-stage formulation of parsing where intra-clausal relations are identified in the 1st stage and inter-clausal relations are identified in the 2nd stage. We compare two ways of implementing this idea, one based on hard constraints (similar to the one used in constraint-based parsing) and one based on soft constraints (using a kind of parser stacking). Our results show that the approach using hard constraints seems most promising and performs significantly better than single-stage parsing. Our best result gives significant increase in LAS and UAS, respectively, over the previous best result using single-stage parsing.

1 Introduction

There has been a recent surge in addressing parsing for morphologically rich free word order languages such as Czech, Turkish, Hindi, etc. These languages pose various challenges for the task of parsing mainly because the syntactic cues necessary to identify various relations are complex and distributed (Tsarfaty et al., 2010; Ambati et al., 2010; Nivre and McDonald, 2008; Tsarfaty and Sima'an, 2008; Seddah et al., 2009; Gadde et al., 2010; Husain et al., 2009; Eryigit et al., 2008). There has also been a lot of interest in building ensemble systems (Zeman and Zabokrtsky, 2005; Sagae and Lavie, 2006) and parser stacking (Nivre and McDonald, 2008; Martins et al., 2009) to improve the overall parsing accuracy by combining the strengths of multiple parsers.

In this paper, we formulate clausal parsing as a two-stage setup where intra-clausal relations are identified in the 1st stage and inter-clausal relations are identified in the 2nd stage. We attempt to find out whether this two-stage parsing approach that has earlier been successful in constraint-based systems for parsing Hindi (Bharati et al., 2009) can also benefit data-driven parsing approaches (Nivre et al., 2006), and compare two ways of implementing this idea, one based on hard constraints (similar to the one used in constraint-based parsing), and one based on soft constraints (using a kind of parser stacking; (Nivre and McDonald, 2008). We show that one of the ways in which clausal parsing helps is by better learning of features that leads to improved label accuracy for Hindi. In particular we show that ambiguous case markers (or suffixes) that appear with many relations can be disambiguated successfully. We also show that the setup reduces many of the traditional MaltParser (Nivre et al., 2006) errors (McDonald and Nivre, 2007). Our results show that the approach using hard constraints seems most promising and performs significantly better than single-stage parsing.

The paper is arranged as follows. In Section 2, we introduce the clause as a basic parsing unit. Section 3 gives a brief overview of two-stage parsing. In Section 4 we discuss data-driven parsing for Hindi and present two methods for implementing two-stage parsing within this framework. Section 5 explains the experimental setup, and Section 6 discusses the results. We conclude the paper in Section 7.

2 Clauses as minimal parsing units

We begin with the observation that certain dependency relations are more likely to occur between the elements inside a clause and a different set of relations are more likely in showing dependencies across clauses. We also note that the notion of clause can be correlated with short distance and long distance dependencies.

Chiang Mai, Thailand, November 8 – 13, 2011.

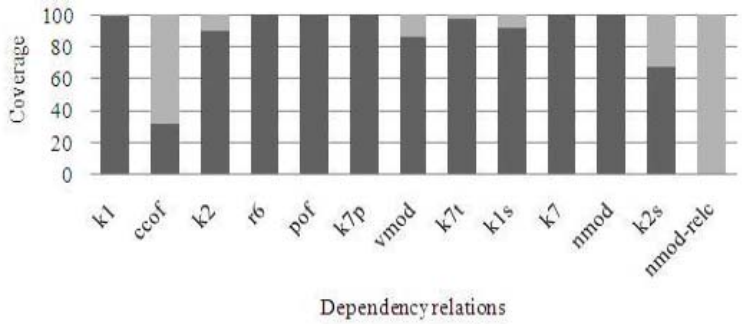

Fig 1. Dependency label distribution.

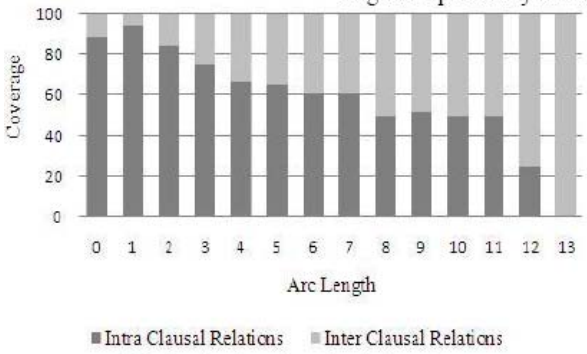

Fig 2. Arc length and relation type

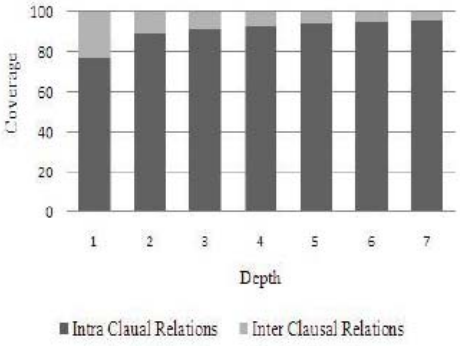

Fig 3. Depth and relation type

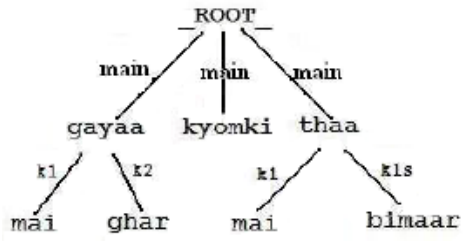
Figure 1 shows the distribution of dependency labels with respect to clause type (intra-clausal vs. inter-clausal) in the Hyderabad dependency treebank (Begum et al., 2008; Husain 2009). For ease of exposition, Figure 1 only shows the labels with considerable coverage, together amounting to 93% of all dependency label occurrences. We can see clearly that many labels like k1 [1], r6, etc. are overwhelmingly intra-clausal relation, while others like nmod-relc, ccof, etc. have an inter-clausal bias.

Figure 2 shows that short-distance dependencies are mostly intra-clausal, whereas long-distance dependencies tend to be inter-clausal. It is clear from Figure 1 and 2 that there is a clear correlation between labels and relation type on one hand and arc length and relation type on the other. Further, there is a correlation between inter- vs. intra-clausal relations with respect to depth of relations as well. Figure 3 shows that low depth dependencies are both inter-clausal (in case of complex sentences involving coordination, relative clauses, embeddings, etc.) and intra-clausal (simple sentences). It also shows that the percentage of inter-clausal relations decrease with increase in depth.

Finally, there is a correlation between clause and non-projectivity: 70% of the non-projective relations are inter-clausal (Mannem et al., 2009).

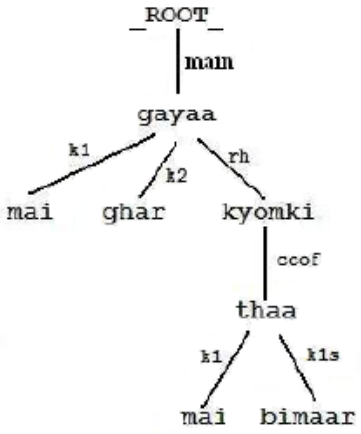
Properties such as relation type, arc length, depth, and non-projectivity are known to have specific effect on errors in data-driven dependency parsing (McDonald and Nivre, 2007). Therefore, it is worth exploring the effect of clause (when treated as a minimal unit) on dependency parsing accuracy. For all the experiment described in this paper, the following definition of clause is used: '*A clause is a group of words containing a single finite verb and its dependents'*. More precisely, let T be the complete dependency tree of a sentence, and let G be a clausal subgraph of T. Then an arc $x \rightarrow y$ in G is a valid arc, if (a) x is a finite verb; (b) y is not a finite verb; (c) there is no z such that $y \rightarrow z$, where z is a finite verb and y is a conjunct.

[1] The dependency label *k1* can be roughly translated to 'agent', *r6* is a dependency label for genitive relation, *ccof* is a relation signifying conjunction and *nmod-relc* is used for relative clause modification. For the complete description of the tagset and the dependency scheme see (Begum et al., 2008).



(a) Intra-Clausal

Fig. 4(a). 1st stage output



(b) Inter-Clausal

Fig. 4(b). 2nd stage output

3 Two-stage parsing

Two-stage parsing has been successfully used in a constraint based system for Hindi (Bharati et al., 2009, 2009b). This parser tries to analyze the given input sentence, which has already been POS tagged and chunked, in 2 stages; it first tries to extract intra-clausal dependency relations. In the 2nd stage it then tries to handle more complex relations such as those involved in constructions of coordination and subordination between clauses.

(1) *mai ghar gayaa kyomki mai*
'I' 'home' 'went' 'because' 'I'
*bi*maar *thaa*
'sick' 'was'
'I went home because I was sick'

The 1st stage output for sentence (1) is shown in Figure 4a. In Figure 4a, the parsed matrix clause subtree *mai ghar gayaa* and the subordinate clause are attached to _ROOT_. The subordinating conjunction *kyomki* is also seen attached to the _ROOT_. The dependency tree thus obtained in the 1st stage is partial, but linguistically sound. By introducing _ROOT_ we are able to attach all unprocessed nodes to it. _ROOT_ ensures that the output we get after each stage is a tree. Later in the 2nd stage the relationship between the two clauses are identified. The 2nd stage parse for the above sentence is shown in Figure 4b. The 2nd stage does not modify the parse sub-trees obtained from the 1st stage, it only establishes the relations between the clauses.

4 Two-stage data-driven parsing

Since the availability of the Hyderabad Dependency Treebank for Hindi (Begum et al., 2008) a considerable amount of work has gone into exploring various data-driven approaches for Hindi parsing (Bharati et al., 2008; Husain et al., 2009; Mannem et al., 2009b; Gadde et al., 2010). The ICON09 and ICON10 tools contests on Indian language parsing (Husain, 2009; Husain et al., 2010) have also showcased various parsing efforts and established the state-of-the-art for Hindi dependency parsing. During both these parsing contest MaltParser was used to achieve the best accuracy for Hindi.

Through the experiments described in this paper, we aim to investigate the following questions:

- What are the different ways in which one can treat clauses as minimal unit during the parsing process?
- Will this help improve parsing accuracy using MaltParser?

We now present two data-driven paradigms that incorporate the notion of clause in different ways. Both paradigms use two stages to parse a sentence, but the way the two stages interact is different.

4.1 2-stage parsing with hard constraints (2-Hard)

The basic idea behind this strategy is essentially the same as constraint-based two-stage parsing. The 2nd stage MaltParser takes as input partial 1st stage trees and establishes relationships be-

tween clauses (and conjunctions). The 1st stage predictions are mutually exclusive of the 2nd stage predictions and cannot be overridden in the 2nd stage. However, they can be used as features in the 2nd stage predictions.

We now define the input to the 2nd stage for 2-Hard more precisely, Let T be the complete tree that should be output by the 2nd stage parser and let G be the subgraph of T that is input to the second stage. Then G should satisfy the following constraint: if the arc x → y is in G, then, for every z such that y → z is in T, y → z is also in G. In other words, if an arc is included in the 1st stage partial parse, the complete subtree under the dependent must also be included. Unless this constraint is satisfied, there are trees that the second-stage parser cannot construct. This means that the 2nd stage MaltParser gets initialized with only those nodes that are attached to the _ROOT_ in the first stage parse (cf. Figure 4(a)). Figure 5 below shows the initial configuration of 2nd stage Malt for sentence 3, the input will be the 1st stage parse shown in Figure 4(a).

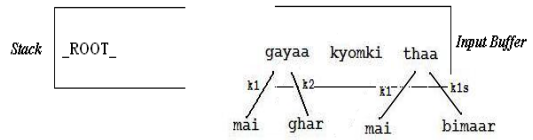


Fig 5. 2nd stage initialization using the 1st stage parse shown in Fig. 4(a)

The 1st stage and 2nd stage parser will cater to different types of constructions. Note that, given the above constraint on the 2nd stage input structures, a relative clause (though being subordinate clause) cannot be handled in the 2nd stage and will have to be handled in the 1st stage itself. We explain the handling of relative clause using sentence (2).

(2) *vaha vahaan waba puhuchaa*
'He' 'there' 'when-COREL' 'reached'
jaba sab jaa chuke the
'when-REL' 'everyone' 'go' 'had'
'He reached there when everyone had left'

Figure 6(a) shows the 1st stage output of a relative clause construction in a standard 2-stage setup. Both the relative clause and the matrix clause are seen attached to the _ROOT_, the analysis of these clauses is complete. In second stage the relation between these two clauses is established (Figure 6b). Recall that we initialize the 2nd stage of 2-Hard with the children of _ROOT_ which in this case is the finite verbs of the two clauses (Figure 6c). Now recall the constraint on the input of the 2nd stage in 2-Hard; given this constraint the 2nd stage can only establish a relation between the two verbs and not, as is correct, between the relative clause verb and a noun dependent on the matrix verb. The noun 'waba' is not present in the input buffer and can never be considered as a head of 'jaa'. Because of this reason, 2-Hard handles relative clauses through a separate classifier after the 1st stage. This parse is then fed into the 2nd stage. This system is discussed in the next section.

4.1.1 Handling relative clauses

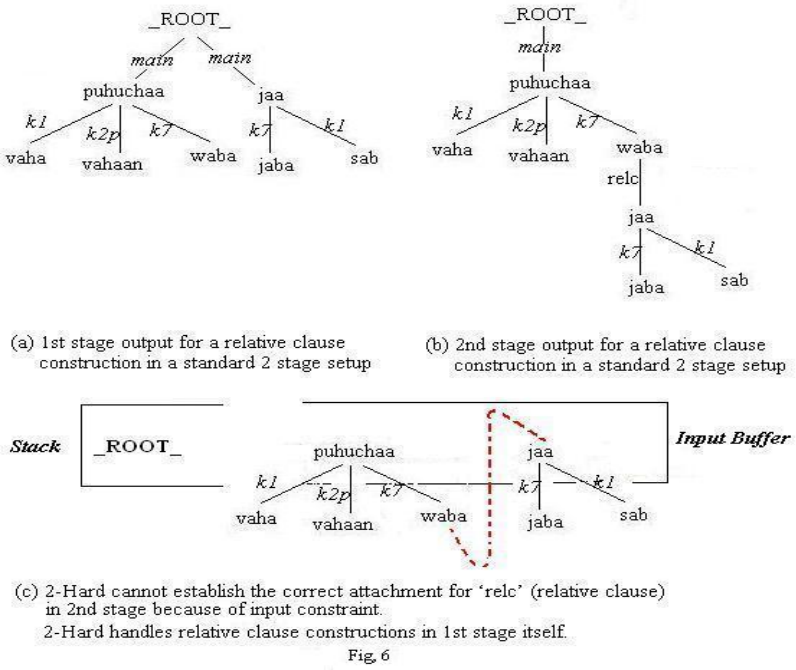
We add the relative clause relations to the 1st stage parse, before they are fed into the 2nd stage. This task comprises of two sub-tasks, a) relative clause identification from the 1st stage output and b) identifying the head of the relative clause from the matrix clause.

Most of the time, relative clause sentences in Hindi contain relative pronouns such as *jo* 'who', *jaba* 'when', *jisa* 'which' in the relative clause, which modifies an element (sometimes identified as a co-relative pronoun) in the matrix clause. The matrix clause, on the other hand, contains co-relative pronouns like *waba* 'then'. This can be seen in the example sentence (2) in the previous section. However, both these elements can be dropped (though dropping relative pronouns is rare). This information is used in doing both the sub-tasks for the relative clause relation identification.

The identification of relative clauses is rule based and depends on the presence of an exhaustive list of relative and co-relative pronouns. Such a lexically driven approach is possible because of nature of relative clause constructions in Hindi. This system has an accuracy of 94%. The errors are mainly due to the dropping of the two type of cues discussed earlier.

Having identified the relative clause in a sentence, the remaining finite clauses are considered as possible matrix clauses. The nodes in each of these clauses are considered as possible heads for the relative clause. We use a maximum entropy (MaxEnt) based boolean classifier [2] to predict whether a node is a head or not. If more than one node is predicted as the head, we pick the node with the highest classifier confidence.

[2] http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.html



(a) 1st stage output for a relative clause construction in a standard 2 stage setup

(b) 2nd stage output for a relative clause construction in a standard 2 stage setup

(c) 2-Hard cannot establish the correct attachment for 'relc' (relative clause) in 2nd stage because of input constraint.
2-Hard handles relative clause constructions in 1st stage itself.

Fig. 6

The Part-Of-Speech (POS) tag of a node, its direction and distance from the relative clause are some of the important features to identify the modified noun. Note that identification of the head noun in the absence of the co-relative pronoun can be very subjective. Table 1 shows the features that are used to train the classifier.

Feature	Description	Values
Lex	Lexical item	the lexical item
POS	POS tag	NN, RB etc..
Dir	Direction of node	-1, 1
Dist	Distance of node	4,8,12, 16, 20, 24
Cue	Relative pronoun	*jaba, jo etc..*

Table 1: Features used in maxent based node classification

Dir is given 1 if a node is to the left of the relative clause and -1 if it is on the right. The distance of the node from the relative clause, *Dist*, is actually the modulus of the distance as direction is already taken care of. Further, it is normalized to the above mentioned values to reduce the sparsity. *Cue* is given "None" if there is no relative pronoun (if it is dropped) modifying the node.

We note that when compared to Husain et al. (2009) (who also do 2 stage parsing and use clauses as hard constraint) our method differs in two significant ways. The first one is obvious; they don't handle constructions such as relative clauses etc in their setup. But more importantly, unlike Husain et al. (2009), the novel thing here is the combination of data-driven parsing and hard constraints, made possible by the new version of MaltParser that accepts partial dependency graphs as input (both during training and parsing) (cf. Figure 5).

4.2 2-stage parsing with soft constraints (2-Soft)

We can, instead of treating the output of the first-stage parser as hard constraints for the second-stage parser, treat them as soft constraints by simply defining features over the arcs produced in the first stage and making a complete parse in the second stage. Technically, this is the same technique that (Nivre and McDonald, 2008) used to integrate Malt and MST, called *guided parsing* or *parser stacking*. In this setup we 'guide' Malt with a 1st stage parse by Malt. The additional features added to the 2nd stage parser during 2-Soft parsing encode the decisions by the 1st stage parser concerning potential arcs and labels considered by the 2nd stage parser, in particular, arcs involving the word currently on top of the stack and the word currently at the head of the input buffer. For more details on the guide features for MaltParser, see (Nivre and McDonald, 2008). Note again that, unlike the standard two-stage setup the 1st stage relations can now be overridden during the 2nd stage (because we are guiding), and unlike the standard guided parsing setup a parser guides with only 1st stage relations.

Unlike the 2-stage parsing, guided parsing parses complete sentences twice. The results from one parser are used to extract features that guide the second parser. In 2-stage parsing, different components of a sentence are parsed in two stages. Interestingly, Gadde et al. (2010) have proposed an alternative way of incorporating clauses as soft constraint by using clause boundary and clausal head/non-head features during parsing. Of course, theirs is not a 2-stage setup.

5 Experimental setup

All the results are reported for Hindi. We use the Hindi data set that was released as part of ICON10 parsing contest (Husain et al., 2010). The training set had 2972 sentences, the development and test set had 543 and 321 sentences respectively. The parser models were trained using 5-fold cross validation; all the results are also reported for the cross-validation data. The setup used by (Ambati et al., 2010) for MaltParser[3] is used as our baseline.

Recall that the 1st stage and 2nd stage parser of 2-Hard will cater to different types of constructions. This is sometimes also reflected in the features that get selected for each stage when compared to the Baseline settings. One such case was the absence of morphological features of lexical items in the 2nd stage for 2-Hard. The morphological properties such as suffix, category, case, etc. are crucial in establishing relations between verbs and its arguments. This in 2-Hard will be handled in the 1st stage. The relations in the 2nd stage do not require such features. On the other hand, the POS category and the lexical item of the elements in Stack and Input buffer are more crucial for 2nd stage relations than for the 1st stage specific relations. This is reflected in the selection of 'lemma' of the word under consideration in 2nd stage and not in baseline.

Both 2-Soft and 2-Hard 1st stage parsers are trained on a modified treebank. The original trees are transformed into 1st stage trees. This is done by using the clause definition described in Section 2. For example, the 1st stage tree for sentence 3 is shown in Figure 4 (a). On the other hand, a normal single stage parser (our baseline parser) is trained on the full tree that looks like Figure 4 (b).

[3] MaltParser (version 1.3.1)

6 Results and discussion

Table 2 shows the performance of the different parsers with 5-fold cross-validation. In all tables statistical significance with respect to baseline is marked with *. Significance is calculated using McNemar's test ($p <= 0.05$). These tests were made with MaltEval (Nilsson and Nivre, 2008).

	LAS	UAS	LA
Baseline	75.02	88.82	77.80
2-Soft	75.24	88.92	78.00
2-Hard	**75.65***	**89.1***	**78.73***

Table 2: Overall parsing accuracy (5-fold cross-validation)

We see that both 2-Soft and 2-Hard outperform the Baseline result. However, only 2-Hard is statistically significant with that of Baseline for LAS, UAS as well as LS. 2-Soft, though giving a minimal improvement in the accuracies, is not statistically significant with the baseline. However, on analyzing the output parses of all the three setups, we found clear and similar improvement patterns (listed below) in case of both 2-Hard and 2-Soft. This led us to look at the sentences having at least two clauses, where the effect of the proposed approaches is more prominent. These constitute 50.4% of the total sentences in the data. Table 3 below shows the parsing accuracies of all the setups on these complex sentences.

	LAS	UAS	LA
Baseline	74.87	88.82	77.44
2-Soft	**75.25***	89.03	**77.78***
2-Hard	**75.83***	**89.36***	**78.85***

Table 3: Parsing accuracy on complex sentences (sentences having >1 finite clauses) (5-fold cross-validation)

Interestingly, the improvements in both 2-Soft and 2-Hard are better than those shown in Table 2. Also, 2-Soft is now statistically significant compared to the Baseline w.r.t. LAS and LS. Overall, both the approaches seem to perform better for labels over attachments. To analyze the results further, we breakdown the overall accuracy (shown in Table 2) into inter-clausal and intra-clausal accuracies. Table 4 below shows these results.

	LAS		UAS		LA	
	Intra	Inter	Intra	Inter	Intra	Inter
Baseline	72.18	85.43	89.05	87.98	75.26	87.13
2-Soft	**72.44**	85.54	**89.13**	88.16	**75.49**	87.17
2-Hard	72.36	**87.71**	88.87	**90.10**	75.47	**90.68**

Table 4: Overall accuracy for intra- and inter-clausal dependency relations

Table 4 shows some interesting facts. 2-Hard performs far better than Baseline and 2-Soft in case of inter-clausal relations, where as its effect is less for intra-clausal relations. 2-Soft, on the other hand, gives the best accuracies for intra-clausal relations over all the metrics. Note that the 2nd stage in 2-Soft approach has the flexibility to modify the dependencies given by the 1st stage parse. This could be the possible reason for 2-Soft performing better than 2-Hard for the intra-clausal relations, which are large in number as well as consisting of more deviant patterns compared to the inter-clausal relations.

These experiments show us that there is a clear pattern in cases where parsing benefits from 2-Soft and 2-Hard. These benefits are spread over both 1st stage and 2nd stage. These cases are:

1. Better identification of some relations with deviant/ambiguous postpositions in the 1st stage. For example, when 'se' appears for beneficiary/cause, instead of its default usage for instrument. Table 5 shows the label identification for some frequent postpositions.
2. Better handling of non-finite verbs in the 1st stage
3. Better handling of NULL nodes in the 2nd stage. Most NULL nodes are cases of ellipses where a syntactic heads such as finite verb or a conjunct is missing. Most of these cases fall into 2nd stage and are being better handled there.
4. Better handling of some 2nd stage specific constructions, e.g. clausal complements.

Closely related to the above four points is the performance of the clausal setups with respect to arc length, depth and non-projectivity. It is known that Malt suffers on the dependencies closer to the root (less depth) due to error-propagation. Also, Malt suffers at long distance dependencies because of local feature optimization (McDonald and Nivre, 2007). In other words, for Malt, depth and errors are negatively correlated while arc-distance and errors are positively correlated.

Figure 7 shows the LAS of relations at various arc-lengths for the Baseline and clausal setups. Figure 8 shows the performance of relations at different depths. The 2nd stage of 2-Hard considers the heads of the partial trees produced by the 1st stage as the nodes (minimal parsing unit), which reduces the arc-length of the inter-clausal dependencies. Hence, as the arc-length increases, the advantage of 2-Hard becomes more pronounced.

Postposition	Baseline	2-Hard/ 2-Soft
0		✓
meM		✓
para	✓	
GEN		✓
ko	✓	
se		✓

Table 5: Label identification comparison between Baseline and the clausal approaches for ambiguous postpositions. ✓ signifies better performance. 0 and GEN signify null postposition and genitive postpositions respectively

By distinguishing intra-clausal structures from inter-clausal structures, the 2-Hard setup is using shallower trees and is able to take better global decisions by using more contextual information. It is expected to reduce the error propagation for the low-depth dependency relations. This effect is clearly seen in Figure 8, where for less depth 2-Hard outperforms Baseline. Cases (3) and (4) above reflect this.

Cases (1) and (2) on the other hand show that the clausal setups also effects 1st stage performance by learning verbal arguments (both complements and adjuncts) better. It is known that MaltParser has a rich feature representation but with increase in sentence length its performance gets affected due error propagation. By treating a clause as a parsing unit we reduce this error propagation as the features are being exploited properly.

It was found that both the clausal setups did not help in reducing the non-projective relations. As all the setups use the Arc-Eager parsing algorithm, they fare equally badly in handling non-projectivity. There were some sentences where non-projectivity got removed in the 1st stage,

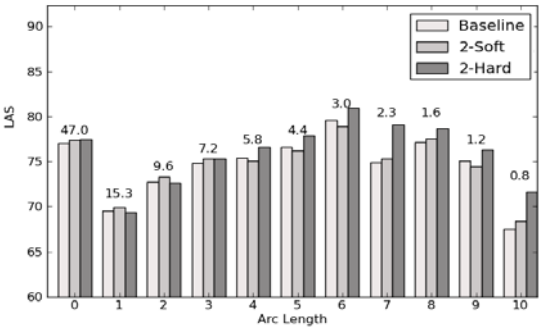


Fig. 7. LAS at arc-length (1-10) for Baseline, 2-Soft and 2-Hard. The numbers above the bars represent the % of relations at respective arc lengths.

however the non-projective arc reappeared in the 2nd stage, this happened in the case of paired connective constructions (cf., Mannem et al., 2009). We are yet to investigate if pseudo-projective parsing in the 2nd stage might prove beneficial in such cases.

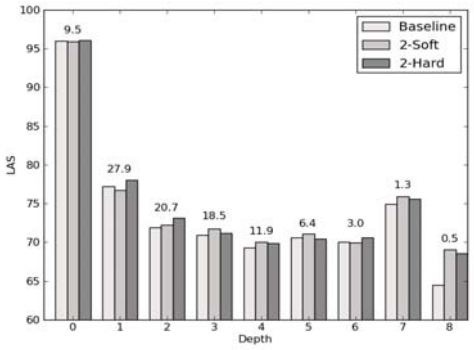

Fig. 8. LAS at depth (1-7) for Baseline, 2-Soft and 2-Hard. The numbers above the bars represent the % of relations at respective depths.

7 Conclusion

This paper investigated clausal data-driven dependency parsing. We implemented this idea using two methods, one based on hard constraints (similar to the one used in constraint-based parsing), and one based on soft constraints (using a kind of parser stacking). Our results showed that the approach using hard constraints seems most promising and performs significantly better than single-stage parsing. We showed that 2-Hard benefits from parsing shallower trees, and shorter arc lengths when compared to the Baseline. We also showed that by better learning of features many case markers that appear with more than one relation can be disambiguated successfully using both 2-Hard and 2-Soft. 2-Hard seems to perform better than 2-Soft in case of inter-clausal relations w.r.t. all the evaluation metrics, whereas 2-Soft is doing good in intra-clausal relations. This gives us a future direction to explore a combination of 2-Hard and 2-Soft for inter and intra-clausal relations respectively, to see if one can benefit from the other.

Since the improvement in LS and LAS in both 2-Hard and 2-Soft seems to be more than in the UAS, it would be interesting to see the effect of clausal parsing on label identification and attachments separately. To do this, we plan to explore sequential parsing by using different feature models for transitions and labels, as the current parsing schemes do both attachments and labels at the same time.

Abstract

In this paper we study the word-reordering problem in the decoding part of statistical machine translation, but independently from the target language generating process. In this model, a permuted sentence is given and the goal is to recover the correct order. We introduce a greedy algorithm called *Local-*(k, l)*-Step*, and show that it performs better than the DP-based algorithm. Our word-reordering algorithm can be used in the statistical machine translation process for improving the quality of the translation. Furthermore, motivated by the rank evaluation method, we introduce a novel way for evaluating the results of word-reordering by calculating the inversion pair cardinality.

1 Introduction

Statistical machine translation is a machine translation method based on statistical models, which is in contrast with rule-based machine translation as well as with example-based machine translation. The most commonly used model in statistical machine translation is the source-channel model built by Brown et. al. (1993). In their proposal of translation between English and French, English strings are generated according to some stochastic process and then transformed stochastically into French strings. Therefore, to translate French to English, it is needed to search for an English source string that is most likely according to the English language model (Ponte and Croft, 1998) and the channel model. This process of translation is called decoding. Usually, a decoding process in statistical machine translation is combined with two sub-processes (Chang and Toutanova, 2007; Koehn, Och and Marcu, 2003): generating the words or phrases of the target language, and deciding the correct order of the words or phrases to get a desired target language sentence. For some language pairs, such as English and Chinese, the word-reordering problem is really hard to solve, as the target word order differs a lot from the source word order and little information about the target word order is obtainable from the source sentence. This is because the grammars of English and Chinese differ from one another significantly.

Language model has been successfully applied in the word-reordering process of statistical machine translation. Generally speaking, a language model assigns a probability to a sequence of words according to some probability distribution. A sentence then gets a score under the language model by means of standard conditional probability. Knight (1999) studied this abstract problem and proved that the word-reordering (also called word-replacement) problem under bigram language model is **NP**-hard.

In this article, we study the word-reordering problem under trigram language model in the decoding part of statistical machine translation, but independently from the target language generating process. More precisely, suppose we want to translate a sentence from one language to another, and some methods have been applied to generate all the target words, whereas the words need reordering because two languages may have totally different grammars (like English and Chinese). Thus, our goal is to recover the correct, or reasonable, word order of the target sentence.

We reduce this problem to the traveling salesman problem (TSP) in 3-uniform hypergraphs. We show that by some modification, the dynamic-programming (DP) based algorithm for TSP (Held and Karp, 1962) can be used in solving this generalized problem. Nevertheless, the time complexity of this DP-based algorithm is exponential in the number of words in the sentence, and is thus unreasonable in practice. We design a class

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1288–1293,
Chiang Mai, Thailand, November 8 – 13, 2011.

of greedy algorithms called **Local-(k,l)-Step**, parameterized by k and l. Roughly speaking, the **Local-(k,l)-Step** algorithm finds, in each step, k words which maximize the language model score, and then add the first l words to the partial sentence. For small k, say $k < 5$, this algorithm runs much faster then the DP-based algorithm.

We also propose a novel way to evaluate the results of word-reordering, motivated by the rank (ordering) evaluation measures in information retrieval. Standard retrieval evaluation measures, such as Mean Average Precision (MAP), are used for evaluating the results of retrieval systems. The reordering or ranking of items is an important task in many real-world applications, and it is needed to compare two different orderings of the same item list. One commonly-used measure is the Kendall's tau coefficient (Kendall, 1938) which uses the notion of *inversion pairs*.

Motivated by these existing methods, we design the following evaluation process for word-reordering: Given a sentence outputted by the algorithm, we regard it as a permutation of the correct sentence, and count the the number of inversion pairs in it, which can be seen as the distance between the result sentence and the correct one. The notion of inversion pairs is often used to measure the distance between permutations. Due to the special structure of our model, it is also a proper measurement of the quality of word-reordering results. Note that to calculate the number of inversion pairs, the correct sentence, or a "standard answer", should be given as well. This can be done by the following design of experiments: We choose 1500 English sentences from http://www.nlp.org.cn, and randomly permute each sentence. Then, the permuted sentences are given as the input to the word-reordering problem, while the original sentences are just "standard answers" which will be used in the evaluation.

We implement both the DP-based algorithm and the **Local-(k,l)-Step** algorithm, and evaluate their results according to their performance on the chosen sentences. From the comparison, it is shown that for well chosen parameters k and l, the **Local-(k,l)-Step** algorithm performs even better than the DP-based algorithm. This seems to contradict with the fact that the latter solves the problem exactly while the former only obtains an "approximate" solution. This, however, is not a real problem since the score under the language model is not always compatible with that under the evaluation using inversion pairs. In fact, neither of the two evaluation methods can accurately measure the "quality" or "correctness" of sentences, because the human language itself comprises many other perspectives that cannot be qualified or characterized exactly by current techniques. It is possible that a sentence that makes no sense obtains a higher language model score than that of a normal sentence in real world.

Finally let us mention that, although throughout the paper we talk about the word-based reordering model, our algorithms can be easily modified to be applicable in the re-ordering process of statistical machine translation whose working unit is phrase (Koehn, Och and Marcu, 2003).

This paper is organized as follows: Section 2 defines the word-reordering model rigorously, and introduces the dynamic programming algorithm and the greedy **Local-(k,l)-step** algorithm. In Section 3 we show the experimental results as well as the evaluation based on the inversion pair cardinality. The last section concludes the whole article with some remarks and future work.

2 The Word-reordering Model

In the word-reordering model, a disordered English sentence is given and the goal is to find the most reasonable order. For example, given the sentence "overrate to is importance their it easy", the best answer should be "It is easy to overrate their importance."

It is hard to establish a standard criterion for evaluating the "quality" of a sentence. In practice, language model is used as a statistical tool to help people find approximate solutions. For our purpose, we adopt the commonly-used trigram source model, given by $lm(w_0|w_1,w_2)$ for all possible English words w_0, w_1 and w_2. Given a disordered sentence, we want to rearrange its words in order to get a maximum score according to the trigram source model. This can be theoretically formalized as the following search problem.

Word-reordering Problem
Input:

1. A dictionary $D = \{d_i \mid 1 \le i \le m\}$;
2. A trigram source model $\{lm(w_i \mid w_j, w_k) : 1 \le i, j, k \le m\}$;
3. A set of words $S = \{s_1, s_2, \ldots, s_n\} \subseteq D$.

Output: A sentence $s_{i_1} s_{i_2} \ldots s_{i_n}$, where $(i_1, i_2, \ldots, i_n)$ is a permutation of $\{1, 2, \ldots, n\}$,

such that $\prod_{j=3}^{n} lm(s_{i_j} \mid s_{i_{j-1}}, s_{i_{j-2}})$ is maximized.

A similar problem with bigram source model $\{lm(w_i|w_j)\}$ is proved to be NP-hard by Knight (1999) using a reduction from the famous HAMILTONIAN PATH problem. The NP-hardness of this problem with trigram source model can be proved analogously.

Despite the hardness result, we can still cope with many instances in practice, since a sentence is usually not so long. The trivial way is to enumerate all $n!$ permutations and find the one achieving maximum score, which takes $O(n \cdot n!)$ time. We will describe better ways for solving it.

2.1 Dynamic Programming

An instance of the TSP problem consists of a directed graph $G = (V, E)$ and a cost function $c : E \to \mathbf{R}$, and the goal is to find a path of minimum cost which visits each vertex in V exactly once (that is, a Hamiltonian path). Note that the word-reordering problem can be reduced to TRAVELING SALESMAN PROBLEM (TSP) with a slight modification that each edge in the graph is a triple instead of a pair (i.e., TSP in 3-uniform hypergraphs). The reduction is as follows: Construct a vertex v_i for each word $s_i \in S$, and then add an hyperedge (v_i, v_j, v_k) with cost $-\ln(lm(w_k|w_i, w_j))$ for every triple (v_i, v_j, v_k). Then, finding a sentence s with maximum score is equivalent to finding a minimum cost Hamiltonian path in this hypergraph, where the cost of a path is defined to be the sum of costs of all triples containing three consecutive nodes in the path. We can assume that the graph is complete (i.e., all possible edges (v_i, v_j, v_k) exist) by adding dummy edges with sufficiently large costs.

Held and Karp (1962) designed a dynamic-programming based (DP-based) algorithm for the original TSP which runs in time $O(2^n \cdot n^2)$, n being the number of vertices in the graph. Their algorithm runs iteratively on all subsets of vertices and finds a minimum cost tour in that subset, with the start and end points specified. We will describe a similar algorithm for solving TSP on 3-uniform hypergraphs, which can be directly applied to the word-reordering problem.

DP-based algorithm for TSP in 3-uniform hypergraphs (3-uni-DP)

Input: A 3-uniform hypergraph $G = (V, E)$; a cost function $c : E \to \mathbf{R}$.

Output: A minimum cost Hamiltonian path.

Algorithm:

- Return $fail$ if $|V| < 3$.
- For each triple (v_i, v_j, v_k) where all three vertices are pairwise distinct, let $C(\{v_i, v_j, v_k\}, v_i, v_j, v_k) = c(v_i, v_j, v_k)$.
- For $m = 4$ to $|V|$ do
  - For each tuple (V', v_1, v_2, v_3) where $\{v_1, v_2, v_3\} \subseteq V' \subset V$ and $|V'| = m$, compute: $C(V', v_1, v_2, v_3) = \min_{v_4 \in V'} \{C(V' \setminus \{v_3\}, v_1, v_4, v_2) + c(v_4, v_2, v_3)\}$
- Find the vertices v_1, v_2, v_3 for which $C(V, v_1, v_2, v_3)$ is minimized. Trace back to find the corresponding path.

The algorithm **3-uni-DP** runs in time $O(2^n \cdot n^4)$, where $n = |V|$. In each step it computes $C(V', v_1, v_2, v_3)$, which stands for the minimum cost Hamiltonian path in V' that starts with v_1 and ends at (v_2, v_3), by enumerating the third vertex on the path from end and concatenating the shorter path and the last edge. It is not hard to see that this algorithm correctly computes the minimum cost Hamiltonian path in 3-uniform hypergraphs.

2.2 Local-(k, l)-Step Algorithm

The DP-based algorithm **3-uni-DP** solves the word-reordering problem exactly but runs in exponential time, which is unaffordable for long sentences. An idea for reducing the running time is to consider the problem "locally". In each step, we look for a fixed number of unvisited points and try to minimize the cost of the "local path" in which these points are involved. More specifically, we seek for k unvisited points $v_2, v_3, \ldots, v_{k+1}$ minimizing $\sum_{i=0}^{k-1} c(v_i, v_{i+1}, v_{i+2})$, where v_0 and v_1 are the last two nodes in the current partial path. Then, we add the first l points to our partial path, for some $l \leq k$. We give a more formal description as follows.

Algorithm Local-(k, l)-Step

Input: A 3-uniform hypergraph $G = (V, E)$; a cost function $c : E \to \mathbf{R}$.
Output: A minimum cost Hamiltonian path.

Algorithm:

Do the following for all vertex pairs (v_0, v_1) to find the best solution:

- $V' \leftarrow V \setminus \{v_0, v_1\}$.
- $PartialPath \leftarrow (v_0, v_1)$.
- While $|V'| \geq k$ do
  - Find k distinct vertices $v_2, v_3, \ldots, v_{k+1}$ in V' which minimizes $\sum_{i=0}^{k-1} c(v_i, v_{i+1}, v_{i+2})$.
  - Add $(v_2, \ldots, v_{l+1})$ to the end of $PartialPath$.
  - $V' \leftarrow V' \setminus \{v_2, v_3, \ldots, v_{l+1}\}$.
- In case $V' \neq \emptyset$, perform an exhaustive search to find the best order to visit the remaining vertices in V', and add this to $PartialPath$.

Return the best $PartialPath$ (with the minimum cost) over all start pairs (v_0, v_1).

The algorithm **Local-**(k, l)**-Step** runs in time $O(n^2 \cdot n^k \cdot \frac{n}{l}) = O(n^{k+3}/l)$, where n is the number of vertices in the graph. This is efficient in practice if we choose a small k, say, $k < 5$. It should be noticed that this algorithm cannot be a constant-factor approximation algorithm for TSP, since for any constant k it runs in polynomial time, and thus cannot approximate TSP within any constant ratio unless **P** = **NP**. However, it may perform well on real-world instances of the word-reordering problem.

In fact we will show that, for some well chosen parameters k and l, the algorithm **Local-**(k, l)**-Step** performs even better than the algorithm **3-uni-DP**. This seems to contradict with the fact that the latter solves the problem optimally while the former only looks for a reasonable solution. However, this is not a problem because our word-reordering model itself cannot catch accurately the quality of a sentence. Thus, when evaluating the outcomes of our algorithms, it is more proper to use some other measurements, like the *inversion pair* which will be introduced later. The reason why this measurement cannot be adopted in the design of our algorithms is that it can only be calculated if a standard answer to the problem is given.

3 Experiments

3.1 The trigram language model training

In order to build a reasonable trigram language model for the experiment, we download the third version of the Europarl corpus (Koehn, 2005) which is extracted from the proceedings of the European Parliament. This data set is usually used as a base material in statistical machine translation contest or other research projects involving European languages, and the English part can be used for training a trigram English language model. There are about 0.307 million English sentences in the material. Thus, the trigram language model built by SRILM (Stolcke, 2002) can reflect the properties of the English language.

3.2 The reordering experiment

How to evaluate the results of our algorithms is a key problem in our research, as there is no standard for testing the accuracy of word-reordering. Usually, the reordering of words in sentences serves as a subprocess in statistical machine translation, especially in the decoding step. All the existing methods and standards are designed to test the accuracy of the translation results, but not the single process of word-reordering. Therefore, we designed an experiment model and a testing principle for our own purpose, shown as follows.

First, we choose 1500 English-Chinese sentence pairs (from http://www.nlp.org.cn) as the collection of standard answers. We then choose from them all sentences of length less than 10 as our data set. For every sentence in this data set, we generate a disordered sentence by performing a random permutation on the set of words in the original sentence. For example, if the original sentences is "sometimes you are overly frank", one possible disordered sentence could be "overly are sometimes frank you". The original sentence is used as a standard answer for later evaluation. We run the **Local-**(k, l)**-Step** algorithm on all the permuted sentences for all pair of parameters (k, l) such that $1 \leq l \leq k \leq 4$. We also run the **3-uni-DP** algorithm on these sentences for the sake of contrast.

There is another issue considering the start of a sentence. Since the language model includes the possibility of a word being the first word of a sentence, we may add a special "start symbol" to every disordered sentence and force it to be the first word in the output sentence. This is easy to implement in practice, and will make the result more reasonable. In all the experiments we adopt this setting.

Now comes the evaluation part. How to measure the quality of our results, or, the distances

between the output sentences and the standard answers? It turns out that any method for determining the distance between permutations also works in our model. The concept of *inversion pairs* is usually used to measure the distance between two permutations, and is thus brought into our experiments. Let σ be a permutation of $\{1, 2, \ldots, n\}$. A pair of indices (i, j), where $1 \leq i < j \leq n$, is called an *inversion pair* of σ if $\sigma(i) > \sigma(j)$. The total number of inversion pairs of σ, also called *inversion pair cardinality* of σ, is a proper measurement of the distance between σ and the identity permutation $(1, 2, \ldots, n)$. Although distances between two arbitrary permutations can be similarly defined, this measurement already suffices for our purpose since we only need to calculate the distance between a permuted sentence and the standard answer.

Take again the sentence "sometimes you are overly frank" as an illustration. We mark this sentence as the identity permutation $(1, 2, 3, 4, 5)$. If the disordered sentence is "sometimes are you frank overly", it should be associated with the permutation $(1, 3, 2, 5, 4)$, and thus has 2 inversion pairs in total (3 comes before 2, and 5 appears before 4).

In this way we can calculate the number of inversion pairs to measure the degree of disordering. For every pair of parameters (k, l) used in the **Local-**(k, l)**-Step** algorithm, we count the number of output sentences which have smaller inversion pair cardinality than the corresponding randomly permuted sentences. Call this number $Better(k, l)$. We then choose the pair (k, l) which maximizes $Better(k, l)$, denoted by (k_0, l_0), and adopt it as the proper parameter for our algorithm. We also calculate $Better(DP)$, which is the number of sentences outputted by the **3-uni-DP** algorithm having smaller inversion pair cardinality than the corresponding disordered ones.

All the experiments are conducted repeatedly for 5 times, each time generating different randomly disordered sentences. The final result $Better(DP)$ and $Better(k, l)$ are the average of the results of 5 independent experiments. These results are shown in Tables 1 and 2.

3.3 Analysis

The experimental result shows that setting $(k, l) = (4, 3)$ gives the best outcome among all chosen parameters. Thus we let $k_0 = 4$ and $l_0 = 3$. It is a little surprising that $Better(DP)$ is less than $Better(k_0, l_0)$, which indicates that the exact algorithm performs worse than the "approximate" algorithm. As explained before, this is due to our lack of modeling the "quality" or "correctness" of sentences. It is possible that a sentence with high score under trigram language model makes little sense, and a normal sentence appearing in real word obtains a low score under this language model. The algorithm **Local-**(k, l)**-Step**, on the other hand, makes use of the locality of English sentences, and thus it should be expected to perform well.

4 Conclusions

In this paper, we study the word-reordering problem in the decoding process of statistical machine translation. We adopt the commonly-used trigram language model, and abstract the word-reordering problem as instances of Traveling Salesman Problem in 3-uniform hypergraphs. We show that Held and Karp's dynamic-programming based algorithm for solving TSP (in normal graphs) can be adapted to solve this problem. We also design a greedy algorithm called **Local-**(k, l)**-Step**, parameterized by k and l, which has a faster running time

but gets a non-optimal solution, where by optimal we mean achieving maximum score under the trigram language model.

We implement both algorithms and conduct some experiments. To evaluate the results, we adopt the concept of inversion pairs to measure the distances between the standard answers and the sentences outputted by the algorithms. From the experimental results, we find that setting $k = 4$ and $l = 3$ makes the **Local-**(k, l)**-Step** algorithm perform best. Moreover, the result obtained by the greedy algorithm is even better than that of the dynamic-programming based algorithm. This is because we are not able to model the quality and correctness of sentences accurately, and thus a sentence with maximum score under trigram language model is not necessarily a best answer to the reordering problem.

Since we study the word-reordering problem independently from the target language generating process, one future direction for our research is to combine the two parts, namely, predicting the collection of words and deciding the correct order of the target sentences, together to design better decoding algorithms.

Abstract

Word alignment is a fundamental step in machine translation. Current statistical machine translation systems suffer from a major drawback: they only extract rules from 1-best alignments, which adversely affects the rule sets quality due to alignment mistakes. To alleviate this problem, we extract hierarchical rules from *weighted alignment matrix* (Liu et al., 2009). Since the sub-phrase pairs would change the inside and outside areas in the weighted alignment matrix of the hierarchical rules, we propose a new algorithm to calculate the relative frequencies and lexical weights of hierarchical rules. To achieve a balance between rule table size and performance, we construct a scoring measure that incorporates both frequency and lexical weight to select the best target phrase for each source phrase. Experiments show that our approach improves BLEU score by ranging from 1.4 to 1.9 points over baseline for hierarchical phrase-based, and 1.4 to 1.5 points for tree-to-string model.

1 Introduction

Word alignment plays an important role in statistical machine translation (SMT). Most SMT systems, not only phrase-based models (Och and Ney, 2004; Koehn et al., 2003; Xiong et al., 2006), but also syntax-based models (Chiang, 2005; Liu et al., 2006; Galley et al., 2006; Huang et al., 2006; Shen et al., 2008), usually extract rules from word aligned corpora. However, these systems suffer from a major drawback: they only extract rules from 1-best alignments, which adversely affects the rule sets quality due to alignment mistakes.

Typically, syntax-based models are more sensitive to word alignments because they care about inside (i.e., subtracted phrases). Figure 1(a) shows an alignment of a sentence pair. Since there is a wrong link (*de*, *of*), we could not extract many useful hierarchical rules such as (*zhongguo* X_1 *jingji*, *China* X_1 *economy*).To alleviate this problem, a natural solution is to extract rules from n-best alignments (Venugopal et al., 2008).

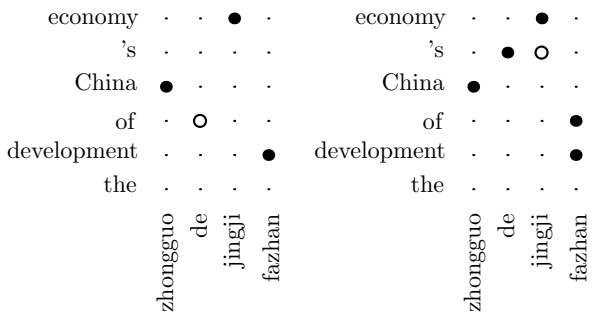

Figure 1: (a) One alignment of a sentence pair; (b) another alignment of the same sentence pair. Here coreless dots denote wrong links.

However, using n-best alignments still face two major challenges. First, n-best alignments have to be processed individually although they share many links, see (*zhongguo*, *China*) and (*jingji*, *economy*) in Figure 1. Second, regardless of probabilities of links in each alignment, numerous wrong rule would be extracted from n-best alignments. For example, a wrong rule (X_1 *de jingji*, *of* X_1 *'s economy*) would be extracted from the alignment in Figure 1(a).

Since Liu et al. (2009) show that weighted alignment matrix provides an elegant solution to these two drawbacks, we apply it to the hierarchical phrase-based model (Chiang, 2005) and the tree-to-string model (Liu et al., 2006; Huang et al., 2006). While such an idea seems intuitive, it is non-trivial to extract hierarchical rules from weighted alignment matrices.

Our work faces two major challenges. The first is how to calculate the relative frequencies and lex-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1294–1303,

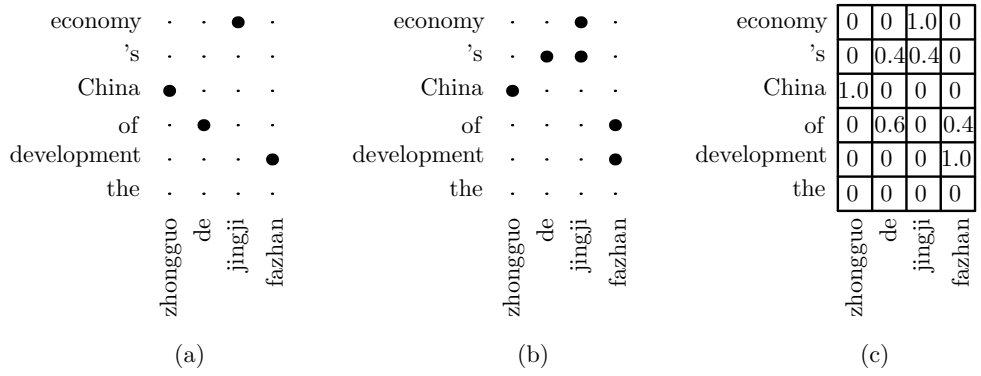

Figure 2: (a) One alignment of a sentence pair; (b) another alignment of the same sentence pair; (c) the resulting weighted alignment matrix that samples the two alignments, of which the initial probabilities are 0.6 and 0.4 respectively.

ical weights of the rules with non-terminals (NTs). The sub-phrase pairs that are replaced with NTs in a rule, would change the inside and outside areas in the weighted alignment matrix of the rule. In addition, the sub-phrase pairs have their own probabilities and we should incorporate them to better estimate the probabilities of the hierarchical rules. Therefore, the calculations of relative frequencies and lexical weights for hierarchical rules are more complicated.

Another challenge is how to achieve a balance between performance and rule table size. Note that given a source phrase, there would be plenty of "potential" candidate target phrases in weighted matrices (Liu et al., 2009). If we retain all of them, these phrase pairs would produce even more hierarchical rules. For computational tractability, we need to design a measure to score the phrase pairs and wipe out the low-quality ones.

We propose a new algorithm to calculate the relative frequencies of rules, and construct a measure that incorporates both frequency and lexical weight to score target phrases. Experiments (Section 4) show that our approach improves BLEU score by ranging from 1.4 to 1.9 points over baseline for hierarchical phrase-based, and 1.4 to 1.8 points for tree-to-string model.

2 Weighted Alignment Matrix

A weighted alignment matrix (Liu et al., 2009) m is a $J \times I$ matrix to encode the probabilities of n-best alignments of the same sentence pair. Each element in the matrix stores a link probability $p_m(j,i)$, which is estimated from an n-best list by calculating relative frequencies:

$$p_m(j,i) = \frac{\sum_{a \in \mathcal{N}} p(a) \times \delta(a,j,i)}{\sum_{a \in \mathcal{N}} p(a)} \quad (1)$$

where

$$\delta(a,j,i) = \begin{cases} 1 & (j,i) \in a \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

Here $\mathcal{N}$ is an n-best list, $p(a)$ is the probability of an alignment a in the n-best list. The numbers in the cells in Figure 2(c) are the corresponding p_m.

Since $p_m(j,i)$ is the probability that f_j and e_i are aligned, the probability that the two words are not aligned is

$$\bar{p}_m(j,i) = 1.0 - p_m(j,i) \quad (3)$$

Figure 2 shows an example. The probability for the two words *zhongguo* and *China* being aligned is 1.0 and the probability that they are not aligned is 0.0. In another way, the two words are definitely aligned.

Given a phrase pair ($f_{j_1}^{j_2}$, $e_{i_1}^{i_2}$), Liu et al. (2009) calculate relative frequencies following Och and Ney (2004):

$$\phi(\tilde{e}|\tilde{f}) = \frac{count(f_{j_1}^{j_2}, e_{i_1}^{i_2})}{\sum_{e_{i'_1}^{i'_2}} count(f_{j_1}^{j_2}, e_{i'_1}^{i'_2})} \quad (4)$$

The key point to calculate the relative frequency of the phrase pair is to obtain its fractional count. Liu et al. (2009) use the product of inside and outside probabilities as the fractional count of a phrase pair. Liu et al. (2009) define that inside probability indicates the probability that at least

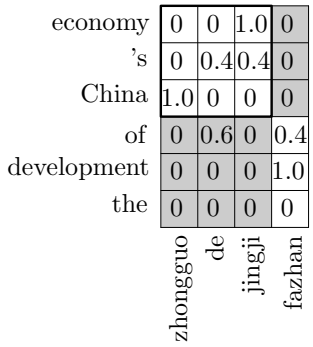

Figure 3: A weighted alignment matrix of a phrase pair. The light shading area is the outside area of phrase pair, and the area inside the pane with bold lines is the inside area.

one word in source phrase is aligned to a word in target phrase, and outside probability indicates the chance that no words in one phrase are aligned to a word outside the other phrase. The fractional count is calculated:

$$count(f_{j_1}^{j_2}, e_{i_1}^{i_2}) = \alpha(f_{j_1}^{j_2}, e_{i_1}^{i_2}) \times \beta(f_{j_1}^{j_2}, e_{i_1}^{i_2}) \quad (5)$$

where $\alpha(\cdot)$ and $\beta(\cdot)$ denote the inside and outside probabilities respectively, which can be calculated as

$$\alpha(\cdot) = 1 - \prod_{(j,i)\in in(\cdot)} \bar{p}_m(j,i) \quad (6)$$

$$\beta(\cdot) = \prod_{(j,i)\in out(\cdot)} \bar{p}_m(j,i) \quad (7)$$

Here $in(\cdot)$ denotes the inside area, which includes elements that fall inside the phrase pair, while $out(\cdot)$ denotes the outside area including elements that fall outside the phrase pair while fall in the same row or the same column. Figure 3 shows an example. The light shading area is the outside area of phrase pair and the area inside the pane with bold lines is the inside area.

To calculate the lexical weights, Liu et al. (2009) adapt $p_m(j,i)$ as the fractional count $count(f_j, e_i)$. The fractional counts of NULL words can be calculated as:

$$count(f_j, e_0) = \prod_{i=1}^{I} \bar{p}_m(j,i)$$

For example, in Figure 2, $count(de,'s)$ is 0.4 and $count(de, NULL)$ is 0.24.

Then the lexical weight can be calculated as:

$$p_w(\tilde{e}|\tilde{f}, m) = \prod_{i=1}^{|\tilde{e}|} \Bigg(\Bigg(\frac{1}{\{j|p_m(j,i)>0\}} \times \sum_{\forall j: p_m(j,i)>0} p(e_i|f_j) \times p_m(j,i) \Bigg) + p(e_i|f_0) \times \prod_{j=1}^{|\tilde{f}|} \bar{p}_m(j,i) \Bigg) \quad (8)$$

where

$$p(e_i|f_j) = \frac{count(f_j, e_i)}{\sum_{e_i'} count(f_j, e_i')} \quad (9)$$

We apply weighted alignment matrix to the hierarchical phrase-based model (Chiang, 2007) and the tree-to-string model (Liu et al., 2006; Huang et al., 2006).

3 Rule Extraction

In hierarchical rules, both source and target sides are strings with NTs. In tree-to-string rules, the source side is a tree with NTs, while the target side is a string with NTs. Since the tree structure of source side has no effect on the calculations of relative frequencies and lexical weights, we can represent both tree-to-string and hierarchical rules as below:

$$X \rightarrow \langle \gamma, \alpha, \sim \rangle$$

where X is a nonterminal, γ and α are source and target strings (consist of terminals and NTs), and $\sim$ represents word alignments between NTs in γ and α.

The bulk of syntax grammars consists of two parts: *phrase pairs* and *variable rules*. The difference between them is containing NTs or not. Since we can calculate relative frequencies and lexical weights of phrase pairs as in Liu et al. (2009), we only focus on the calculation of variable rules.

3.1 Extraction Algorithm

Following Chiang (2007) and Liu et al. (2006), our extraction algorithm involves two steps. First, we extract phrase pairs from weighted alignment matrices. Then, we obtain variable rules by replacing sub-phrase pairs with NTs.

Figure 4 shows the algorithm of extracting phrase pairs from a weighted matrix for the hierarchical phrase-based model. The input of the algorithm is a sentence pair (f_1^J, e_1^I) that are both

```
1: procedure PHRASEEXTRACTION(f_1^J, e_1^I, m, l)
2:     R ← ∅
3:     for j_1 ← 1 ... J do
4:         j_2 ← j_1
5:         while j_2 < J ∧ j_2 − j_1 < l do
6:             T ← {i|∃j : j_1 ≤ j ≤ j_2 ∧ p_m(j, i) > 0}
7:             i_l ← MIN(T)
8:             i_u ← MAX(T)
9:             r ← NULL
10:            s(r) ← −1
11:            for n ← 1 ... l do
12:                for i_1 ← i_l − n + 1 ... i_u do
13:                    i_2 ← i_1 + n − 1
14:                    if s(f_{j_1}^{j_2}, e_{i_1}^{i_2}) > s(r) then
15:                        r ← (f_{j_1}^{j_2}, e_{i_1}^{i_2})
16:                        s(r) ← s(f_{j_1}^{j_2}, e_{i_1}^{i_2})
17:            R ← R ∪ {r}
18:            j_2 ← j_2 + 1
19:    return R
```

Figure 4: Algorithm of extracting phrase pairs from a sentence pair $\langle f_1^J, e_1^I \rangle$ annotated with a weighted alignment matrix m. We just retain the best target phrase for each source phrase. Here $s(\cdot)$ denotes the selection criteria in Section 3.2

target phrase	α	β	$count$
China 's economy	1.0	0.4	0.4
of China 's economy	1.0	0.6	0.6
China 's	1.0	0.0	0.0
of China 's	1.0	0.0	0.0

Table 1: Some candidate target phrases of the source phrase *zhongguo de jingji* in Figure 3 (suppose the structure of *zhongguo de jingji* is a complete sub-tree). Here α is inside probability, β is outside probability, and $count$ is fractional count.

strings, a weighted alignment matrix m, and a phrase length limit l. Note that we just retain the target phrase of highest score for each source phrase (lines 13-16). We describe these in Section 3.2. After we extract phrase pairs, we can obtain variable rules by replacing sub-phrase pairs with NTs.

We can also extend this algorithm to tree-to-string model. The difference is that the source sentence should be a tree instead of a string and additional syntactic constraints operate.

3.2 Selection Criteria

(Liu et al., 2009) show that given a source phrase, there would be multiple "potential" candidate target phrases in weighted matrices. Table 1 lists some candidate target phrases of the source phrase *zhongguo de jingji* in Figure 3. If we retain all of them, it will lead to an exponentially increasing rule table. To achieve balance between rule table size and performance, we just select the best candidate target phrase.

An interesting finding is that a target phrase with the largest fractional count is not always the best one. For example in Table 1, the target phrase *of China 's economy* has a larger fractional count than *China 's economy*. However, we can see that (*zhongguo de jingji*, *China 's economy*) is better.

To alleviate this problem, we incorporate lexical weight to distinguish good target phrases from bad ones. While frequency indicates how often the source phrase and target phrase occur together, lexical weight models the correspondence between them. Therefore, we can construct a scoring measure that incorporates both frequency and lexical weight. The scoring equation below models this effect:

$$s(\tilde{f}, \tilde{e}) = \omega \cdot count(\tilde{f}, \tilde{e}) + (1 - \omega) \cdot p_w(\tilde{e}|\tilde{f}, m) \quad (10)$$

where ω is the interpolation weight, $count(\tilde{f}, \tilde{e})$ is calculated by Equation 5, and $p_w(\tilde{e}|\tilde{f}, m)$ by Equation 8. In practice, we set $\omega = 0.5$.[1] Suppose $p_w($*China 's economy* $|$ *zhongguo de jingji*$)$ is 0.7 and $p_w($*of China 's economy* $|$ *zhongguo de jingji*$)$ is 0.4, then we should choose the target phrase *China 's economy* although *of China 's economy* has a larger fractional count.

Note that we select the best target phrase for each source phrase for just one sentence. It means there could still be many target phrases for each source phrase during decoding.

3.3 Calculating Relative Frequencies

Figure 5 shows an example of the matrix of a hierarchical rule, which is generated from the phrase pair in Figure 3. Due to the existence of sub-phrase pairs, the inside and outside areas changes (see the difference between Figure 3 and Figure 5). Therefore, we can not simply calculate the outside probability of the hierarchical rule using the product of outside probabilities of phrase pair and sub-phrase pairs.

We follow Liu et al. (2009) to calculate relative frequencies using the product of inside and outside probabilities. We now extend the definitions of inside and outside probabilities to hierarchical rules that contain NTs.

[1] We tried a few other settings and found them to be less effective.

rule	α	β	$count$
X_1 *de jingji,* X_1 *'s economy*	1.0	0.4	0.4
zhongguo X_1*, China* X_1	1.0	0.4	0.4
zhongguo de X_1*, China 's* X_1	1.0	0.24	0.24
X_1 *de* X_2*,* X_1 *'s* X_2	1.0	0.24	0.24

Table 2: Some hierarchical rules generated from the phrase pair (*zhongguo de jingji, China's economy*) in Figure 3 (suppose the structure of *zhongguo de jingji* is a complete sub-tree). Here α is inside probability, β is outside probability, and $count$ is fractional count.

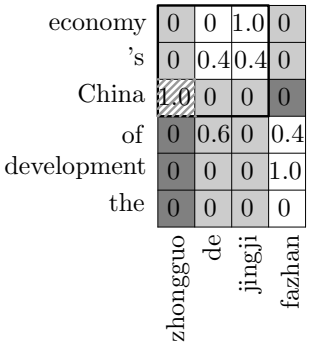

Figure 5: A weighted alignment matrix of a variable rule, which is obtained by replacing (*zhongguo,China*) with X in (*zhongguo de jingji,China 's economy*). The diagonal area is the inside area of the sub-phrase pair. The shading area is the outside area of the variable rule, and heavy shading area is the duplicate outside area. The no shading area inside the pane with bold lines is the inside area.

Given a variable rule (f', e'), which is generated from the phrase pair ($f_{j_1}^{j_2}$, $e_{i_1}^{i_2}$) by replacing sub-phrase pairs with X. We denote R as the variable rule, P as the phrase pair ($f_{j_1}^{j_2}$, $e_{i_1}^{i_2}$), and X_k as the kth sub-phrase pair that is replaced with X. Therefore, the inside probability of a variable rule is calculated as:

$$\alpha(R) = \prod_k \alpha(X_k) \quad (11)$$

We tried to follow the constraints of Chiang (2007): (1) unaligned words are not allowed at the edges of phrases; (2) a rule must have at least one pair of aligned words. This would take into account the terminals in the variable rule, but make the calculation more complicated (especially constraint (1)). However, it didn't work well. Therefore, we only constraint that the rule should respect the word alignment, which means one terminal in a phrase could not align to another word outside the phrase (using outside probability).

Accordingly, the outside probability is calculated as:

$$\beta(R) = \prod_{(j,i)\in out(R)} \bar{p}_m(j,i) \quad (12)$$

where

$$out(R) = out(P) \bigcup \Big(\bigcup_k out(X_k) \Big)$$

For example, the inside probability of (X_1 *de jingji,* X_1 *'s economy*) in Figure 5 is 1.0, and its outside probability is 0.4.

We also use Equation 5 to calculate the fractional counts of hierarchical rules. We follow Liu et al. (2009) to prune rule table using a threshold of frequency. Table 2 lists some hierarchical rules generated from the phrase pair (*zhongguo de jingji, China's economy*) in Figure 3. If the threshold is 0.2, we retain all the rules in Table 2.

3.4 Calculating Lexical Weights

We denote S_R as all words in source side of the inside area of variable rule R, and T_R as the words in target side. For the rule (X_1 *de jingji,* X_1 *'s economy*) in Figure 5, S_R is {*de, jingji*} and T_R is {*'s, economy*}. Then, we can calculate the lexical weight as:

$$p_w(\tilde{e}|\tilde{f}, m) = \prod_{i\in T_R} \Bigg(\Bigg(\frac{1}{|\{j|p_m(j,i)>0|\}} \times \sum_{\forall j: p_m(j,i)>0} p(e_i|f_j) \times p_m(j,i) \Bigg) + p(e_i|f_0) \times \prod_{j\in S_R} \bar{p}_m(j,i) \Bigg) \quad (13)$$

Note that we only consider each word pair (f_j, e_i) in the inside area of the variable rule. For example, the lexical weight of (X_1 *de jingji,* X_1 *'s*

economy) is

$$\Big(\frac{1}{2} \times \big(p('s|de) \times 0.4 + p('s|jingji) \times 0.4\big) + p('s|NULL) \times 0.36\Big) \times \Big(p(economy|jingji) \times 1.0\Big)$$

Here the probability that *economy* translates a source NULL token is 0.0.

4 Experiments

4.1 Data Preparation

Our experiments are on Chinese-English translation based on replications of hierarchical phrase-based system (Chiang, 2007) and tree-to-string system (Liu et al., 2006). We train a 4-gram language model on the Xinhua portion of GIGAWORD corpus using the SRI Language Modeling Toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Kneser and Ney, 1995). We optimize feature weights using the minimum error rate training algorithm (Och and Ney, 2002) on the NIST 2002 test set. We evaluate the translation quality using case-insensitive BLEU metric (Papineni et al., 2002) on the NIST 2003/2004/2005 test sets.

To obtain weighted alignment matrices, we follow Venugopal et al. (2008) to produce n-best lists via GIZA++. We produce 20-best lists in two translation directions, then used "grow-diag-final-and" (Koehn et al., 2003) to all 20×20 bidirectional alignment pairs. We follow Liu et al. (2009) to use $p_{s2t} \times p_{t2s}$ as the probabilities of an alignment pair. Analogously, we abandon duplicate alignments that are produced from different alignment pairs. After these steps, there are 110 candidate alignments on average for each sentence pair. We obtained n-best lists by selecting the top n alignments from 110-best lists. We re-estimated the probability of each alignment in the n-best list using re-normalization (Venugopal et al., 2008). Finally, we construct weighted alignment matrices from these n-best alignments.

We will first report results trained on a small-scaled corpus, and then scale to a larger one. When extracting tree-to-string rules, we limit the maximal height of rules to 3. We use the pruning threshold: $t = 0.5$.

4.2 Results on Small Data

To test the effect of our approach, we firstly carried out experiments on FBIS corpus, which contains 230K sentence pairs. Table 3 shows the rule table size and translation quality. Using n-best alignments slightly improved the BLEU score, but at the cost of much slower extraction, since each of top-n alignments has to be processed individually although they share many align links. Matrix-based extraction, by contrast, is much faster due to packing and produces consistently better BLEU scores. The absolute improvements of ranging from +1.6 to +1.8 BLEU points and +1.4 to +1.8 BLEU points over 1-best alignments for hierarchical phrase-based and tree-to-string models respectively, are statistically significant at $p < 0.01$ by using *sign-test* (Collins et al., 2005).

Basically, in the matrix case of the hierarchical phrase-based model, we can use about twice as many rules as in the 1-best case, or 1.3 times of 10-best extraction. However, in tree-to-string scenario, matrix-based extraction produces less rules than k-best extraction. We contribute this to the extra complete sub-tree constraint.

4.3 Results on Large Data

We also conducted experiments on a larger training data, which contains 1.5M sentence pairs coming from LDC dataset.[2]

The ruletable size and BLEU score are shown in Table 4. An interesting finding is that BLEU scores decline when using k-best extraction in some cases. We conjecture that some low-quality rules that harm the performance of decoder, are extracted from k-best alignments. Using weighted matrices on larger corpus also achieved significant and consistent improvements over using 1-best and n-best lists. These results confirm that our approach is a promising direction for syntax-based machine translation.

4.4 Comparison of Parameter Estimation

In this section we investigated the question of how many rules are shared by n-best and matrix-based extractions on small data (FBIS corpus). Our motivation is that weighted alignment matrices have been reported to be beneficial for better estimation of rule translation probabilities and lexical weights

[2]The corpus includes LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

Rules from...	Extraction	Total Rules	NIST03		NIST04		NIST05	
			Rules	BLEU	Rules	BLEU	Rules	BLEU

Table 3: Results with different rule extraction methods on small data. Here 1-best, 10-best and m(10) denote 1-best alignments, 10-best lists and weighted matrices estimated from 10-best lists respectively. The rules are filtered on the corresponding test set. "Extraction" denotes extraction time in millsecs per sentence pair. We evaluate the translation quality using 4-grams case-insensitive BLEU metric.

Rules from...	Total Rules	NIST03		NIST04		NIST05	
		Rules	BLEU	Rules	BLEU	Rules	BLEU
hierarchical phrase-based model							
1-best	204M	10.3M	33.40	16.1M	34.65	11.7M	32.88
10-best	288M	16.5M	33.18	25.2M	34.75	18.6M	32.47
m(10)	524M	26.1M	**35.10**	40.7M	**36.56**	29.5M	**34.31**
tree-to-string model							
1-best	30.7M	1.99M	30.76	2.68M	32.69	2.21M	30.36
10-best	71.4M	3.53M	31.54	4.63M	33.47	3.89M	31.09
m(10)	30.7M	2.24M	**32.23**	2.99M	**34.24**	2.48M	**31.88**

Table 4: Results with different rule extraction methods on large data. We use m(10) for the weighted matrices estimated from 10-best lists.

(Liu et al., 2009). The experiments are tested on NIST 2005 dataset.

Table 5 gives some statistics. We use m(10) for the weighted matrices estimated from 10-best lists. "All" denotes the full rule table, "Shared" denotes the intersection of two tables, and "Non-shared" denotes the complement. There were 18.8% of rules learned from weighted matrices included by both tables in hierarchical phrase-based case, while 36.5% for tree-to-string rules, indicating that complete sub-tree constraint played an important role in matrix-based tree-to-string rule extraction. Note that the probabilities of "Shared" rules are different for the two approaches. Liu et al. (2009) shows that using matrices outperformed using n-best lists even with the same rules. Our experiments confirmed these findings.

4.5 Best Rule or More Rules

Someone would argue that using more rules could improve the performance, especially for the tree-to-string model. Therefore, we carried out experiments on small data for tree-to-string model to investigate which one is better. Note that even though we retain the best target side for each source side for each sentence, there could still be many target sides for each source side when decoding.

Table 6 shows the results of different criterions. The first column "Criteria" indicates how many target phrases are preserved: the best one or all phrases that reach pruning threshold. We can see that "More Rules" could not outperform "Best Rule" even using almost 2.5 times rules. One possible reason is that it might introduce some low-quality target phrase such as *of China 's economy* in Table 1, which will generate more substandard variable rules.

5 Related Works

Recent works have shown that machine translation can benefit when offered more alternatives. Mi

Table 6: Comparison of rule tables learned from weighted matrices using different criterions. "Best Rule" denotes the rule table using the criteria described in Section 3.2, "More Rules" denotes the rule table using the criteria that retains all candidate target phrases that reach pruning threshold.

and Huang (2008) and Tu et al. (2010) use forests instead of 1-best trees; Venugopal et al. (2003) and Deng et al. (2008) soft the alignment consistency constraint to extract more rules; Dyer et al. (2008) use word lattices instead of 1-best segmentations to generate more alignments for a sentence pair; Venugopal et al. (2008) use n-best alignments directly for rule extraction.

To generate larger rule sets, de Gispert et al. (2010) extract hierarchical rules from alignment posterior probabilities. They concern how to extract larger rule sets using simple yet powerful hierarchical grammar, while we focus on whether weighted alignment matrix could overcome the alignment errors for different translation models (e.g. phrase-based, hierarchical phrase-based and tree-based models). They use phrase posteriors as the fractional count, while we use the product of inside and outside probabilities. Besides, they filter rules after extracting all rules from corpus, while we prune rules when extracting.

6 Conclusion and Future Works

Liu et al. (2009) proposed a new structure named weighted alignment matrix that make a better use of noisy alignments. Since weighted matrices proves effective for phrase-based model, we apply it to syntax-based models, which are more sensitive to word alignments. Due to the difference in structure between phrases and hierarchical rule, we develop new algorithms to calculate relative frequencies and lexical weights of hierarchical rules. To achieve a balance between rule table size and performance, we develop a scoring measure that incorporates both frequency and lexical weight to select the best target phrase for each source phrase. Our experiments show that our approach improves BLEU score significantly, with reasonable extraction speed, indicating that weighted alignment matrix also works for syntax-based models.

Besides the hierarchical phrase-based model and tree-to-string model, our method is also applicable to other paradigms such as the string-to-tree models (Galley et al., 2006) and the string-to-dependency models (Shen et al., 2008). Another interesting direction is to use a simpler alignment model that can compute alignment point posteriors directly, such as word-based ITG model (Zhang and Gildea, 2005; Haghighi et al., 2009).

Abstract

The language specific Multiword expressions (MWEs) play important roles in many natural language processing (NLP) tasks. Integrating reduplicated multiword expressions (RMWEs) into the Phrase Based Statistical Machine Translation (PBSMT) to improve translation quality is reported in the present work between Manipuri, a highly agglutinative Tibeto-Burman language and English. In addition, Multiword Named Entities (MNEs) coupled with Transliterated non-named entities (non-NE) between Manipuri and English phrase based SMT system are also integrated. The tighter integration of RMWEs and NEs into the PBSMT is carried out after automatic extraction using SVM based machine learning technique followed by automatic bilingual RMWE and MNE extraction using GIZA++ alignment. Our experimental results show improvement in the PBSMT system BLEU and NIST scores over the baseline system. Subjective evaluation indicates the improvement in the adequacy.

1 Introduction

Multiword expressions (MWEs) are a key challenge for the development of large-scale, linguistically sound natural language processing technology (Sag et al, 2002). The various kinds of multiword expressions should be analyzed in distinct ways. An adequate comprehensive analysis of multiword expressions must employ both symbolic and statistical techniques. MWEs span a range of constructions, from completely frozen, semantically opaque idiomatic expressions, to frequent but morphologically productive and semantically compositional collocations. Various linguistic processes (orthographic, morphological, syntactic, semantic and cognitive) apply to MWEs in idiosyncratic ways. Notably, MWEs blur the distinction between the lexicon and the grammar, since they often have some properties of words and some properties of phrases. The MWE identification works concentrate on compound nouns, noun-verb combination, idioms and phrases for several languages such as Hindi and Hebrew but not much on RMWEs. The reason may be that the reduplicated words are either rare or easy to identify for these languages since only complete duplication and some amount of partial reduplication may be present in these languages.

On the other hand, reduplicated MWEs (RMWE) of several varieties are widely present in Manipuri[1]. In the present work, the identification of Manipuri Named Entities (NEs) and the identification and classification of RMWEs is carried out using the SVM based machine learning approach.

† Presently at Center for Development of Advanced Computing (CDAC), Mumbai, India

[1] Manipuri, locally known as Meiteilon or Meeteilon, is a less privileged, morphologically rich, highly agglutinative language spoken basically in the states of Manipur, Assam, Tripura and Mizoram in India and in the neighboring countries of Myanmar and Bangladesh approximately by three million speakers. Manipuri became the first Tibeto-Burman (TB) language to receive recognition in the year 1992 as a schedule VIII language of India.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1304–1312,
Chiang Mai, Thailand, November 8 – 13, 2011.

Manipuri is very rich in RMWEs like other Tibeto-Burman languages. The work of (Singh, 2000) describes the linguistic rules for identifying reduplicated words. Manipuri is the direct descendant of the conglomeration of Tibeto-Burman dialects of seven different clans. This is reflected in the commonly found use of double synonyms in Manipuri, technically known as 'semantic reduplication'. The process of reduplication (Singh, 2000) is defined as: 'reduplication is that repetition, the result of which constitutes a unit word'. These single unit words are the MWEs. The RMWEs in Manipuri are classified as: (i) Complete RMWEs, (ii) Partial RMWEs, (iii) Echo RMWEs and (iv) Mimic RMWEs. Apart from these four types of RMWEs, there are also cases of (a) Double RMWEs and (b) Semantic RMWEs.

Complete RMWEs: In the complete RMWEs the single word or phrase is repeated once forming a single unit regardless of the phonological or morphological variations. Interestingly in Manipuri these complete reduplicated MWEs can occur as Noun, Adjective, Adverb, *Wh*- question type, Verbs, Command and Request.

মরিক মরিক ('*marik marik*') which means 'drop by drop'. [Noun]

অটেক অটেকপা ('*atek atek-pa*') which means 'fresh' [Adjective]

করি করি ('*kari kari*') means 'what/which'. [Wh-question]

Partial RMWEs*:* In case of partial reduplication the second word carries some part of the first word as an affix to the second word, either as a suffix or a prefix.

For example, চত্থোক চত্সিন ('chat-thok chat-sin') means 'to go to and fro'; শামী লানমী ('*saa-mi laan-mi*') means 'army'.

Mimic RMWEs: In the mimic reduplication the words are complete reduplications but the morphemes are onomatopoetic, usually emotional or natural sounds. For example, করক করক ('*krak krak*') means 'cracking sound of earth in drought'.

Echo RMWEs: The second word does not have a dictionary meaning and is basically an echo word of the first word. For example, থকসি খাসি ('*thak-si kha-si*') means 'good manner'.

Double RMWEs: Such type of reduplication generally consists of three words where the prefix or suffix of the first two words is reduplicated but in the third word the prefix or suffix is absent. An example of double prefix reduplication is ইমুন ইমুন মুনবা ('*i-mun i-mun mun-ba*') which means, 'completely ripe'.

Semantic RMWEs: Both the reduplication words have the same meaning that is shared by the MWE itself. Such types of MWEs are very special to the Manipuri language. For example, পামবা কৈ ('paamba kei') means 'tiger' and each of the component words means 'tiger'.

The performance of the SMT is heavily dependent on the quality of the Parallel Corpora and the alignment models used. Integrating MWEs into the Machine Translation (MT) systems in general and phrase based Statistical Machine Translation (PBSMT) system in particular is a critical problem. Thus, there is the need for identifying Manipuri RMWE and integrating into the PBSMT system. In the present work, we integrate Manipuri Named entities (both single word and multiword), RMWEs and non-NE transliterated entities into the existing phrase-based model.

2 Related Works

Koehn and Knight (2003) discussed empirical methods for compound splitting by learning rules from monolingual and parallel corpora. Lambert and Banchs (2005) proposed technique for extracting bilingual MWEs based on grouping as units before performing the statistical alignment. (Ren et al., 2009) presented the Log Likelihood Ratio based hierarchical reducing algorithm to automatically extract bilingual MWE and investigated the performance of three different strategies in applying bilingual MWEs for SMT system using Moses (Koehn et al., 2007). Carpuat and Diab (2010) explored static integration strategy that segments training and test sentences according to the MWE vocabulary, and dynamic integration strategy that adds a new MWE-based feature in SMT translation lexicon. Handling of

named entities and compound verbs in PBSMT (Pal et al., 2010) has been reported in the English-Bengali task in the Indian language context. They established prior NE alignments in the parallel corpora by transliterating source NEs into the target language using modified joint source channel transliteration technique (Ekbal et al., 2006) which incorporates different contextual information into the model. In the process, the identified NEs and compound verbs are converted into a single token by replacing spaces between the constituent words by underscores.

3 Manipuri-English Parallel Corpora

The Manipuri-English Parallel corpus (Singh and Bandyopadhyay, 2010b) on News Domain is used for training and testing. The Manipuri news corpus is collected from the website http://www.thesangaiexpress.com/. On analyzing the corpus, the statistics shows that Named entities (both single word and multiword), RMWEs and non-NE transliterated entities are present in significant numbers.

The presence of NEs in the Manipuri News corpus is approximated at 11.39%. However, the presence of non-NE transliterated entities is lesser and estimated at 9.2%. The following example (a) demonstrates the usage of the transliterated non-NE in the Manipuri news.

The following translation examples demonstrate the usage of NEs, transliterated non-NEs and RMWEs in the Manipuri source sentences.

(a)

হায় পৱার কম্মিটিগী ইন্সত্রক্সন মতুং ইন্না য়ুঠ এফিয়ার্স এণ্ড স্পোর্টসকি জোইন্ট সেক্রেটরিনা চহি অসিগী এপ্রিল ২৪ দা ডিপার্টমেন্টশিংদগী অহাঙবা পোষ্টশিং পীখল্লক্লবা খঙহনখ্রবনি

According to the instruction of the high power committee, the joint secretary of youth affairs and sports notified to submit the vacant posts in the departments on 24 April of this year.

Considering the above translation example (a) between Manipuri and English sentence, the Manipuri transliteration of the non-NE is shown in Table 1. This significant presence of these entities plays an important role in the news corpus. These are the examples of enrichment of Manipuri languages using Manipuri transliteration from English.

4 NE Transliteration

A transliteration system takes as input a character string in the source language and generates a character string in the target language as output. The process can be conceptualized as two levels of decoding: segmentation of the source string into transliteration units; and relating the source language transliteration units to units in the target language, by resolving different combinations of alignments and unit mappings. The problem of machine transliteration has been studied extensively in the paradigm of the noisy channel model. Translation of named entities is a tricky task: it involves both translation and transliteration. For example, the organization name *Jadavpur viswavidyalaya* is translated to *Jadavpur University* in which *Jadavpur* is transliterated to *Jadavpur* and *viswavidyalaya* is translated to *University*.

A bilingual training set of Manipuri NEs and their respective English transliterations, has been created by collecting Manipuri person, location and organization names from Manipuri news corpus and then manually entering their English transliterations. This bilingual training set is automatically analyzed to acquire mapping knowledge in order to transliterate new Manipuri person, location and organization names to English. Transliteration units (TUs) are extracted from the Manipuri-English name pairs and Manipuri TUs are associated with their English counterparts. Some examples are given below:

(a) মনিপুর(*manipur*) → ম । নি । পু । র

manipur → ma | ni | pu | r

(b) রাজকুমার(*rajkumar*) →রা । জ । কু । মা । র

rajkumar → ra | j | ku | ma | r

(c) অভিনন্দন(*abhinandan*)→অ । ভি । ন । ন্দ ।ন

abhinandan → a | bhi | na | nda | n

The TUs are the lexical units for machine transliteration. The Manipuri NE is divided into Transliteration Units (TU) with patterns C+M?, where C represents a consonant or a vowel or a conjunct and M represents the vowel modifier or matra. An English NE is divided into TUs with patterns C*V*, where C represents a consonant and V represents a vowel. The system automatically learns mappings from the bilingual training set of 20,000 NEs. Aligned TUs along with their contexts are automatically derived from this bilingual training set to generate the collocation statistics.Transliteration units (TUs) are extracted from the Manipuri and the corresponding English names, and Manipuri TUs are associated with their English counterparts along with the TUs in context. For *K* aligned TUs, the Manipuri-English transliteration model based on the Modified Joint Source Channel Model for transliteration (Ekbal et. al., 2006) is given by the following equations (1) and (2).

$$P(S,T) = \prod_{k=1}^{K} P(< s,t >_k \mid < s,t >_{k-1}) \, s_{k+1} \quad (1)$$

$$S \rightarrow T(S) = \arg\max_T \{P(T) \times P(S,T)\} \quad (2)$$

A TU correspondence <s, t> is called a transliteration pair of the source language S and the target language T. In this model, the previous TUs in both the source and target sides are considered as context. This model is extended to Manipuri since the Bengali script is used in Manipuri also.

5 SVM based RMWEs identification and Bilingual RMWE Extraction

The Support Vector Machine (SVM) based machine learning approach (Vapnik, 1995) works on discriminative approach and makes use of both positive and negative examples to learn the distinction between the two classes. The SVMs are known to robustly handle large feature sets and to develop models that maximize their generalizability. Consider a set of training data for a two-class problem: $\{(x_1, y_1),.....(x_N, y_N)\}$, where $x_i \varepsilon R^D$ is a feature vector of the i^{th} sample in the training data and $y_i \varepsilon \{+1, -1\}$ is the class to which x_i belongs. The goal is to find a decision function that accurately predicts class y for an input vector x.

A non-linear SVM classifier gives a decision function f (x) = sign ($g(x)$) for an input vector where,

$$g(x) = \sum_{i=1}^{m} w_i K(x, z_i) + b \qquad (3)$$

Here, f(x) = +1 means x is a member of a certain class and f(x) = -1 means x is not a member. The support vectors that are representatives of training examples are z_i and m is the number of support vectors. Therefore, the computational complexity of g(x) is proportional to m. Support vectors and other constants are determined by solving a certain quadratic programming problem. $K(x, z_i)$ is a *kernel* that implicitly maps vectors into a higher dimensional space. Typical kernels use dot products: $K(x, z_i) = k(x.z)$. A polynomial kernel of degree d is given by $K(x, z_i) = (1+x)^d$. We can use various kernels and the design of an appropriate kernel for a particular application is an important research issue.

The MNE/RMWE tagging system includes two main phases: training and classification. The training process has been carried out by YamCha[2] toolkit, an SVM based tool for detecting classes in documents and formulating the MNE/RMWE tagging task as a sequence labeling problem. Here, both one vs rest and pairwise multi-class decision methods have been used. Different experiments with the various degrees of the polynomial kernel function have been carried out. In one vs rest strategy, K binary SVM classifiers may be created where each classifier is trained to distinguish one class from the remaining K-1 classes. In pairwise classification, we constructed K (K-1)/2 classifiers considering all pairs of classes, and the final decision is taken by their weighted voting. For classification, the TinySVM-0.07[3] classifier has been used that seems to be one of the best optimized among publicly available SVM toolkits.

In the present work, the bilingual RMWEs are extracted automatically. The difficulty lies in how to integrate the bilingual MWEs into existing the SMT system to improve system performance. The RMWEs are identified from the Manipuri source side of the parallel corpora. The RMWEs are identified (Singh and Bandyopadhyay, 2010) using support vector machine (SVM) based machine learning technique. The various features used are context word, prefix, suffix, previous RMWE information, POS information, word length, digit and infrequent word features. The SVM based RMWE identification system shows recall, precision and F-Score of 94.62%, 93.53% and 94.07% respectively.

The target equivalents of the RMWEs are extracted by running the GIZA++ alignment tool followed be candidate translation extraction from the sentence pairs using the algorithm described in (Och, 2002). There are 25,921 RMWEs in the training corpus. Thus, an additional phrase table containing the automatically extracted RMWEs is constructed.

6 Bilingual NEs Extraction

Named Entities (NEs) are indentified using the SVM based Manipuri named entity recognition technique (Singh et al., 2010a) on news corpus. At present, 4649016 Manipuri wordforms has been collected from the website. The NE identification in Manipuri is difficult and challenging because (a) Manipuri is less privileged and resource constrained language, (b) unlike English, Manipuri lacks capitalization, (c) NEs can appear in the Manipuri dictionary as well and (d) Manipuri is highly agglutinative. The major NE tags are person name, location name, organization name and miscellaneous name. The identified Manipuri NEs are transliterated using the modified joint source channel techniques discussed in Section 4. There

[2]http://chasen-org/~taku/software/yamcha/

[3]http://cl.aist-nara.ac.jp/~taku-ku/software/TinySVM

are 529522 NEs identified and transliterated of which 284521 are multiword named entities (MNE). An additional phrase table of the bilingual NEs is constructed.

7 Transliterated non-NE list Preparation

Manipuri is influenced and enriched by the Indo-Aryan languages of Sanskrit origin and English. So the presence of transliterated English words in the Manipuri news corpus is significantly high and it is important to handle these words during the translation process at the appropriate step. So, a list of 2611 Manipuri words and their English transliterations is developed from the news corpus. The non-NE list consists of both single word as well as multiple words. An additional phrase table based on this non-NE transliteration list is built in order to integrate in the present system.

8 Integration of MWE

In the present task, we employed multiple phrase tables using the Moses decoder. One phrase table is trained from the parallel corpora and second one is built using the MWEs extracted using the techniques described in section 5 and 6. For simplicity, the probability 1 is assigned to all the four probabilities of the MWE phrase table. During the decoding process, the MWEs are searched in both the phrase tables.

One of the possible techniques of integrating MWE in the SMT system is by introducing a new feature in a phrase table that indicates the presence of MWE.

9 The SMT Systems

We developed the Manipuri-English SMT systems using the state-of-the-art Moses. The various features are combined in the log-linear model. The log linear model to obtain the best translation ê of the source sentence f is given by the equation below:

$$\hat{e} = \arg\max_{e} P(e|f) = \arg\max_{e} \sum_{i=1}^{n} \lambda_i h_i(e, f) \quad (4)$$

where, h_i and λ_i denote the i[th] feature function and weight respectively. The feature weight λ_i in the log linear model is determined by using the minimum error rate training method (Och, 2003). Intuitively, the $P(e|f)$ depend on *language model* — $P(e)$ and *translation model* — $P(f|e)$.

10 Experimental Setup

The first Manipuri-English SMT task is reported in (Singh and Bandyopadhyay, 2010c) on news domain using factored translation model demonstrating improvement not only in the BLEU and NIST scores but also improvement in the fluency and adequacy by subjective evaluation method. Earlier, an English-Manipuri SMT system using morpho-syntactic and semantic information is reported by (Singh and Bandyopadhyay, 2010d). In the present experimental setup, Moses decoder (Koehn et al., 2005) is used which can support multiple phrase tables. The target language model is developed using the SRILM (Stolcke, 2002) toolkit. The language model is the 4-gram model using Kneser-Ney smoothing (Kneser and Ney, 1995) of the target language news corpus collected from the www.thesangaiexpress.com. GIZA++ is used to build IBM Model 4. The minimum error rate training (Och, 2003) determine the feature weights on the development set.

Several experiments are conducted using the phrase tables built from the MWEs. There is also an experiment on the combination of all the phrase tables consisting of the baseline, RMWE, NEs and transliterated non-NEs.

11 Evaluation Results

The corpus statistics used in the experiment is given in the table below.

	Number of sentences	Number of words
Training	10350	296728
Development	600	16520
Test	500	15204

Table 4: Corpus Statistics

The automatic scoring metrics are useful for fast evaluation of higher number of test sentences. The

automatic evaluation scores are carried out using the BLEU (Papineni, 2002) with brevity penalty and NIST (Doddington, 2002). The BLEU and NIST automatic scores of various models are given in the table below:

Model	**BLEU**	**NIST**
Baseline	**13.452**	**4.31**
Baseline + RMWE	13.829	4.43
Baseline +NE	13.901	4.47
Baseline + Transliterated non-NE	13.911	4.21
Baseline + RMWE + NE + Transliterated non-NE	**15.023**	**5.21**

Table 5: Automatic Scores of Manipuri-English SMT systems

Level	**Interpretation**
4	Flawless with no grammatical error
3	Good output with minor errors
2	Disfluent ungrammatical with correct phrase
1	Incomprehensible

Table 6: Fluency scale

Level	**Interpretation**
4	Full meaning is conveyed
3	Most of the meaning is conveyed
2	Poor meaning is conveyed
1	No meaning is conveyed

Table 7: Adequacy scale

Subjective evaluation is carried out on 100 test sentences using the fluency and adequacy scales given in the Tables 6 and 7. The subjective evaluation is carried out by two bilingual human judges. The evaluation indicates the improvement in adequacy but not much on fluency as shown in Table 8. The case markers and the inflectional suffixes are not taken care of with special treatment despite the agglutinative behavior of Manipuri language towards RMWEs, NEs and non-NEs; hence the fluency is not addressed significantly.

Statistical significant test is performed to judge if a change in score that comes from a change in the system reflects a change in the overall translation quality. It is found that the difference between the baseline and the (Baseline + RMWE + NE + Transliterated non-NE) model is significant producing statistically significant improvements as measured by the bootstrap resampling method (Koehn, 2004) on BLEU.

	Manipuri Sentence length	**Fluency**	**Adequacy**
Baseline	<=15 words	1.93	2.31
	>15 words	1.51	1.76
Baseline+ RMWE	<=15 words	1.92	2.85
	>15 words	1.62	2.07
Baseline + NE	<=15 words	2.06	2.82
	>15 words	1.75	2.10
Baseline + Transliterated non-NE	<=15 words	2.10	2.79
	>15 words	1.67	2.10
Baseline + RMWE + NE + Transliterated non-NE	<=15 words	2.11	3.11
	>15 words	1.72	2.78

Table 8: Subjective Evaluation Scores

12 Conclusion and Future Work

The present work reports the tight integration of the RMWE, named entities (both single word and multiword) and transliterated non-NE entities into the Manipuri-English SMT task. The presence of these entities in the Manipuri news corpus is significantly high and their special treatment in the machine translation is absolutely necessary. In order to identify the language specific multiword expressions, the SVM based machine learning technique is utilized. Since the translation output of the SMT system is further propagated from the quality of the automatic RMWE and MNE identification using SVM based machine learning

technique and multiword extraction using GIZA++ alignment, it is very important that these steps are better addressed in an effective way with more training data in future. By integrating RMWEs, MNEs and non-NEs, the adequacy of the translation output is improved; however, there is no significant improvement in the fluency. The fluency can be better addressed by incorporating morphological information such as proper handling of the case markers of the MNEs. On the other hand, the BLEU and NIST scores are improved over the baseline from 13.452 and 4.31 to 15.023 and 5.21 respectively.

Regularizing Mono- and Bi-Word Models for Word Alignment

Thomas Schoenemann
Lund University, Sweden

Abstract

Conditional probabilistic models for word alignment are popular due to the elegant way of handling them in the training stage. However, they have weaknesses such as garbage collection and scale poorly beyond single word based models (DeNero et al., 2006): not all parameters should actually be used.

To alleviate the problem, in this paper we explore regularity terms that penalize the used parameters. They share the advantages of the standard training in that iterative schemes decompose over the sentence pairs. We explore the models IBM-1 and HMM, then generalize to models we term *Bi-word* models, where each target word can be aligned to up to *two* source words.

We give two optimization strategies for the arising tasks, using EM and projected gradient descent. While both are well-known, to our knowledge they have never been compared experimentally for the task of word alignment. As a side-effect, we show that, against common belief, for parametric HMMs the M-step is *not* solved by renormalizing expectations.

We demonstrate that the regularity terms improve on the f-measures of the standard HMMs and that they improve translation quality.

1 Introduction

State-of-the art approaches for word alignment are based on probabilistic models. They can be split into joint models (Melamed, 2000; Marcu and Wong, 2002) and conditional models (Brown et al., 1993; Vogel et al., 1996; Wang and Waibel, 1998; Toutanova et al., 2002; Sumita et al., 2004; Deng and Byrne, 2005; Fraser and Marcu, 2007a). While in early works the underlying basic entity was a single word, today's advanced approaches build on sequences of words, called *phrases*.

For joint models the advanced models are standalone approaches (Marcu and Wong, 2002). However, these models are computationally hard to handle, which frequently results in maximum approximations being made. This is different for the conditional models, which are easier to handle but where most approaches are based on initializing from single-word based models (Brown et al., 1993; Vogel et al., 1996; Al-Onaizan et al., 1999). However, the recent work of Mauser et al. (2009) deals with pairs of source words and is trained without considering single word based models.

In this paper we much generalize on this work, considering a class of models we term *Bi-word models*. We consider a variant of (Mauser et al., 2009) which we call Bi-1, then proceed to derive a Bi-HMM. Our main focus is however on regularizing such models. We first address known conditional models called *single-word based* models, focusing on a weakness known as *garbage collection*. We show that this weakness can be alleviated by adding an entry to every dictionary distribution as well as adding a regularity term (a weighted L_1 norm). Afterwards we generalize this idea to Bi-word models. The regularity term will now become crucial since the garbage problem is known to worsen for conditional models that generalize single-word based ones (DeNero et al., 2006).

We cast all this as compact objective functions subject to simplex constraints, and show two ways to optimize these: via EM and via projected gradient descent (Bertsekas, 1999, chap. 2.1). Since each iteration decomposes over the sentence pairs, the approach is efficient and scalable. In contrast to our recent work (Schoenemann, 2011) (where we used an L_0-norm) we do not use the maximum approximation and also address Bi-word models.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1313–1322,
Chiang Mai, Thailand, November 8 – 13, 2011.

Related Work on Word Alignment For a systematic comparison of the most commonly used models see (Och and Ney, 2003). Apart from the classical approaches, a few other lines of work have been pursued. Indeed, for single word based models regularity terms have been considered before, in particular in our recent work on the L_0-norm (Schoenemann, 2011). Otherwise most of the work has focused on combining asymmetric conditional approaches. Zens et al. (2004) intertwine the training of both directions by exchanging information in-between the iterations. Liang et al. (2006) propose to include the products of the conditional marginals for each training direction into the objective function. Graça et al. (2010) postulate that the posterior marginals for both directions be equal. They also propose an asymmetric variant that favors 1-to-1 alignments. The idea of posterior regularization has further been pursued in the machine learning community (Mann and McCallum, 2007).

We further note the approaches (Matusov et al., 2004; Taskar et al., 2005; Lacoste-Julien et al., 2006) that focus on the computation of alignments given symmetrized cost. Some of them also include novel ways to train the models.

Finally, our EM-scheme bears resemblance to the works (Berg-Kirkpatrick et al., 2010; Ganchev et al., 2010), but we address substantially different models.

2 Mono-Word Models

In this section we review the employed single word based models. We call them *Mono-word models* as we find the term more handy, in particular when it comes to distinguishing them from the pair-based models in the next section.

All discussed models formalize the (conditional) probability that a given English sentence $\mathbf{e} = e_1^I$, consisting of I words, produces a foreign sentence $\mathbf{f} = f_1^J$ with J words. This probability is denoted $p(\mathbf{f}|\mathbf{e})$. We will refer to $\mathbf{e}$ as the source sentence and to $\mathbf{f}$ as the target sentence. The considered models are all based on hidden variables called *alignments*. For Mono-word models the assumption is that each target word is aligned to at most one source position. The aligned position of target word j is denoted $a_j \in \{0, \ldots, I\}$, where 0 indicates unaligned words. The alignment of the entire sentence pair is denoted $\mathbf{a} = a_1^J$ and the probability is modeled as

$$p(\mathbf{f}|\mathbf{e}) = \sum_{\mathbf{a}} p(\mathbf{f}, \mathbf{a}|\mathbf{e}) \ .$$

The models differ in how this new joint probability is modeled, but they all factor it as

$$p(\mathbf{f}, \mathbf{a} \,|\, \mathbf{e}) = \prod_j p(f_j \,|\, e_{a_j}) \cdot p(a_j \,|\, a_{j-1}, j, I) \ .$$

For the first term (dictionary probability) all models use the same non-parametric representation. For the second term (alignment probability) they differ. The IBM-1 simply sets $p(a_j|a_{j-1}, j, I) = 1/(I+1)$, resulting in a convex model. We also consider the non-convex HMM, which models $p(a_j|a_{j-1}, I)$, getting rid of the dependence on j. To avoid overfitting a parametric model is used, based on considering the difference $a_j - a_{j-1}$. Details are given in the next section.

3 Bi-Word Models

In this paper we consider a more general class of conditional models, which we call Bi-word models. Here we are much generalizing on the work of (Mauser et al., 2009).

Now each target word is allowed to align to up to *two* source words. The alignment of target word j is expressed as the tuple $(a_{j,1}, a_{j,2})$, where the allowed set of values is a subset of $\{0, \ldots, I\} \times \{0, \ldots, I\}$. The value $(0, 0)$ will denote unaligned words. In any other case we require that $a_{j,2} > a_{j,1}$. If $a_{j,1}$ is 0 the word is aligned only once. If $a_{j,1} > 0$ it is aligned twice. We further forbid the case where $a_{j,1} > 0$ and $a_{j,2} = I$ since at the sentence end the considered data usually contain a punctuation mark which aligns only once. Note that otherwise there are no restrictions, in particular we do not require that the two aligned words are at consecutive positions (although such knowledge could be enforced in our framework).

In the generative story of the models we first take a decision of whether the alignment of position j is a double alignment or not. We denote this by a binary variable $b_j \in \{0, 1\}$, where a value of 1 denotes a Bi-alignment. Obviously $b_j = 0$ implies $a_{j,1} = 0$. Afterwards we decide on the aligned positions and the identity of the target word:

$$\begin{aligned} p(\mathbf{f}, \mathbf{a}|\mathbf{e}) \ = \ \prod_j & p(f_j \,|\, e_{a_{j,1}}, e_{a_{j,2}}) \cdot p(b_j) \\ & \cdot p(a_{j,1}, a_{j,2} \,|\, b_j, a_{j-1,1}, a_{j-1,2}, I) \ . \end{aligned} \tag{1}$$

Note that compared to the Mono-word models we have now many more dictionary parameters, as well as much more probability mass to spread. Moreover, $e_{a_{j,1}}$ and $e_{a_{j,2}}$ can be the empty word $NULL$.

In this work we consider two models that generalize the IBM-1 and the HMM to the new set of alignments. We call them Bi-1 (a variant of Mauser et al.'s model) and Bi-HMM, and again they differ only in the alignment probabilities. The values $p(b_j=0)$ and $p(b_j=1)$ are chosen independently of j and fixed to 0.1 and 0.9 in this work.

The **Bi-1** is a convex model and treats non-Bi-alignments as $p(0, a_{j,2} \,|\, b_j = 0, I) = 1/(I+1)$, just like the IBM-1. For Bi-alignments it sets $p(a_{j,1}, a_{j,2} \,|\, b_j = 1, I) = 1/K$, where K is the number of possible Bi-alignments (and where $a_{j,1}, a_{j,2}$ is an allowed constellation). Note the (subtle) difference to the work of Mauser et al.: this work did not consider the variables b_j, so for long sentences the pairwise alignments become dominant. Further, for our models the word order matters, i.e. generally $p(f|e_1, e_2) \neq p(f|e_2, e_1)$.

The proposed **Bi-HMM** factors the alignment probability in a manner similar to the Mono-HMM. First of all, for a given alignment we introduce the notion of the *head* of target position j, denoted h_j. In case the position was aligned at least once, we define h_j as the smallest target position aligned to j, i.e. $h_j = a_{j,1}$ if $a_{j,1} \neq 0$ and $h_j = a_{j,2}$ else. In case of unaligned positions h_j is set to the head of the largest *aligned* previous target position. Hence we use a full first-order dependence, which in practice requires doubling the state space - see (Vogel et al., 1996). The alignment probabilities are now

$$p(0, a_{j,2} \,|\, h_{j-1}, b{=}0, I) \;=\; p_{inter}(a_{j,2} \,|\, h_{j-1}, I)$$

and for $a_{j,1} > 0$

$$p(a_{j,1}, a_{j,2} | h_{j-1}, b{=}1, I) = p_{inter}(a_{j,1} \,|\, h_{j-1}, I) \cdot p_{intra}(a_{j,2} \,|\, a_{j,1})\,.$$

Note that both cases rely on the same probability model $p_{inter}(\cdot|\cdot)$. The second case has an additional distribution $p_{intra}(\cdot|\cdot)$. Both are modeled separately using a parametric distribution described below. Note that $p_{intra}(i|i') = 0$ if $i \leq i'$.

Superficially the Bi-HMM looks similar to (Deng and Byrne, 2005). However, this latter is actually a Mono-word model.

Parametric HMMs. It is well-known that HMMs for word alignment perform best using parametric alignment probabilities. For both the Mono-HMM and the Bi-HMM, we follow Vogel et al. (1996) and consider only the difference $i - i'$ to model $p_{inter}(i|i', I)$. Here, only differences between -5 and 5 are modeled by separate parameters $r_{-5}, \ldots, r_5$, all larger differences are captured by a single parameter r_L. To make this a probability distribution, the latter parameter is spread uniformly over all possible differences (with absolute larger than 5) in the respective context. Lastly, we introduce parameters p_0 and p_1 ($p_0{+}p_1{=}1$), where p_0 denotes the probability for unaligned words. The alignment probability is now

$$p_{inter}(i \,|\, i', I) = \begin{cases} p_0 & \text{if } i = 0 \\ p_1 \, \frac{r_{i-i'}}{\tau_{i',I}} & \text{if } i > 0,\ |i - i'| \leq 5 \\ \dfrac{p_1 \cdot r_L}{\tau_{i',I} \, |\{i'' : |i'' - i'| > 5\}|} & \text{else,} \end{cases}$$

with[1]

$$\tau_{i',I} = \sum_{1 \leq i \leq I : |i-i'| \leq 5} r_{i-i'} + r_L \quad . \qquad (2)$$

A special case arises for the initial alignment probabilities $p(h_1{=}i|I)$. Rather than fixing them to $1/(2I)$ (including empty words), as is common, we model these parametrically (with renormalization, but without grouping).

In case of the Bi-HMM, there is further the probability $p_{intra}(\cdot|\cdot)$, which we also parameterize based on positive distances, grouping those larger than 5. In principle, each of the three arising distributions has its own parameter set. However, the initial probability and the inter-alignment model share the parameters p_0 and p_1.

4 Objective Functions

In word alignment one is given a large set of sentence pairs, not a single pair. We denote the sth pair by $\mathbf{f}^s, \mathbf{e}^s$. The standard approach to word alignment is maximum likelihood, i.e. minimizing

$$-\sum_s \log(p(\mathbf{f}^s \,|\, \mathbf{e}^s))$$

over the parameters of the model. Here, we are considering a conditional model, which can be any of the above mentioned.

[1] If differences of more than 5 are impossible, the term r_L is dropped from the equation.

Such models are known to have weaknesses called *garbage collection*. This refers to the phenomenon that rarely occurring source words tend to align to a significant portion of the target words in the respective sentences, since the probability mass of the frequent words is better used to explain the sentences without rare words. The effect is known to worsen when one moves beyond single word based models (DeNero et al., 2006).

It is known that joint models suffer less from this deficiency when dealing with the same set of possible alignments. However, joint models are usually hard to handle computationally, whereas the mentioned conditional models behave quite nicely. Hence, we use conditional models, but propose to alter the training criterion. We add a regularity term that penalizes the used probability mass in a (non-negative) weighted L_1 manner. We state this for Bi-word models, but note that the Mono-word models are included by fixing $e_1 = NULL$:

$$-\sum_s \log(p(\mathbf{f}^s \mid \mathbf{e}^s)) + \sum_{\mathbf{e_1},\mathbf{e_2},f} w^f_{e_1,e_2}\, p(f|e_1,e_2) \quad (3)$$

Here $w_{e_1,e_2} \geq 0$ are known weights (see below). For the new objective to make sense, we need to augment the parameter space: for every constellation e_1, e_2, we add a probability $p(NULL|e_1,e_2)$. In the standard ML-criterion this entry will always be set to 0. Not so with our new criterion: since we set the respective weighting factor $w^{NULL}_{e_1,e_2}$ to 0 it may be cheaper not to use the entire mass to explain the corpus.

Choice of Weights. When dealing with Mono-word models we only penalize rare words since they cause the garbage collection phenomenon. Let $N(e)$ be the number of times the source word e occurs in the corpus. If $N(e) \geq 6$ we set $w^*_{0,e}$ to 0, otherwise it is set to $\lambda[6 - N(e)]$, where λ is some weight. We found $\lambda = 2.5$ to work well.

For Bi-word models we presently set all Mono-word weights $w^*_{0,*}$ to 0. The Bi-word penalties are based on a value of $\lambda = 0.5$, but rare source word pairs pay a larger penalty (The equation is $\lambda \cdot \max\{1, 5 - N(e_1,e_2)\}$, where $N(e_1,e_2)$ is the number of times the pair e_1, e_2 occurred).

5 Optimization Strategies

We present two optimization schemes to handle the arising minimization problems: one is based on Expectation Maximization (EM), the other on projected gradient descent (PGD). To make the paper self-contained, we include a sketch of the relevant equations, noting that they are probably known in other contexts. We detail the scheme on the Bi-word models, the Mono-word models can be handled analogously.

Constraints First of all we note that we are dealing with a *constrained* optimization problem, since the objective (3) is minimized over the parameters of probability distributions. For the dictionary parameters we have positivity constraints and normalization constraints:

$$p(f|e_1,e_2) \geq 0 \quad \forall f, e_1, e_2 \ ,$$

$$\sum_f p(f|e_1,e_2) = 1 \quad \forall e_1, e_2 \ .$$

This is known as a *product of simplices*, a relatively easy constraint system. For the Bi-1 there are no more parameters to optimize.

For the Bi-HMM (and also the Mono-HMM) there are the parameters $r_{-5}, \ldots r_5$ and r_L of the inter-alignment model. Each one comes with a positivity constraint. Moreover, these parameters are determined only up to scale, so we introduce the simplex constraint that they sum to 1: $\sum_{k=-5}^{5} r_k + r_L = 1$. The same principle applies to the parameters of the initial probability and of $p_{intra}(\cdot|\cdot)$.

5.1 Projected Gradient Descent

We first present a solution based on *projected gradient descent* (PGD) (Bertsekas, 1999, chap. 2), which is applicable since our constraint set is convex. Even though EM is usually the better suited method, we recommend reading this section as some auxiliary problems of EM are optimized by a very similar method.

PGD is similar to unconstrained gradient descent: one iteratively computes the gradient of the objective and takes a step in this direction. In general one will leave the feasible region, so one takes the closest feasible point instead. This operation is called *projection*. In our case we use the method of (Michelot, 1986). Finally, this point can have a higher energy than the previous, but the direction between the two points is a *descent direction*. We do a backtracking line-search to find a step in this direction that gives a sufficient decrease in the objective value. For the convex Bi-1 model this will eventually reach the global optimum, for the Bi-HMM a local optimum (as is standard for HMMs).

Obviously, the gradient of the regularity term (w.r.t. the dictionary parameters) is the weight vector with entries $w^f_{e_1,e_2}$. Further, the gradient of the standard maximum likelihood term is additive over the sentences. Hence, in the following we only state the gradients of a single sentence pair, i.e. $\frac{\partial}{\partial\theta} - \log(p(\mathbf{f}^s|\mathbf{e}^s))$, where θ is either a dictionary or an alignment parameter.

All considered models are so-called *multinomial* distributions. As shown in the appendix, for such distributions the gradient w.r.t. the dictionary parameters is given by

$$\frac{\partial}{\partial p(f|e_1,e_2)} - \log(p(\mathbf{f}^s|\mathbf{e}^s)) = -\frac{\sum_{\mathbf{a}} k_{\mathbf{a}}(f,e_1,e_2)\, p(\mathbf{a}|\mathbf{f}^s,\mathbf{e}^s)}{p(f|e_1,e_2)} \tag{4}$$

where $k_{\mathbf{a}}(f,e_1,e_2)$ is the number of times f aligns to both e_1 and e_2 in the alignment $\mathbf{a}$ and for the considered sentence pair. Note that the numerator of the ratio is the *expectation* of f aligning to e_1 and e_2 in the given sentence pair. This expression is also a fundamental building block of standard EM. For the Mono-1 and Bi-1 this is simply a sum over the source positions j. For the Mono- and Bi-HMM it can be calculated by the forward-backward algorithm (Baum et al., 1970).

With a similar argument one can derive the partial derivatives of the alignment parameters. We exemplarily detail this for $p_{\text{inter}\cdot}$. Let θ denote any of the parameters $p_0, p_1, r_{-5}, \ldots, r_5$ and r_L. Then one can show that

$$\frac{\partial}{\partial\theta} - \log(p(\mathbf{f}^s|\mathbf{e}^s)) = -\sum_{i,i'} \frac{\sum_{\mathbf{a}} k_{\mathbf{a}}(i|i',I_s)\, p(\mathbf{a}|\mathbf{f}^s,\mathbf{e}^s)}{p(i|i',I_s)} \cdot \frac{\partial p(i|i',I_s)}{\partial\theta}, \tag{5}$$

where $k_{\mathbf{a}}(i|i')$ denotes the number of times a source word is aligned to position i when the head of the previous source word was i'.

It remains to derive the partial derivatives of $p(i|i',I_s)$ w.r.t. the alignment parameters. For p_0 and p_1 this is straightforward. For a regular count r_k with $|k| \leq 5$ we have

$$\frac{\partial}{\partial r_k} p(i|i',I) = \begin{cases} p_1 \frac{\tau_{i',I} - r_k}{\tau^2_{i',I}} & \text{if } k = i - i' \\ p_1 \frac{-r_{i-i'}}{\tau^2_{i',I}} & \text{if } |i-i'| \leq 5 \\ p_1 \frac{-r_L}{\tau^2_{i',I} \cdot n^L_{i',I}} & \text{else}, \end{cases}$$

where $\tau_{i',I}$ is as in (2). The derivative w.r.t. r_L is

$$\frac{\partial}{\partial r_L} p(i|i',I) = \begin{cases} p_1 \frac{\tau_{i',I} - r_L}{\tau^2_{i',I} \cdot n^L_{i',I}} & \text{if } |i-i'| > 5 \\ p_1 \frac{-r_{i-i'}}{\tau^2_{i',I} \cdot n^L_{i',I}} & \text{else}, \end{cases}$$

with $n^L_{i',I} = |\{i'' : 1 \leq i'' \leq I, |i''-i'| > 5\}|$.

5.2 Expectation Maximization

A very commonly used method for word alignment is *expectation maximization* (Neal and Hinton, 1998). We give a modified version that handles our new objective function. Note that modifications of EM have been derived before, e.g. (Ganchev et al., 2010).

Traditionally, EM is used for standard maximum likelihood optimization. Denoting the parameters of the model as $\boldsymbol{\theta}$, the respective minimization problem would be

$$\min_{\boldsymbol{\theta}} \sum_{s=1}^{S} -\log(p(\mathbf{f}_s|\mathbf{e}_s,\boldsymbol{\theta})) \ .$$

The function to be minimized is called *negative log-likelihood*. It follows from (Neal and Hinton, 1998) that the function

$$F(\boldsymbol{\theta},\tilde{\boldsymbol{\theta}}) = \sum_{s=1}^{S} \sum_{\mathbf{a_s}} -p(\mathbf{a_s}|\mathbf{f}_s,\mathbf{e}_s,\tilde{\boldsymbol{\theta}}) \Big[\log(p(\mathbf{f}_s,\mathbf{a}_s|\mathbf{e}_s,\boldsymbol{\theta})) - \log(p(\mathbf{a_s}|\mathbf{f}_s,\mathbf{e}_s,\tilde{\boldsymbol{\theta}})) \Big]$$

is an upper bound on the negative log-likelihood function, independent of the choice of $\tilde{\boldsymbol{\theta}}$. In fact, $F(\boldsymbol{\theta},\boldsymbol{\theta})$ is exactly the negative log-likelihood for $\boldsymbol{\theta}$. As a consequence,

$$F(\boldsymbol{\theta},\tilde{\boldsymbol{\theta}}) + \sum_{\mathbf{e_1},\mathbf{e_2}} \sum_{f} w^f_{e_1,e_2}\, p(f\,|e_1,e_2) \tag{6}$$

upper bounds our new objective (3) - note that all $p(f|e_1,e_2)$ are entries in the vector $\boldsymbol{\theta}$. As in standard EM, we now perform coordinate descent on this new function: we iteratively update $\tilde{\boldsymbol{\theta}}$ to the vector that minimizes the objective for fixed $\boldsymbol{\theta}$. The optimal value is given as the expectation of alignments given $\boldsymbol{\theta}$ (Neal and Hinton, 1998), which is why this term is generally called E-step. The respective calculations in our case are exactly as the ones performed in gradient descent.

The second step in each iteration is called M-step and consists of setting $\boldsymbol{\theta}$ to the optimal value

for the given $\tilde{\boldsymbol{\theta}}$ and hence the given coefficients $p(\mathbf{a_s} \mid \mathbf{f}_s, \mathbf{e}_s, \tilde{\boldsymbol{\theta}})$. While for simple models there is often an analytic solution, in our case we are not aware of one for *any* of the parameters (except for special cases, e.g. when all $w^f_{e_1,e_2}$ are 0). Note, that this implies that the popular toolkit GIZA++ is not doing the M-step correctly: when applying the equations derived below, we verified that renormalizing expectations does *not* minimize the M-step energy. Moreover, with the common procedure the total energy usually only decreases in the first few iterations, after that it often increases.

The arising M-step decomposes into several independent optimization problems. In particular, there is a separate problem for each e_1, e_2 to update the respective dictionary distribution. The function to be minimized is

$$\sum_f \left[w^f_{e_1,e_2} p(f|e_1,e_2) - c^f_{e_1,e_2} \log(p(f|e_1,e_2)) \right] \ ,$$

where the weights c_{f,e_1,e_2} are the expectations (under the previous $\boldsymbol{\theta}$) of f aligning to e_1 and e_2. We solve this via gradient descent with the gradient

$$\frac{\partial}{\partial p(f|e_1,e_2)} = \sum_f \left[w^f_{e_1,e_2} - \frac{c^f_{e_1,e_2}}{p(f|e_1,e_2)} \right] \ ,$$

In special cases more efficient schemes are applicable. In particular it is well-known that if $w^f_{e_1,e_2} = 0$ for all f the optimal solution is given by re-normalizing the coefficients $c^f_{e_1,e_2}$. If $w^f_{e_1,e_2}$ is constant for all $f \neq NULL$, then in principle one only has to determine the probability $p(NULL|e_1,e_2)$. The remaining mass can again be spread according to normalized coefficients.

For the alignment parameters, we again only discuss $p_{\text{inter}}(\cdot|\cdot)$, where the auxiliary energy is

$$\sum_I \sum_{i,i'=1}^{I} -c^I_{i,i'} \log(p(i|i',I)) \ ,$$

and the gradient for an alignment parameter θ

$$\frac{\partial}{\partial \theta} = \sum_{i,i'=1}^{I} -\frac{c^I_{i,i'}}{p(i|i',I)} \frac{\partial p(i|i',I)}{\partial \theta} \ .$$

The inner derivatives were given in section 5.1. The parameters p_0 and p_1 are very simple to derive.

6 Experiments

We report results on three different data sets, in both directions each. The first two are Europarl sets (in the original casing), where we consider English-German[2] and English-Spanish[3]. Further, we consider the well-known Canadian Hansards task (French-English, lowercased). In all cases we report weighted f-measures (Fraser and Marcu, 2007b) on the publicly available gold alignments. We use a weighting factor of $\alpha = 0.1$, which performed well in Fraser and Marcu's work.

	EP De-En	**EP** Es-En	**Hs.** Fr-En
#sentences (large task)	500K	500K	1M
#sentences (small task)	15K	15K	25K
sent. length	80	75	40

Table 1: Statistics of the considered tasks. Es = Spanish, De = German, Fr = French, En = English, Hs. = Canadian Hansards, EP = Europarl. "K" denotes a thousand, "M" a million.

For the Mono-word models we consider large scale tasks with at least 500000 sentence pairs. For the Bi-word models the demand on computational resources is much higher, so we use tasks with 15000 to 25000 sentence pairs. We also evaluate the Mono-word models here, showing that the regularity term becomes more important in the case of scarce training data.

The most important statistics of all tasks are listed in Table 1. The methods required no more than 4 GB memory on these tasks. The running times on the large scale tasks sometimes slightly exceeded a day. For the small scale tasks even the Bi-word models need less than 12 hours. Without regularity, EM is clearly faster. But with regularity terms, EM and PGD are roughly equal in speed. In general, PGD finds a slightly higher energy than EM.

6.1 Comparison of Models

In this paper we have introduced new objective functions and argued that they alleviate some of the deficiencies of standard maximum likelihood for conditional models. As a consequence, we are interested in comparing models and objective functions, and not so much in getting the last bit of practical performance (f-measure).

Hence, when comparing[4] to GIZA++ we turn

[2] Gold alignments available at `http://www.maths.lth.se/matematiklth/personal/tosch/download.html`.

[3] Gold alignments from (Lambert et al., 2005).

[4] It is common to run GIZA++ with smoothing and only 5 iterations. Indeed, this improves the f-measures. However,

off smoothing. Also, we run more iterations than usual: for all methods (GIZA++, EM, PGD) we run 30 iterations of IBM-1, followed by 50 for the HMM. Here we use the same regularity terms for both models. For reference, we also evaluate the IBM-4 as implemented in GIZA++ (starting from the 50 HMM iterations, then doing 5 iterations of IBM-3 and 5 iterations of IBM-4).

For the Bi-word models we initialize the non-convex Bi-HMM by running the Bi-1 first (with the same regularity term, if any). The number of iterations is the same as for the respective Mono-word models.

Large Scale Tasks. In Table 2 we show the resulting f-measures on the large scale tasks for all mentioned strategies, including GIZA++'s HMM and IBM-4. Often our HMM outperforms GIZA++ (without smoothing), which may be due to the more precise M-step. Moreover, the regularity terms usually improve the results, where the effect is generally stronger the higher inflected the source language is. Still, the IBM-4 performs best everywhere, so in future work we will transfer our new objective to this model.

Small Scale Tasks. The results for the small tasks are given in Table 3. Here it can be seen that adding the regularity to the Mono-word models greatly improves on the f-measures of the baseline HMM and sometimes gets close to the IBM-4. For the Bi-word models the regularity terms also help greatly, and in the majority of cases beat the baseline Mono-HMM (without regularity).

Like for the large scale tasks, EM performs better than PGD and the corrected M-steps often beat GIZA++.

with the new objective function we also get better results for less iterations. A systematic comparison of this is left for future work.

6.2 Effect on Phrase-based Translation

We give a first evaluation of the effect of our alignments on phrase-based translation, where we ran MOSES with a 5-gram language model. We randomly picked translation from German to English with 750 unseen development and 3000 unseen test sentences.

As shown in the tables 4 and 5 the regularity terms do improve translation for Mono-word models. The Bi-word models are presently not competetive. Here we are showing the BLEU accuracy measure and the Translation Edit Rate (TER).

7 Conclusion

This paper has introduced the idea of regularizing the mass of the probability parameters that is

Table 3: Resulting F-measures ($\times 100$) for the small scale tasks.

used to explain the data. We have argued that these terms reduce overfitting and demonstrated experimentally that the introduced objectives improve the f-measures of the generated alignments. We often beat the baseline HMM, and transferring our objective to the IBM-4 would probably beat a baseline IBM-4.

Our comparison of projected gradient descent (PGD) and expectation maximization (EM) revealed that EM leads to better alignments, although PGD finds a comparable but slightly higher objective value. We also showed that parametric HMMs induce non-trivial M-steps.

In future work we want to address IBM-3 and IBM-4 and explore the effect on phrase-based translation in greater detail.

To facilitate further research in this area, the source code associated to this work is integrated into a tool called **RegAligner**, publicly available at the author's homepage and at `https://github.com/Thomas1205/RegAligner`.

Acknowledgments The author thanks Ben Taskar and João Graça for helpful discussions, as well as Alexander Engau and UC Denver for helping out with computational resources after the author had left Lund University. This work was in large part funded by the European Research Council (GlobalVision grant no. 209480).

Appendix

We now derive the partial derivative of the negative log-likelihood of a general (multinomial) probability w.r.t. a dictionary parameter $p(f|e_1, e_2)$. This derivation is probably not novel, but included here for completeness. The partial derivative is given by

$$\frac{\partial}{\partial p(f|e_1,e_2)} - \log(p(\mathbf{f}^s|\mathbf{e}^s)) = -\frac{1}{p(\mathbf{f}^s|\mathbf{e}^s)} \cdot \left[\sum_{\mathbf{a}^s} \frac{\partial}{\partial p(f|e_1,e_2)} p(\mathbf{f}^s, \mathbf{a}^s|\mathbf{e}^s) \right] .$$

Now take a fixed $\mathbf{a}$, and denote $k_{\mathbf{a}} \in \mathbb{N}_0$ the number of times the factor $p(f|e_1, e_2)$ is used in its probability, i.e.

$$p(\mathbf{f}^s, \mathbf{a}|\mathbf{e}^s) = c_{\mathbf{a}} \cdot p(f|e_1, e_2)^{k_{\mathbf{a}}} \ ,$$

where $c_{\mathbf{a}}$ is constant w.r.t. $p(f|e_1, e_2)$. Clearly

$$\begin{aligned} \frac{\partial p(\mathbf{f}^s, \mathbf{a}|\mathbf{e}^s)}{\partial p(f|e_1,e_2)} &= c_{\mathbf{a}} \cdot k_{\mathbf{a}} \cdot p(f|e_1, e_2)^{k_{\mathbf{a}}-1} \\ &= k_{\mathbf{a}} \frac{p(\mathbf{f}^s, \mathbf{a}|\mathbf{e}^s)}{p(f|e_1, e_2)} . \end{aligned}$$

This is how the claimed formula arises, i.e. the entire derivative is

$$-\frac{\sum_{\mathbf{a}} k_{\mathbf{a}}\, p(\mathbf{a}|\mathbf{f}^s, \mathbf{e}^s)}{p(f|e_1, e_2)} .$$

Parametric Weighting of Parallel Data for Statistical Machine Translation

Kashif Shah, Loïc Barrault, Holger Schwenk
LIUM, University of Le Mans
Le Mans, France.
FirstName.LastName@lium.univ-lemans.fr

Abstract

During the last years there is increasing interest in methods that perform some kind of weighting of heterogeneous parallel training data when building a statistical machine translation system. It was for instance observed that training data that is close to the period of the test data is more valuable than older data (Hardt and Elming, 2010; Levenberg et al., 2010). In this paper we obtain such a weighting by resampling alignments using weights that decrease with the temporal distance of bitexts to the test set. By these means, we can use all the available bitexts and still put an emphasis on the most recent one. The main idea of our approach is to use a parametric form or meta-weights for the weighting of the different parts of the bitexts. This ensures that our approach has only few parameters to optimize. We report experimental results on the Europarl corpus, translating from French to English and further verified it on the official WMT'11 task, translating from English to French. Our method achieves improvements of about 0.6 points BLEU on the test set with respect to a system trained on data without any weighting.

1 Introduction

Statistical machine translation (SMT) systems are based on two types of resources: monolingual data to build a language model (LM) and bilingual data – also called bitexts – to train the translation model (TM). The parallel data often comes from different sources, *e.g.* Europarl, UN, in-domain data in limited amounts, data crawled from the Internet or even bitexts automatically extracted from comparable corpora. It seems obvious that the appropriateness and the usefulness of this parallel data for a particular translation task may vary quite a lot. Nevertheless, the standard procedure is to concatenate all available parallel data, to perform word alignment using GIZA++ (Och and Ney, 2000) and to extract and score the phrase pairs by simple relative frequency. Doing this, the parallel data is (wrongly) considered as one homogeneous pool of knowledge. We argue that the parallel data is quite inhomogeneous in many practical applications with respect to several factors:

- the data may come from different sources that are more or less relevant to the translation task (in-domain versus out-of-domain data).
- more generally, the topic or genre of the data may be more or less relevant.
- the data may be of different quality (carefully performed human translations versus automatically crawled and aligned data).
- the recency of the data with respect to the task may have an influence. This is of interest in the news domain where named entities, etc change over time.

There have been several attempts in the literature to address some of these problems. Matsoukas et al. (2009) proposed to weight each sentence in the training bitexts by optimizing a discriminative function on a tuning set. Sentence-level features are extracted to estimate the weights that are relevant to the given task. Foster et al. (2010) proposed an extended approach by an instant weighting scheme which learns weights on individual phrase pairs instead of sentences and incorporated the instance-weighting model into a linear combination of feature functions.

The technique presented in this paper is related to these previous works as it concerns the weighting of corpora or sentences. However, it does not

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1323–1331,
Chiang Mai, Thailand, November 8 – 13, 2011.

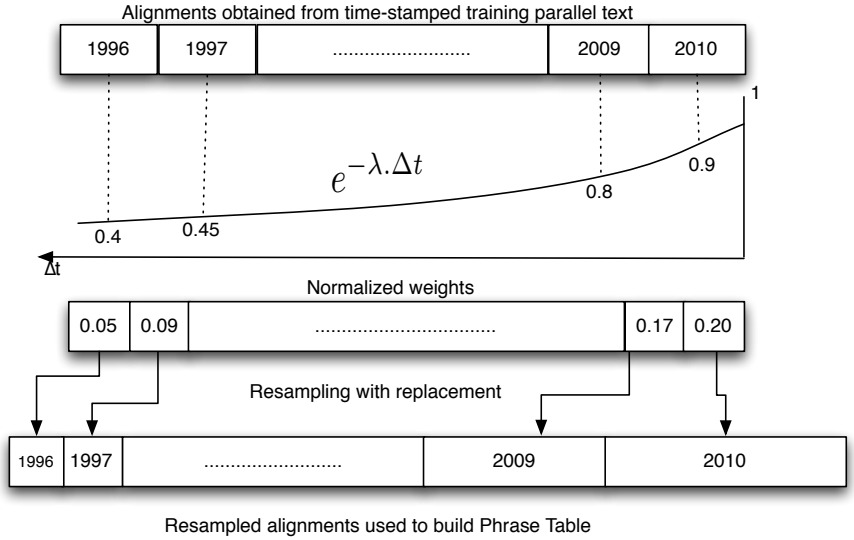

Figure 1: Overview of the weighting scheme. The alignments are weighted by an exponential decay function, parameterized by λ. Resampling with replacement is used to create a new corpus (parts with higher weight will appear more often). The phrase table is built from this corpus using the standard procedure.

require the calculation of additional sentence-level features.

In our previous work Shah et al. (2010) we proposed a technique to weight heterogeneous data by weighted resampling of the alignments. The weights were numerically optimized on development data.

Hardt and Elming (2010) has shown recency effect in terms of file-context and concluded that the data within the same file is of greater importance than the rest. Levenberg et al. (2010) proposed an incremental training procedure to deal with a continuous stream of parallel text. Word alignment was performed by the stepwise online EM algorithm and the phrase table was represented with suffix arrays. The authors showed that it is better to use parallel data close to the test data than all the available data.

The research presented in this paper is the extension of our previous work Shah et al. (2010) to weight corpora by resampling and is inspired by the work of Levenberg et al. (2010) to consider the recency of the training data. In fact, we could split the training data into several parts over time scale and use our previous resampling approach Shah et al. (2010) to automatically optimize the weights of each time period. However, this approach does not seem to scale very well when the number of individual corpora increases. Numerical optimization of more than ten corpus weights would probably need a large number of iterations, each one consisting in the creation of a complete phrase table and its evaluation on the development data.

The main idea of our work is to consider some kind of meta-weights for each part of the training data. Instead of numerically optimizing all the weights, these meta-weights only depend on few parameters that need to be optimized. Concretely, in this work we study the exponential decrease of the importance of parallel data in function of its temporal distance to the development and test data. The weighting of the parts is still done by resampling the alignments. However, our general approach is not limited to weighting the training data with respect to recency to the development and test data. Any other criterion could be used as long as it can be calculated by a parametric function, *i.e.* to measure the topic appropriateness.

2 Weighting Scheme

The main idea of our work is summarized in Figure 1. We consider that time information is available for the bitexts. If this is not the case, one can consider that the time advances sequentially with the lines in the file. First, the data is considered in parts according to the time information. In Figure 1, we group together all data within the same year, but any other granularity is possible (months, weeks, days, etc). Given the observation that more recent training data seems to be more

important than older one, we apply an exponential decay function:

$$e^{-\lambda \cdot \Delta t} \quad (1)$$

where λ is the decay factor and Δt is the discretized time distance (0 for most recent part, 1 for the next one, etc.). Therefore, our weighting scheme has only one parameter to be optimized.

Following our previous work Shah et al. (2010), we resample the alignments in order to obtain a weighting of the bitexts according to their recency. The weight of each part of the bitexts is normalized (sum to one). The normalized weights represent the percentage of final aligned corpus that is originated from each part of the source corpus: word alignments corresponding to bitexts that are close to the test period will appear more often than the older ones in the final corpus.

In addition, we considered the quality of the alignments during resampling, as described in our previous work (Shah et al., 2010). Alignments produced by GIZA++ have alignment scores associated with each sentence pair in both direction, *i.e.* source to target and target to source. Alignment scores have a very large dynamic range and are concentrated around very low values, consequently the following logarithmic mapping is applied in order to flatten the distribution:

$$\log(\alpha \cdot \frac{(\sqrt[n_{trg}]{a_{src\_trg}} + \sqrt[n_{src}]{a_{trg\_src}})}{2}) \quad (2)$$

where a is the alignment score, n the size of a sentence and α a smoothing coefficient to optimize. We used these normalized alignment scores as confidence measurement for each sentence pair.

3 Description of the algorithm

The architecture is presented in Figure 2. The starting point is a parallel corpus. We performed word alignment in both directions using GIZA++. The corpus is then separated into several parts on the basis of a given time span. We performed experiments with different span sizes, namely year, month, week and day. The decaying function is scaled so that the range does not change when using different span sizes. A weighting coefficient obtained with the exponential decay function is then associated to each part.

[1]required_size depends upon the number of times we resample - see section 5.

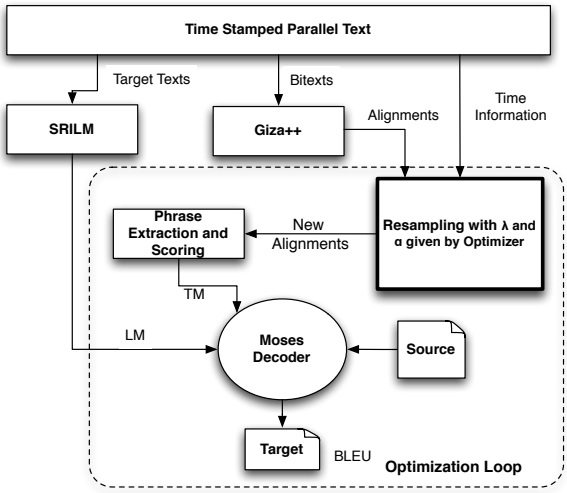

Figure 2: Architecture of SMT Weighting System.

Algorithm 1 Weighting with Exponential Decay function using resampling

1: Determine word to word alignment with GIZA++ on concatenated bitexts.
2: Initialize λ and α with equal weights.
3: **while** not Optimized **do**
4: Compute *time-spans* weights by eq. 1
5: Normalize weights
6: **for** $i = 0$ to *#time-span* **do**
7: $proportion \leftarrow$ required_size[1] $*$ weights$[i]$
8: j = 0
9: **while** $j < proportion$ **do**
10: $Al \leftarrow$ Random alignment
11: $Al_{score} \leftarrow$ normalized score of Al
12: Flatten Al_{score} with α
13: $Threshold \leftarrow$ rand[0, 1]
14: **if** $Al_{score} > Threshold$ **then**
15: keep it
16: $j = j + 1$
17: **end if**
18: **end while**
19: **end for**
20: Create new resampled alignment file.
21: Extract phrases and build the phrase table.
22: Decode
23: Calculate the BLEU score on Dev
24: Update λ and α
25: **end while**

Then, for each part, resampling with replacement is performed in order to select the required number of alignments and form the final corpus. The resampling is done as follows: for each alignment considered, a new random threshold is gen-

erated and compared to the alignment score. The alignment is kept only if its score is above the threshold. This ensures that all alignments have a chance to be selected, but this chance is proportional to its alignment score.

Note that some alignments may appear several times, but this is exactly what is expected as it will increase the probability of certain phrase pairs which are supposed to be more related to the test data (in terms of recency) and of better quality. The smoothing and decay factors, α and λ respectively, are optimized with a numerical optimizer called CONDOR (Berghen and Bersini, 2005). The procedure and steps involved in our weighting scheme are shown in algorithm 1.

4 Experimental evaluation

Our first experiments are based on the French-English portion of the freely available time-stamped Europarl data (Koehn, 2005) from April 1996 to December 2010. We have built several phrase-based systems using the Moses toolkit (Koehn et al., 2007), though our approach is equally applicable to any other approach based on alignments and could be used for any language pairs. In our system, fourteen feature functions are used. These feature functions include phrase and lexical translation probabilities in both directions, seven features for the lexicalized distortion model, a word and phrase penalty, and the target language model. The coefficients of these feature functions are optimized by minimum error training.

In the first experiments, the whole Europarl corpus was split into train, development and test as shown in Figure 3. The most recent 5K sentences are split into two sets of equal size, one for development and the other for testing. The remaining data was used as training bitexts to build the different systems.

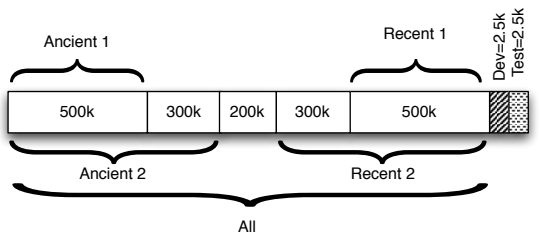

Figure 3: Data used to build the different systems (# sentences)

Since we want to focus on the impact of the weighting scheme of the bitexts, we used the same language model for all systems. It has been trained with the SRILM toolkit (Stolcke, 2002) on the target side of all the training data. In addition, the weights of the feature functions were tuned once for the system that uses all the training data and then kept constant for all the subsequent experiments, *i.e.* no tuning of the feature functions weights is done during the optimization of the weighting coefficients λ and α.

Table 1 presents the results of the systems trained on various parts of the available bitexts without using the proposed weighting scheme. The best performance is obtained when using all the data (55M words, BLEU=30.48), but almost the same BLEU score is obtained by using only the most recent part of the data (24M words, part *Recent 2*). However, if we use the same amount of data that is further away from the time period of the test data (25M words, part *Ancient 2*), we observe a significant loss in performance. These results are in agreement with the observations already described in (Levenberg et al., 2010). Using less data, but still close to the evaluation period (15M words, part *Recent 1*) results in a small loss in the BLEU score. The goal of the proposed weighting scheme is to be able to take advantage of all the data while giving more weight to recent data than to older one. By these means we are not obliged to disregard older parts of the data that may contain additional useful translations. If the weighting scheme does work correctly, we cannot perform worse than using all the data. Of course, we expect to achieve better results by finding the optimal weighting between recent and ancient data.

The amount of data per year in the Europarl data can vary substantially in function of time period since it depends on the frequency and length of the sessions of the European Parliament. As an example Figure 4 shows the histogram of the data per year.

One can ask which time granularity should be used to achieve best weights. Only one weight is given to each time span, consequently the span size will have an impact on the alignment selection process. Using smaller spans results in a more fine grained weighting scheme. We have tested different settings with different time spans to see whether the impact of weighting changes with the

Europarl	Ancient data		Recent data		
	Ancient 1	Ancient 2	Recent 1	Recent 2	All
# of sentences/words	500K/15M	800K/25M	500K/15M	800K/24M	1800K/55M
BLEU (on dev)	29.84	30.08	30.80	31.09	**31.34**
BLEU (on test)	29.30	29.43	30.32	30.44	**30.48**

Table 1: BLEU scores obtained with systems trained on data coming from different time spans.

Europarl	Weighting + alignment selection				Best+retune
Time span	Days	Weeks	Months	Years	Years
Optimized λ	0.0099	0.0109	0.0110	0.0130	0.0130
BLEU (on dev)	31.73	31.82	31.75	31.80	**31.92**
BLEU (on test)	30.94	30.97	30.92	**30.98**	**31.09**

Table 2: Results in BLEU score after weighting.

size of each span. The results are shown in Table 2.

It is observed that all four systems obtained very similar results, which indicates that the size of the spans is not very important. One surprising observation is that the optimized decay factor for all time span sizes are really close to each other. The reason to this could be the scaling of the exponential decaying function based on the time span size. In fact scaled values ensure that the oldest data point get roughly the same value independent of using years, months or days as time span. Looking at the optimized values of λ in Table 2, we can observe that the relative difference between recent and ancient data is rather small, *i.e.* the ancient data is still somehow important and cannot be neglected.

By using years as time span, we obtain an improvement of +0.50 BLEU score on the test set compared to using all data without weighting (30.48 $\rightarrow$ 30.98). It is clear that recency has a positive impact on system performance, however, weighting properly the different parts gives better performance than using the most recent or all available data.

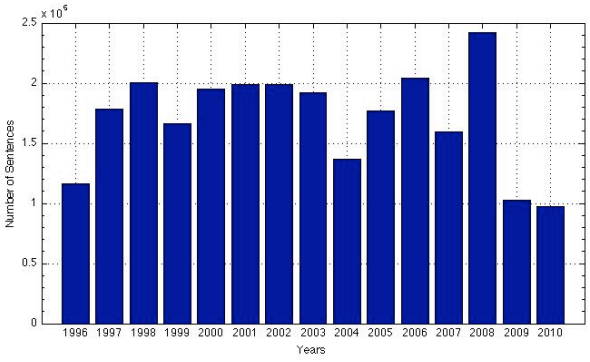

Figure 4: Amount of data available in the Europarl corpus for each year

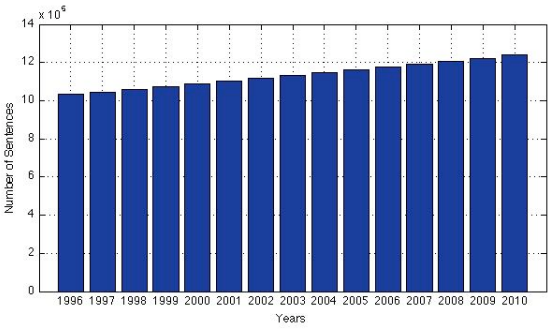

Figure 5: Distribution of data after weighting

Finally, the best system is retuned (feature functions weights) and an overall improvement of +0.61 in the BLEU score is observed on test set.

5 Discussion

The optimal decay factor of approximately 0.01 actually leads to an almost linear decrease over time. The difference in the quantity of data taken from most recent and least recent data is only 1.4% (which still represent 200k sentences). Therefore, one could think that the weighting does not favor recent data that much. This is not the case as we can see in Figure 5 where the distribution of data used to build the adapted model is presented.

Europarl	Resampling only	Weighting only	alignment selection only
BLEU (on dev)	31.36	31.69	31.45
BLEU (on test)	30.51	30.84	30.64

Table 3: Results in BLEU score with different settings.

B:	no Member State has led to **tests on the ground** as regards BST .
R:	No Member State has yet carried out **field tests** with BST .

Table 4: Example translations produced by systems *All* (A) and *Best+retune* (B) versus reference (R)

When comparing to Figure 4, the overall proportion of data coming from recent years is clearly bigger when using our resampling approach. This leads to different word choices while decoding.

Note that resampling is performed several times to estimate and select the samples which better represent the target data set. The more often we resample, the closer we get to the true probability distribution. The *required-size* in algorithm 1 depends upon the number of times we resample. We resampled ten times in our experiments. It is also worth to note that, we keep the original training data along with resampled one. It ensures that no information is lost and the set of extracted phrase pairs remain the same - only the corresponding probability distributions in the phrase table are changed.

In order to get more insight in our method, we separately performed the different techniques:

- resampling the training data without weighting;
- resampling the training data using weighting only (with respect to recency);
- resampling the training data using alignment selection.

These results are summarized in Table 3.

Note that the first case does not correspond to duplicating the training data a certain amount of time (which would of course produce exactly the same phrase-table). Since we perform resampling with replacement, this procedure introduces some randomness which could be beneficial. According to our results, this is not the case: we obtained exactly the same BLEU scores on the dev and test data than with the standard training procedure. Weighting with respect to recency or alignment quality both slightly improve the BLEU, but not as much as both techniques together. The performance increase seems actually to be complementary.

Some comparative examples between the translations produced by systems *All* and *Best+retune* versus the reference translations are given in Table 4. It was noticed that a lot of occurrences of *"will"* in the reference are actually translated into *"shall"* with system *All* whereas the correct word choice is made by the system *Best+retune* as shown in Example 1. This could be explained by the fact that recently the word *"will"* is more frequently seen in the training corpus and adapting the model by weighting the most recent data pro-

WMT Task	Baseline	Receny weighting + alignment selection	Recency weighting + alignment selection + relative importance
BLEU (on dev)	26.08	26.51	**26.60**
BLEU (on test)	28.16	28.59	**28.69**

Table 5: Results in BLEU score after weighting on English to French WMT Task.

duced correct translation. Actually, it was found that the word *"will"* is 10% more frequent in recent data (*Recent 1*) than in ancient data (*Ancient 1*) while the word *"shall"* is 2% less frequent.

Another interesting example is Example 2, in which the correct name for the *European Court of Justice* is proposed by the adapted system unlike the system *All* which proposed *Court of Justice of the European Communities*. Actually, it appears that the *Court of Justice of the European Communities* is the former name of the *European Court of Justice* prior to December 2009. The use of recent data allows to correctly translate the named entities which can change over time. The correct translation proposed by System *Best+retune* could be observed in Example 3 because of alignment selection procedure.

In our experiments, we assume that the test data is in present time (the usual case in a news translation system), and consequently we decrease the weight of the bitexts towards the past. This principle could be of course adapted to other scenarios.

An alternative approach could be to directly use the time decay function as the count for each extracted phrase. However, resampling the alignments and changing the counts of extracted phrases is not exactly the same. Same phrase pairs could be extracted from different parallel sentences coming from different time spans. Furthermore, weighting the alignments with their scores has shown improvements in the BLEU score as presented in Table 3, but considering the alignment score at the phrase level is not straight forward.

6 Experiments on the WMT task

To further verify whether our results are robust beyond the narrow experimental conditions, we considered a task where the development and test data do not come from the same source than the bitexts. We took the official test sets of the 2011 WMT translation tasks as dev and test sets (Schwenk et al., 2011) *i.e* news-test09 and news-test10 respectively. We built English-French systems by using the Europarl and News-Commentary (NC) corpora, both contain news data over a long time period.

For this set-up, there are three coefficients to optimize: the decay factor for Europarl λ_1, the decay factor for the news-commentary texts λ_2 and a coefficient for the alignments α. The Europarl corpus was divided into time span according to years and *NC* corpus was assumed to be sorted over time since time-stamp information was not available for the *NC* corpus. Remaining settings are kept same as mentioned in previous experiments to build the system *Best+retune*. The results are shown in Table 5. Finally, we considered the relative importance of the Europarl and *NC* corpora. For this, a weight is attached to each corpus which represents the percentage of the final aligned corpus that comes from each source corpus. These weights are also optimized on the development data using the same technique as proposed in our previous work (Shah et al., 2010). Using all these methods, we have achieved an overall improvement of approximately +0.5 BLEU on the development and test data, as shown in Table 5.

7 Conclusion and future work

In this paper, a parametric weighting technique along with resampling is proposed to weight the training data of the translation model of an SMT system. By using a parametric weighting function we circumvented the difficult problem to numerically optimize a large number of parameters. Using this formalism, we were able to weight the parallel training data according to the recency with respect to the period of the test data. By these means, the system can still take advantage of all data, in contrast to methods which only use a part of the available bitexts. We evaluated our approach on the Europarl corpus, translating from French into English and further tested it on official English to French WMT Task. A reasonable improvement in

BLEU score on the test data was observed in comparison to using all the data or only the most recent one. We argue that weighting the training data with respect to its temporal closeness should be quite important for translating news material since word choice in this domain is rapidly changing.

An interesting continuation of this work is to consider other criteria for weighting the corpora than the temporal distance. It is clear that recency is a relevant information and this could be associated with other features, *e.g.* thematic or linguistic distance. Also, this work can be included into a stream-based framework where new data is incorporated in an existing system by exponential growth function and making use of online retraining procedure as discussed in (Levenberg et al., 2010).

Abstract

Transliteration is the process of proper name translation based on pronunciation. It is an important process in many multilingual natural language tasks. A common and essential component of transliteration approaches is a verification mechanism that tests if the two names in different languages are translations of each other. Although many transliteration systems have verification as a component, verification as a stand-alone problem is relatively new. In this paper, we propose a simple, effective and robust training framework for the task of verification. We show the many applications of the verification techniques. Our proposed method can operate on both phonemic and orthographic inputs. Our best results show that a simple, straightforward orthographic representation is sufficient and no complex training method is needed. It is effective because it achieves remarkable accuracies. It is robust because it is language-independent. We show that on Chinese and Korean our technique achieves equal error rate well below 1% and around 1% for Japanese using 2009 and 2010 NEWS transliteration generation share task dataset. Our results also show that the orthographic system outperforms the phonemic system. This is especially encouraging because the orthographic inputs are easier to generate and secondly, one does not need to resort to more complex training algorithm to achieve excellent results. This approach is integrated for proper name based cross lingual information retrieval without translation.

This work was partially sponsored by "Aim for the Top University Plan" of National Taiwan Normal University and Ministry of Education, Taiwan.

1 Introduction

Proper name transliteration is important in many multilingual natural language processing tasks, such as Machine Translation (MT), Cross Lingual Information Retrieval (CLIR), multilingual spoken document retrieval and transliteration mining. The research community has investigated automatic proper name transliteration generation. The best performance with 10 references is approximately 70% for alphabet based edit distance error (Li et al., 2009). With one reference, the error rate can be as high as 50% (Meng et al., 2001; Virga and Khudanpur, 2003). If the error rate is measured using the whole proper name as a unit, the error rate will be even higher.

Alternatively, method for transliteration verification starts to draw attention in the research community. Given a pair of proper names in the source and target languages, the task is to decide whether they are transliterations of each other. This task is important for many applications. For example, in word alignment (Ittycheriah and Roukos, 2005), the unknown words are handled by computing a similarity score with the words in the target language. A similarity score derived from transliteration verification has been successfully applied to CLIR (Jan et. al., 2010). In their approach, CLIR can be achieved without translation of input proper name queries. More importantly, this technique is extremely useful in creating proper name pair training data (Kumaran et al., 2010). Given the vast amount of comparable data on the Internet, a technique that can reliably identify name pairs in different language is indispensable. (Kumaran et al., 2010) launched a new NEWS Transliteration Mining task. This task depends heavily on the accuracy of proper name verification techniques. In this paper, we propose a framework for the problem of transliteration verification. We show a highly accurate scoring mechanism that achieves very impressive results. This mechanism can be used as a tool for screening the transliteration par-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1332–1340,
Chiang Mai, Thailand, November 8 – 13, 2011.

allel corpus, validating good data and filtering out bad data. In addition to the applications mentioned above, our method can also be used as an evaluation metric. The research community has been using methods such as word error rate, EER, precision and recall and its many variants as metrics to evaluate systems. However, due to homonyms and phone-set differences across multiple languages, word error rate is not always sufficient to distinguish transliteration accuracy. We envision our method as a novel and reliable metric in evaluating transliteration systems. Its simplicity, accuracy, and robustness will serve well as an automatic metric.

2 Background and Related Work

The problem of name transliteration was previously viewed as a translation problem. Virga and Khudanpur (2003) applied SMT models to translate English names into Chinese characters. Knight and Graehl (1997) proposed a generative transliteration model for Japanese and English using finite state transducers. Meng et al. (2001) developed an English-Chinese Named Entity transliteration technique using pronunciation lexicon and phonetic mapping rules. Li et al. (2004) proposed direct orthographic mapping with a joint source-channel model for proper name transliteration.

There have also been other approaches to transliteration. Al-Onaizan and Knight (2002) used verification as a stepping stone to transliteration. More recently, the JHU Workshop (2008) reported on the importance of the similarity scoring method and conducted a comparative study on the various scoring methods for name transliterations.

Data harvesting is another way of improving transliteration. Additional data source such as comparable corpora (Klementiev and Roth, 2006; Kuo et al., 2007; Sproat et al., 2006) and the web (Jiang et al., 2007) have also been explored to improve the performance. One of the vital building blocks in all of these approaches is a scoring component that tests how likely a given pair of names in source and target languages is transliteration of each other. This is a key component and is the aspect we focus on in this work. We propose a method for transliteration verification that achieves the best EER compared to other approaches on the same dataset.

Our work differentiates itself from the previous work in the following areas. We take the verification as a stand-alone problem the solution of which has a variety of NLP applications. We tackle the problem by using highly accurate and robust techniques. The verification task can be cast into an alignment problem. We use a generative model for alignment which renders similarity relationships between the source and target name pairs in phone sequences. In phoneme-based systems where phoneme generation might be ambiguous and error prone, we show a discriminative training method together with an HMM-based decoding strategy that works remarkably well within the framework. In orthographic systems where the input can be reliably generated, we show that the HMM-based strategy is sufficient. Section 3 presents our novel approach to verification. Section 4 and 5 show experiments and results. Section 6 and 7 demonstrate an application of our approach and future work.

3 A Highly Reliable Similarity Score

Transliteration between English and foreign language, especially Asian languages: e.g. Chinese, remains a big challenge. We investigate ways of using verification techniques for transliteration. To that end, we need a high quality verification mechanism. For a given proper name pair, one from source language and the other from target language, we want to verify with high precision if this pair refers to the same proper name. Our goal is to devise a scoring method that yields high accuracy with low computational complexity.

Intuitively, proper name transliteration "translates" a proper name based on pronunciation. For a pair of foreign name w_f, and English name w_e, the similarity can be defined as:

$$Sim(w_f, w_e) \cong Sim(ph_f, ph_e), \quad (1)$$

where ph_f and ph_e are the corresponding phonetic sequences for the English and foreign names, respectively. Eq. (1) can be formulated as

$$Sim(ph_f, ph_e) = \lambda P(ph_f \mid \Lambda_{ph_e}) + (1-\lambda) P(ph_e \mid \Lambda_{ph_f}) \quad (2)$$

where Λ_{ph_e} and Λ_{ph_f} are the English and foreign phonetic models, respectively. For simplifica-

tion, it can be assumed that $\lambda = 0.5$ since the similarity function could be symmetric. Because the distributions of $P(ph_f \mid \Lambda_{ph_e})$ and $P(ph_e \mid \Lambda_{ph_f})$ are unknown, they need to be estimated through learning. Section 3.1 details the discriminative training process and section 3.2 presents an HMM-based decoding strategies to find the optimal alignment between ph_f *and* ph_e.

3.1 Model Estimation via SMT

One straightforward way to estimate the model parameters is to utilize the phrase tables produced by a phrase-based SMT framework. The phrase tables contain conditional probabilities of both *p(e|f)* and *p(f|e)*, which are the probabilities of English phrase given by foreign phrase and foreign phrase given by English phrase, respectively. When the phonetic sequences (either phonemic or orthographic) of English and foreign name pairs are the input into the SMT, the "phrase" table contains the phone set mappings between English and foreign phone sets together with their probabilities. We use these probabilities as the observation model in our HMM. We refer to this model as M_{SMT}.

3.2 Model Estimation via Discriminative Training

The discriminative training process involves finding an initial seed model and training in a decision-feedback learning framework.

One straightforward way to get an initial estimation for $P(ph_f \mid \Lambda_{ph_e})$ and $P(ph_e \mid \Lambda_{ph_f})$ is to utilize the phrase tables produced by the widely used phrase-based SMT system. The phrase tables contain both conditional probabilities of p(e|f) and p(f|e), which are the probabilities of English phrase given by foreign phrase and foreign phrase given by English phrase, respectively. When the phonetic sequences of English and foreign name pairs are fed into SMT, the "phrase" table contains the phone set mappings between English and foreign phone sets together with their probabilities. The phone set mapping is now data driven, and is free from the expensive and less flexible hand crafted linguistic phone set mapping rules. We refer to this model as M_{SMT}.

M_{SMT} is a straightforward and effective way to estimate the model parameters. Phoneme-based systems rely on the input texts being correctly converted to baseforms (phonemic sequences) representation. This process could be ambiguous, context-dependent, and error prone. In such systems, M_{SMT} serves as a good initial model. The model parameters can be further improved in a decision feed-back learning framework. The minimum classification error (MCE) training algorithm widely used in speech recognition can be applied here to improve the discrimination of the translation probability. We call this model M_{MCE}. Given a correct transliteration pair and other competitive transliteration hypotheses, we can define the transliteration error function as:

$$d_i(ph_f \mid \Lambda_{\mathbf{P}_e}) = -P(ph_f \mid \Lambda_{ph_e}) + \max_{f', f' \neq f} P(ph_{f'} \mid \Lambda_{ph_e}) \tag{3}$$

where $P(ph_f \mid \Lambda_{ph_e})$ is the alignment score obtained from the correct transliteration pair and $\max_{f', f' \neq f} P(ph_{f'} \mid \Lambda_{ph_e})$ is the highest competing score obtained from error transliteration pairs. The transliteration error function can be further transformed to a loss function ranging from 0 to 1 with the sigmoid operator:

$$l(d_i(ph_f \mid \Lambda_{ph_e})) = \frac{1}{1 + e^{(-\gamma d_i(ph_f \mid \Lambda_{ph_e}) + \theta)}} \tag{4}$$

where γ is used to control the slope of the function and θ is an offset factor. Above equation was then applied iteratively to update the translation probability:

$$p^{t+1}(ph_f \mid ph_e) = p^t(ph_f \mid ph_e) - \varepsilon \frac{\partial l(d_i(ph_f \mid \Lambda_{\mathbf{P}_e}))}{\partial p(ph_f \mid ph_e)} \tag{5}$$

3. 2 Decoding: Similarity Score Calculation

In order to calculate the similarity score for a given proper name pair (w_f, w_e), their respective phonetic sequence (ph_f, ph_e) is first determined. Then, for this task, we employ an HMM-based decoding strategy. The models $P(ph_f \mid \Lambda_{ph_e})$ and $P(ph_e \mid \Lambda_{ph_f})$ learned in section 3.1 are used as observation models. Two monotonic HMM models (one with ph_f as states and one with ph_e

as states) are then used to align the phonetic sequences according to Eq. (6) below:

$$P^*(ph_f \mid \Lambda_{ph_e}) = \arg\max_{\mathbf{s}_e} P(ph_f, \mathbf{S}_e \mid \Lambda_{ph_e}),$$
$$P^*(ph_e \mid \Lambda_{ph_f}) = \arg\max_{\mathbf{s}_f} P(ph_e, \mathbf{S}_f \mid \Lambda_{ph_f}) \quad (6)$$

where S_e is the English state sequence and S_f is the foreign state sequence.

The state transition probabilities are set to be uniform. We extend the traditional HMM to allow a broader range of phone mapping configurations. Specifically, the null transition (Bahl et al., 1982) is used to represent skipping a state without consuming any observations. This allows one to null mapping. The null state is introduced so it can emit those observations without any correspondence states. This allows null to one mapping. The combination of null transition and null state allow many to many and many to one configurations as well. The valid state transition is constrained to be from left to right with self loop, and with maximum jump of three states as well as a null state and a null transition.

Figure 1 depicts the actions of the HMM trellis at decode time. In Figure 1, the x-axis represents the observations (foreign language) and the y-axis represents the states (English). Take for example, the circle where dashed lines with arrows are emanating from. When this circle makes a horizontal move (from ph_{f2} to ph_{f3}), the single state ph_{e2} produces multiple observations. Null transition happens when the shaded circle makes a vertical move (from ph_{e2} to ph_{e3}) without consuming any observation.

4 Experiment setup for transliteration similarity

We evaluate the performance of our similarity scoring mechanism on 3 language pairs, Chinese-English (CE), Korean-English (KE), and Japanese-English (JE). Both Type I errors (false reject of the matched pairs) and Type II errors (false accept of the unmatched pairs) are evaluated. The Equal Error Rate (EER) is used as the evaluation metric.

For Chinese-English, a parallel corpus of proper name pairs is extracted from the *people* section of the multilingual Wikipedia. Among these, approximately 3,000 pairs are used for training and 300 pairs for testing. The 300 pairs are used as a matched condition test. A separate 1000 unmatched test pairs are created randomly from the 300 matched pairs.

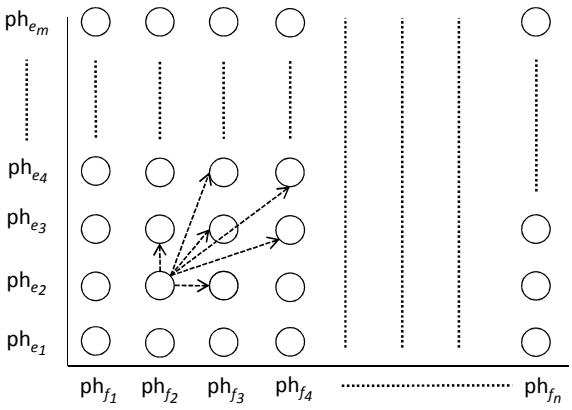

Figure 1 HMM Trellis

We also use the 2009 and 2010 NEWS transliteration generation shared task data as our test data. Although test our objective is different from those in the shared task, we choose this data because it is publicly available and can be used in the future for fair comparisons. We did not use NEWS 2010 transliteration miming shared task dataset because it did not contain Korean or Japanese. For Chinese, the 2009 data consists of 30K training and 2896 testing proper name pairs. Three systems are developed using 30K, 3K and 1K pairs of training data for our experiments. The 2896 proper name test pairs are used as matched pairs. Three unmatched test set pairs of size 10k, 100k and 1M are randomly generated. A 9M (2985x2986) unmatched pairs are also generated as an extreme test condition.

The Korean-English data comes from the 2010 NEWS transliteration generation data. It consists of 4,785 training pairs and 1,082 test pairs. Two systems with 1K and 4K of training pairs are developed; three sets unmatched pairs of size 10K, 100K, and 1M are generated. The Katakana Japanese-English data is from the same set (2010 NEWS data). It is bigger than the Korean data with 28K training instances and 1941 test pairs. Three systems with 1K, 4K and 28K training pairs are developed; three sets of unmatched pairs of size 10K, 100K, and 1M are also generated.

Training on 1K data matches the 2010 NEWS transliteration miming shared task (Kumaran et al., 2010) seed condition. Training on 3K-4K data matches the Wikipedia condition. Training on 28k for Japanese-English and 30K on Chinese-English

demonstrates the best performance we can achieve while using all of the available training corpus.

We experiment with both phonemic and orthographic representations of input texts. The phonemic approach seems more intuitive since the transliteration is a pronunciation based translation. The orthographic system is simple because it does not require additional baseform generation tools to convert proper name to phonemic sequences, and it does not need to address the multiple pronunciation issue. For Chinese, the orthographic form of a character is its Pinyin. Tones in Pinyin are removed. Korean characters are converted according to Romanization tables from the web[1] . Japanese characters are Romanized in the same way using a different table[2] . We add 11 additional rules to the Japanese conversion process to deal with short versions of a few vowels and consonants. These 11 characters are: ァ, ィ, ゥ, ェ, ォ, ャ, ュ, ョ, ワ, ー, and ッ. In orthographic systems, the Pinyin (for Chinese), Romanized spellings (for Korean and Japanese), and word spellings (for English) are then segmented into space delimited alphabet streams. For example, the English word 'Clinton' is segmented into seven letters separated by space 'c l i n t o n'. In phoneme-based systems, diphthongs (such as 'oi', 'ae') and compound constants (such as 'sh') are treated as one unit. The English and Chinese baseforms are generated automatically from a speech recognition vendor toolkit. Multiple pronunciations for a given word are considered uniformly distributed. All possible combinations of pronunciation are created in both the training and the testing sets. All possible pronunciation combinations are used for training. The best score for all possible pronunciation combinations for a given proper pair is used for final score in testing.

In addition to the new approach described in section 3, we also build two phrase-based SMT systems, orthographic and phonemic based approach, for the Chinese-English Wikipedia datasets as a baseline. This SMT approach has been widely used and yields solid performance in shared task (Li et al, 2009, 2010). Equation (1) is reformulated as:

$$Sim(w_e, w_f) \cong Sim(tr(w_e), w_f) \approx BLEU(tr(w_e), w_f) \quad (7)$$

[1] The Korean Romanization table is from www.thelapan.com .

[2] The Japanese Romanization table is from http://www.omniglot.com/writing/japanese_katakana.htm

Table 4. JE 2010 NEWS Data

where tr(w_e) is the translation of w_e .

We chose BLEU (Papeneni et al., 2001) because it is more favorable to n-gram matches and is smoother than edit distance. We build a phonetic-based SMT and an alphabet orthographic-based SMT. In the former, the parallel data is converted to phonetic sequences using its own phone set. In

the orthographic SMT, the proper names are converted to their Pinyin in spelling form. The English proper names are put into spelling form as well. The standard SMT training recipe is then applied.

5 Results and discussions

The CE Wikipedia results are shown in Table 1. Our method with model M_{SMT} outperforms the traditional SMT methods and the orthographic edit distance approach. Our M_{MCE} further reduces the EER and achieves the best EER of 3.33%. This low EER shows that our verification approach is highly reliable.

Phoneme-based results on the NEWS data are shown in Tables 2, 3 and 4 for CE, KE, and JE respectively. Each table shows results of M_{SMT}, M_{MCE} and relative improvement (in that order) under different training and test conditions. From table 2, our approach yields less than 1.4% of EER using only 1K training pairs. Using 3K training data, the proposed method achieves ERR under 1.2%, which is comparable to the system using 30K training pairs. The MCE can further improve the performance relatively by 5-14%. In additions, the performance is very stable against to all different unmatched test conditions, especially at the 9M unmatched test pair condition.

The Japanese-English set performs worse than either Chinese or Korean. Upon inspection of the data, we find that the majority of the problems are due to incorrect baseforms representations. This, in turn, is because the Japanese data contains more non-English names. For example, in JE test set, there are 1941 matched pairs. For a 2% false reject rate, approximately 38 matched pairs are false rejected. Out of these false-reject entries, about a third is European names. Table 5 shows a few such examples. The bottom two entries in this table are actually incorrect transliteration pairs, which means they should be rejected but the system is penalized because the reference truth is not entirely clean. This is an example of using our method as a data screening tool to sift through the data and automatically pick out suspicious pairs. Because of our high accuracies, those questionable pairs can be either reliably excluded or down-weighted. They can also be given to annotators for further inspection. Instead of scanning through the entire dataset, human annotators can focus on just the disputable pairs that the system picks out. This annotation process is both efficient and cost-effective.

Table 8. $\mathbf{M_{SMT}}$ on orthographic JE

Orthographic results are shown in Tables 6, 7, and 8 for CE, KE, and JE respectively. It is evident from the tables that orthographic-based systems are significantly better than the phoneme-based systems without using the more complex model M_{MCE}. These results are very promising because first, orthographic representations do not need to deal with diphthongs and compound consonants. Every alphabet is a token by itself. In Table 5 for example, 'r e_ b u' in the first row will have '_' separated from 'e' in its orthographic form. Secondly, results in Tables 6, 7, and 8 are from systems using the straightforward SMT

method without further discriminative training by *MCE*. This simplifies the overall system architecture and makes the system more efficient and effective.

One reason orthographic models perform better than phonemic models is that baseforms generation is ambiguous and error-prone. Our baseforms are statistically trained from a generic model. The conversion from input texts to their baseforms is a lossy process. The errors in Japanese show a clear example. When the names are non-English, the English baseforms all become incorrect which leads to verification errors. The orthographic representation alleviates this problem quite significantly and thus is able to improve the system. In addition to measuring ERR, we also measure False Rejection (FR) rate of the matched proper name pairs and False Acceptance (FA) rate of the unmatched pairs. Tables 9, 10, and 11 detail the results for all the language pairs under all testing and training conditions. For each language pair, under the same training condition, the FR rate is the same because given a fixed threshold, the number of matched pairs is the same.

FA and FR results in the above tables show that the system is very robust. Across all language pairs, FA and FR rates improve consistently as the training data size gets larger. The rates also remain stable across test data of different sizes.

6 Application

We incorporate the verification component into the retrieval model for CLIR. We use a language model (LM) based retrieval model. The query Q is treated as a sequence of words, $Q = w_1 w_2 \ldots w_N$. The query words are assumed to be independent of each other and conditionally independent given the document. The relevance score of a document to the query can be computed by Eq. (8):

$$P(Q|D) = \prod_{w_i \in Q} P(w_i|D)^{c(w_i,Q)}, \quad (8)$$

where $c(w_i, Q)$ is the number of times that each distinct word w_i occurs in Q and $P(w_i|D)$ is the probability of the word w_i generated by the document model. For CLIR, we rewrite (8) as:

$$P(Q_e \mid D_f) = \prod_{w_e \in Q_e} P(w_e \mid D_f)^{c(w_e,Q_e)} \overset{\text{rank}}{=} \sum_{w_e \in Q_e} c(w_e, Q_e) \log \left(\sum_{w_f \in D_f} P(w_e \mid w_f) P(w_f \mid D_f) \right) \quad (9)$$

where the $P(w_e \mid w_f)$ is the probability of the English token given by foreign token. We propose to estimate this probability by a combination function of similarity function and translation table.

$$P(w_e \mid w_f) = \lambda \delta_0(w_e, w_f) + (1-\lambda)\delta_1(w_e, w_f), \quad (10)$$

where

$$\delta_0(w_e, w_f) = \frac{1}{1+\exp(-\gamma \cdot sim(w_e, w_f) + \beta)},$$

$$\delta_1(w_e, w_f) = f(Tr(w_f \mid w_e))$$

$$f(Tr(w_f \mid w_e)) = \frac{1}{1+\exp(-\gamma_1 \cdot sim(w_e, w_f) - \gamma_2 P(w_f \mid w_e) + \beta)}, \quad (11)$$

Where, $sim(w_e, w_f)$ is the similarity function discussed in previous section, $Tr(w_e \mid w_f)$ is translations from the SMT phrase table, and f is a function to validate the phrase table entries. f is a function that combines the scores of the valid entries in the phrase table, $p(w_f \mid w_e)$, and the similarity score, $\delta_0(w_e, w_f)$, with higher recall rate. Thus, the entries in the phrase table with high scores are the candidates. These candidates will be discarded only if they are incorrect in pronunciation. The λ is the weighted factor for transliteration similarity scores, which can be a function of the total similarity scores. In our experiments, it is estimated by:

$$\lambda = \frac{k}{\sum_{w_f \in V_f} \delta_0(w_e, w_f)}, \quad (13)$$

where v_f is the vocabulary and k is a constant.

We conduct experiments on the NTCIR-7 Information Retrieval for QA (IR4QA) task (Sakai et al. 2008). We select 10 proper name query topics as the query set. To test CLIR with multiple transliterations, we need a document collection with controlled multiple transliterations. We create a homogenous name list for those proper names used in the test query topics and uniformly place those names into the original document collections. Thus, each proper name in the query is replaced by 4-5 different names with similar pronunciation. The baseline (unigram document LM with Dirichlet smoothing) performance using the original queries against the synthetic document collection is 0.18 (in mAP). Without any given transliterations, the mAP of our method is 0.406, substantially better than 0.18 if one transliteration is given. This is shown in Table 12 where $\lambda = 1$ and # of known translations = 0. (λ is defined in Eq. (10)). In Table 12, $\lambda = 1$ implies all transliterations are ignored. We then test when two, or all transliterations are given without using the transliteration similarity by setting $\lambda = 0$. The results are 0.3819 and 0.7268, respectively. The mAP of 0.7268 is better than the mAP of 0.6911 from the ad-hoc baseline. It implies that the original document collections already have multiple transliterations. We further assume that all transliterations are known and one additional incorrect transliteration is provided. By disabling the filtering capability in Eq (11), (i.e. $f(Tr(w_f \mid w_e)$ =1, when $p(w_f \mid w_e)$ exists), the performance is degraded to 0.55. Table 12 shows that our approach is, in contrast, quite robust and maintains the performance of 0.65. This scenario with one incorrect transliteration can be very common because the entries in phrase table can be very noisy. We also evaluate the effect of name entities. If the entire document vocabulary is used to calculate similarity score, (cf. Eq (10)), the mAP=0.40, which means this task is very difficult and the name entities do not help significantly because too many name entities are extracted from the document collection. In fact, the name entities extraction may not be necessary while using our approach because the similarity score can be calculated based on the document vocabulary.

# of known Transliterations	λ =0	λ = variable	λ =1
0	0	0.4062	0.4062
1	0.1983	0.42	0.4062
2	0.3819	0.48	0.4062
All	0.7268	0.65	0.4062
All plus 1 wrong	0.55	0.65	0.4062

Table 12: mAP under various expanded transliterations for proper name queries

7 Conclusion and Future Work

In this paper, we propose a simple and effective transliteration verification framework. On the 2009 and 2010 NEWS transliteration generation shared task data, we achieve EER well below 1% for Chinese and Korean, and around 1% for Japanese. These promising results show that verification can not only provide an alternative approach to transliteration but also can be reliably used for exploring name pairs from comparable data. We show how the method is used in CLIR applications. It can also serve as a parallel corpus screening tool to indentify possible incorrect name pairs. In addition, it can be used for post processing of transliteration generation by filtering out incorrect top-n hypothesis to improve performance. Moreover, this approach can be turned into an automatic transliteration evaluation tool for such task as the NEWS shared task. In the future, we will explore each of these possibilities.

Abstract

We present and evaluate a set of architectures for conversational dialogue systems, exploring rule-based and statistical classification approaches. In a case study, we show that while a rule-based dialogue policy is capable of high performance if perfect natural language understanding is assumed, a direct classification approach that combines the dialogue policy with NLU has practical advantages.

1 Introduction

In this paper we present and evaluate a set of alternative dialogue system architectures that could be used to implement dialogue policies for conversational characters or virtual humans. The motivation for this work is to improve our understanding of the development costs and performance benefits associated with alternative system architectures for virtual human dialogue systems (Traum et al., 2005; Swartout et al., 2006; Kenny et al., 2009; Jan et al., 2009; Swartout et al., 2010).

We focus on the language processing steps used in a specific virtual human system described in Section 2. We analyze the relationship between Natural Language Understanding (NLU), which maps a user's natural language input to system-specific semantic representations, and Dialogue Management (DM), which executes a dialogue policy that dictates what the virtual human will say or do in response to the user's input.

Traditionally, designing a two step NLU+DM pipeline involves defining semantic representations for the dialogue domain and writing rules that constitute the dialogue policy. This modular design has the benefit of making the DM policy easy to express in explicit rules, but carries the development cost of requiring significant linguistic expertise. Additionally, as we illustrate in this paper, its performance can depend critically on the reliability of the NLU module.

As an alternative, we contrast this design with a direct classification approach that relies only on textual examples and effectively combines the dialogue policy with NLU. In our case study evaluation, we find that this approach offers superior performance, owing to the high frequency of NLU errors in the two step pipeline.

The research presented in this paper extends our previous work. As we summarize in Section 2, this paper relies on the same data set and evaluation metric as DeVault et al. (2011), which reports results for learned policies based on maximum entropy models. In this paper, we add a comparison to a hand-authored policy (Rules) and a new policy based on relevance models (RM). These new policies are described in Section 3. We conclude with some discussion of our new findings.

2 Research Setting and Data Set

We begin by summarizing our research setting, data set, and evaluation metric. We refer the reader to DeVault et al. (2011) for additional details.

We use an existing virtual human scenario designed for Tactical Questioning (TACQ) (Traum et al., 2008), where military personnel interview individuals for information of military value. TACQ characters are designed to be non-cooperative at times. They may answer some of the interviewer's questions, but either lie or refuse to answer others until certain conditions are met (Gandhe et al., 2009). The dialogue policy for a TACQ character is relatively simple in that the character is willing to answer most questions, but correctly implementing the policy requires that certain questions only be answered under certain conditions.

Our work builds on an existing TACQ scenario involving a virtual human called Amani (Gandhe et al., 2009). The user plays the role of a commander whose unit has been attacked by a sniper. The

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1341–1345,
Chiang Mai, Thailand, November 8 – 13, 2011.

Lieutenant: *(User Utterance)*
can you tell me what you know of the incident?
NLU Speech Act: `elicit-whq-tellmemoreabouttheincident`
Paraphrases:
- what information do you have about the incident?
- could you please tell me what you saw?
- what can you tell me about the incident?
- can you tell me about the incident?
- please, tell me what you know about the incident
- tell me what you saw, please

Amani: *(System Response, as English text)*
- i saw the shooting. what do you want to know about it?
Other appropriate speech acts, as English text:
- i remember that the gun fire was coming from the window on the second floor of assad's shop.
- what is it you want to know about the incident?

Figure 1: A dialogue turn from the Amani dataset.

user interviews Amani, who was a witness to the incident and has information about the identity of the sniper. Amani is willing to tell the interviewer what she knows, but she will only reveal certain information in exchange for specific promises of safety, secrecy, and monetary compensation (Artstein et al., 2009). Figure 1 provides an excerpt of a user interaction with Amani.

Gandhe et al.'s TACQ system uses speech acts (SAs) to represent the meaning of user and system utterances. In this paper, user utterances are modeled using 46 distinct SA labels. For example, the label `elicit-whq-tellmemoreabouttheincident` is assigned to the user's utterance of *can you tell me what you know of the incident?* in Figure 1. The system also defines a different set of 96 unique SAs (responses) for the Amani character.

We perform our experiments and evaluation using an existing set of 19 annotated Amani dialogues (DeVault et al., 2011). The dialogues were collected through teletype-based role play. Each dialogue turn includes a single user utterance followed by the response chosen by a human role player in the role of Amani. There are a total of 296 turns, for an average of 15.6 turns/dialogue.

The task of Amani's dialogue manager (DM) is to select the most appropriate system SA to use in response to a user utterance. In the experiments reported here, the user's utterance may be provided to the DM either directly as text or using a SA label. We call the DM's decision process a *dialogue policy*. The system builders' intended policy for Amani is detailed in DeVault et al. (2011).

Because Amani has only a fixed set of system responses, the policy problem looks like a traditional classification task. However, there are two sources of uncertainty that complicate the task. Firstly, the mapping between the user's utterance and an appropriate system SA is often one-to-many. In our data set, 6 referees independently linked each user utterance to the best system SA response. In Figure 1, we provide an example in which three different system SAs were selected by the 6 referees. In other cases, up to 6 different system SAs were selected (DeVault et al., 2011). Our first experimental question is therefore: how well can a dialogue policy select an appropriate system SA, if it is provided with an accurate user SA? Would a statistical classification-based policy perform as well as a rule-based policy?

Secondly, the user SAs in the Amani dataset were assigned to the user's utterance by a computational linguist, and we may assume that these "gold" SAs accurately represent the user's intended meaning. In a run-time system, however, the SAs are identified by an automatic NLU module that is likely to introduce errors. It is not obvious *a priori* to what extent the dialogue policy will suffer due to these NLU errors, and our second experimental question is therefore: how well can a policy select an appropriate system SA, if provided with the NLU's hypothesized user SA?

In training the NLU module, as well as our dialogue policies, we can make use of an additional resource in the Amani data set, which is the availability of approximately 6 textual paraphrases for each utterance; see Figure 1 for an example.

As a final empirical question, we consider combining the NLU and DM in a design that classifies user utterances, together with shallow features of the dialogue history, directly into system responses. This approach is similar to the NLU module, but tries to determine system SAs instead of user SAs. This makes unnecessary the labor and knowledge intensive steps of developing the user SA set and annotating utterances with these SAs.

2.1 Evaluation Metric

We evaluate the dialogue policies learned in each of our experimental conditions through 19-fold cross-validation of our set of 19 dialogues. In each fold, we hold out one dialogue and use the remaining 18 dialogues as training data.

To measure the performance of the dialogue policy, we follow the approach of DeVault et al. (2011), which counts an automatically produced

system SA as correct if that SA was chosen by at least one referee for that dialogue turn in the data set. We then count the proportion of the correct SAs among all the SAs produced across all 19 dialogues, and use this measure of *weak accuracy* to score competing dialogue policies.

We can use the weak accuracy of one referee, measured against all the others, to establish a performance ceiling for this metric. (We do not expect that an automatic system would outperform a human referee.) This score is .79; see DeVault et al. (2011) for discussion.

3 Experimental Setup

Our experimental setup evaluates three different dialogue policy models: a rule-based approach (Rules), discussed in Section 3.2; a statistical classification technique that uses maximum-entropy classification (MaxEnt), discussed in Section 3.3; and another statistical technique called relevance models (RM), discussed in Section 3.4.

For the Rules approach, the user's utterance is represented in SA form, and we evaluate the performance of the rules using both hand-annotated or "gold" SA (G-SA) as well as automatically assigned NLU SAs (NLU-SA), as described in Section 3.1. For the two statistical policy techniques, MaxEnt and RM, the user's utterance may be represented in SA form or in plain text form. In the latter case, the NLU and DM modules are effectively consolidated into a single classification step.

3.1 NLU

Our NLU module treats the problem of mapping an utterance text to a single SA label as a multi-class classification problem, which it solves using a maximum-entropy model (Berger et al., 1996). The utterance is represented using shallow features such as unigrams and the length of the user utterance (Sagae et al., 2009). Paraphrases of user utterances are included in the training set.

3.2 Rule-based Policy

We developed our rule-based policy (Rules) by manually writing the simple rules needed to implement Amani's dialogue policy. Given a user SA label A_t for turn t, the rules for determining Amani's response R_t take one of three forms:

$$\text{if } A_t = \text{SA}_i \text{ then } R_t = \text{SA}_j$$
$$\text{if } A_t = \text{SA}_i \wedge \quad \exists k\, A_{t-k} = \text{SA}_l \text{ then } R_t = \text{SA}_j$$
$$\text{if } A_t = \text{SA}_i \wedge \neg\exists k\, A_{t-k} = \text{SA}_l \text{ then } R_t = \text{SA}_j$$

The first rule form specifies that a given user SA should always lead to a given system response. The second and third rule forms enable the system's response to depend on the user having previously performed (or not performed) a specific SA. For example, Amani will only tell the name of the shooter if the user has previously promised to protect her from danger. If such a promise has not yet been made, she will ask the user to protect her in exchange for the information.

Amani's set of 51 rules was developed in 115 minutes by a computational linguist and system developer. Given the existing set of SAs, the rules were very straightforward to develop.

3.3 MaxEnt Policy

Like the NLU, the MaxEnt policy is based on a multi-class maximum-entropy classifier. It uses text-based features including unigrams and the length of the current and previous user utterance, as well as the SA label for Amani's previous utterance. For experiments in which user utterances are represented as text, the MaxEnt policy is trained using all available paraphrases of user utterances. In experiments in which the user utterance is represented using SA labels rather than text, the paraphrase data is ignored, and the MaxEnt policy is trained using the user SA label in place of the text-based features. In all cases, the MaxEnt policy is trained using all the alternative acceptable Amani SA responses as examples of correct output.

3.4 Relevance Model Policy

The text classification task of assigning the system SAs using either the user SAs or the user text input can be viewed as a cross-language information retrieval (IR) task: we have a fixed collection of system SAs ("documents") and a user's input ("query"), and we need to find the best SA that matches the user's input. This is similar to the task of searching Chinese documents using an English query, where the training data that maps user inputs to the system SAs can be viewed as a "parallel corpus" (Lavrenko et al., 2002).

For our third approach we use the Relevance Model (RM) information retrieval technique first suggested by Lavrenko et al. (2002) and recently adapted to a question-answering task by Leuski et al. (2006). We have experimented with different feature sets and we found that (1) when the text data is not available, the combination of the current user SA and the last system SA is the most

	Policy models		
Utterance Features	Rules	MaxEnt	RM
G-SA	.79	.71	.73
NLU-SA	.58	.57	.60
NLU-SA+Text	-	-	.65
Text	-	.66	.71

Table 1: Weak accuracy results for alternative system architectures.

effective; (2) when both the utterance text and SA are available, the combination of the current user SA and unigram text features from all available paraphrases works the best; and (3) when only the text is available, the unigram word features work well by themselves. We should note that we found it is significantly better to train the model on "gold" SAs even when testing on NLU-SAs. We also observed that integrating the unigram features with the history information in the form of SAs or words from previous utterances tended to over-fit the model, resulting in degraded performance.

4 Results and Discussion

We present our results in Table 1. The highest performance is achieved when "gold" SAs (G-SA) are provided to Rules. Indeed, the weak accuracy of .79 is approximately at the ceiling level of performance observed when one human referee is scored against 5 other human referees. This suggests that, with human-level NLU performance, a hand-authored rule-based policy can effectively implement Amani's intended dialogue policy. However, the table also shows that when automatically-assigned NLU speech acts (NLU-SA) are provided as input to Rules, the performance drops significantly to .58. Note that Rules cannot interpret text representations of user utterances; SA labels are needed, which is a cost of using Rules.

For the MaxEnt policy, a score of .71 is achieved with "gold" SAs, and a lower .57 with run-time SAs. Note that .71 is an inferior performance to the .79 achieved with G-SA/Rules, indicating that MaxEnt does not learn a policy as effective as the hand-authored Rules, even if it is trained and evaluated on gold SA labels. As previously reported in DeVault et al. (2011), a performance of .66 is achieved with the MaxEnt policy when trained on text-based features. It is interesting to see here, however, that this .66 performance is significantly higher than the .58 that is achieved using Rules together with run-time SAs. In fact, the accuracy of the NLU-SA labels in this data set, with respect to the gold SAs, is 53%. Thus, while Rules can achieve very good performance with gold SAs, the high frequency of NLU errors causes a significant degradation in policy performance. Interestingly, the alternative Text/MaxEnt design that combines NLU and DM into a single step ends up performing significantly better (.66).

The RM performance shows a pattern broadly similar to MaxEnt; performance is highest (.73) with gold SAs, and when trained to classify directly from Text to system SAs, performance is significantly better (.71) than NLU-SA/Rules (.58). For RM, we additionally explored using both Text features as well as the NLU-SA label as input features, but observed performance degraded to .65 (presumably due to NLU errors). Our best overall performance not requiring gold SAs, .71, was achieved by Text/RM. Our intuition is that a couple of factors helped RM to outperform the MaxEnt approach: (1) MaxEnt treats word features as binary, while RM explicitly takes into account the word occurrence frequencies; (2) RM is better designed to handle multi-label classification, where a single input instance can be assigned to multiple classes.

5 Conclusion and Future Work

We have presented and evaluated a set of alternative dialogue system architectures in a case study domain. In this domain, we have shown that the theoretical performance that is achievable with a rule-based dialogue policy is high, but that two classification approaches that omit a separate NLU step and directly select system responses perform significantly better. In future work, we plan to address some of the remaining questions, including how these learned policies would perform in live dialogues, how these results would change if NLU performance could be improved, and to what extent this pattern of results would transfer to other domains with more complex NLU and policy requirements.

Reducing Asymmetry between language-pairs to Improve Alignment and Translation Quality

Rashmi Gangadharaiah
IBM Research, India
rashgang@in.ibm.com

Abstract

This paper presents a novel method to remove asymmetry between the source and the target languages thereby improving alignment and machine translation (MT) quality. Some words in the source language are redundant for MT tasks but necessary for the source sentence to be grammatical. This paper proposes a method to automatically detect such words. In addition, constraints under which these words should or should not be removed are extracted automatically from the target language. A lattice scheme is used for test sentences to provide alternate paths with and without removal of these words. Such a constraint-based removal technique gives a significant improvement ($p < 0.001$) of 5.29 BLEU points over the baseline Phrase-based MT system for the English-Hindi language-pair.

1 Introduction

Different languages express the same piece of information with different number of words. As a result, in many language-pairs, not all source words have correspondences in the target half of the sentence-pair. The aligner is expected to align these redundant source words to an empty word ("*NULL*") in the target sentence. However, in data-sparse conditions, this is not perfectly learnt.

The IBM models in *GIZA++* (Och and Ney, 2003) align each source word to exactly one target word and a target word can be aligned to multiple source words. Currently in most MT systems, this limitation in alignment is overcome by aligning the data bi-directionally (Koehn et al., 2003) and later combining the resulting alignments. Inspite of using information from bi-directional alignments, due to the noisy nature and limitations in the amount of parallel data available, low quality word-alignments are obtained. To illustrate this, consider the top ten maximum likelihood lexical translation-table entries for the English source words, "*the*" and "*india*" obtained after combining the bi-directional alignments with the English-Hindi language-pair in Figures 3A and 3B. For the sake of clarity, the actual English translations of the Hindi words (with case-markers transliterated) are displayed instead of the Hindi words themselves. As seen, the probability mass is used up by many other Hindi words that are not the right translations of the source words. Also, in Figure 3B, "*india*" has a higher probability of being aligned to "*NULL*" than to its actual translation. The most common errors in data that result in low quality alignments and translations are:

1) Property of a language-pair: Certain words are necessary to be present in a sentence for the sentence to be grammatical but unnecessary for MT. For example, *the* in *"the government was highly perturbed by his activities"* has no correspondence in Hindi. For MT, these words can hurt the performance of the aligner (illustrated in Figure 1) and translation quality (Section 4). This is true for many language-pairs including English to all Indian languages.

2) Noisy and Imperfect nature of the data: (a) Human translation errors: Humans cause typograpical errors (many times the same error is created consistently) during translation. Usually monolingual data is first collected from a source such as the world-wide-web and then given to human translators who are usually non-experts in MT and add redundant words or leave certain source words untranslated.

(b) Errors in automatic extraction: the world-wide-web is often used to obtain parallel data. Articles describing the same event in multiple languages are aligned at the sentence-level to create parallel corpora. Sentence-alignment is not

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1346–1350,
Chiang Mai, Thailand, November 8 – 13, 2011.

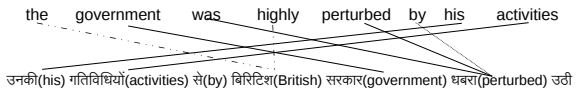

Figure 1: Alignment links provided by the aligner. Dotted lines indicate alignment errors. Correct translations of the Hindi words given in brackets.

perfect when the data used to train the sentence-aligner is limited. Also, not all words in a source sentence have actual correspondences in the target (and vice versa). Errors in word-alignments are seen when a word-aligner is forced to align words in this noisy corpus. For example, the Hindi sentence in Figure 1 has a word that corresponds to "*British*" which is absent in the English sentence.

2 Related Work

Lee (2004) induced only morphological symmetry by identifying morphemes to be merged or deleted from their stems in the morphologically rich source language. They implement the idea that if a morpheme in the source language is robustly translated into a distinct POS in the other language, the morpheme is likely to have an independent counterpart in the other language.

Since unaligned words cause ambiguity in phrase-pairs, Zhang et al. (2009) remove unaligned words before extracting phrase-pairs. Candidates for deletion are collected based on their POS tags and a simple threshold scheme on the probability of a word being aligned.

Lee et al. (2006) found many unaligned function words while translating from Korean to English and removed them using their POS information. In Li et al. (2008), source words that do not have an alignment are added to the phrase-table with ϵ as their translation. Only source context and POS features are used to determine if a word is spurious. For many language-pairs including languages considered in this paper, source context and POS tags of words do not always indicate their 'spuriousness'. Hence, we need other features.

All the above methods depend on a POS tagger to collect redundant source words which may not be available for rare and low density languages. Li et al. (2008) and Zhang et al. (2009) only modify the phrase-extractor or the phrase-pairs and do not concentrate on improving the word-alignments between the language-pair. As will be shown in this paper, the information that a source word is spurious can be valuable even for word-alignment which in turn improves translation quality.

Hong et al. (2008) insert pseudo words and reorder the source and the target sentences to have similar lengths. Pseudo words are generated with the help of dependency parsers. Chung and Gildea (2010) look at recovering dropped pronouns while translating from pro-drop languages like, Chinese and Korean to English.

In this paper, frequently occuring redundant source words caused due to the inherent nature of the language-pair or noise are automatically detected and removed to improve alignments of other words in the corpus and ultimately translation scores when data available is limited. The method does not make use of any rich knowledge sources. Features extracted from word-alignment models are used to score and rank words that form candidates for removal. Top ranking N Redundant source words satisfying target constraints are removed from the training corpus and the corpus is re-aligned. Redundancy is not removed in the target as it hinders the translation generation process and would require post-processing of the translations. During testing, a lattice scheme is used to provide alternate paths, both with and without removal of redundant words.

3 Method for detecting redundant words

Bi-directional word-alignments of the training data are first obtained using GIZA++ and later combined using *grow-diag-final-and* in Moses (Koehn et al., 2007). A maximum likelihood lexical translation table $p(w_i|w_j)$ is estimated between the source words (w_j) and target words (w_i) from the alignments. Features are extracted from the resultant lexical probabilities and linearly combined to obtain a score (eqn. 1). The weights can be tuned with the objective of improving the alignment (with hand alignments) or the translation quality on a tuning set. This can be done using a simple hill climbing procedure or any unconstrained optimization technique that does not require derivatives (Powell, 1964).

$$score = \sum_i \lambda_i f_i \quad where, \sum_i \lambda_i = 1 \qquad (1)$$

3.1 Features

Entropy: If the distribution of the lexical translation probabilities ($P(w_i|w_j)$) for a source word, w_j, (excluding its "*NULL*" probability) is close to

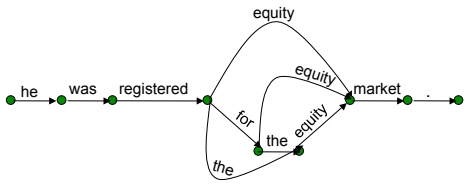

Figure 2: Test/input sentences as a lattice.

a uniform distribution, the entropies seen will be higher than seen with a non-uniform distribution. For example, English words such as "*the*" do not have translations in Indian languages. A plot of the top ten lexical translation probabilities and corresponding lexical translations for "*the*" is given in Figure 3A. Since the "*NULL*" alignment probability is not considered in eqn. 2, the remaining lexical translation probabilities for a source word are re-normalized to sum to 1.

$$f_1(w_j) = \sum_i -p(w_i|w_j)logp(w_i|w_j) \quad (2)$$

Probability of corresponding to "*NULL*": A very high probability of being aligned to "*NULL*" ($f_2(w_j) = p(NULL|w_j)$) is a good indicator that w_j has no target correspondences.

Number of unique target words: The number of lexical translation probability entries for w_j,

$$f_3(w_j) = \frac{\#unique\ translations\ for\ w_j}{\#target\ words\ in\ the\ corpus} \quad (3)$$

Constraints for removal of source words: certain words like "*a*" or "*an*" in English do not always have translations in Hindi. When these words do have a translation, we do not want to remove them from the source sentence. Hence, constraints are extracted from the lexical translation table to determine when a word from a source sentence can be removed. Figure 3 shows the top ranking lexical translations for the source words, "*the*" and "*india*". Target words (w_i) for a given source word (w_j) with translation probability ($p(w_i|w_j)$) less than the thresholds in eqn. 4 are removed from the constraint list of w_j. The thresholds are determined from all the translation probabilities for a given source word (w_j). The ratio between the number of target words removed to the number of words the source word was originally aligned to is also considered as a feature ($f_4(w_j)$).

$$th_1(w_j) = median[p(w_1|w_j), p(w_2|w_j)...] \&\&$$
$$th_2(w_j) = 0.7 * max[p(w_1|w_j), p(w_2|w_j)...] \quad (4)$$

Table 1: Constraints for English source words, "*a*", "*the*" and "*india*".

Top ranking N redundant candidates are removed from the source half of the training corpus based on their target constraints. However, during testing, as the reference translations cannot be used, test sentences are converted into a lattice (Dyer et al., 2008) where two alternate paths are included, one with the redundant source word removed and another with the redundant source word as is. An example input lattice for the test sentence "*he was registered for the equity market .*" is given in Figure 2. The scores for taking each of the paths are computed as follows. For any redundant source word, the ratio between the number of times the source word was removed from the training corpus to the total number of times it appeared in the training corpus ($score_1$) is used to score the path that does not include the source word. ($score_2 = 1 - score_1$) is added to the alternate path. If a path contains multiple source words removed, the products of the probabilities ($score_1$) of the redundant source words is taken.

4 Preliminary Results and Analysis

The experiments in this paper are performed with the English-Hindi language-pair. We chose Hindi as it is one of the few Indian languages that have moderate amounts of data to perform translation tasks. However, the method adopted and the analysis done in this paper can be applied to all Indian languages. Indian languages not only suffer from data sparsity, many of these languages also do not have rich knowledge sources (like, POS taggers, parsers, etc.). The parallel corpus included the Darpa TIDES surprise language dataset in 2002 and internally collected parallel corpus from news articles. 200k sentence-pairs were used for training both the Baseline (no removal of redundant source words) and the system with removal of redundant source words using Moses. The basic parameters of Moses were tuned using MERT (Och,

f_1	f_2	f_3	f_4	$comb$

2003) on a development set of 500 sentences. The test set contained 4000 sentences. The test set was divided into 20 sub files to determine the statistical significance with the Wilcoxon signed-rank test (1945).

Features from Section 3.1 are normalized to fall within [0,1]. The weights are tuned using a simple grid-search that tried multiple combinations of weights, starting from 0 and keeping the sum of the weights equal to 1. The weights were incremented in steps of 0.2. The objective chosen was to improve the translation quality score (BLEU (Papineni et al., 2002)) on a small tune set of 200 sentence-pairs. For each set of parameters, the training corpus was modified by removing top ranking N redundant candidates based on target constraints and aligned, the tune set was also modified each time into a lattice and translated to compute the translation quality. As translation for every set of parameters with a large training set is computationally expensive, a small training corpus of size 15k sentence-pairs was chosen to tune the parameters. As alignment is also expensive, only four iterations of IBM Model 1 and two iterations of HMM alignments were performed. The lexical translation table obtained from the alignment of 15k sentence-pairs showed that 798 source words had more than two possible translations. The best N was found to be 42 which contained function words and content words.

Top ranking candidates based on each of the features, $f_1(w_j)$, $f_2(w_j)$, $f_3(w_j)$ and $f_4(w_j)$ along with their tuned combination (eqn. 1) are given in Table 2. Examples of target constraints extracted for the words, “*a*”, “*the*” and “*india*”, are given in Table 1. The target constraints of “*the*” mostly include case-markers. Blind removal of all instances of “*the*” in the training corpus resulted in a drop of 0.3 BLEU points over the constraint-

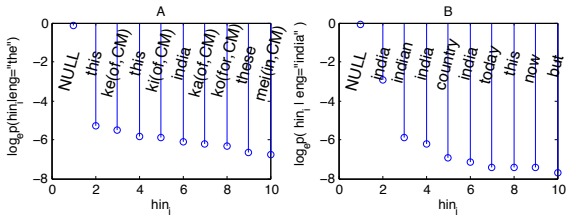

Figure 3: Lexical translation probabilities for source words, “*the*” and “*india*” obtained without removal of redundant source words from the training corpus. CM: case-markers in Hindi.

Score	Base	Rem
3-gram BLEU	12.09	18.57
4-gram BLEU	7.06	12.35
f-score (4k)	49.08	50.74

Table 3: Alignment scores (w.r.t 4k hand-aligned sentence-pairs), n-gram BLEU scores and modified precision scores (p_k) obtained with (Rem) and without (Base) removal of redundant words.

based removal of “*the*”. The reason is that, the case-markers in Hindi have no correspondences in English and require spurious words on the source for their generation. This suggests that redundancy has to be tackled both in the source and in the target to bring about balance in the number of words in the source and target sentences.

A small set of 4k sentence-pairs (from the 15k sentence-pairs) were hand-aligned to compute the f-score on the automatic alignments. While computing the alignment score, alignments of redundant source words were not considered in order to see the alignment improvements of other source words in the training corpus. Improvements in alignment and translation scores w.r.t the baseline are shown in Table 3. Statistically significant improvement ($p<0.001$) of 5.29 BLEU points in translation quality was seen on the test set with removal of redundant words.

5 Conclusion and Future Work

A novel approach to detect and remove redundancy was proposed which gave improvements in alignment as well as translation quality.

Future work will concentrate on removing redundancy even in the target before aligning the corpus and during testing, perform post-processing to insert target words in the translation. It would be interesting to see the performance of the method with other language-pairs.

Abstract

We demonstrate that statistical machine translation (SMT) can be improved substantially by imposing clause-based reordering constraints during decoding. Our analysis of clause-wise translation of different types of clauses shows that it is beneficial to apply these constraints for finite clauses, but not for non-finite clauses. In our experiments in English-Hindi translation with an SMT system (DTM2), on a test corpus containing around 850 sentences with manually annotated clause boundaries, BLEU improves to 20.4 from the baseline score of 19.4. This statistically significant improvement is also confirmed by subjective (human) evaluation. We also report preliminary work on automatically identifying the kind of clause boundaries appropriate for enforcing reordering constraints.

1 Introduction

It has been recognized widely that reordering is the Achilles' heel of most SMT models (Birch et al., 2009; Hoang and Koehn, 2009), especially when applied to languages with large syntactic differences. In our experiments in English-Hindi SMT, we observe that it is quite frequent in multi-clause sentences for phrases to move out of their respective clauses due to incorrect reordering. While such mistakes can be avoided by restricting reordering over clause boundaries, this paper demonstrates that such a strategy works well only for finite clauses, and not for non-finite clauses.

Clause-wise or part-by-part translation has been a standard approach in traditional transfer-based systems. In Systran, as described by Hutchins and Somers (1992), conjunct and relative clauses were segmented in a preprocessing step. Similar methods were used in the the Stanford Machine Translation project (Wilks, 1973). Chandrasekar (1994) applies a sentence simplification method to machine translation, where sentences are split at conjunctions, relative pronouns, etc., before translation. Rao *et al.* (2000) describe a clause-wise translation strategy within an English-Hindi transfer-based MT system.

In the context of SMT, Koehn and Knight (2003) use a dedicated noun phrase (NP) translation subsystem to obtain significant improvements in German-English translation. Other similar work includes (Watanabe et al., 2003) for Japanese-English SMT and (Hewavitharana et al., 2007) for Arabic-English. Sudoh et al. (2010) propose methods to perform clause-level alignment of the parallel corpus, and to translate clauses (all clauses identified by a syntactic parser) as a unit to improve long-distance reordering in a specialized domain – English-Japanese translation of research paper abstracts in the medical domain.

While our approach draws from many of the above, it is novel in the following ways: (i) We provide an analysis of different clause types in translation – we show that only some kinds of clauses benefit from the use of reordering constraints, and (ii) We demonstrate significant improvements using this strategy for English-Hindi SMT in a general domain.

2 Problem Statement

We analyzed a set of 225 sentences translated through the baseline system. Of the 120 sentences in this set which had more than one clause, 45 sentences were found to have inter-clause reordering problems; that is, some words or phrases are wrongly placed in a clause where they do not belong. Such long-range reordering problems obviously have a serious detrimental effect on transla-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1351–1355,
Chiang Mai, Thailand, November 8 – 13, 2011.

tion quality, and it is quite likely that even limiting the reordering problems to the respective clauses will aid comprehensibility.

3 Analysis of Clause Types in Translation

We will now look at how finite and non-finite clauses behave in translation. Finite clauses are basically tensed clauses, while non-finite clauses are untensed.

- **Finite clauses**: Finite clauses appear most commonly in conjunct or relative constructions. In such cases, each finite clause can be translated separately and glued together using the correct translation of the conjunction or the relative pronoun. While this strategy works very well for conjunct clauses, in relative clauses the resulting translation is sometimes not completely natural, but it is nevertheless always clearly understandable. Consider the following example:

  Input: The boy, who stays in Delhi, won the match.

  Using a clause-wise translation approach, this would be translated as,

  लडका, जो दिल्ली में रेहता है, मैच जीत गया।

  ladakaa, jo dillii men rehtaa hai, match jiita gayaa

  Gloss:boy, who Delhi in stays, match won

  However, a more natural translation would be using correlatives:

  जो लडका दिल्ली में रेहता है, वो मैच जीत गया।

  jo ladakaa dillii men rehtaa hai, vo match jiita gayaa

  Gloss:which boy Delhi in stays, he match won

  Certain kinds of nominal clauses also result in similar disfluencies. For example, in the sentence "The playground is where the statue is situated", putting a reordering constraint around the clause "where the statue is situated" results in an unnatural translation.

- **Non-finite clauses**: Compared to finite clauses, the translation of a non-finite clause is much more dependent on its role within the sentence. There are two main issues: (i) all or part of the non-finite clause could get reordered with the surrounding clause, or (ii) the overall meaning is conveyed by a phrase or group of words from the non-finite clause and a surrounding or neighbouring clause.

  Taking *to-infinitives* as the example category, consider the following constructions:

  a. *To-infinitive clause in raising constructions*: Here the embedded clause with the raised element is translated as a finite clause with *that* as a complementizer. For example,

  Input: John is certain to win,

  which is translated as "It is certain that John will win":

  यह तय है कि जॉन जीतेगा।

  yaha tay hai ki John jiitega

  Gloss:it certain is that John will-win

  It is the combination of "certain" (or similar word) and the to-infinitive that results in this translation.

  b. *To-infinitive with a copular verb*: In such cases, the infinitive is inflected with a कर (*kara*) ending to indicate sequentiality:

  Input: John was happy to see him

  जॉन उसे देखकर खुश हुआ।

  John use dekhakara khusha huaa

  Gloss:John him-to seen-having happy was/became

  Here, the non-finite clause "to see him", gets reordered into the main clause, something that will not be possible if reordering constraints are applied.

  Similarly, there are differences in the way other non-finite clauses (with -ed and -ing participles) are treated. The point being made here is that handling these differences is crucial to the correct meaning being conveyed. In other words, simply translating non-finite clauses separately with reordering constraints around them, will not lead to good translation, because the translation of these clauses is often dependent on the superordinate clause, and also there is reordering between these clauses and the superordinate clause.

	BLEU	Adequacy	Fluency
baseline	19.4	2.04	2.41
finite	20.4^{δ}	2.32^{δ}	2.67^{δ}
non-finite	19.6	2.17^{ψ}	2.5
finite + non-finite	19.8^{ψ}	2.17	2.51^{ψ}

Table 1: Manually identified clauses. δ: 99% statistical significance; ψ: 95% statistical significance

Method	ACI accuracy	BLEU	Adequacy	Fluency
parser	0.42	19.3	-	-
CRF – word and pos	0.69	19.8^{ψ}	2.27^{δ}	2.59^{δ}

Table 2: Automatically identified finite clauses

Based on the above analysis, we are encouraged to test the hypothesis that it is helpful to put reordering constraints around finite clauses, but not around non-finite clauses.

Finiteness is one broad dimension along which clauses may be categorized. Subordinate clauses can be further classified based on the position in which they occur in the sentence – that is, whether they occur in the complement position, the specifier position, or the adjunct position. We may also classify clauses based on whether they play an adjectival, nominal, or adverbial role in the sentence. The focus of the present work, however, is only on the finiteness aspect.

4 Experiments

In this section, we first describe briefly our baseline system and our approach to handling clauses within this system. We then summarize the datasets used and our evaluation methodology, before describing the results of various experiments.

4.1 Approach

The baseline system we use is *DTM2* (a direct translation model) (Ittycheriah and Roukos, 2007). The word-alignments were done using an HMM aligner. We used the best-performing parameter setting in the decoder [1].

A beam search decoder (Ittycheriah and Roukos, 2007) similar to other phrase-based decoders (Tillmann and Ney, 2003) is used for translation. The reordering restriction is applied by treating the relevant clause-boundaries as *barriers*, and putting a hard constraint on reordering across barriers – that is, during decoding, if a new hypothesis requires reordering over a barrier, the hypothesis is discarded.

We experiment with clause boundaries identified in three ways: (i) manually (section 4.3.1), (ii) automatically using a constituency parser (section 4.3.2), and (iii) automatically using a CRF-based clause-boundary classifer using part-of-speech and parser features (section 4.3.3).

4.2 Data and Evaluation

The system was trained on a parallel corpus with 289k sentences (combining the LDC English-Hindi parallel texts with internal datasets) consisting of various domains including news, and tested on 844 sentences. The language model was trained on around 1.5 million sentences.

Automatic evaluation was done using BLEU (Papineni et al., 2001) with a single reference translation per sentence. Statistical significance of the test results with BLEU was computed using paired bootstrap resampling (Koehn, 2004). Subjective evaluation was performed on hundred randomly selected multi-clause sentences, using a five-point scale.

4.3 Results

4.3.1 Manual annotation: finite vs. non-finite clauses

For this experiment, the sentences in the test sets were manually annotated with finite and non-finite clause boundaries. The results in table 1 indicate that reordering constraints around finite clauses work much better than around non-finite clauses.

[1] Specifically, the skip-length (distortion limit) was set to 8. Lower skip-lengths led to much poorer performance. For example, with a skip-length of 4, the BLEU score dropped by around 2 points compared to a skip-length of 8

	improved	degraded
finite (manual)	36	8
finite (auto)	35	17
non-finite (manual)	17	10
finite + non-finite (manual)	19	11

Table 3: Number of translations improved/degraded

4.3.2 Automatic clause identification using a parser

The goal of this experiment was to determine whether clauses obtained from a parser could be used for the purpose of imposing clause-based constraints. We performed the experiment by using a state-of-the-art maxent parser (Ratnaparkhi, 1999) to mark all clause boundaries (clause-level nodes based on the Penn Treebank II Style bracketing guidelines – S, S-BAR, SQ, SBARQ, and SINV). The results were negative (table 2 – row titled *parser*), indicating that straightforward use of a parser is not sufficient to help in identifying clauses suitable for reordering constraints. The column titled *ACI accuracy* has the F-measure for automatic clause-boundary identification measured over the entire test corpus.

4.3.3 Automatic clause identification using a CRF classifier

We annotated a set of 1500 English sentences with finite-clause boundaries, and used this to train a CRF-based clause-boundary classifier (Ram and Devi, 2008; Tjong et al., 2001). Unigram and bigram word features, unigram, bigram and trigram POS features, and the POS of the following verb group were used in the model (Kashioka et al., 2003) [2]. We see (table 2) that a reasonable gain is obtained using the classifier, though not nearly as much as with manual annotation.

5 Discussion

The subjective evaluation scores reveal that only a few translations degrade in quality when reordering constraints are used with finite clauses (largely due to fluency issues of the kind described in section 3). Table 3 shows the number of translations that improved (i.e., the average adequacy and fluency score increased) due to clause-based translation, and the number which degraded, among the hundred sentences taken up for subjective evaluation. The following is an illustration of the kind of improvements clause-based translation brings:

Input: America claims that Iran wants to continue its nuclear programme, and secretly builds atomic weapons.

Baseline translation: अमरीका का दावा है कि उसके परमाणु कार्यक्रम रहना चाहते हैं और् ईरान परमाणु हथियार निर्माण करता है।

amerika kaa daavaa hai ki usake paramaanu kaaryakrama rahanaa caahate hain aur iraana paramaanu hathiyaara nirmaana karataa hai

Gloss: America's claim is that their nuclear programme continue want and Iran nuclear weapons builds

Clause-based translation: अमरीका का दावा है कि ईरान अपने परमाणु कार्यक्रम को जारी रखना चाहता है और परमाणु हथियार निर्माण करता है।

amerika kaa daavaa hai ki iran apane paramaanu kaaryakrama ko jaarii rakhanaa caahataa hai aura paramaanu hathiyaara nirmaana kartaa hai

Gloss: America's claim is that Iran its nuclear programme to continue wants and nuclear weapons builds

6 Conclusion and Future Work

We have shown that the quality of English-Hindi statistical machine translation can be improved by performing clause-wise translation. An important finding in our work is that, in general, finite clauses are more directly suited for such translation compared to non-finite clauses.

Possible directions of future work include: (i) using clause-based constraints also in training, (ii) learning from word-alignments, the kinds of clauses that can benefit from reordering constraints, (iii) analyzing the impact of finer-grained clause types (as mentioned in section 3) on translation, (iv) comparing with other SMT models (Galley and Manning, 2010; Chiang, 2005), and (v) using soft constraints instead of hard constraints for reordering (Marton and Resnik, 2008).

[2] Adding clause-boundary information from the parser as features in the classifier resulted in a lower F-measure of 0.65

Abstract

Minimum Bayes Risk (MBR) has been used as a decision rule for both single-system decoding and system combination in machine translation. For system combination, we argue that common MBR implementations are actually not correct, since probabilities in the hypothesis space cannot be reliably estimated. These implementations achieve the effect of consensus decoding (which may be beneficial in its own right), but does not reduce Bayes Risk in the true Bayesian sense.

We introduce *Generalized* MBR, which parameterizes the loss function in MBR and allows it to be optimized in the given hypothesis space of multiple systems. This extension better approximates the true Bayes Risk decision rule and empirically improves over MBR, even in cases where the combined systems are of mixed quality.

1 Introduction

Minimum Bayes Risk (MBR) is a theoretically-elegant decision rule that has been used for single-system decoding and system combination in machine translation (MT). MBR arose in Bayes decision theory (Duda et al., 2000) and has since been applied to speech recognition (Goel and Byrne, 2000) and machine translation (Kumar and Byrne, 2004). The idea is to choose hypotheses that minimize *Bayes Risk* as oppose to those that maximize posterior probability. This enables the use of task-specific loss functions (e.g BLEU).

However, the definition of Bayes Risk depends critically on the posterior probability of hypotheses. In single-system decoding, one could approximate this probability using model scores. However, for system combination, the various systems have incompatible scores. In practice, MT designers resort to uniform probability, but the result is that the chosen hypothesis no longer has anything to do with Bayes Risk. This hypothesis can be seen as a *consensus* of multiple hypotheses, and in practice the consensus translation is often good, but it cannot be accurately thought of as MBR.

Here, we propose a method that better achieves MBR in system combination settings. The insight is to generalize the loss function in the MBR equation and allow it to be parameterized. The parameters are then tuned on a small development data so that the loss function is converted to one that gives low Bayes Risk under the assumption of uniform posteriors. We will show that a small bitext is sufficient for tuning this generalized loss, and that it vastly outperforms the conventional MBR approach in system combination.

In the following, we first review MBR and explain the difficulty in applying it to system combination (Section 2). Then, we propose our Generalized MBR (Section 3) and evaluate it under the NTCIR Patent Translation tasks (Section 4). Finally, we conclude in Section 5.

2 The Difficulty with MBR

Consider the task of translation from a French sentence (f) to an English sentence (e). Our goal is to find a decision rule $\delta(f) \rightarrow e'$, which takes f as input and generates a e' as output, to minimize the expected loss (i.e. Bayes Risk) over the possible space of sentence pairs ($p(e, f)$):

$$E_{p(e,f)}[L(\delta(f)|e)] \quad (1)$$

Note that we write loss $L(\delta(f)|e)$ rather than the conventional $L(\delta(f), e)$ to emphasize that it is asymmetric. The loss allows us to incorporate task-specific knowledge. For example, with 1-BLEU as the loss function, we can quantify that the sentence with 2-word mismatch is preferable

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1356–1360,
Chiang Mai, Thailand, November 8 – 13, 2011.

to one that has 3-word mismatch, even though both do not perfectly match the reference. The incorporation of the task-specific loss is why MBR is attractive in applications.

What decision rule minimizes the expected loss? By reorganizing Eq. 1 as follows:

$$\begin{aligned} E_{p(e,f)}[L(\delta(f)|e)] &= \sum_{e,f} L(\delta(f)|e)p(e,f) \\ &= \sum_{e,f} L(\delta(f)|e)p(e|f)p(f) \\ &= \sum_{f} \left[\sum_{e} L(\delta(f)|e)p(e|f) \right] p(f) \qquad (2) \end{aligned}$$

we observe that expected loss can be minimized if the term in the bracket (known as the *conditional risk*) is minimized for each f:

$$\begin{aligned} & \arg\min_{\delta(f)} \sum_{e} L(\delta(f)|e)p(e|f) \qquad (3) \\ \approx \; & \arg\min_{e' \in N(f)} \sum_{e \in N(f)} L(e'|e)p(e|f) \qquad (4) \end{aligned}$$

Eq. 3 is the Minimum Bayes Risk (MBR) decision rule. Eq. 4 is the N-best approximation commonly used in practice: $N(f)$ contains the set of hypotheses in the N-best list, and the argmin and sum is only performed within this finite set. There are two difficulties with Eq. 4:

1. The N-best approximation is much smaller than the *true* space of *all* English hypotheses in the argmin and sum of Eq. 3. The approximation in the argmin causes search errors, while the approximation in the sum introduces bias. This problem can be somewhat mitigated by increasing the N-best list size or extending this space using lattices and hypergraphs (Tromble et al., 2008; DeNero et al., 2009; Kumar et al., 2009). We do not address this issue here.

2. The posterior probability $p(e|f)$ in Eq.3 and Eq. 4 refers to the *true* posterior probability arising from $E_{p(e,f)}[\cdot]$ in the derivation of Eq. 2. In practice, this can only be estimated from the MT decoder's model scores:

$$p(e|f) \approx \frac{(\exp \sum_i \lambda_i h_i(e,f))^\alpha}{\sum_{e' \in N(f)} (\exp \sum_i \lambda_i h_i(e',f))^\alpha} \qquad (5)$$

where $h_i(e,f)$ are features, λ_i are feature weights, and α is a scaling factor that determines the flatness of the posterior distribution (Ehling et al., 2007). It is important to emphasize that we are *assuming* that the decoder's score is an accurate surrogate for the true posterior distribution $p(e|f)$.

The second difficulty poses a particular problem for system combination. Although the assumption in Eq. 5 is reasonable for single-system MT, it becomes unclear how to compare the model scores $\sum_i \lambda_i h_i(e,f)$ in a multi-system setting. To illustrate, consider two MT systems, their 2-best lists, and corresponding model scores:

- System A: e_1, score=7; e_2, score=3;
- System B: e_3, score=90; e_4, score=10;

It is unclear what is the ranking of posterior probabilities in the space of these four hypotheses. The possibilities include:

- $p(e_1|f) > p(e_2|f) > p(e_3|f) > p(e_4|f)$,
- $p(e_3|f) > p(e_4|f) > p(e_1|f) > p(e_2|f)$,
- $p(e_1|f) > p(e_3|f) > p(e_2|f) > p(e_4|f), \ldots$

From the model scores, we can assume that $p(e_1|f) > p(e_2|f)$ and $p(e_3|f) > p(e_4|f)$ but we cannot say anything about how, e.g., $p(e_1|f)$ and $p(e_3|f)$ compare because the scores are not calibrated across systems. If we cannot even rank the posteriors, there is little hope of estimating its actual values.

Due to this difficulty, previous work in MBR system combination disregard the estimation and assume that $p(e|f)$ is an uniform distribution. The effect is *consensus decoding*, i.e. picking a sentence most similar to others in the N-best list. Consensus decoding may be beneficial in its own right, as shown by positive results in (de Gispert et al., 2009; Sim et al., 2007), but the consensus rule and the MBR rule are *different*.

In fact, the consensus rule may suffer if the N-best list contains many poor translations that are similar to each other. On the other hand, if these poor translations all have small posterior (which ought to be), it does not affect the MBR rule whatsoever. Unfortunately, the bottleneck is the difficulty in estimating the posteriors.

3 Generalized MBR

3.1 Theory

The idea of *Generalized* MBR (GMBR) is to parameterize the loss function in Eq. 4 and allow it to adapt to the hypothesis space of a set of given systems. Specifically, we write a loss function $L(e'|e;\boldsymbol{\theta})$, parameterized by $\boldsymbol{\theta}$, as a linear combination of sub-components:

$$L(e'|e;\theta) = \sum_{k=1}^{K} \theta_k L_k(e'|e) \tag{6}$$

The sub-components are related to the original loss function in some fashion. For example, suppose the desired loss function is 1-BLEU. Then the sub-components could be: $L_1(e'|e)$=1 - 1gramPrecision, $L_2(e'|e)$=1 - 2gramPrecision, $L_3(e'|e)$=1 - 3gramPrecision, $L_4(e'|e)$=1 - 4gramPrecision, $L_5(e'|e)$=brevaltyPenalty.

The GMBR rule is defined generically as:

$$\arg\min_{e' \in N(f)} \sum_{e \in N(f)} L(e'|e;\boldsymbol{\theta}) p(e|f) \tag{7}$$

And in the case of system combination, we will assume uniform $p(e|f)$ and re-write the GMBR decision rule as:

$$\arg\min_{e' \in N(f)} \sum_{e \in N(f)} L(e'|e;\boldsymbol{\theta}) \frac{1}{|N(f)|} \tag{8}$$

$$= \arg\min_{e' \in N(f)} \sum_{e \in N(f)} \sum_{k=1}^{K} \theta_k L_k(e'|e) \tag{9}$$

Our goal is to minimize the expected loss (Eq. 1) under the constraint of uniform $p(e|f)$. The central idea is this: we will tune $\theta_k, k = 1, \ldots, K$ so that the generalized loss in the uniform hypotheses space gives the same decision as the original loss in the true space $p(e|f)$.

This can be done if a small dev set is available: For any two hypotheses e_1, e_2, and a reference e_r (not in $N(f)$) we first compute the true loss: $L(e_1|e_r)$ and $L(e_2|e_r)$. If $L(e_1|e_r) < L(e_2|e_r)$, then we would want $\boldsymbol{\theta}$ such that:

$$\sum_{e \in N(f)} \sum_{k=1}^{K} \theta_k L_k(e_1|e) < \sum_{e \in N(f)} \sum_{k=1}^{K} \theta_k L_k(e_2|e) \tag{10}$$

so that GMBR would select the hypothesis achieving lower loss. Conversely, if e_2 is a better hypothesis, then we want the opposite relation: $\sum_e \sum_k \theta_k L_k(e_1|e) > \sum_e \sum_k \theta_k L_k(e_2|e)$. Thus, in light of the fact that posterior probabilities $p(e|f)$ are not reliable, we directly compute the true loss (using a development set) and ensure that our GMBR decision rule minimizes this loss.

The disadvantage of GMBR is, of course, that a development set is needed. Note, however, that MBR may also require tuning the global scaling factor (Eq. 5). Empirically, we observe that a small set (500 sentences) seems sufficient.

Algorithm 1 Tuning $\boldsymbol{\theta}$ for GMBR

Input: Development data $\mathcal{D}$, with $(e_r, f) \in \mathcal{D}$
Input: N-best list $N(f)\ \forall f \in \mathcal{D}$.
Input: Regularization hyperparameter c
Output: $\theta_k, k = 1, \ldots, K$ such that Eq. 9 minimizes $L()$ on $\mathcal{D}$.

1: $\mathcal{P} = \emptyset$
2: **for** $f \in \mathcal{D}$ **do**
3: Compute true loss $L(e|e_r)\ \forall e \in N(f)$
4: **for** All pair $e_i, e_j \in N(f)$ **do**
5: Add (e_i, e_j) to $\mathcal{P}$ if $L(e_i|e_r) < L(e_j|e_r)$
6: **end for**
7: **end for**
8: $\arg\min_{\boldsymbol{\theta}} ||\theta||^2 + c \sum_{ij} \xi_{ij}$
s.t. $\sum_k \theta_k C_k(e_j) - \sum_k \theta_k C_k(e_i) \geq 1 - \xi_{ij}$
$\forall (e_i, e_j) \in \mathcal{P}$

3.2 Implementation

We now describe how GMBR and the tuning procedure can be implemented in practice. First, note that we can reorganize the sums in the GMBR decision rule: $\sum_e \sum_k \theta_k L_k(e'|e) = \sum_k \theta_k \sum_e L_k(e'|e) = \sum_{k=1}^{K} \theta_k C_k(e')$, where $C_k(e') = \sum_e L_k(e'|e)$ represents the combined loss for e'. So we first compute $C_k(\cdot)$ for all hypotheses, for an $O(|N(f)|^2)$ run-time. To find the GMBR decision then requires a search $\arg\min_{e' \in N(f)} \sum_{k=1}^{K} \theta_k C_k(e')$. So in test, GMBR is on the same order as conventional MBR.

To tune $\boldsymbol{\theta}$, we first extract all pairs of hypotheses where a difference exists in the true loss, then optimize $\boldsymbol{\theta}$ in a formulation similar to RankSVM (Joachims, 2006). The pair-wise nature of Eq. 10 makes the problem amenable to solutions in "learning to rank" literature (He et al., 2008a). The pseudocode is shown in Algorithm 1. The RankSVM (line 8) tries to satisfy the relations (Eq. 10) in its constraints while allowing for some slack ξ, whose amount depends on hyperparameter c.

4 Experiments

We experiment with the NTCIR-9 (2011) English-to-Japanese Patent Translation task[1]. This includes 3 million sentences for training individual MT systems; the official dev set is split into 1000 sentences for MERT of individual systems, 500 for system combination optimization (MBR, GMBR), and 500 for final evaluation. We combine three systems:

- Phrase-based Moses with lexical reordering, distortion=6 (Koehn and others, 2007)
- Forest-to-string system (Mi et al., 2008)
- Weighted finite-state Transducer (WFST) (Zhou et al., 2006) with rule-based reordering as preprocessing (Isozaki et al., 2010b).

Each system generates a 100-best list, so our system combination task involves hypothesis selection out of 300 hypotheses. As evaluation measure, we focus on BLEU, Normalized Kendall's Tau (NKT), a metric that has been shown to correlate well with humans on this language pair (Isozaki et al., 2010a)[2], and a combination thereof. The loss function used for MBR is therefore the sum of BLEU and NKT. For GMBR, the sub-components of this loss function are derived from the n-gram precisions, brevity penalty, and Kendall's score. We also multiply the n-gram precisions with the Kendall score as additional loss sub-components. Finally we add identity features indicating which of the three systems the hypothesis comes from, for a total of $K = 14$ sub-components. The hyperparameter c in Algorithm 1 is chosen by 80/20% cross-validation from the set $\{0.001, 0.01, 0.1, 1, 10, 100\}$.

The test scores for MBR, GMBR, and the single systems are shown in Table 1. The single systems are anonymized by A, B, C and sorted by decreasing performance. The top1 indicates the first hypothesis in the 100-best list, while bottom1 indicates the 100st (last) hypothesis. Observations:

1. GMBR outperforms MBR on all metrics.

2. GMBR is able to improve upon the best single system (A), despite the fact that a poor system (C) is included. This implies that criteria like Eq. 10 is effective.

3. For MBR, the inclusion of C drastically degrades performance since it implements consensus decoding, not Bayes Risk.

We also summarize results for Chinese-English and Japanese-English tasks in NTCIR9. The system combination setting is similar (3-way combination of 100-best lists) but uses different MT systems. In Chinese-English, GMBR outperforms the best single system by 1 BLEU point (32.08 vs. 31.08); in Japanese-English, GMBR outperforms by 1.85 BLEU points (29.39 vs. 27.54).

We conclude that GMBR is a robust method for system combination. It consistently improves over the top system, even when the combinations are of varying quality (e.g., the range of BLEU score in the 300-best list can be more than 10 BLEU points between A-top1 and C-bottom1). This degrades MBR and consensus decoding, but does not impact GMBR because these poor translation would achieve high loss on the development set, and therefore $\boldsymbol{\theta}$ will be optimized away from them.[3]

	BLEU	NKT	(BLEU+NKT)/2
GMBR	**36.65**	**77.50**	**57.08**
MBR	35.45	76.25	55.85
A top1	35.87	76.87	56.37
B top1	34.20	75.93	55.07
C top1	24.23	67.68	45.96
A bottom1	34.92	76.20	55.56
B bottom1	33.97	75.99	54.93
C bottom1	22.95	65.99	44.47
oracle	45.82	84.32	65.07

Table 1: Test results on English-Japanese.

5 Conclusions

We introduced *Generalized* MBR, which enables one to adapt the loss function of MBR to a given hypothesis space. By tuning this generalized loss under the constraint of uniform posteriors, we show that GMBR can consistently outperform MBR in system combination. Future work includes (1) combination with methods that can generate novel hypotheses (Rosti et al., 2007; He et al., 2008b; Matusov et al., 2006; Bangalore et al., 2001), and (2) comparison with recent work that attempts to directly estimate posteriors with mixture models (Duan et al., 2010).

[1] `http://ntcir.nii.ac.jp/PatentMT/`

[2] Code available at `http://www.kecl.ntt.co.jp/icl/lirg/ribes`

[3] It's worth noting that system identity features account for less than 30% of weights in all GMBR systems, implying that the flexibility of adjustable loss function is important and a straightforward weighted version of MBR is insufficient.

Abstract

Chinese and Spanish are the most spoken languages in the world. However, there is not much research done in machine translation for this language pair. We experiment with the parallel Chinese-Spanish corpus (United Nations) to explore alternatives of SMT strategies which consist on using a pivot language. Particularly, two well-known alternatives are shown for pivoting: the cascade system and the pseudo-corpus. As Pivot language we use English, Arabic and French. Results show that English is the best pivot language between Chinese and Spanish. As a new strategy, we propose to perform a combination of the pivot strategies which is capable to highly outperform the direct translation strategy.

1 Introduction

Although they are very distant languages, Chinese and Spanish are very close to each other in the ranking of the most spoken languages in the world[1]. Nevertheless, when interested in bilingual resources between these two languages they become far apart again. Similarly, the related amount of work we have found within the computational linguistic community, can be reduced to a very small set of references.The most popular research event recently performed was the 2008 IWSLT evaluation campaign [2]. This evaluation organized two Chinese-to-Spanish tracks. One of them was focused on direct translation and the other one on pivot translation through English. Best translation results were obtained by far in the pivot task. The best system in the pivot task (Wang et al., 2008) compared two different approaches: The first one, training two translation models on the Chinese-English corpus and English-Spanish corpus, and then building a pivot translation model for Chinese-Spanish translation using English as a pivot language as proposed in (Wu and Wang, 2007); the second one obtained better results and it was based on a cascade approach. The idea here is to translate from Chinese into English and then from English to Spanish, which means performing two translations. Besides the research mentioned above, which directly addressed the Chinese-Spanish language pair, we may also find in the literature another approach similar to Wu's (2007) authored by Cohn and Lapata (2007). Basically, they also used several intermediate pivot language to create source-to-target phrases that are lately interpolate with a direct system build with a source-to-target parallel corpus.

Apart from the BTEC[3] corpus available through the IWSLT[4] competition and *Holy Bible* datasets described in (Paul, 2008) and (Banchs and Li, 2008), respectively, there is a recent release of a six language parallel corpus (including both Chinese and Spanish) from United Nations (UN) for research purposes (Rafalovith and Dale, 2009). Using the recently released UN parallel corpus as a starting point, this work focuses on the problem of developing Chinese-Spanish phrase-based SMT technologies with a limited set of bilingual resources. We explore and evaluate different alternatives for the

problem in hand by means of pivot-language strategies through the other languages available in the UN parallel corpus, such as Arabic, English and French. More specifically, strategies such as system cascading and pseudo-corpus generation are implemented and compared against a baseline system implementing a direct translation approach. We propose a system combination different from previous ones (Wu and Wang, 2009) and based on the Minimum Bayes Risk (MBR) (Kumar and Byrne, 2004) technique using both pivot strategies which is capable to highly outperform the direct system. To the best of our knowledge, this idea was not explored before and it is a way of increasing the quality of translation between languages with scarce bilingual resources. In addition, we are performing a combination of the same system but introducing new information through the pivot language.

The paper is structured as follows. Section 2 describes the main strategies for performing Chinese-to-Spanish translation which are tested in this work. Section 3 presents the evaluation framework. Then, section 4 reports the experiments (including the system combination) and the results. Finally, section 5 concludes and proposes new research directions.

2 Direct and pivot statistical machine translation approaches

There are several strategies that we can follow when translating a pair of languages in Statistical Machine Translation. The next three sub-sections present the details of the ones we are using in this work.

2.1 Direct system

Our direct system uses the phrase-based translation system (Koehn et al., 2003). This popular system implements a log-linear model in which a source language sentence $f^J = f_1, f_2, \ldots, f_J$ is translated into another language (target) sentence $e^I = e_1, e_2, \ldots, e_I$ by searching for the translation hypothesis $\hat{e}^I$ maximizing a log-linear combination of several feature models (Och, 2003).

The main system models are the translation model and the language model. The first one deals with the issue of which target language phrase f_j translates a source language phrase e_i and the latter model estimates the probability of translation hypothesis. Apart from these two models, there are other standard models such as the lexical models, the word bonus, and the reordering model.

For decoding, we used the MOSES toolkit (Koehn et al., 2007) with the option of Minimum Bayes Risk (MBR) (Kumar and Byrne, 2004) decoding. Therefore the 1best translation obtained is not the one with highest priority but the one that is most similar to the most likely translation. The option was activated with its default parameters so it considered the top 200 distinct hypothesis to compute the 1best.

2.2 Cascade System

This approach handles the source-pivot and the pivot-target system independently. They are both built and tuned to improve their local translation quality and then joined to translate from the source language to the target language in two steps: first, the 1best translation output from source to pivot is computed and, second, it is used to obtain the 1best target translation output as the final translation.

There is an alternative approach that considers the nbest list in each step instead of the 1best. For instance, it was used in (Khalilov et al., 2008) with their cascade approach in order to obtain the best Chinese-Spanish translation. We also implemented it but the results were similar that those using MBR decoding in each system and keeping the 1best translation. Therefore we maintained MBR decoding for the rest of the experiments, which is also easier to work with.

2.3 Pseudo-Corpus System

This approach translates the pivot section of the source-pivot parallel corpus to the target language using a pivot-target system built previously. Then, a source-target SMT system is built using the source side and the translated pivot side of the source-pivot corpus. The pseudo-corpus system is tuned using a direct source-target development corpus.

2.4 Pivot combination

Using the 1-best translation output from the different pivot strategies, we built an N-best list and computed the final translation using MBR. MBR has been used both during decoding (Kumar and Byrne, 2004; Ehling et al., 2007) and as a postprocess over an N-best list. The current version of the MOSES

toolkit includes both MBR implementations. For the system combinations we used the second one.

The MBR algorithm implemented in MOSES uses $(1 - BLEU)\beta$ as the Loss Function. The value β weights the hypothesis proportionally to its translation score, but we considered all our hypothesis as equal so β was a constant and therefore could be discarded. At the end, MBR choose the hypotheses E' that fulfills:

$$E' = \arg\min_{\hat{E}'} \left(\sum_{E \neq \hat{E}'} 1 - BLEU(E, \hat{E}') \right) \quad (1)$$

It is important to mention that all N-best list must have at least 3 hypothesis per sentence. Having only two hypothesis would not work as expected because the Loss Function would always choose the longest one, which can be explained by the definition of BLEU:

$$BLEU(E, E') = \exp\left(\sum_{n=1}^{N} \log \frac{p_n(E, E')}{N} \right) * \gamma(E, E') \quad (2)$$

where $p_n(E, E')$ is the precision of n-grams in the hypothesis E' with reference E; and $\gamma(E, E')$ is a brevity penalty if the hypothesis E' is shorter than the reference E. Then $p_n(E, E') = p_n(E', E)$ and

$$\forall E, E' : length(E) > length(E') :$$
$$1 - BLEU(E, E') \geq 1 - BLEU(E', E) \quad (3)$$

3 Evaluation Framework

This section introduces the details of the evaluation framework used. We report the UN corpus statistics, a description of how we built the systems and the evaluation details.

3.1 Corpus statistics

In this study we use the UN corpus taking advantage of the fact that (as far as we are concerned) it is the biggest parallel corpus freely-available in Chinese-Spanish and it contains the same sentences in six other languages, therefore we can experiment with different pivot languages.

When experimenting with different pivot languages, in order to make the systems as comparable as possible, we first did a sentence selection over the corpus so all systems were built exactly with the same training, tuning and testing sets. All corpora were tokenized, using the standard MOSES tokenizer for Spanish, English and French; ictclass (Zhang et al., 2003) for Chinese; and MADA+TOKAN (Habash and Rambow, 2005) for Arabic. The Spanish, English and French corpora were lowercased. If a sentence had more than 100 words in any language, it was deleted from all corpora. If a sentence pair had a word ratio bigger than three for any Chinese-Pivot or Pivot-Spanish parallel corpora, it was deleted from all corpora. For all languages, we identify all sentences that occur only once in the corpora. The tuning and testing sets where drawn from the available multilingual corpus by using a maximum perplexity and lowest out-of-vocabulary word criterion over the English part of the dataset. In order to do this, perplexity was computed on a sentence-by-sentence basis by using a leave-one-out strategy; then, we selected the two thousand sentences which had the highest perplexity and the lowest out-of-vocabulary words for constructing the tuning and testing sets. Table 1 shows the main statistics for all corpora.

	training		development		test	
	s	w	s	w	s	w
Zh	58.6k	1.6M	1k	30.9k	1k	32.6k
Es	58.6k	2.3M	1k	42.2k	1k	44.0k
En	58.6k	2.0M	1k	36.7k	1k	38.3k
Ar	58.6k	2.6M	1k	47.9k	1k	49.9k
Fr	58.6k	2.3M	1k	42.1k	1k	43.9k

Table 1: UN Corpus Statistics (s stands for number of sentences and w for number of words)

3.2 System details

Our systems were build using MOSES. For all systems, we used the default MOSES parameters, which includes the grow-final-diagonal alignment symmetrization, the lexicalized reordering, a 5-gram language model using Kneser-Ney smoothing and phrases up to length 10. The optimization was done using MERT (Och, 2003). The decoding was done using MBR.

4 Chinese-to-Spanish MT strategies

Given the different languages available in the UN corpora, we tested three different pivot languages. Additionally, we compared the cascade and the pseudo-corpus pivot strategies. Finally, we combined the system outputs.

4.1 Experimenting with different pivot languages

Using most of the languages available in the UN parallel corpora (English, Spanish, Chinese, Arabic and French) we built and compare several translation systems in order to study the impact of the different pivot languages when translating from Chinese to Spanish.

Specifically, we built seven Chinese-Spanish systems: the direct Chinese-Spanish system as a quality upper bound; three cascade approach and three pseudo-corpus, using English, Arabic and French as pivots.

Therefore, the first step was to build the different Chinese-Pivot and Pivot-Spanish systems. Table 2 shows the BLEU achieved with the intermediate systems trained with the UN Corpus. These systems are used in the next section when experimenting with different pivot languages.

	BLEU
Chinese-English	35.67
Chinese-Arabic	**46.11**
Chinese-French	28.31
English-Spanish	**51.64**
Arabic-Spanish	41.79
French-Spanish	46.42

Table 2: UN Pivot Systems

As we can see in Table 2 the best Chinese-Pivot system is the Chinese-Arabic system. As for the Pivot-Spanish system, the one that achieved the best BLEU score was the English-Spanish system.

Tables 3 shows the results for our Chinese-Spanish configurations with the UN corpus. We can see there that the best pivot system used the cascade approach with English as the pivot language.

The fact that the pseudo-corpus through English outperforms cascade through English is not statistically significant, with a 95% confidence

Languages	System	BLEU
Chinese-Spanish	direct	**33.06**
Chinese-English-Spanish	cascade	**32.90**
Chinese-French-Spanish	cascade	30.37
Chinese-Arabic-Spanish	cascade	28.88
Chinese-English-Spanish	pseudo	**32.97**
Chinese-French-Spanish	pseudo	32.61
Chinese-Arabic-Spanish	pseudo	32.23

Table 3: UN pivot languages. Best results in bold.

(Koehn, 2004). These results, however, are coherent with previous works using the same language pair (Bertoldi et al., 2008; Henríquez Q. et al., 2010) that also reported the pseudo-corpus strategy was better than the cascade strategy.

In all cases English is statistically significant the best pivot language, with a 99% confidence, which is coherent with the Pivot-Spanish results in table 2. Further analysis is required in order to understand why the cascade through English is able to help so much in the Chinese-to-Spanish translation.

4.2 Pivot combination

Table 4 shows the results of the different output systems combined (from table 3) with the MBR technique. $En + Ar + Fr\ Cascade + Pseudo$ (which combines all system outputs from table 3 except the direct approach) is better than the Chinese-to-Spanish direct system and it is significant with a 99% of confidence. When adding the direct approach (dir) it increases the translation performance slightly and we obtain the best Chinese-to-Spanish translation.

	casc	pseudo	casc+pseudo
En+Ar+Fr	32.66	33.30*	**33.97***
dir+En+Ar+Fr	33.60*	33.77*	**34.09***

Table 4: Output system combination using MBR. * shows statistically significantly better results than the direct system (with a 99% of confidence). Best results in bold. Casc stands for cascade.

5 Conclusions

This work has presented experimental research for the Chinese-Spanish translation pair. The main con-

clusions derived from our study are:

- English is the best Pivot language for Chinese-to-Spanish compared to languages such as French or Arabic. The system built using English as Pivot was significantly better than the ones built with either French or Arabic, with a 99% confidence in both cases.
- There is not a significant difference among the best cascade and pseudo-corpus pivot approaches.
- The output combination using MBR is able to improve the direct system in 1 BLEU point in the best case. This improvement is significantly better with a 99% confidence.

A Baseline System for Chinese Near-Synonym Choice

Liang-Chih Yu[1], Wei-Nan Chien[1,2] and Shih-Ting Chen[1]

Abstract

Near-synonym sets represent groups of words with similar meaning, which are useful knowledge resources for many natural language applications such as query expansion for information retrieval (IR) and computer-assisted language learning. However, near-synonyms are not necessarily interchangeable in contexts due to their specific usage and syntactic constraints. Previous studies have developed various methods for near-synonym choice in English sentences. To our best knowledge, there is no such evaluation on Chinese sentences. Therefore, this paper implements two baseline systems: *pointwise mutual information (PMI)* and a *5-gram language model* that are widely used in previous work for Chinese near-synonym choice evaluation. Experimental results show that the 5-gram language model achieves higher accuracy than PMI.

1 Introduction

Lexical semantics plays an important role in many natural language applications. For instance, knowing that the word "arm" has (at least) the senses *weapon* and *bodypart* enables systems to perform word sense disambiguation. Knowing in addition the near-synonyms of a word can further improve the applications' effectiveness. For instance, knowing that the weapon sense of "arm" corresponds to the weapon sense of "weapon" and of "arsenal" means that systems can in addition perform term expansion for information retrieval (Moldovan and Mihalcea, 2000; Bhogal et al., 2007), (near-)duplicate detection for summarization, alternative word selection for writing support systems (Inkpen and Hirst, 2006; Inkpen, 2007; Wu et al., 2010), as well as computer-assisted language learning (Cheng et al., 2004; Ouyang et al., 2009).

Recent studies have shown that near-synonyms are not necessarily interchangeable in practical use due to their specific usage and collocational constraints, as shown in the following examples.

(1) {strong, powerful} coffee (Pearce, 2001)

(2) ghastly {error, mistake} (Inkpen, 2007)

(3) {bridge, overpass, tunnel} under the bay (Yu et al., 2010)

Example (1) and (2) present an example of collocational constraints in given contexts. In (1), the word "strong" in the near-synonym set {strong, powerful} is more suitable than "powerful" to fit the given context "coffee", since "powerful coffee" is an anti-collocation. Similarly, in (2), "mistake" is more suitable than "error" because "ghastly mistake" is a collocation and "ghastly error" is an anti-collocation. In (3), the near-synonym set {bridge, overpass, tunnel} represents the meaning of a physical structure that connects separate places by traversing an obstacle. Suppose that the original word in the given context "under the bay" is "tunnel". It can be found that the word "tunnel" cannot be substituted by the other words in the same set because all the substitutions are semantically implausible. The above examples indicate that not all words in a near-synonym set can be substituted with each other even though they share the same or similar meaning. Actually, some near-synonyms may produce inadequate substitutions, which may reduce the applications' effectiveness.

In order to verify whether near-synonyms do match the given contexts, previous studies have formulated the problem of near-synonym choice

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1366–1370,
Chiang Mai, Thailand, November 8 – 13, 2011.

English Sentence: This will make the _____ message easier to interpret.
Original word: error
Near-synonym set: {error, mistake, oversight}
Chinese Sentence: 這 將 使 這 _____ 訊息 容易 解釋
Original word: 錯誤
Near-synonym set: {錯誤, 錯, 差錯, 失察, 過失}

Figure 1. Example of the near-synonym choice evaluation for English and Chinese sentences.

as the "fill-in-the-blank" (FITB) task, and evaluated on English sentences (Edmonds, 1997; Inkpen, 2007; Gardiner and Dras, 2007, Islam and Inkpen, 2010). Figure 1 illustrates an example of FITB task on English and Chinese sentences. Given a near-synonym set and a sentence with one of the near-synonyms in it, the near-synonym is removed from the sentence to form a lexical gap. The goal is to predict an answer (best near-synonym) that can fill the gap from the given near-synonym set (including the original word). An evaluation can then be performed to examine whether the involved systems can restore the original word by filling the gap with the best near-synonym. To our best knowledge, there is no such evaluation for Chinese sentences. Therefore, this paper follows the FITB procedure to build a baseline system for Chinese near-synonym choice evaluation. Applications can benefit from such evaluation to provide more effective services. For instance, a writing support system can assist users, especially Chinese as Second Language (CSL) learners, to select a best alternative near-synonym when they have a need to avoid repeating the same word in composing a text.

In the following sections, we first present some previous work on near-synonym choice. Section 3 describes the two baseline systems: pointwise mutual information (PMI) and a 5-gram language model for Chinese near-synonym choice evaluation. Section 4 first introduces the Chinese near-synonym sets and test sets used in experiments, and then shows the evaluation results of the two baseline systems. Conclusions are finally drawn in Section 5.

2 Related Work

In the field of lexical semantics, the contextual information is useful for representing the meaning of words, phrases, as well as sentences (Mitchell and Lapata, 2008; Erk and Pado, 2008; Thater et al., 2010; Ó Séaghdha and Korhonen, 2011; Grefenstette et al., 2011). Therefore, the co-occurrences between a target word (the gap) and its context words have been commonly used in statistical approaches to measuring the substitutability of words. Edmonds (1997) built a lexical co-occurrence network from 1989 Wall Street Journal to determine the near-synonym that is most typical or expected in a given context. Inkpen (2007) used the PMI formula to select the best near-synonym that can fill the gap in a given context. The PMI scores for each candidate near-synonym are computed using a larger web corpus, the Waterloo terabyte corpus, which can alleviate the data sparseness problem encountered in Edmonds' approach. Following Inkpen's approach, Gardiner and Dras (2007) also used the PMI formula with a different corpus (the Web 1T 5-gram corpus) to explore whether near-synonyms differ in attitude.

Islam and Inkpen (2010) also used the Web 1T 5-gram corpus to build a 5-gram language model for near-synonym choice. Yu *et al*. (2010) presented a method to compute the substitution scores for each near-synonym based on n-gram frequencies obtained by querying Google. The dataset used in their experiments are derived from the OntoNotes copus (Hovy et al., 2006; Pradhan et al., 2007; Yu et al., 2008), where each near-synonym set corresponds to a *sense pool* in OntoNotes.

Besides the PMI and n-gram-based methods, another direction is to identify the senses of a target word and its near-synonyms using word sense disambiguation (WSD), comparing whether they were of the same sense (McCarthy, 2002; Dagan et al., 2006). Dagan *et al.* (2006) described that the use of WSD is an indirect approach since it requires the intermediate sense identification step, and thus presented a sense matching technique to address the task directly.

3 Baseline Systems

The baseline systems used for Chinese near-synonym choice are the PMI-based method (Inkpen, 2007; Gardiner and Dras, 2007) and the 5-gram language model (Islam and Inkpen, 2010). We choose these two methods because they are commonly used in previous work.

3.1 PMI-based method

The mutual information can measure the co-occurrence strength between a near-synonym and the words in a given context. A higher mutual information score indicates that the near-synonym fits well in the given context, thus is more likely to be the correct answer. The pointwise mutual information (Church and Hanks, 1991) between two words *x* and *y* is defined as

$$PMI(x,y) = \log_2 \frac{P(x,y)}{P(x)P(y)}, \quad (1)$$

where $P(x,y) = C(x,y)/N$ denotes the probability that *x* and *y* co-occur; $C(x,y)$ is the number of times *x* and *y* co-occur in the corpus, and *N* is the total number of words in the corpus. Similarly, $P(x) = C(x)/N$, where $C(x)$ is the number of times *x* occurs in the corpus, and $P(y) = C(y)/N$, where $C(y)$ is the number of times *y* occurs in the corpus. Therefore, (1) can be re-written as

$$PMI(x,y) = \log_2 \frac{C(x,y) \cdot N}{C(x) \cdot C(y)}. \quad (2)$$

Inkpen (2007) computed the PMI scores for each near-synonym using the Waterloo terabyte corpus and a context window of size $2k$ (k=2). Given a sentence *s* with a gap, $s = ...w_1...w_k \_\_\_\_ w_{k+1}...w_{2k}...$, the PMI score for a near-synonym NS_i to fill the gap is defined as

$$PMI(NS_j, s) = \sum_{i=1}^{2k} PMI(NS_j, w_i). \quad (3)$$

The near-synonym with the highest score is considered as the answer. In this paper, we use the Chinese Web 5-gram corpus to compute PMI scores. The frequency counts $C(\cdot)$ are retrieved from this corpus in the same manner within the 5-gram boundary.

3.2 5-gram language model

The n-grams can capture contiguous word associations in given contexts. Given a sentence $s = ...w_{i-4}w_{i-3}w_{i-2}w_{i-1}w_i w_{i+1}w_{i-2}w_{i-3}w_{i+4}...$, where w_i represents a near-synonym in a set. In computing the 5-gram scores for each near-synonym, Islam and Inkpen (2010) considers only the five product items $P(w_i | w_{i-4}^{i-1})$, $P(w_{i+1} | w_{i-3}^{i})$, $P(w_{i+2} | w_{i-2}^{i+1})$, $P(w_{i+3} | w_{i-1}^{i+2})$, and $P(w_{i+4} | w_{i}^{i+3})$. The other items are excluded because they do not contain the near-synonym and thus will have the same values. Accordingly, the 5-gram language model (n=5) with a smoothing method can be defined as

$$\begin{aligned} P(s) &= \prod_{i=0}^{5} P(w_i | w_{i-n+1}^{i-1}) \\ &= \prod_{i=0}^{5} \frac{C(w_{i-n+1}^{i}) + (1+\alpha_n) M(w_{i-n+1}^{i-1}) P(w_i | w_{i-n+2}^{i-1})}{C(w_{i-n+1}^{i-1}) + \alpha_n M(w_{i-n+1}^{i-1})} \end{aligned} \quad (4)$$

where $M(w_{i-n+1}^{i-1})$ denotes a missing count used in the smooth method, defined as

$$M(w_{i-n+1}^{i-1}) = C(w_{i-n+1}^{i-1}) - \sum_{w_i} C(w_{i-n+1}^{i}) \quad (5)$$

where $C(\cdot)$ denotes an n-gram frequency, which can be retrieved from the Chinese Web 5-gram corpus. Additionally, the 5-gram language model is implemented as a back-off model. That is, if the frequency of a higher-order n-gram is zero, then its lower-order n-grams will be considered. Conversely, if the frequency of a higher-order n-gram is not zero, then the lower-order n-grams will not be included in computation.

4 Experimental Results

4.1 Experiment setup

1) Chinese near-synonym sets: Since there is no standard dataset for Chinese near-synonym sets, we created seven Chinese near-synonym sets based on the seven English near-synonym sets used as the standard dataset in the previous studies (Edmonds, 1997; Inkpen, 2007; Gardiner and Dras, 2007, Islam and Inkpen, 2010). For each English near-synonym set, we first identified its corresponding senses (entries) in the Chinese WordNet (CWN) (Huang et al., 2008). Each corresponding Chinese near-synonym set

	Near-Synonym sets	Sinica Corpus		News Corpus		All	
		PMI	5GRAM	PMI	5GRAM	PMI	5GRAM
1	難懂的, 困難的, 艱難的, 艱苦的 (difficult, hard, tough)	67.14%	**70.32%**	71.51%	71.51%	68.83%	**70.78%**
2	錯誤, 錯, 差錯, 失察, 過失 (error, mistake, oversight)	**67.25%**	52.64%	**60.13%**	54.22%	**63.58%**	53.46%
3	任務, 工作, 義務 (job, task, duty)	65.08%	**76.43%**	67.62%	**70.91%**	66.54%	**73.26%**
4	責任, 職責, 職務, 約定 (responsibility, burden, obligation, commitment)	50.03%	**68.05%**	**56.79%**	56.67%	54.41%	**60.67%**
5	質料, 物質, 材料 (material, stuff, substance)	**72.98%**	59.84%	**75.90%**	65.32%	**74.09%**	61.92%
6	給, 給予, 給與, 供應, 供給 (give, provide, offer)	**69.39%**	65.89%	51.88%	**58.11%**	60.59%	**61.98%**
7	決定, 定奪, 終結, 確定 (settle, resolve)	61.43%	**71.97%**	60.59%	**72.35%**	60.85%	**72.23%**
	Average	65.20%	**70.05%***	61.38%	**66.62%***	62.99%	**68.07%***
	Number of test cases	26,504		36,427		62,931	

***** Statistically significant ($p < 0.05$) using *Binomial Exact Text*

Table 1. Accuracy of PMI and 5GRAM on different test sets.

can then be created by selecting the Chinese translations of the identified entries in the Chinese WordNet. Table 1 shows the seven Chinese near-synonym sets.

2) Test set: The test sentences containing the near-synonyms were selected from two corpora: the Sinica Corpus and Chinese News Corpus, released by the Association for Computational Linguistics and Chinese Language Processing (ACLCLP). If a test sentence contained two (or more) near-synonyms, then this sentence was divided into two (or more) test examples. The near-synonyms were then removed from the test examples for FITB evaluation.

3) Implementation of baseline systems: The two baseline system, PMI and 5GRAM, were implemented using the (3) and (4), respectively. For PMI, the size of the context window k was set to 2. For 5GRAM, only the 5-gram with a near-synonym in the middle position of each test example was selected the s for testing.

4) Evaluation metric: The answers proposed by PMI and 5GRAM are the near-synonyms with the highest score. The correct answers are the near-synonyms originally in the gap of the test examples. The performance is measure by the accuracy, which is defined as the number of correct answers made by each baseline system, divided by the total number of test examples.

4.2 Evaluation results

Table 1 shows the evaluation results of Chinese near-synonym choice using PMI and 5GRAM. The results show that 5GRAM achieved better performance than PMI on both test corpora. In comparison with the results on the seven English near-synonym sets, previous studies reported that the accuracy of PMI and the 5-gram language model were 66.0 (Inkpen, 2007) and 69.9 (Islam and Inkpen, 2010), respectively, which was greater than 62.99 and 68.07 reported in Table 1. One possible reason is that the total number of near-synonyms in the seven Chinese near-synonyms sets is 28 and the average is 4 for each set, and that in the seven English near-synonyms sets is 21 and the average is 3 for each set. More near-synonyms in a set may decrease systems' ability to discriminate among near-synonyms.

5 Conclusion

This work has presented the use of the PMI and 5-gram language model for Chinese near-synonym choice. Additionally, this work has also created seven Chinese near-synonym sets based on the standard dataset of the seven English near-synonym sets. Experimental results show that the 5-gram language model that can capture contiguous word associations in given contexts achieved higher accuracy than PMI.

Abstract

This paper addresses the issue of cluster labeling and presents a method for assigning labels by using concepts in a machine-readable dictionary. We assume that salient terms in the cluster content have the same hypernym because hypernymic semantic relation represents a generalization that goes from specific to generic. Our experimental results reveal that hypernymic semantic relations can be exploited to increase labeling accuracy, as the results of 0.441 F-score improves over the two baselines.

1 Introduction

With the exponential growth of information on the Internet, finding and organizing relevant materials on the Internet is becoming increasingly difficult. Internet directories such as Yahoo! and Google, which classify Web pages into pre-defined hierarchical categories, provide one solution to the problem. Categories in the hierarchical structures are carefully defined by human experts and documents are well-organized. However, manual category-tagging is extremely costly. Moreover, categories on some Internet is often insufficient in finding relevant documents for users. Because these categories tend to have some bias in both defining and classifying documents. Cluster labeling is one of the techniques to attack the problem.

Most of the work on cluster labeling identifies salient terms in the cluster content that characterize the cluster in contrast to other clusters. Salient terms are extracted by using statistical feature selection, *e.g.*, maximum sum of the individual term frequencies of documents assigned to a cluster (Cutting et al., 1992), an adapted versions of Information Gain (Geraci et al., 2007), χ^2 method (Popescul and Ungar, 2000), and the Jensen-Shannon Divergence (Camel et al., 2009). Other works based on salient terms are frequent phrases by (Osinski and Weiss, 2005), and integration of hierarchical information by (Muhr et al., 2010). However, the suggested terms, even when related to each other, tend to represent different aspects of the topic underlying the cluster, and it is often the case that a good label does not occur directly in the document. Carmel *et. al* addressed the issue and presented a method to use Wikipedia as an external knowledge. They showed the effectiveness of the method. However, Wikipedia is the free online encyclopedia, and everyone can access and edit the information. Therefore, it is often included noise information such as categories which do not characterize the cluster in the pages. Chin *et. al* presented a method to use WordNet (Chin et al., 2006). They used machine learning through extending the given term set with synonyms, hypernyms, hyponyms and so on. However, their method needs training data to determine the actual weights. Through supervised training in the labeling process the actual influence of synonyms, hypernyms, hyponyms information remains unclear.

This paper focuses on cluster labeling, and presents a method for assigning labels automatically by using concepts in a machine-readable dictionary. Similar to Chin *et. al* work, we focused on semantic relation in a dictionary, namely hypernymic semantic relation that represents a generalization, *i.e.*, goes from specific to generic (Fellbaum, 1998), and used it in the cluster labeling process. We assume that salient terms in the cluster content have the same hypernym in a hierarchical structure of a dictionary. The hypernym represents generic concepts of a set of documents, thus can be a label of a cluster.

2 Cluster Labeling

The procedure for cluster labeling consists of four steps: documents clustering, term weighting, hy-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1371–1375,
Chiang Mai, Thailand, November 8 – 13, 2011.

pernym extraction, and ranking labels.

2.1 Documents clustering

The first step is to classify documents into a set with semantically similar documents. In the document clustering, we do not know how many clusters there are in a given input documents. Moreover, the algorithm should allow each data point to belong to more than one cluster because of multi-label classification. We used a graph-based unsupervised clustering technique developed by (Reichardt and Bomholdt, 2006); we call this the RB algorithm. This algorithm detects the node configuration that minimizes the energy of the material. The energy function, called the Hamiltonian, for assignment of nodes into communities clusters together those that are linked, and keeps separate those that are not by rewarding internal edges between different clusters. Here, "community" or "cluster" have in common that they are groups of densely interconnected nodes that are only sparsely connected with the rest of the network. Only local information is used to update the nodes which makes parallelization of the algorithm straightforward and allows the application to very large networks. Moreover, comparing global and local minima of the energy function allows the detection of overlapping nodes. Reichardt et al. evaluated their method by applying several data including a large protein folding network, and reported that the algorithm successfully detected overlapping nodes (Reichardt and Bornholdt, 2004). We thus used the algorithm to cluster documents. Let d_i ($1 \leq i \leq n$) be a document in the input, and σ_i be a label assigned to the cluster in which d_i is placed. The Hamiltonian H is defined as:

$$H(\{\sigma_i\}) = -\sum_{i<j}(A_{ij}(\theta) - \gamma p_{ij})\delta_{\sigma_i\sigma_j}. \quad (1)$$

δ denotes the Kronecker delta. The function $A_{ij}(\theta)$ refers to the adjacency matrix of the graph, which is defined as:

$$A_{ij}(\theta) = \begin{cases} 1 & \text{if } sim(d_i, d_j) > 0 \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

$sim(d_i, d_j)$ in Eq (2) refers to cosine similarity between d_i and d_j. The matrix p_{ij} in Eq. (1) denotes the probability that a link exists between d_i and d_j, and is defined as:

$$p_{ij} = \sum_{i<j} \frac{A_{ij}(\theta)}{N(N-1)/2}, \quad (3)$$

where N refers to the number of documents and $\frac{N(N-1)}{2}$ is the total number of document pairs. As the parameter γ in Eq. (1) increases, each document is distributed into larger number of clusters. Eq. (1) thus shows comparison of the actual values of internal or external edges with its respective expectation value under the assumption of equally probable links and given data sizes. The minima of the Hamiltonian H are obtained by simulated annealing (Kirkpatrick et al., 1983). We applied simulated annealing for T runs [1].

2.2 Term weighting

For the results of clustering, we extracted salient terms from each clusters obtained by the RB algorithm. We tested four metrics which are commonly used as feature selection, *i.e.*, TF∗IDF, mutual information, χ^2 statistics, and information gain. The terms we used are noun words in the documents. Each term is scored according to its contribution to the metrics between the cluster and other clusters. The top k scored terms are then selected as a candidate of the cluster salient terms.

2.3 Hypernym extraction

The third step is to extract hypernym for each term selected by term weighting method. We used Japanese word and concept dictionaries of EDR [2]. The word dictionary consists of 270,000 words. Each word has concept identifier as well as lexical and grammatical information. The concept identifier is to identify words and their concepts. The concept dictionary consists of 410,000 concepts. Each concept is linked to other concepts, and the link is a relation between concepts, namely super-sub relation. We used this super-sub relation as hypernymic semantic relation. Let W = {w_1, w_2, $\cdots$, w_n} be a set of words in a cluster selected by feature selection. For each pair of words, w_i and w_j, we identified its hypernym c_k by using Eq. (4).

$$c_k = hy(w_i) \cap hy(w_j) \quad (4)$$

where $hy(w_i)$ and $hy(w_j)$ satisfy $min(dis(hy(w_i), w_i))$ and $min(dis(hy(w_j), w_j))$, respectively. In Eq. (4), $hy(x)$ refers to the hypernym of a word x. $min(dis(hy(w_i), w_i))$ shows the minimum distance between $hy(w_i)$ and w_i. We extracted hypernym by using Eq. (4), and regarded these as label candidates.

[1] We set T to 1,000 in the experiments

Table 1: Categories

2.4 Ranking Labels

The final step for cluster labeling is to rank label candidates according to their scores. The score of candidate c is obtained by using Eq. (5).

$$Score(c) \quad = \quad -\log \frac{freq\_p(c)}{N} \qquad (5)$$

where $N = \frac{1}{freq\_p(w_i)+freq\_p(w_j)}$. w_i and w_j are words selected by feature selection. $freq\_p(x)$ is the number of senses that the word x has.

3 Experiments

3.1 Data

We used two types of test data: one is a collection that correct labels occur directly in the documents. Another is that a label does not appear in the documents. The data we used is RWCP corpus labeled with UDC codes selected from 1994 Mainichi newspaper (RWC, 1998). It consists of 27,755 documents organized into fine-grained categories, 9,951 categories with a seven-level hierarchy. We used categories/labels assigned to the second, third and fourth level of a hierarchy, each of which has more than five documents [3]. Each level consists of 17 categories shown in Table 1. For each category, we randomly selected five documents, and created each type of test data. We extracted the top 20 scored words by term weighting as a candidate of the cluster salient terms.

[3]We did not use categories assigned to the top level, as it was defined by only one label.

	RB						EM		
Level	γ	θ	C	Prec	Rec	F	Prec	Rec	F

Avg	–	–	10	.539	.674	.595	.472	.682	.553

Table 2: Clustering Results

3.2 Clustering accuracy

For each category, we randomly selected five documents and created a training data to estimate two parameters, γ and θ. We represented each document as a vector of noun word frequencies, and applied RB algorithm. For evaluation of document clustering, we used F-score, especially to capture how many documents does the algorithm actually detect more than just one category. Precision was defined by the percentage of documents appearing in the correct clusters compared to the number of documents appearing in any cluster, and recall was defined by the percentage of documents within the correct clusters compared to the total number of documents to be clustered. For comparison of clustering algorithm, we used the EM algorithm that is widely used as a soft clustering technique(Nock et al., 2009). We set the initial probabilities by using the result of k-means clustering, where k is set to the number of correct clusters,1 7. We used up to 30 iterations to learn the model probabilities. The results are shown in Table 2.

Table 2 shows average performance between two types of test data. γ and θ in Table 2 denote the values that maximized the F-score obtained by using the training data. "C" refers to the number of clusters obtained by RB. The overall results obtained by the RB algorithm were better to those obtained by the EM algorithm regardless of the level of a hierarchy.

3.3 Labeling accuracy

We tested two types of document collection. For evaluation of cluster labeling, we used 11-point average precision. For comparison of the method, we used two baselines: (i) a feature selection by TF$*$IDF, and (ii) the use of Wikipedia for labeling. The method using Wikipedia is based on (Camel et al., 2009) [4]. The difference is that we used RB for clustering, and TF$*$IDF to extract salient

Table 4: Lists of top 2 terms (The top 20 term weighting scored terms)

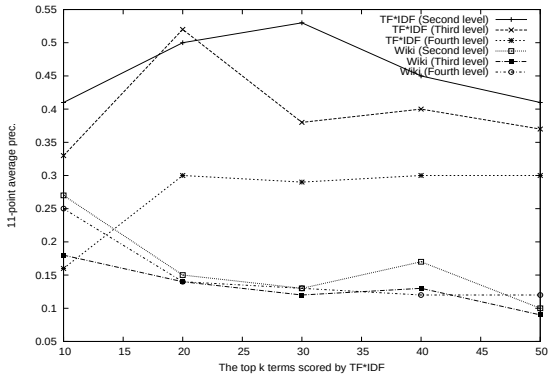

Figure 1: Performance against the top k terms

terms. The results are shown in Table 3. As can be seen clearly from Table 3, the results obtained by concepts based method were better than TF∗IDF and Wikipedia in both types of data. The results obtained by concepts based method show that there is no significant difference between two types of data, while the results by Wikipedia go down when we tested data that correct labels do not occur in the documents. This shows that the use of concepts in a dictionary improves overall performance. Table 4 shows a list of top 2 terms identified by concepts based method. Bold font terms are correctly identified by the method. Table 4 shows that more than half of the terms are correctly identified in the second and third level of a hierarchy.

We note that we set the number of scored terms to 20. To examine how the number of scored terms affects the overall performance, we performed an experiment by varying the values. Figure 1 shows performance plots against the top k terms scored by TF∗IDF. The best performance by both methods was around the top 20 terms scored by TF∗IDF term weighting method. The larger the number of scored terms becomes low precision. This is reasonable because a good label for a cluster generally consists of a few words.

4 Conclusions

We focused on cluster labeling, and presented a method for assigning labels by using concepts in a machine readable dictionary. Comparison with baselines showed improvements regardless of the level of a hierarchy. Future work will include: (i) incorporating hierarchical structure of documents, and (ii) applying the method to other data and thesaurus such as ODP dataset and WordNet.

Abstract

This paper proposes a weakly-supervised approach for extracting instances of semantic classes. This method constructs simple wrappers automatically based on specified seed instances and uses a compression model to assess the contextual evidence of its extraction. By adopting this compression model, our approach can better avoid erroneous extractions in a noisy corpus such as the Web. The empirical results show that our system performs quite consistently even when operating on a noisy text with a lot of possibly irrelevant documents.

1 Introduction

Extracting instances of semantic classes is a fundamental task in natural language processing (NLP). Such a task aims to extract instances belonging to a specific category such as acquiring *Tom Hanks* and *Al Pacino* into a list containing other actors. This kind of information serves as building blocks for various NLP tasks. For example, major search engines such as Yahoo and Google gather large amount of such classes (Paşca, 2007; Chaudhuri et al., 2009) to better interpret queries and provide search suggestions. Other applications include ontology learning (Cimiano et al., 2004), co-reference resolution (McCarthy and Lehnert, 1995) and advertisement matching (Chang et al., 2009).

Most of the approaches for this task can be roughly classified into two categories: distributional and pattern-based. The distributional approaches use contextual similarity to model the instances of a given class. Following the distributional hypothesis (Harris, 1970), these methods take a small set of seed instances and generate new instances from noun phrases that are most similar to the seeds in terms of the distributions of surrounding words (Sarmento et al., 2007; Pantel et al., 2009).

The pattern-based approaches use text patterns to extract instances of a given semantic class (Riloff and Shepherd, 1997; Riloff and Jones, 1999; Banko et al., 2007; Paşca, 2007). The most representative study is the group of patterns proposed by Hearst (1992). For example, patterns like '*X such as Y*' and '*X including Y*' can be applied to extract instances from '*actors such as Tom Hanks*' and '*countries including Japan*'. In these approaches, semantic classes are specified by providing small sets of seed instances or seed patterns such as (Kozareva et al., 2008) which utilized a single hyponym pattern combined with graph structure to extract semantic lexicons from the Web. In addition to natural language patterns, Wang and Cohen (2007) demonstrated an approach that learns the pattern of specific meta-structure of the document (e.g., tags in HTML) automatically from seed instances.

In this paper, we propose a method similar to (Kozareva et al., 2008) and (Wang and Cohen, 2007) in that it also employs graph ranking algorithm to assess the reliability of the extracted candidates and uses the Web as the source of extraction. Different from them, the wrappers we induced from web pages are less specific and do not contain any structural cues such as HTML tags. In our approach, those wrappers serve primarily as a means to bracket candidate mentions. The main discriminative power resides in adopting a text compression model called Prediction by Partial Matching (PPM) (Cleary and Witten, 1984) to evaluate the contextual similarity between a mention and seed instances. The similarity is measured by compression ratio achieved when compressing the surrounding context of the mention using the PPM model loaded with context statistics of seed instances. In this work, we focused on

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1376–1381,
Chiang Mai, Thailand, November 8 – 13, 2011.

assessing the effectiveness of such measurement and this effort can potentially be extended to systems that adopt more elaborated text patterns.

The rest of this paper is organized as follows. Section 2 briefly describe the PPM compression model. In section 3, we detail the idea of using compression ratio as similarity measure. Section 4 outlines our approach. Section 5 shows the results of experiments and section 6 concludes this paper.

2 Prediction by Partial Matching

In this work, we use the Prediction by Partial Matching (PPM) compression scheme (Cleary and Witten, 1984) which has become a benchmark in the lossless text compression. It generates "predictions" for each input token in turn. Each prediction takes the form of a probability distribution that is provided to an encoder, which is usually an arithmetic coder. However, the details of actual coding technique are of no relevance to this paper.

PPM can be seen as an n-gram approach that uses finite-context models of tokens, where the previous few tokens predict the upcoming one. The conditional probability distribution of tokens, conditioned on the preceding context, is maintained and updated as each token of input is processed. This distribution, along with the the preceding few input tokens, is used to predict each upcoming token. Exactly the same distributions are maintained by the decoder, which updates the appropriate distribution as each token is received.

Rather than using a fixed context length, the PPM chooses a maximum context length, say ℓ, and maintains statistics for this and all shorter contexts. To combine these statistics, for each upcoming token, the PPM starts with the order ℓ model. If that model contains a prediction for the token, the token is encoded according to the order ℓ model. Otherwise, both encoder and decoder *escape* down to order $\ell - 1$. There are two possible situations. If the order ℓ context has not been encountered before, then escaping to order $\ell - 1$ is inevitable, and both encoder and decoder can arrive at that fact without any communication. On the other hand, if the preceding ℓ tokens have been encountered in sequence before but not followed by the upcoming character, then only the encoder knows that an escape is necessary. In this case, it must signal the decoder by transmitting an *escape event*. Thus, space must be reserved for this event in every probability distribution that encoder and decoder maintain.

Once any necessary escape event has been transmitted and received, both encoder and decoder agree that the upcoming token will be coded by $\ell - 1$ order model. Of course, this may not be possible either, and further escapes may take place. Ultimately, the order 0 model may be reached; in this case, the token can be encoded if it has occurred before. Otherwise, there is one further escape, and both encoder and decoder will agree that the token itself will be literally transmitted.

There is one remaining question regarding this backoff strategy: how much space to preserve for the escape probability. In this work, we assign the escape probability in particular context as

$$\frac{\frac{1}{2}d}{n}$$

where n is the number of times that context has appeared and d is the number of different tokens that have directly followed it. And the probability of a token that has occurred c times in that context before is

$$\frac{c - \frac{1}{2}}{n}$$

This allocation strategy is called PPMD (Howard, 1993) and has shown great performance in text compression. Once the token has been processed, the model will be updated to include this context-to-token prediction.

Most of the discourses of PPM were on character-based compression, although the above backoff strategy can be equally applied to other class of symbols such as words. Previous experiments with a wide range of English text has shown that word-based models consistently outperform the character-based counterpart (Teahan and Cleary, 1997). In this work, we adopt the word-based model for our task. A more comprehensive description of the PPM algorithm can be found in (Bell et al., 1990).

3 Compression Ratio as Similarity

In this work, we use the compression ratio as a measure of similarity between the context of a mention and the contexts of seed instances. More specifically, this ratio is defined as

$$\frac{\lambda_M(\mathbf{x})}{\lambda_B(\mathbf{x})}$$

where $\mathbf{x}$ is the sequence of words surrounding the mention, $\lambda_B(\mathbf{x})$ is the code length of $\mathbf{x}$ encoded by a blank PPM, i.e., the PPM without any context statistics pre-loaded. And $\lambda_M(\mathbf{x})$ is the code length of $\mathbf{x}$ compressed by the model M which loaded with the context statistics of seed instances, i.e., the model that has run through the contexts collected from the vicinity of seed instances observed in the corpus.

The encoding of a token x_i in $\mathbf{x} = x_1 x_2 \cdots x_n$ is based on the probability predicted by the PPM, which conditioned on the preceding tokens $\mathbf{y_i} = \cdots x_{i-2} x_{i-1}$. Let p_M and p_B be the probabilities predicted by those two models, from an information theoretic perspective, the above ratio can be interpreted as follows,

$$\begin{aligned}\frac{\lambda_M(\mathbf{x})}{\lambda_B(\mathbf{x})} &= \frac{\sum_{i=1}^{n} -log_2 p_M(x_i|\mathbf{y_i})}{\sum_{i=1}^{n} -log_2 p_B(x_i|\mathbf{y_i})} \\ &= \frac{-log_2 \prod_{i=1}^{n} p_M(x_i|\mathbf{y_i})}{-log_2 \prod_{i=1}^{n} p_B(x_i|\mathbf{y_i})}\end{aligned}$$

which is the log-likelihood ratio. Intuitively, this ratio gives an estimate of how much better M predicts $\mathbf{x}$ compared to the prediction without any prior assumptions. And the more effective the prediction, the more similar $\mathbf{x}$ and the contexts of seed instances, which M was built upon.

Leveraging this concept, we can filter possibly irrelevant mentions by comparing the ratio to a threshold θ. More specifically, we test whether

$$\frac{\lambda_M(\mathbf{x})}{\lambda_B(\mathbf{x})} > \theta \quad (1)$$

If this inequality holds, we skip the corresponding mention. In this work, we adopt $\theta = 0.3$, which empirically gives a good performance.

4 Proposed Approach

Our approach is outlined in Algorithm 1. The procedure starts at collecting the contexts of seed instances observed in the corpus and making wrappers based on these occurrences. In this work, a wrapper is constructed as a regular expression of two tokens[1] preceding and one or two tokens following a seed occurrence depending on what next to the occurrence is a punctuation or word. The collected contexts are then fed into a PPM. Utilizing this PPM, we filter the mentions according to Inequality 1. Following that, a graph G is build based on the wrappers and remaining mentions. In this graph, a vertex represents either a wrapper or a mention, and an edge denotes a captured-by or produced-by relationship. The vertices in G are then ranked by graph ranking algorithm. In this work, we adopt RageRank with Prior (White and Smyth, 2003). Finally, we obtain a list of mentions according to the vertices ranking in G.

[1] A token means a word or a punctuation.

Algorithm 1 The Proposed Approach

Input: A set of seed instances S and corpus C
Output: A ranked list of extracted instances

```
W = φ, T = φ
for each s in S do
    for each occurrence of s in C do
        Make a wrapper and add it into W.
        Collect the surrounding text into T.
    end for
end for
Build a PPM M based on T.
for each w in W do
    for each mention in C captured by w do
        x ← text surrounding this mention
        if λ_M(x)/λ_B(x) > θ then
            Skip this mention.
        end if
    end for
end for
Construct a wrapper-mention graph G.
Rank the vertices in G by graph random walk.
return ranked list of mentions.
```

5 Experiment Settings and Results

In this work, the experiments are designed to evaluate the effectiveness of the proposed filtering strategy in learning semantic classes. The proposed approach is compared with a baseline counterpart which runs *without* the filtering mechanism. A noted impediment (McIntosh and Curran, 2009) to a fair evaluation is that the same seeds used to initiate the algorithms can cause different algorithms to generate diverse lexicons which vary greatly in precision. This makes evaluation unreliable — seeds which perform well on one algorithm can perform poorly on another.

To conduct a fair comparison, we adopt a bagging approach which resembles to the one used by McIntosh and Curran (2009) to aggregate the results over 30 runs for each algorithm. In each run, our system uses three seeds randomly selected from a set of ten prepared instances. The resulting 30 lexicons are then merged by a weighted vot-

ing function which is based on two hypotheses of the ranked lexicons: firstly, the candidates ranked higher in lexicons are considered more reliable; secondly, this ranking evidence can be better supported if a run extracted more candidates. More specifically, for each run, the candidate extracted with the r-th rank is assigned with a score by

$$S_c(r) = \frac{m}{log(r)}$$

in which m is the number of candidates extracted in this run. This score is averaged over all lexicons in which the candidate is listed.

In this work, we evaluated the algorithms on nine semantic classes as listed in Table 1. In each run, the systems operate on 50 web pages retrieved from Google by submitting a query containing three seed instances. To further test the ability of the filtering mechanism, we also conducted experiments which added another 500 web pages gathered from `reddit.com`[2] into the original retrieval to simulate a noisy source.

It can be observed from the results that the proposed approach consistently outperforms the baseline system and maintains the precision better as the evaluation includes more instances. Moreover, the results of experiments that includes noise web pages further demonstrate the effectiveness of the filtering mechanism. In those experiments, the baseline system often exhibits a performance drop compared to the results obtained without the additional noise web pages. On the other hand, the proposed approach displays a consistent performance regardless whether there is additional noise or not. This shows that the filtering mechanism does help the overall performance and is better in preventing erroneous extractions.

Class	Method	Noise	Precision @

6 Conclusion and Future Works

In this work, we have proposed a weakly-supervised approach for extracting instances of semantic classes. The proposed approach utilizes a compression model for filtering possibly irrelevant mentions, and uses a graph ranking algorithm for sorting the extraction.

This study focused primarily on assessing the effectiveness of using PPM model for evaluating the contextual evidence, and thus we use only very simple wrappers. Our approach can potentially be extended to adopt more elaborated patterns such as Kozareva et al. (2008) and Xu et al. (2007). In addition, as our future work, we plan to apply this method to other languages such as Japanese and Chinese.

Potts Model on the Case Fillers for Word Sense Disambiguation

oku@pi.titech.ac.jp

Abstract

We propose a new method for word sense disambiguation for verbs. In our method, sense-dependent selectional preference of verbs is obtained through the probabilistic model on the lexical network. The mean-field approximation is employed to compute the state of the lexical network. The outcome of the computation is used as features for discriminative classifiers. The method is evaluated on the dataset of the Japanese word sense disambiguation.

1 Introduction

Polysemous words can be obstacles to many applications of natural language processing such as information retrieval, question answering, and machine translation. The task of distinguishing word senses given a token of a polysemous word and its context is often referred to as word sense disambiguation and has been studied by many researchers (Agirre and Edmonds, 2006). Among a number of word sense disambiguation tasks including noun sense disambiguation, adjective sense disambiguation, and named entity disambiguation, we focus on the verb sense disambiguation with the supervised setting, where we are supposed to construct a classifier given labeled training instances.

It is learned in the previous work that case fillers are often good clues for the verb sense disambiguation. Consider, for example, the following two sentences:

1. "He drove a car to the next town."
2. "He drove the dogs away."

The "drive" in Sentence 1 means "operate (a vehicle)", while "drive" in Sentence 2 means "urge (something to move)". Although there might be long contexts to these instances, looking at the case fillers "car" and "dog" alone would lead to the correct interpretations of the meanings. This kind of preference on nouns as case fillers is called $selectional\ preference$, which in this case depends on sense. It is sometimes impractical, however, to expect that the training dataset covers all the nouns as case fillers, if case fillers of the target verb are diverse. The purpose of this article is to propose a method for propagating the information on the case fillers in the training dataset to other nouns, so that the sense of polysemous words is correctly disambiguated. In our method, the information propagation is implemented as estimation of the state of the probabilisitc model on the lexical network. One advantage of our method is that we can overcome the difficulty caused by the noise contained in the lexical network.

2 Related Work

Recent work on general word sense disambiguation is summarized in the book edited by Agirre and Edmonds (2006). We focus on the work of the verb sense disambiguation.

The idea of using case frames for the verb sense disambiguation is not novel, and dates back to 90's. Fujii et al. (1998) proposed a method for the verb sense disambiguation, which is based on the k-nearest neighbors. In their method, each instance is represented as a case frame and the similarity of two instances is calculated as a weighted sum of the similarities of case fillers. Fujii et al. also proposed a framework of active learning.

To disambiguate verb senses, Chen and Palmer (2009) proposed to use linguistic and semantic features including the voice of the given sentence, the presence of a PP adjunct, and the named entity tags. Dligach and Palmer (2008) proposed to use co-occurrence with other verbs as features. Wagner et al. (2009) proposed to use verb clusters generated with statistics on verb subcategorization.

3 Potts Model

We introduce the probability model that we will use for our task. This model gives the probability distribution over a set of nodes associated with random variables, where some pairs of variables are dependent on each other. If the variables can have more than two values and there is no order relation between the values, the network comprised of such variables is called *Potts* model (Wu, 1982), which has been used in applications such as image restoration (Tanaka and Morita, 1996) and rumor transmission (Liu et al., 2001).

Suppose a network consisting of nodes and weighted edges is given. Let c denote the value of a node, and w_{ij} the weight between i and j. Energy function $H(\mathbf{c})$ is represented as

$$H(\mathbf{c}) = -\beta \sum_{ij} w_{ij}\delta(c_i, c_j) - \alpha \sum_{i \in L} \delta(c_i, a_i), \quad (1)$$

where β is a constant called *the inverse-temperature*, L is the index set for the observed variables, a_i is the value of an observed variable i, and α is a positive constant representing a weight on labeled data. δ returns 1 if two arguments are equal to each other, 0 otherwise. The state is penalized if c_i $(i \in L)$ is different from a_i. The probability distribution of the network is represented as $P(\mathbf{c}) = \exp\{-H(\mathbf{c})\}/Z$, where Z is a normalization factor.

Instead of minimizing $H(\mathbf{c})$, we attempt to minimize the free energy, which is defined to be the sum of $H(\mathbf{c})$ and the negative entropy. However, this minimization is computationally hard. We hence resort to the mean-field approximation method (Nishimori, 2001), in which $P(\mathbf{c})$ is replaced by factorized function $\rho(\mathbf{c}) = \prod_i \rho_i(c_i)$. The evergy function with the factorized probability function is called *variational free energy*:

$$\begin{aligned} F(\mathbf{c}) &= \sum_{\mathbf{c}} \rho(\mathbf{c}) H(\mathbf{c}) - \sum_{\mathbf{c}} -\rho(\mathbf{c}) \log \rho(\mathbf{c}) \\ &= -\alpha \sum_i \sum_{c_i} \rho_i(c_i)\delta(c_i, a_i) \\ &\quad -\beta \sum_{ij} \sum_{c_i, c_j} \rho_i(c_i)\rho_j(c_j) w_{ij}\delta(c_i, c_j) \\ &\quad -\sum_i \sum_{c_i} -\rho_i(c_i) \log \rho_i(c_i). \end{aligned} \quad (2)$$

By minimizing $F(\mathbf{c})$ under the condition that $\forall i, \sum_{c_i} \rho_i(c_i) = 1$, we obtain the following fixed point equation for $i \in L$:

$$\rho_i(c) = \frac{\exp(\alpha\delta(c, a_i) + \beta \sum_j w_{ij}\rho_j(c))}{\sum_n \exp(\alpha\delta(n, a_i) + \beta \sum_j w_{ij}\rho_j(n))}. \quad (3)$$

The fixed point equation for $i \notin L$ can be obtained by removing $\alpha\delta(c, a_i)$ from above. This fixed point equation is solved by an iterative computation. In the actual implementation, we represent ρ_i with a linear combination of the discrete Tchebycheff polynomials (Tanaka and Morita, 1996). Details on the Potts model and its computation can be found in the literature (Nishimori, 2001).

4 Proposed Method

4.1 Construction of Lexical Networks

We follow the work by Takamura et al. (2005) to construct a lexical network. We link two words if one word appears in the gloss of the other. Each link belongs to one of two groups: the same-orientation links SL and the different-orientation links DL. If a negation word appears in the gloss of an entry word, the words after the negation word are linked to the entry word with DL. Otherwise, those words are linked with SL. In case of Japanese, the auxiliaries "nai" and "nu" are regarded as negation words.

We next set weights $W = (w_{ij})$ to links :

$$w_{ij} = \begin{cases} \frac{1}{\sqrt{d(i)d(j)}} & (l_{ij} \in SL) \\ -\frac{1}{\sqrt{d(i)d(j)}} & (l_{ij} \in DL) \\ 0 & otherwise \end{cases}, \quad (4)$$

where l_{ij} denotes the link between word i and word j, and $d(i)$ denotes the degree of word i, which indicates the number of words linked with word i. We call this network *the gloss network (G)*. We construct another network, *the thesaurus network (T)*, by linking synonyms and hypernyms in a thesaurus. We also merge the two networks above to construct another network *the gloss-thesaurus network (GT)*.

4.2 Use of Potts Model

We estimate the tendency of each word to be the case filler for a verb sense. For example, "car" would have a high tendency to be the case filler for "drive" with the sense "operate (a vehicle)". Such tendency is measured as the probability $P_i(c)$ over senses c for noun n_i. We will use the Potts model for this purpose. Namely, the local approximate

probability $\rho_i(c)$, equivalently the mariginal probability $\sum_{\boldsymbol{c}} \rho(\boldsymbol{c})$, is regarded as probability $P_i(c)$.

The values of each random variable are senses of the target verb. For each case and each verb, we estimate the probability of the sense assignments on the whole set of nodes by means of the mean-field approximation. The case fillers of the training instances are used as observed variables, with their index set being L in Equation (2). $P_i(c)$ is estimated for each case.

In our experiments on Japanese, surface cases are employed: wo (accusative), ga (nominative), ni (dative/locative), de (locative/instrumental), no (genitive/others), e (locative/illative), to (comitative), $kara$ (elative), $yori$ (comparative), $made$ (terminative). Although our model is also applicable to deep cases, we focus on surface cases since deep case recognition itself is a challenging task.

4.3 Estimation of β

In some pieces of previous work (Takamura et al., 2005; Takamura et al., 2007), it has been shown that the optimal β can be obtained by estimating the critical temperature, at which phase transition occurs from *paramagnetic phase* (variables are randomly oriented) to *ferromagnetic phase* (most of the variables have the same value). We follow these pieces of previous work.

In practice, when the maximum of the spatial averages of the approximated probabilities $\max_c \sum_i \rho_i(c)/N$ exceeds a threshold during increasing β, we consider that the phase transition has occurred. We select the value of β slightly before the phase transition.

4.4 Discriminative Training

Probability $\rho_i(c)$ is expected to be a strong clue for sense disambiguation. However, it is not clear how we can effectively use the probabilities of different cases c; $\rho_i(c)$ for some cases would be reliable, while some others less reliable. In addition, the word tokens that appear before and after the target word also give evidence for senses. We therefore use a discriminative approach to construct a classifier with those various clues as features. Support vector machines are employed in this work, although other classifiers are also applicable.

Note that even if a case filler in the test instance did not appear in the training data, the feature $\rho_i(c)$ corresponding to this case filler conveys the information on the selectional preference of the verb against the case filler.

5 Experiments

5.1 Experimental Settings

The proposed method for verb sense disambiguation is evaluated on the white paper part of BCCWJ corpus, the first balanced corpus of contemporary written Japanese (Maekawa, 2008), which was also used as a test set for SemEval-2 Japanese word sense disambiguation task (Okumura et al., 2010). The dataset used in this research was created by the preliminary annotation for SemEval-2. The senses are defined in the Iwanami Kokugo Jiten (Nishio et al., 1994), a Japanese dictionary. Among three levels of sense IDs defined in this dictionary, the middle-level sense was used in the empirical evaluation, which is the same level of senses used in the SemEval-2. From the dataset above, we selected most ambiguous 14 verbs whose empirical sense distributions (i.e., estimated with the maximum likelihood principle) have a high entropy and appear more than 100 times in the dataset. The statistics of this dataset is shown in the middle columns of Table 1. 5-fold cross-validation was employed for each verb.

TinySVM version 0.09[1] was used for SVM training and classification. The linear kernel was used as a kernel function of SVM. The soft-margin parameter C indicating the tradeoff between the model complexity and the training error was tuned to the best value among $0.01, 0.1, 1, 10$ for each method. The glosses of the Iwanami Kokugo Jiten Japanese dictionary are used to construct a lexical network G (gloss network). Japanese WordNet version 0.9 (Bond et al., 2009) was used to construct a lexical network T (thesaurus network). The numbers of nodes in G, T, and GT are respectively 35225, 66218, and 87038. Due to a large number of polysemous words in the thesaurus, many synsets of Japanese WordNet are connected.

Two baselines are evaluated on the test datasets. Baseline 1 is SVMs trained with basic features: the target verb itself and 3 words before and after the target verb. Baseline 2 is also SVMs trained with the basic features above and the case filler features: the nouns that appear as case fillers.

The proposed methods are SVMs trained with the basic features, the case filler features, and the lexical network features: the probability $\rho_i(c)$ introduced in Section 4 for each case and each sense c when w_i appears as a case filler.

[1] http://chasen.org/~taku/software/TinySVM/

Table 1: Classification accuracy on $hard$ verbs (%)

target word	English translation	# of instances	# of senses	baselines 1	baselines 2	G	T	GT
$ataru$	hit, correspond	463	7	83.2	85.3	87.9	88.1	87.7
$dasu$	take out, cause	173	3	73.4	75.1	74.6	79.2	75.1
$deru$	go out, appear	189	3	86.2	86.8	89.4	87.8	87.8
$kiku$	listen, be effective	141	2	87.2	87.2	87.2	86.5	87.2
$susumu$	proceed, advance	931	2	81.8	83.1	84.2	83.5	84.4
average	–	379.4	3.4	82.0	83.5	84.7	84.6	84.8

Table 2: Average classification accuracy on $easy$ verbs (%)

	# of instances	# of senses	baselines 1	baselines 2	G	T	GT
average on $easy$ verbs	1216.9	3.0	94.6	94.8	95.0	95.1	95.0
total average	917.8	3.1	93.1	93.4	93.7	93.8	93.7

The classification accuracy, i.e., the number of correctly classified instances divided by the total number of instances, is employed as evaluation measure. Averages in this paper are micro averages. The methods are evaluated first for $hard$ verbs, for which the classification accuracy of the baseline method is less than 90 %. There are 5 $hard$ verbs; the other 9 verbs are $easy$ verbs, for which the classification accuracy is already equal to or better than 90 %. Note that the proposed method aims at $hard$ verbs as mentioned in Section 1, although we would like the proposed method not to degrade the classification performance for $easy$ verbs.

5.2 Results

The classification result for $hard$ verbs is shown in Table 1. Baseline 2 is better than baseline 1, meaning that the simple information on the word as a case filler improves the classification performance. The proposed methods on lexical networks G, T, and GT mostly outperformed baselines with a few exceptions. On average, the proposed method on GT increases the classification accuracy by 2.8 points compared with the baseline 1, 1.3 points compared with the baseline 2. This result shows that the information propagation on the lexical network offers useful clues for verb sense disambiguation. Table 2 shows that the proposed method is at least comparable to the baselines when it is applied to $easy$ verbs. The accuracy for each $easy$ verb was omitted from the table due to the space limitation, and only the average values are written in the table. These results also show that the difference of lexical networks does not have a significant effect on the average classification performance.

In order to gain more intuitive understanding on the method, we give an example of the computational result for case wo (accusative) of verb $dasu$. We used all of the 173 instances that are available. Nouns that have high probability $\rho_i(c)$ for $c = sense1$ (take out, let out, send, pay) are, for example, price, application, permission, demand, request, wish, command, permit, and certificate. Nouns that have high $\rho_i(c)$ for $c = sense2$ (show) are, for example, speed, advance, agility, effect, driving force, breakthrough, and activity.

6 Conclusion

We proposed a new method for word sense disambiguation for verbs. In our method, sense-dependent selectional preference of verbs was obtained through the probabilistic model on the lexical network. The mean-field approximation was employed to compute the state of the lexical network. The outcome of the computation was used as features for discriminative classifiers. The method is evaluated on the dataset of the Japanese word sense disambiguation.

Future work includes the use of words that are not on the lexical network, the incorporation of interactions between multiple cases, and theoretical study of the Potts model for lexical network.

Improving Word Sense Induction by Exploiting Semantic Relevance

Abstract

Word Sense Induction (WSI) is the task of automatically inducing the different senses of a target word from unannotated text. Traditional approaches based on the vector space model (VSM) represent each context of a target word as a vector of selected features (e.g. the words occurring in the context). These approaches assume that the words occurring in the context are independent and do not exploit semantic relevance between words. In this paper we propose a WSI method which can exploit semantic relevance between words by incorporating a word graph into the framework of clustering of context vectors. The method is evaluated on the testing data of the Chinese Word Sense Induction task of the first CIPS-SIGHAN Joint Conference on Chinese Language Processing (CLP2010). Experimental results show that our method significantly outperforms the baseline methods.

1 Introduction

It has been shown that using word senses instead of surface word forms can improve performance on many natural language processing tasks such as machine translation (Vickrey et al., 2005) and information retrieval (Uzuner et al., 1999; Véronis, 2004). Historically, using word senses usually involved the use of manually compiled resources in which word senses were represented as a fixed list of definitions. However, there seem to be some disadvantages associated with such fixed list of senses paradigm. Firstly, since dictionaries usually contain general definitions, they can not reflect the exact contents of the contexts where target words appear (Véronis, 2004). Secondly, because the "fixed list of senses" paradigm makes the fixed granularity assumption of the senses distinction, it may not be suitable in different applications (Kilgarriff, 1997; Brody and Lapata, 2009).

To overcome these limitations, some techniques like WSI have been proposed for discovering words senses automatically from unannoteted corpuses. WSI algorithms are usually based on the Distributional Hypothesis which shows that words with similar meanings appear in similar contexts (Harris, 1954). This concept can be leveraged to induce different senses of a target word by clustering the contexts where the target word appears.

Much work in WSI is based on the vector space model, in which each context of a target word is represented by a vector of selected features (e.g. the words occurring in the context). These context vectors are clustered and the resulting clusters are taken to represent the induced senses. However, when constructing context vectors, the approaches based on VSM assume that the words occurring in the contexts are independent and do not exploit semantic relevance between words. This will cause the problem that two contexts using semantically related but distinct words will show no similarity. Figure 1 shows a simple example of three context vectors taken from three contexts of the target word *bank*, which appears with one sense i.e. *sloping land*. If we assume that context words are independent, the similarity between context 1 and context 3 will be zero, which means that the senses of the target word *bank* in the two contexts are different. But, in practice, *bank* appears with one sense in the two contexts. Some methods have been proposed to use information beyond that which is found in the immediately surrounding context. For example, in (Schűtze, 1998), second order co-occurrence matrix was used to construct rich vectors of word contexts.

In this paper, we propose a WSI method which can exploit semantic relevance between words by incorporating a word graph into the framework of clustering of context vectors. Firstly, we build a graph, where each vertex corresponds to a selected word and edges between vertices are weighted based on the semantic relevance between their associated words. Then we adapt the Personalized PageRank method (Agirre and Soroa, 2009) for incorporating semantic relevance between words into context vectors. The resulting vectors are clustered and each cluster represents an induced sense of the target word. Our method bears some similarity with some graph-based methods of WSI since they all need a graph of words. But in our method the graph is used to incorporate semantic relevance between words into context vectors while in graph-based approaches of WSI it is clustered to induce different senses of a target word. We use two vector-based approaches and one graph-based approach as baselines. Our evaluation under the framework of CLP2010 Chinese Word Sense Induction task shows that our approach significantly outperforms the baseline systems.

The structure of this paper is as follows: in Section 2, we will present our approach. In Section 3, we will introduce the experimental setup and show the experimental results. We will end with a conclusion and future work in Section 4.

2 Our Approach

In this section, we introduce how to build a word graph and how to use Personalized PageRank method to incorporate semantic relevance between words into context vectors. Then we describe how to cluster the resulting context vectors to induce senses of target words.

2.1 Building A Word Graph

In this section, we aim to build a graph where each vertex corresponds to a word and edges between vertices are weighted based on the semantic relevance between their associated words. Initially, we construct a word-by-context matrix P with the entry $P_{i,j}$ giving the weight of word i in context j. In this paper, we set

$$P_{i,j} = \frac{n_{i,j}}{\sum_i n_{i,j}} \times \log \frac{N}{n(i)} \quad (1)$$

where $n_{i,j}$ is the frequency of word i occurring in the context j, and $n(i)$ is the number of the contexts containing the word i and N is the total number of contexts. Just like contexts can be seen as bags of words, words can be viewed as bags of contexts. So a row of the matrix P can be seen as the context-vector for a word. We assume that two words that have more correlated context-vectors will have a greater semantic relevance. In this case, the semantic relevance of two words is evaluated through the inner product of vectors corresponding to the two words. Support that $M=PP^T$, then $M_{i,j}$ gives the semantic relevance between word i and j. Singular Value Decomposition (SVD) is used to reduce the dimensionality of matrix M. M is evaluated by the equation (2)

$$M \approx \sum_{i=1}^{K} \lambda_i x_i x_i^T \quad (2)$$

where x_i is the eigenvector of M, and λ_i is the corresponding eigenvalue and x_i^T denotes the transpose of x_i. K is the minimum k that satisfies $\sum_{i=1}^{k} \lambda_i \geq 0.85 \times \sum_{i=1}^{D} \lambda_i$, where D is the number of eigenvectors of M. Now we have built the graph, in which each vertex corresponds to a word and the weight of edge between vertex i and j is given by $M_{i,j}$ indicating the semantic relevance between the word i and j.

2.2 Incorporating semantic relevance between words into context vectors

Personalized PageRank algorithm is adapted from PageRank algorithm (Brin and Page, 1998). In the PageRank formulation ($\Pr = cM\Pr + (1-c)v$), the element values of the vector v are all $\frac{1}{N}$, where N is the total number of vertices in the graph. But in the Personalized PageRank, the vector v can be non-uniform and assign stronger probabilities to certain kinds of vertices.

We assume that the weight of a feature (word) in the context vector depends on not only its frequency in contexts but also the words that co-

occur with it. This means, if two words *i* and *j* co-occur in a context and are semantic related, the weight of *i* (or *j*) should be strengthened by *j* (or *i*). We adapt Personalized PageRank algorithm for this process. The weight of the word i at t+1 step is defined as:

$$W(i)^{t+1} = (1-d)W(i)^0 + d\sum_{j\in In(i)} \frac{M_{j,i}}{\sum_{k\in In(j)} M_{j,k}} W(j)^t \quad (3)$$

where $M_{j,i}$ is the weight of the edge between vertices *i* and *j*, which is defined in Section 2.1. $W(j)^t$ is the weight of the word *j* at t step and $W(i)^0$ is the initial weight of the word *i* in the context. *In(i)* stands for the set of vertices that connect to *i*. *d* is the damping factor and is usually set at 0.85.

The weight of each word is initialized based on its frequency and the Personalized PageRank algorithm iterates until convergence. After the running of the Personalized PageRank algorithm, each word gets a new weight. In this way, we incorporate semantic relevance between words into context vectors.

2.3 Inducing Word Senses

The k-means algorithm is used for clustering the resulting vectors produced in Section 2.2. The similarity between two objects is computed using cosine function. The number of clusters, k, is automatically determined using PK2 criterion function (Pedersen and Kulkarni, 2006). Each resulting cluster represents a kind of sense of the target word.

3 Experiments

3.1 Experimental Setup

Our experiments are based on the CLP2010 Chinese Word Sense Induction task testing dataset which contains 100 target words (22 target words are constituted by a single character and 78 target words are constituted by two or more characters) and total 5000 instances. The number of senses on average per word is 2.5. The original testing data contains the number of target word senses. But in practice, the number of target word senses is unknown and it need to be indentified automatically. So in the experiments we discover the number of target word senses automatically using the PK2 criterion.

Each instance of a target word is processed by segmenting Chinese word and removing stopwords and target words. The remaining words are used to build the word graphs and construct the vectors of contexts.

We use two vector-based approaches and one graph-based approach as baselines. The first one is a vector-based WSI approach, which represents the contexts of a target word using second order co-occurrence vectors (Schűtze, 1998). This approach constructs a word-by-word co-occurrence matrix by identifying bigrams whose number of occurrences is greater than a pre-specified threshold. A row in the matrix is the vector for a context word. Each context is represented by the centroid of all vectors of the words which make up the context. Then these context vectors are clustered to induce senses of target words. This approach has a good performance in public evaluation (e.g. Semeval-2007 task 02) (Agirre and Soroa, 2007).

The second one is also a vector-based WSI approach which represents the contexts of a target word using bag-of-words vectors and weights each feature (word) based on its TF and IDF. The two vector-based WSI approaches use k-means algorithm to cluster the context vectors of target words and the maximum number of k-means iterations is set to 100.

The third one is a graph-based WSI approach. We build a graph according to the approach described in (Agirre et al., 2006). Chinese Whispers algorithm (Biemann, 2006) is used to cluster the graph. The maximum number of Chinese Whispers iterations is set to 100. We also include the "one cluster per word" baseline (1c1w), where all instances of a target word are grouped into a single cluster. In SemEval-2010 task 14, none of the participating systems outperform this baseline in paired F-score (Artiles et al., 2009), which indicates that this baseline is quite strong.

According to (Pedersen, 2010), we employ paired F-score as evaluation measure. Let $C=\{C_j|j=1,2,\ldots,n\}$ be a set of clusters generated by a WSI system and $S=\{G_i|i=1,2,\ldots,m\}$ be the set of gold standard classes. For each cluster C_j, we generate $\binom{|C_j|}{2}$ instance pairs, in which $|C_j|$ is the total number of instances that belong to C_j. Similarly, we generate $\binom{|G_i|}{2}$ instance pairs for each gold standard class G_i. Let *F(C)* is the set of instance pairs generated from any clusters in *C* and *F(S)* is the set of instance pairs generated from any gold standard classes in *S*. Precision and recall are defined in Equation 4 and 5 respectively.

$$P = \frac{|F(C) \cap F(S)|}{|F(C)|} \quad (4)$$

$$R = \frac{|F(C) \cap F(S)|}{|F(S)|} \quad (5)$$

Then the paired F-score is defined in Equation 6.

$$Fs = \frac{2 \times P \times R}{P + R} \quad (6)$$

3.2 Experimental Results

Table 1 shows the results of experiments with 100 target words (total 5000 instances). Just like what have been shown in (Agirre and Soroa, 2007) and (Manandhar et al., 2010), the 1c1w baseline shows the best performance. However, it only discoveries one sense for each target word, which is the most frequent sense of the target word. In contrast, WSI_SR and WSI_SOV predict 2.1 and 2.4 senses on average per word respectively, which is more close to the actual number of senses (2.5).

System	Fs(%) (All)	Fs(%) (C)	Fs(%) (W)	#Cl
WSI_SR	58.5	42.78	62.82	2.1
WSI_SOV	56.37	42.46	60.28	2.4
WSI_BOW	51.24	40.68	54.25	3.7
WSI_CW	40.99	30.68	43.72	6.7
1c1w	60.6	44.5	65.14	1

Table 1: Evaluation of WSI systems. WSI_SR stands for our method which can exploit semantic relevance between words for WSI system, WSI_SOV for the WSI system based on second-order vectors, WSI_BOW for the WSI system based on bag-of-words vectors, WSI_CW for the graph-based WSI system which employs Chinese Whispers clustering algorithm. C stands for the target words which are constituted by one character while W stands for the target words which are constituted by two or more characters.

WSI_SR achieves 0.585 paired F-score, outperforming WSI_BOW with absolute improvements of 7.26%, which indicates that exploiting semantic relevance between words can improve the performance of WSI systems.

The performance of WSI_SR is well above that of WSI_SOV. This may be due to the fact that WSI_SOV only exploits semantic relevance between words occurring in the certain contexts while WSI_SR can exploit semantic relevance between words occurring in the all contexts. For example, in Figure 1, if we use the binary weighting scheme, WSI_SOV will set the weight for word *lake* and *bridge* to 0, which indicates that WSI_SOV cannot exploit the semantic relevance between the words occurring in context #1 and the two words. In contrast, WSI_SR sets the weight for word *lake* and *bridge* to 0.08, which shows that WSI_SR can exploit the semantic relevance between the words occurring in context #1 and them.

The system WSI_CW performs the worst. The possible reason is that the graph constructed from the testing dataset is made up of lots of unconnected subgraphs, which causes that the Chinese Whispers algorithm cannot cluster words correctly and induces too many senses. Compared to WSI_CW, WSI_SR incorporates the word graph into the framework of clustering of context vectors, which makes it avoid the drawback of WSI_CW.

A Chinese word can be constituted by a single character or multiple characters, which is different from English. Usually, the Chinese word containing only one character has more senses (e.g. Chinese word, "打" (beat), has twenty one senses in the testing dataset), which makes it more difficult to induce the senses of such words. In Table 1, we report the performance of systems on Chinese characters and Chinese words containing two or more characters. WSI_SR performs better than three baseline systems on Chinese words but has a similar performance with WSI_SOV on Chinese characters, which indicates that other information (e.g. syntactic information) should be exploited to improve the performance on Chinese characters.

4 Conclusions

In this paper, we present a WSI method, which can exploit semantic relevance between words by incorporating a word graph into the framework of clustering of context vectors. We build a word graph and use it to incorporate semantic relevance between words into context vectors. The resulting vectors are clustered to induce the senses of target words. Experimental results on the testing data of CLP2010 Chinese Word Sense Induction task demonstrate the effectiveness of our method.

Further work focuses on exploiting different kinds of information such as topic information and syntactic information to improve the performance of our method, especially for Chinese characters.

Predicting Word Clipping with Latent Semantic Analysis

Julian Brooke **Tong Wang** **Graeme Hirst**
Department of Computer Science
University of Toronto
{jbrooke,tong,gh}@cs.toronto.edu

Abstract

In this paper, we compare a resource-driven approach with a task-specific classification model for a new near-synonym word choice sub-task, predicting whether a full or a clipped form of a word will be used (e.g. *doctor* or *doc*) in a given context. Our results indicate that the resource-driven approach, the use of a formality lexicon, can provide competitive performance, with the parameters of the task-specific model mirroring the parameters under which the lexicon was built.

1 Introduction

Lexical resources, though the focus of much work in computational linguistics, often compare poorly to direct statistical methods when applied to problems such as sentiment classification (Kennedy and Inkpen, 2006). Nevertheless, such resources offer advantages in terms of human interpretability and portability to many different tasks (Argamon et al., 2007). In this paper, we introduce a new sub-task of near-synonym word choice (Edmonds and Hirst, 2002), prediction of word clipping, in order to provide some new evidence that resource-driven approaches have general potential.

Clipping is a type of word formation where the beginning and/or the end of a longer word is omitted (Kreidler, 1979). This phenomenon is attested in various languages; well-known examples in English include words such as *hippo* (*hippopotamus*) and *blog* (*weblog*). Clipping and related kinds of word formation have received attention in computational linguistics with respect to the task of identifying source words from abbreviated forms, which has been studied, for instance, in the biomedical and text messaging domains (Okazaki and Ananiadou, 2006; Cook and Stevenson, 2009).

Compared to many near-synonyms, clipped forms have the important property that the differences between full and abbreviated forms are almost entirely connotational or stylistic, closely tied to the formality of the discourse.[1] This fact allows us to pursue two distinct though related approaches to this task, comparing a supervised model of word choice (Wang and Hirst, 2010) with a mostly unsupervised system that leverages an automatically-built lexicon of formality (Brooke et al., 2010). Our findings indicate that the lexicon-based method is highly competitive with the supervised, task-specific method. Both models approach the human performance evidenced in an independent crowdsourced annotation.

2 Methods

2.1 Latent Semantic Analysis

Both approaches that we are investigating make use of Latent Semantic Analysis (LSA) as a dimensionality-reduction technique (Landauer and Dumais, 1997).[2] In LSA, the first step is to create a matrix representing the association between words as determined by their co-occurrence in a corpus, and then apply singular value decomposition (SVD) to identify the first k most significant dimensions of variation. After this step, each word can be represented as a vector of length k, which can be compared or combined with the vectors of other words. The best k is usually determined empirically. For a more detailed introduction to this method, see also the discussion by Turney and Littman (2003).

[1] Shortened forms might also be preferred in cases where space is at a premium, e.g. newspaper headlines or tweets.

[2] Note that neither technique is feasible using the full co-occurrence vectors, which have several hundred thousand dimensions in both cases; in addition, previous work has shown that performance drops off with increased dimensionality.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1392–1396,
Chiang Mai, Thailand, November 8 – 13, 2011.

2.2 Classifying Context Vectors

Our first method is the lexical choice model proposed by Wang and Hirst (2010). This approach performs SVD on a term–term co-occurrence matrix, which has been shown to outperform traditional LSA models that use term–document co-occurrence information. Specifically, a given word w is initially represented by a vector v of all its co-occurring words in a small collocation context (a 5-word window), i.e., $v = (v_1, \ldots, v_n)$, where n is the size of the vocabulary, and $v_i = 1$ if w co-occurs with the i-th word in lexicon, or $v_i = 0$ otherwise. The dimensionality of the original vector is then reduced by SVD.

A context, typically comprising a set of words within a small collocation context around the target word for prediction (though we test larger contexts here), is represented by a weighted centroid of the word vectors. Together with the candidate words for prediction, this context vector can then be used as a feature vector for supervised learning; we follow Wang and Hirst in using support vector machines (SVMs) as implemented in WEKA (Witten and Frank, 2005), training a separate classifier for each full/clipped word form pair. The prediction performance varies by k, which can be tested efficiently by simply truncating a single high-k vector to smaller dimensions. The optimal k value reported by Wang and Hirst testing on a standard set of seven near-synonyms was 415; they achieved an accuracy of 74.5%, an improvement over previous statistical approaches, e.g. Inkpen (2007).

2.3 Using Formality Lexicons

The competing method involves building lexicons of formality, using our method from Brooke et al. (2010), which is itself an adaption of an approach used for sentiment lexicon building (Turney and Littman, 2003). Though it relies on LSA, there are several key differences as compared to the context vector approach. First, the pre-LSA matrix is a binary word–document matrix, rather than word–word. For the LSA step, we showed that a very low k value (20) was appropriate choice for identifying variation in formality. After dimensionality reduction, each word vector is compared, using cosine similarity, to words from two sets of seed terms, each representing prototypical formal and informal words, which provides a formality score for each word in the range of -1 to 1. The derivation of the final formality score involves several normalization steps, and therefore a full discussion is precluded here for space reasons; for the details, please see Brooke et al. (2010). Our evaluation suggests that, given a large-enough blog corpus, this method almost perfectly distinguishes words of extreme formality, and is able to identify the more formal of two near-synonyms over 80% of the time, better than a word-length baseline.

Given a lexicon of formality scores, the preferred form for a context is identified by averaging the formality scores of the words in the context and comparing the average score to a cutoff value. Here, the context is generally understood to be the entire text, though we also test smaller contexts. We take the cutoff to be midpoints of the average scores for the contexts of known instances; although technically supervised, we have found that in practice just a few instances is enough to find a stable, high-performing cutoff. Note that the cutoff is analogous to the decision hyperplane of an SVM. In our case, building a lexical resource corresponds to additional task-independent reduction in the dimensionality of the space, greatly simplifying the decision.

3 Resources

Blog data is an ideal resource for this task, since it clearly contains a wide variety of language registers. For our exploration here, we used a collection of over 900,000 blogs (216 million tokens) originally crawled from the web in May 2008. We segmented the texts, filtered out short documents (less than 100 words), and then split the corpus into two halves, training and testing. For each of the two methods described in the previous section, we derived the corresponding LSA-reduced vectors for all lower-case words using the collocation information contained within the training portion.[3] The testing portion was used only as a source for test contexts.

We independently collected a set of common full/clipped word pairs from web resources such as Wikipedia, limiting ourselves to phonologically-realized clippings. This excludes orthographic shortenings like *thx* or *ppl* which cannot be pro-

[3] We used the same dataset for each method so that the difference in raw co-occurence information available to each method was not a confounding factor. However, we also tested the lexicon method using the full formality lexicon from Brooke et al. (2010), built on the larger ICWSM blog corpus; the difference in performance was negligible.

nounced. We also removed pairs where one of the words was quite rare (fewer than 150 tokens in the entire corpus) or where, based on examples pulled from the corpus, there was a common confounding homonym–for instance the word *prob*, which is a common clipped form of both *problem* and *probably*. However, we did keep words like *doc*, where the *doctor* sense was much more common than the *document* sense. After this filtering, 38 full/clipped word pairs remained in our set. For each pair, we automatically extracted a sample of usage contexts from texts in the corpus where only one of the two forms appears. For each word form in each of our training and testing corpora, we manually removed duplicate and near-duplicate contexts, non-English and unintelligible contexts, and any remaining instances of homonymy until we had 50 acceptable usage examples for each word form in each sub-corpus (100 for each of the word pairs), a total of 3800 contexts for each of training and testing.

One gold standard is provided by the original choice of the writer, but another possible comparison is with reference to an independent human annotation, as has been done for other near-synonym word choice test sets (Inkpen, 2007). For our annotation, we used the crowdsourcing website Crowdflower (www.crowdflower.com), which is built on top of the well-known Amazon Mechanical Turk (www.mturk.com), which has been used, for instance, to create emotion lexicons (Mohammad and Turney, 2010). In general terms, these crowdsourcing platforms provide access to a pool of online workers who do small tasks (HITs) for a few cents each. Crowdflower, in particular, offers a worker-filtering feature where gold standard HITs (75 clear instances taken from the training data) are interspersed within the test HITs, and workers are removed from the task if they fail to answer a certain percentage correct (90%). For each word form, we randomly selected 20 of 50 test contexts to be judged, or 1520 altogether. For each case, the workers were presented with the word pair and three sentences of context (additional context was provided if less than 40 tokens), and asked to guess which word the writer used. To get more information and allow participants to express a tentative opinion, we gave the workers five options for a word pair A/B: "Probably A/B", "Definitely A/B", and "I'm not sure"; for our purposes here, however, we will not distinguish between "Probably" and "Definitely". We queried for five different judgments per test case in our test corpus, and took the majority judgment as the standard, or "I'm not sure" if there was no majority judgment.

4 Evaluation

First, we compare our crowdsourced annotation to our writer's choice gold standard, which provides a useful baseline for the difficulty of the task. The agreement is surprisingly low; even if "I'm not sure" responses are discounted, agreement with the writer's choice gold standard is just 71.7% for the remaining datapoints. For certain words (such as *professor*, *doctor*), workers avoided the non-standard clipped forms almost entirely, though there were other pairs, like *photo/photograph*, where the clipped form dominated. Expected frequency, rather than document context, is clearly playing a role here.

Our main evaluation consists of comparing the predictions of our two methods to the original choice of the writer, as seen in our corpus. Accuracy is calculated as the number of predictions that agree with this standard across all the (3800) contexts in our test set. We first calibrated each model using the training set, and then prompted for predictions with various amount of context.[4] The 3-sentence context includes the sentences where the word appeared, and the sentences on either side. Other options we investigated were, for the vector classification, the option of using a single classifier for all pairs, or using a different k-value for each pair, and, for the lexicon-based prediction, the option of using a single cutoff for all pairs. The best k were determined by 10-fold cross-validation on the training set. The results are given in Table 1. Since our test sets are balanced, the random guessing performance is 50%.

A chi-square test indicates the difference between the best performing result for each method is not statistically significant. We see that both methods show an improvement with the addition of context beyond the sentence where the word appears, with full document context providing the best results; the improvement with full document context is statistically significant for the vector classification model ($p < 0.001$). Overall, the two methods make similar choices, with the agreement

[4] In all cases, other appearances of the word or an inflected form in the context were removed.

Table 1: Clipping prediction results, all pairs

Vector classification	
Options	**Accuracy**
Sentence context only (k=17)	62.9
3-sentence context (k=15)	64.6
Full document (FD) (k=16)	**67.9**
FD, single (generalized) classifier	66.8
FD, best k for each pair	65.9
Formality lexicon	
Options	**Accuracy**
Sentence context only	65.2
3-sentence context	65.5
Full document (FD)	**66.7**
FD, single (generalized) cutoff	65.1

Table 2: Clipping prediction results, by pair

	Accuracy	
Clipped pair	**VC model**	**FL model**
prof/professor	68	74
tourney/tournament	64	55
plane/airplane	61	42
doc/doctor	81	78
stats/statistics	74	75
meds/medication	82	82
fridge/refrigerator	65	63
app/application	66	62
mic/microphone	54	59
fam/family	84	85

of the predictions at 78.1% for the full document models. Another result that points to the similarity of the final models is that the best single k value is very close to the best k value for lexicon building from Brooke et al. (2010) The generalized clipping models (of both kinds) do worse than the pair-specific models, but the drop is fairly modest. An even more individualized vector classification model, in the form of individual k values for each pair, does not improve performance. If we instead take the worker judgements as a gold standard, the performance of our two models on that subset of the test data is worse than with a writer-based standard: 61.1% for the best lexicon-based model, and 63.6% for the best vector classification model.

Finally, we look at individual full/clipped word pairs. Table 2 contains the results for a sample of these pairs, using the best models from Table 1. Some word pairs (e.g. *mic/microphone*) were very difficult for the models, while others can usually be distinguished. The main difference between the two models is that there are certain pairs (e.g. *plane/airplane*) where the vector classification works much better, perhaps indicating that formality is not the most relevant kind of variation for these pairs.

5 Discussion

Our initial hypothesis was that the formality of the discourse plays a key role in determining whether a clipped form of a word will be used in place of a full form, and thus a lexicon of formality could be a useful tool for this kind of word choice. Our results mostly bear this out: although the vector classification model has a slight advantage, the lexicon-based method, which has the advantage of compactness, interpretability, and portability, does reasonably well. Tellingly, the best vector-based model is very similar to the lexicon in terms of its parameters, including a preference for the use of the entire document as context window and low LSA k, rather than the local context and high LSA k that was preferred for a previous near-synonym choice task (Wang and Hirst, 2010). In comparison to that task, clipping prediction is clearly more difficult, a fact that is confirmed by the results of our crowdsourced annotation.

The fact that the models do better on certain individual word pairs and more poorly on others indicates that the degree of formality difference between clipped and full forms is probably quite variable, and in some cases may be barely noticeable. Under those circumstances, the advantages of a vector classification model, which might base the classification on other kinds of relevant context (e.g. topic), are clear. We conclude by noting that for a highly specialized problem such as word clipping prediction, a single lexical resource can, it appears, complete with a task-based supervised approach, but even here we see signs that a single resource might be insufficient to cover all cases. For wider, more complex tasks, any particular resource may address only a limited part of the task space, and therefore a good deal of work may be required before a lexicon-based method can reasonably compete with a more straightforward statistical approach.

Abstract

We describe a new semantic relatedness measure combining the Wikipedia-based Explicit Semantic Analysis measure, the WordNet path measure and the mixed collocation index. Our measure achieves the currently highest results on the WS-353 test: a Spearman ρ coefficient of 0.79 (vs. 0.75 in (Gabrilovich and Markovitch, 2007)) when applying the measure directly, and a value of 0.87 (vs. 0.78 in (Agirre et al., 2009)) when using the prediction of a polynomial SVM classifier trained on our measure.

In the appendix we discuss the adaptation of ESA to 2011 Wikipedia data, as well as various unsuccessful attempts to enhance ESA by filtering at word, sentence, and section level.

1 Introduction

1.1 Semantic Relatedness and Corpora

Semantic relatedness describes the degree to which concepts are associated via any kind of semantic relationship (Scriver, 2006). Its evaluation is a fundamental NLP problem, with applications in word-sense disambiguation, text classification, information retrieval, automatic summarization and many other fields. In recent decades, a great variety of relatedness measures have been defined, based on corpora such as Wikipedia, Wiktionary, WordNet, etc.

Wikipedia is one of the most successful collaborative projects of all time. By a constantly growing number of additions, corrections and verifications, its contents grows in both quantity and quality, and is considered by many linguists as the corpus they had always dreamed of (Medelyan et al., 2008).

By measuring the normalized tfidf values of words in a page, we can consider the page to be a weighted vector in the space of words. Inverting the matrix of these vectors we obtain weighted vectors of words in the space of pages. As every page deals with a single topic, we consider these vectors as being concept vectors. The ESA (Explicit Semantic Analysis) measure between two words is obtained by taking the cosine of their concept vectors (Gabrilovich and Markovitch, 2007).

Unlike Wikipedia, WordNet (Miller, 1995), a semi-formal lexical ontology (Huang et al., 2010), has a fine and carefully-crafted ontological structure: word senses are represented by sets of synonyms ("synsets"), and there is a graph structure on synsets based on hypernymic relations. Several WordNet-based semantic relatedness measures have been defined, based on distances in the hypernymic graph, and often combined with word distribution in sense-tagged corpora.

1.2 Evaluation of Results, WS-353 Test

(Finkelstein et al., 2001) introduce WS-353, a semantic relatedness test set consisting of 353 word pairs[1] and a gold standard defined as the mean value of evaluations by up to 17 human judges. Although this test suite contains some quite controversial word pairs,[2] it has been widely used in literature and has become the de facto standard for semantic relatedness measure evaluation.

Technically, the final result of the test is the Spearman ρ rank correlation coefficient (Spearman, 1904) between the relatedness ranking of pairs by human judges and that by the tested algorithm. So, in fact, it is not the value obtained for each pair that counts, but only the ranks.

1.3 Our Approach

By closely examining word pairs that failed to be ranked correctly by ESA, we came to the conclusion that the WS-353 word pairs belong (non-exclusively) to four classes, corresponding to different kinds of semantic relatedness and requiring different kinds of knowledge:

1. *encyclopedic*: see Section 2;
2. *ontological*: see Section 3;
3. *collocational*: see Section 4;
4. *pragmatic*: see Section 6.

In this paper, we define a new semantic relatedness measure by combining knowledge related to these four classes.

[1] Actually 352 pairs, since "money / cash" appears twice.

[2] For example: "Arafat / terror" (0.765), "Arafat / peace" (0.673), "Jerusalem / Israel" (0.846), "Jerusalem / Palestinian" (0.765), etc.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1397–1402,
Chiang Mai, Thailand, November 8 – 13, 2011.

2 Encyclopedic Knowledge

This class contains pairs that are best sorted by ESA. We note that (Agirre et al., 2009) qualify ESA as a distributional approach. Indeed, technically two words are semantically related in ESA if they appear together frequently in Wikipedia pages. But since pages are descriptions of topics (= concepts), words are ESA-close when they appear frequently in common concept descriptions, and therefore in common semantic domains. Hence, ESA is semantically richer than a merely distributional approach.

ESA is the first and most important component of our combined relatedness measure. By adapting our implementation of the ESA algorithm to 2011 Wikipedia data (see App. A), we obtain a Spearman $\rho = 0.7394$. In the following sections we describe the components added to ESA in order to optimize its performance even further.

3 Ontological knowledge

To get a better insight into the shortcomings of ESA on WS-353, we calculate Spearman ρ for the WS-353 set minus a single pair, for every pair. In Fig. 1 one can see the top 40 "most problematic" pairs: those whose removal increases ρ the most. By taking a closer look at them we can get hints for further improvements of the measure.

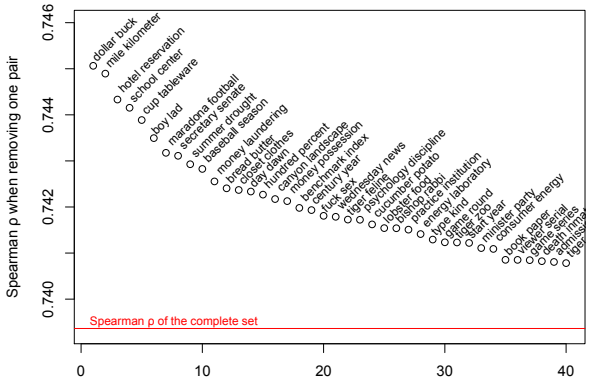

Figure 1: Spearman ρ when removing a single pair from WS-353.

First of all, we see pairs having a relation that is ontological in nature: "tiger / feline" (hyponym), "mile / kilometer" (coordinate terms, or "classmates" (Kuroda et al., 2010b)), "dollar / buck" (synonyms), etc. These relations are strong enough to justify the presence of the pairs in the test set, but do not necessarily imply high frequency of terms in common Wikipedia pages.

A good place for information of an ontological nature is WordNet. There have been several WordNet-based measures defined in the literature. When applying them[3] to the WS-353 test set we get the following ρ:

WNP (Path-based)	0.2873
WUP (Wu and Palmer, 1994)	0.1356
RES (Resnik, 1995)	0.2112
JCN (Jiang and Conrath, 1997)	**0.3172**
LCH (Leacock and Chodorow, 1998)	0.1437
HSO (Hirst and St-Onge, 1998)	0.1598
LIN (Lin, 1998)	0.1987
LESK (Banerjee and Pedersen, 2002)	0.1304

Despite the fact that JCN (which combines WordNet-graph calculations and word frequencies from a corpus[4]) rates best when used alone, the measure which we are going to use is WNP, which gives the best results when combined with ESA (see below). This measure is based exclusively on the shortest-path distance in WordNet and hence is purely ontological. For example, the WNP-measure of "wood / forest" is 1 (synonyms), "bird / cock" is 0.5 (hypernym), "century / year" is 0.33, "bishop / rabbi" is 0.25, etc.

We found that this measure provides bad results in its lower range (since the path length between distant nodes strongly depends on the density of WordNet for each knowledge domain). To understand the behavior of ESA and WNP measures in their low ranges, we progressively remove pairs from WS-353 *in order of increasing relatedness*.

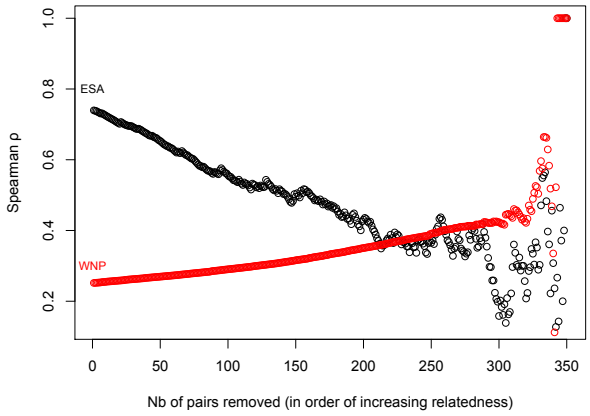

Figure 2: The effect on Spearman ρ of the progressive removal of pairs in order of increasing relatedness, for ESA and WNP measures.

As we can see in Fig. 2, removing pairs in the small-value range of the measure *strongly decreases* ESA (which, after half of the pairs are removed, becomes chaotic), while the same operation steadily *increases* WNP. In other words, small-value pairs are crucial positive contributors for ESA, but rather negative contributors for WNP. For this reason, we use only the upper range of WNP, and ignore its results for low-valued pairs. To achieve a smooth "fade-out" of WNP's lower range we multiply it by a sigmoid logistic function. We

[3] In fact, these measures apply to synsets rather than to words. To avoid going through a sense-disambiguation process, we take the optimistic approach of using for each pair of words, the pair of senses which are the most closely related. Hence, if $\hat{\mu}$ is a synset-measure, s, s' are synsets and w, w' words, we define the induced word-measure μ as $\mu(w, w') := \max_{s \ni w, s' \ni w'} \hat{\mu}(s, s')$.

[4] For the distributional part of Jiang & Conrath, Resnik and Lin, we use the Wikipedia 2011 corpus.

hence define a new measure

$$\mu_{\mathrm{EW}}(w_1, w_2) = \mu_{\mathrm{ESA}}(w_1, w_2) \cdot (1 + \lambda \sigma_{m,s}(\mu_{\mathrm{WNP}}(w_1, w_2))), \quad (1)$$

where λ weights WNP with respect to ESA, m is the sigmoid inflection point (= a soft boundary of WNP's lower range), s is the steepness of the sigmoid (small s makes the central part of the sigmoid closer to a vertical line), and "EW" stands for "ESA and WordNet."

Calculations give the following optimal result:

$\lambda = 4.665, m = 0.26, s = 0.05$	$\rho =$ **0.7779**

which surpasses the (Gabrilovich and Markovitch, 2007) ESA result of 0.75 by 5.2%. The parameter values have been obtained by gradient descent. In the next section we will further enhance this result by taking collocations into account.

4 Collocational Knowledge

Returning to Fig. 1, we see that many "problematic" pairs are in fact collocations: "baseball / season," "money / laundering", "hundred / percent," etc. We claim that the collocational nature of these word pairs has motivated their inclusion in WS-353. To show this, we calculated the collocation index (defined as $\frac{2\#(w_1w_2)}{\#(w_1)+\#(w_2)}$) of all WS-353 pairs[5].

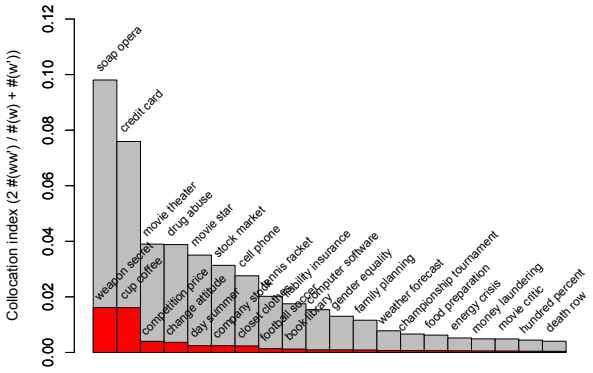

Figure 3: Top twenty direct (in gray) and inverse (in red) collocation indices for WS-353.

The primary goal of WS-353 is to evaluate relatedness measures, and these are symmetric by definition (we always have $\mu(w_1, w_2) = \mu(w_2, w_1)$). If the word pairs were chosen on strictly semantic criteria, and if collocations were purely accidental, then we would have a roughly equal number of pairs (w_1, w_2) where w_1w_2 is a collocation and pairs where w_2w_1 is a collocation.

Fig. 3 shows that this is not the case: for the word pairs concerned, WS-353 developers have almost systematically chosen to write the words in the order in which they form a collocation.

[5]We obtained WS-353 pair and word frequencies from the 53.45 billion-word GoogleBooks corpus (Michel et al., 2011). We considered only books published after 1970.

But neither ESA nor WNP recognize collocations: the former because of the bag-of-words principle underlying tfidf, and the latter only in the case where the collocational pair is a concept on its own. Indeed, most of the collocations in Fig. 3 are WordNet concepts (the exceptions being: "gender / equality," "food / preparation," "secret / weapon," "energy / crisis," etc.) but knowledge of that fact is not sufficient for ranking, since there is no mention in WordNet of the strength of the collocational relation.

We use the collocation index to further enhance our EW relatedness measure.

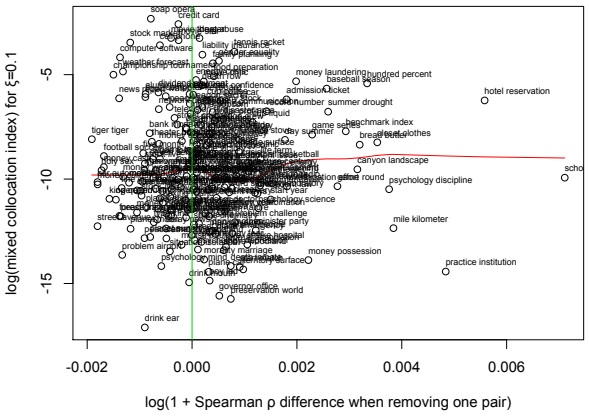

Figure 4: Collocation index vs. Spearman stability of EW. The red line is LOWESS polynomial regression (Cleveland, 1981).

Note that this index is *not* a measure (for example, the collocation index of "tiger / tiger" is not 1) and cannot be used directly as such.

How do collocational pairs contribute to the WS-353 Spearman ρ value? In Fig. 4 one can compare collocation index and Spearman stability (that is, the effect on ρ of the removal of a single word pair). Pairs located on the green vertical line are those whose removal does not affect Spearman ρ. Those on the right increase ρ when removed. We observe that most collocations are on the right; in other words, they are negative contributors. The most problematic ones are collocations which are not individual WordNet concepts (typical examples: "school / center," "hotel / reservation," "canyon / landscape," etc.).

On the other hand, on the left side we find collocations that contribute positively to ρ: in many cases these have a strong ontological relation ("tiger / tiger," "street / avenue," "football / soccer," etc.) which is probably the main reason for their positive contribution. The LOWESS polynomial regression line is quasi-horizontal, so we cannot infer whether or not collocation index is correlated with ρ.

An auxiliary question is whether collocation index values (at least in the high range) are correlated with the actual values of the WS-353 gold standard. Fig. 5 compares these two quantities. As we can see, LOWESS polynomial regression is almost steadily monotonically

increasing, which shows that, although not a measure per se, (high-range) collocation index could be useful for relatedness measurement.

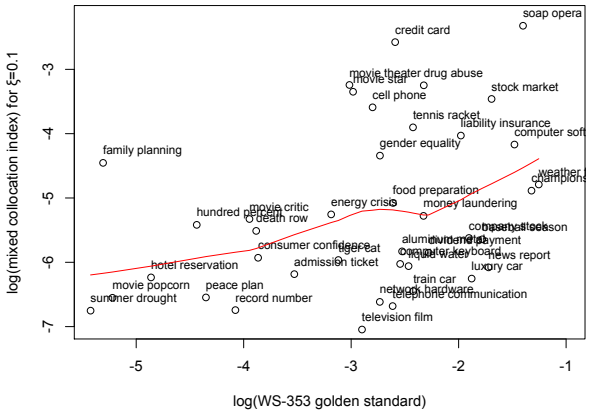

Figure 5: Collocation index vs. WS-353 gold standard. The red line is LOWESS polynomial regression.

We combine the previously defined EW measure with collocation index, by defining measure EWC (= "ESA + WordNet + collocations") as follows:

$$\begin{aligned}\mu_{\mathrm{EWC}}(w_1, w_2) = \mu_{\mathrm{ESA}}(w_1, w_2) \\ \cdot (1 + \lambda\sigma_{m,s}(\mu_{\mathrm{WNP}}(w_1, w_2))) \\ \cdot (1 + \lambda'\sigma_{m',s'}(C_\xi(w_1, w_2))),\end{aligned}$$

where λ, m, s are as in (1), λ', m' and s' are similar, and the *mixed collocation index* C_ξ is defined as follows:

$$C_\xi(w_1, w_2) = \frac{2\#(w_1 w_2)}{\#(w_1) + \#(w_2)} + \xi\frac{2\#(w_2 w_1)}{\#(w_1) + \#(w_2)}$$

where $\#(.)$ is the frequency in the corpus.

Calculations give the following optimal result:

$\lambda = 5.16, \mu = 0.25, \lambda' = 48.7,$ $\mu' = 0.19, s = s' = 0.05, \xi = 0.55$	$\rho =$ **0.7874**

which is 1.2% higher than EW and, to the best of our knowledge, currently the highest result for WS-353 by a direct measure (not using a support vector machine). The parameter values have been obtained by gradient descent.

We can interpret this result as follows: *the EWC measure works best when the lower fourth of WordNet measure and the lower fifth of collocation index values are ignored, and when inverse collocations count half as much as direct ones.*

5 Supervised Approach Using an SVM

(Agirre et al., 2009, p. 25) train an SVM on pairs of WS-353 pairs; this allows them to get an insight on performance increase obtained by combining various measures. By combining knowledge from a Web corpus and from WordNet, they obtain a highest value of Spearman $\rho = 0.78$. We calculated predictions of (4th degree polynomial) SVMs based on our EW and EWC measures, and obtained the following results, using 10-fold cross-validation:

Measure	Result
EW (ESA + WNP)	$\rho = 0.7996$
EWC (ESA + WNP + collocations)	$\rho =$ **0.8654**

We observe that even without collocations we already get a better value than (Agirre et al., 2009), and also that the collocation component increases this value significantly, hence validating our choice of using collocational knowledge to enhance semantic relatedness measurement.

6 Pragmatic Knowledge

This class contains pairs not captured by the previous methods. The typical example is "hotel / reservation": its ESA value is very low, there is no ontological relation, and the collocation index is quite low as well. To capture the relatedness of such a pair, we need specific knowledge domain ontologies, providing relations such as "A is part of a functional process of system B" (in this case: "a 'reservation' is part of the process of renting a room in a 'hotel' "). We leave this as an open task for future development.

7 Conclusion

By combining two pre-existing semantic relatedness measures and by adding a component based on frequency of collocations, we have obtained a new measure that surpasses the one given in (Agirre et al., 2009) by 11% (when comparing results obtained by SVMs). We conjecture that this measure can further be enhanced by using pragmatic knowledge taken, for example, from specialized domain ontologies.

Appendices

A Adapting ESA to 2011 Wikipedia

The original (and unreleased) C++ ESA implementation (Gabrilovich and Markovitch, 2007) is based on 2005 Wikipedia data (2.2 GB) and achieves a Spearman $\rho = 0.75$. A later implementation in Python and Java (Çallı, 2010), based on the same corpus, achieves $\rho = 0.74$. We implemented ESA in Perl and similarly obtained $\rho = 0.7404$ when based on 2005 data. The same algorithms applied to 2011 data (31 GB), produced a disappointing $\rho = 0.7047$. Indeed, between 2005 and 2011, Wikipedia has evolved as follows:

	2005	2011
#concepts	866,881	4,178,454
#terms/concept	96.1971	97.4243

where by "concepts" we mean Wikipedia pages in the main namespace, and by "terms," distinct stemmed words.

Following advice by Gabrilovich (personal communication), we increased the generality of concepts by filtering Wikipedia pages by two criteria: minimum number of terms, and minimum number of in- and outgoing links. The original values were: 100 terms and 5 links; by requiring a minimum of 200 terms and 14

links, we have attained the 2005 ρ value (more precisely: $\rho = \mathbf{0.7394}$). Fig. 6 displays ρ as a function of our two criteria.

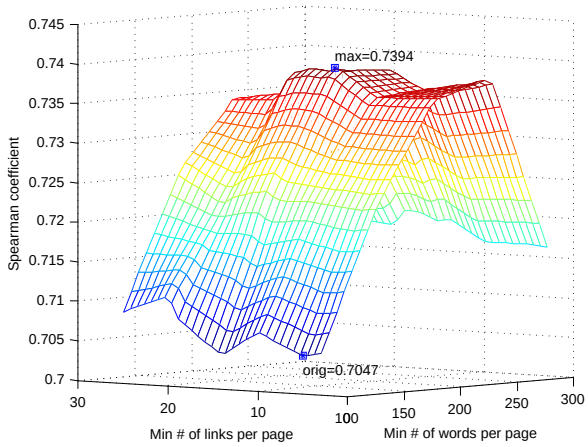

Figure 6: Adapting ESA to 2011 Wikipedia data by increasing the minimum number of distinct (stemmed) words and of in- and outgoing links per page.

In the following table, the column 2011 displays the results with original ESA setting, 2011* the ones with modified settings, $\overline{\text{df}}$ is mean document frequency of terms and term density is $\frac{\overline{\text{df}}}{\#\text{concepts}}$:

	2005	2011	2011*
#concepts	132,689	311,209	155,767
#terms/concept	165	279	414
#terms	187,971	503,368	408,299
$\overline{\text{df}}$	116.3307	173.7199	159.0395
term density	0.00088	0.00056	0.00102

As we see, terms are less densely distributed in the 2011 corpus, since the increase of their mean document frequency, though important, is overruled by an even more important increase in the number of concepts. By more efficiently pruning concepts and leaving $\overline{\text{df}}$ relatively stable, we manage to increase term density anew and hence, enhance performance.

B Experiments

(Giraud-Carrier and Dunham, 2010) emphasize the importance of sharing negative results. Responding to their call, here are some of our failed attempts at increasing ESA performance on the 2005 corpus. Note that the standard ESA value we challenge is $\rho = 0.7404$.

B.1 At the Word Level: Lemmatization and POS Filtering

ESA removes stop words and words with fewer than three letters before applying the Porter stemmer thrice. Instead of stemming, we lemmatized and then applied two strategies: keeping only nouns and proper names (Penn tags NN, NNP, and plurals), or also verbs and adjectives (tags starting with NN, NNP, VB, and JJ). Here are the results obtained:

Penn tags NN, NNS, NNP, NNPS	$\rho = 0.7194$
Penn tags NN*, NNP*, VB*, JJ*	$\rho = 0.7178$

The performance loss is due to lemmatization, proving once again that while Porter stemming may seem a brutal technique, it works better than anything else. Note that, surprisingly, when adding verbs and adjectives we get a (slightly) *smaller* ρ.

B.2 Filtering at the Sentence Level

We attempted to triple the weight of sentences containing either the page title, or one of the (non stop-)words of the page title, or one of the anchors pointing to the page. This operation affected 1,399,165 sentences. Here are the results obtained:

Tripling weight of selected sentences	$\rho = 0.7293$

B.3 Filtering at the Section Level

The idea is to avoid "historical sections" in pages describing current notions or objects. Historical sections are detected by a higher frequency of past-tense verbs, unless of course the whole page is of a historical nature, and hence using primarily the past tense. Let $\pi = \frac{\#\text{ past-tense verbs}}{\#\text{ verbs}}$ for each Wikipedia page. We pruned sections of $\pi \geq 0.8$ when the page had $\pi < 0.8$. We also pruned sections named "History," "External links," "References," "See also," "Further reading," and "Bibliography." This affected 111,028 sections out of 470,948. Here are the results obtained:

Pruning of "historical" and other sections	$\rho = 0.6608$

C Implementation Details

Implementation of ESA was done from scratch in Lex and Perl. To access WordNet v3, we used the Perl module `WordNet::Similarity` (Pedersen et al., 2004). SVM calculations as well as 2D figures were done in R, and the 3D figure in Matlab. For lemmatizing and POS-tagging, we used TreeTagger (Schmid, 1994). Our code is publicly available at `http://omega2.enstb.org/yannis/similarity.php`.

D Acknowledgments

We wish to thank Evgeniy Gabrilovich and Çağatay Çallı for their help in implementing ESA, and Sophia Ananiadou for her helpful advice.

Going Beyond Text: A Hybrid Image-Text Approach for Measuring Word Relatedness

Chee Wee Leong and Rada Mihalcea
Department of Computer Science and Engineering
University of North Texas
cheeweeleong@my.unt.edu, rada@cs.unt.edu

Abstract

Traditional approaches to semantic relatedness are often restricted to text-based methods, which typically disregard other multimodal knowledge sources. In this paper, we propose a novel image-based metric to estimate the relatedness of words, and demonstrate the promise of this method through comparative evaluations on three standard datasets. We also show that a hybrid image-text approach can lead to improvements in word relatedness, confirming the applicability of visual cues as a possible orthogonal information source.

1 Introduction

Measuring the semantic relatedness of words is an important task with applications in information extraction and retrieval, query reformulation, word sense disambiguation, plagiarism detection and textual entailment. Owing mainly to the nature of this task, research efforts in the past have typically centered around methodologies employing the use of knowledge-based or corpus-based textual resources, with only little (if any) work paying attention to evidence provided by other multimodal sources, such as visual cues presented by the images that are associated with a given word. While it can be shown that the human cognitive system is sensitive to visual information, and incorporating a dual linguistic-and-pictorial representation of information can actually enhance knowledge acquisition (Potter and Faulconer, 1975), the use of visual information to improve tasks in natural language processing has been largely unexplored.

In this paper, we hypothesize that the relatedness between the visual representations of a pair of words can be effectively used to gauge their similarity. We first discuss a technique widely used in computer vision termed as "bag of visual words" to show how distinctive features of an image can be harvested. We next introduce the main resource, ImageNet, used in our work to bridge the semantic gap between words and images. Finally, we show how a new relatedness metric based exclusively on visual information can be constructed for the semantic relatedness task. We evaluate this metric alongside existing corpus-based (Turney and Pantel, 2010) and knowledge-based metrics (Pedersen et al., 2004) either in a standalone or combined setting and present our findings.

2 Bag of Visual Words

Inspired by the bag-of-words approach employed in information retrieval, the "bag of visual codewords" is a similar technique used mainly for scene classification (Yang et al., 2007). Starting with an image collection, visual features are first extracted as data points from each image. By projecting data points from all the images into a common space and grouping them into a large number of clusters such that similar data points are assigned to the same cluster, we can treat each cluster as a "visual codeword" and express every image in the collection as a "bag of visual codewords." This representation enables the application of methods used in text retrieval to tasks in image processing and computer vision.

Typically, the type of visual features selected can be *global* – suitable for representing an entire image, or *local* – specific to a given region in the image, depending on task requirement. For a global representation, features are often described using a continuous feature space, such as a color histogram in three different color spaces (RGB, HSV and LAB), or textures using Gabor and Haar wavelets (Makadia et al., 2008). Likewise, local descriptors such as key points (Fei-Fei and Perona, 2005) can also adopt such a representation. Regardless of the features used, visual codeword generation involves the following three important phases.

1. Feature Detection: The image is divided into partitions of varying degrees of granularity from which features can be extracted and represented. We can employ normalized cuts to divide an image into irregular regions, or apply uniform seg-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1403–1407,
Chiang Mai, Thailand, November 8 – 13, 2011.

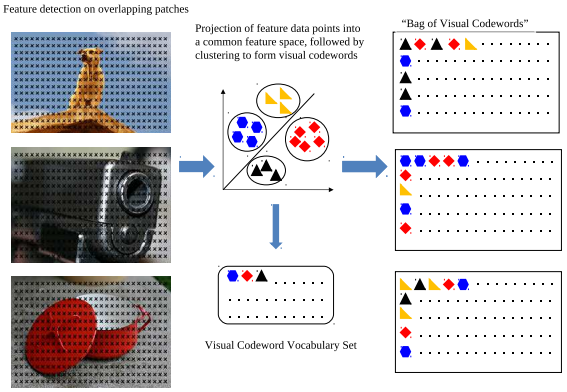

Figure 1: An illustration of the process of generating "Bag of Visual Codewords"

mentation to break it into smaller but fixed grids, or simply locate information-rich local patches on the image using interest point detectors.

2. Feature Description: A descriptor is selected to represent the features extracted from the image. Typically, feature descriptors are represented as numerical vectors, with each vector describing the feature extracted in each region. This way, an image is represented by a set of vectors from its constituent regions.

3. Visual Codeword Generation: Clustering methods are applied to group vectors into clusters, where the center of each cluster is defined as a visual codeword, and the entire set of clusters defines the visual vocabulary for that image collection. Each image region or patch abstracted in feature detection is now represented by the codeword mapped from its corresponding feature vector.

The process of visual codeword generation is illustrated in Figure 1. Fei-Fei and Perona (2005) have shown that, unlike most previous work on object or scene classification that focused on adopting global features, local regions are in fact extremely powerful cues. In our work, we use the Scale-Invariant Feature Transform (SIFT) introduced by Lowe (2004) to describe distinctive local features of an image in the feature description phase. SIFT descriptors are selected for their invariance to image scale, rotation, differences in 3D viewpoints, addition of noise, and change in illumination. They are also robust across affine distortions.

3 ImageNet

Given the maturity of techniques used to extract visual content from images, it is possible to study the synergistic relationships between semantic representations of words and images given the availability of a large lexical resource with associated relevant images. For such a resource, we turn to the ImageNet[1] database (Deng et al., 2009), which is a large-scale ontology of images developed for advancing content-based image search algorithms, and serving as a benchmarking standard for various image processing and computer vision tasks. ImageNet exploits the hierarchical structure of WordNet by attaching relevant images to each synonym set (known as "synset"), hence providing pictorial illustrations of the concept associated with the synset. On average, each synset contains 500-1000 images that are carefully audited through a stringent quality control mechanism. Compared to other image databases with keyword annotations, we believe that ImageNet is suitable for evaluating our hypothesis for two important reasons. First, by leveraging on reliable semantic annotations in WordNet (i.e., words in the synset), we can effectively circumvent the propagation of errors caused by unreliable annotations, and consequently hope to reach more conclusive results for this study. Second, unlike other image databases, ImageNet consists of millions of images, and it is a growing resource with more images added on a regular basis. This aligns with our long-term goal of extending our image-based similarity metric to cover more words in the lexicon. Figure 2 shows an example of a synset and the corresponding images in ImageNet.

Figure 2: A subset of images associated with a node in ImageNet. The WordNet synset illustrated here is {*Dog, domestic dog, Canis familiaris*}

4 Datasets

To evaluate the effectiveness of our image-based model for measuring word-to-word relatedness, we selected three datasets widely used in the past:

[1]http://image-net.org/. ImageNet currently hosts 12,184,113 images in 17624 synsets, each of which is classified under a high level category such as animal, fish, plant, structure etc

Rubenstein and Goodenough (RG65) consists of 65 word pairs ranging from synonymy pairs (e.g., car - automobile) to completely unrelated terms (e.g., noon - string). The 65 noun pairs were annotated by 51 human subjects. All the nouns pairs are non-technical words scored using a scale from 0 (not-related) to 4 (perfect synonymy).

Miller-Charles (MC30) is a subset of the Rubenstein and Goodenough dataset, consisting of 30 word pairs, whose relatedness was rated by 38 human subjects, using a scale from 0 to 4.

WordSimilarity-353 (WS353), also known as Finkelstein-353, consists of 353 word pairs annotated by 13 human experts, on a scale from 0 (unrelated) to 10 (very closely related). The dataset also includes proper names and technical terms, therefore posing an additional degree of difficulty for any relatedness metric.

5 Experiments

In our experiments, we seek answers to the following questions. First, what is the effectiveness of our image-based method in measuring word-to-word relatedness, as compared to existing text-based methods? Second, can our image-based method complement these text-based methods via a combination of their outputs ?

Note that as ImageNet is still a resource under development, not all word pairs in the datasets presented in section 4 are covered. To level the playing field, in our experiments we only select those pairs of words of which both words would appear as surface forms in the synsets of ImageNet with validated images. Moreover, due to coverage issues, an anomaly exists in situations such as $monk - slave$, where both words may appear in single-candidate synsets, i.e., {monk,monastic} and {slave ant} respectively, but are represented using fundamentally different images (person vs animal). To prevent this, we further constrain the selection of word pairs of which at least a pair of candidate synsets each representing a word in the pair belong to the same high level category. Note that both selection steps are performed automatically, and thus the identification of the word pairs that can be used in conjunction with the image-based approach can be effectively applied to any dataset, regardless of size. Our trimmed dataset consists of 10 word-pairs from the Miller-Charles dataset (**MC10**), 18 word-pairs from the Rubenstein-Goodenough dataset (**RG18**) and 56 word-pairs from the Word Similarity dataset (**WS56**).

For each word in a pair, we randomly select 50 images from the validated image pool of its associated synset[2], and extract all the visual codewords from all such images, using the technique explained in section 2. Each image is first preprocessed to have a maximum side length of 300 pixels. Next, SIFT gray-scale descriptors are obtained by densely sampling the image on 20x20 overlapping patches spaced 10 pixels apart using a publicly available image-processing toolkit.[3] K-means clustering is applied on a random subset of 10 million SIFT descriptors to derive a visual vocabulary of 1,000 codewords. Each descriptor is then quantized into a visual codeword by assigning it to the nearest cluster. As such, each image J can now be expressed as a vector $< tf_i.w_i >$, where i=1:1000 and tf_i is the frequency of occurrence of visual codeword w_i in image J. For each synset, we sum the vectors of all 50 images and normalize each w_i by its total frequency in the synset.

Image Metric: Given a word pair w_i and w_j, let $S_i = \{v_k^i\}$ and $S_j = \{v_m^j\}$ be their set of candidate visual vectors respectively. Then, computing the semantic relatedness of two words amounts to finding the maximum visual relatedness between all the possible pairings of synsets representing both words, using the cosine similarity between the visual vectors of the synsets, given below. The dimensionality of the vector, n, is set to 1000, which is the size of the visual codeword vocabulary.

$$Sim_{img}(w_i, w_j) = \max_{v_k \in S_i, v_m \in S_j} \frac{\sum_{p=1}^{n} v_k^p v_m^p}{\sqrt{\sum_{p=1}^{n}(v_k^p)^2}\sqrt{\sum_{p=1}^{n}(v_m^p)^2}}$$

Text Metric: For a comparative study, we evaluate several knowledge-based methods, including Roget and WordNet Edges (Jarmasz, 2003), H&S (Hirst and St-Onge, 1998), L&C (Leacock and Chodorow, 1998), J&C (Jiang and Conrath, 1997), LIN (Lin, 1998), RES (Resnik, 1995), and two corpus-based methods Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997) and Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007).

Combined Metric: In the combined setting, we attempt to integrate the output of our image-based metric with that of existing text-based metrics in a pairwise manner via two combination functions, which were previously noted for

[2]Note that a word may appear as surface forms across multiple synsets. In such cases, we randomly sample 50 images from each of the synsets

Table 1: Results obtained with individual knowledge-based and corpus-based text-based measures, with our image measure, and with two combination functions (SUM and F1). The bold correlation numbers represents the highest among all metrics per text-based measure per dataset.

their effectiveness in Information Retrieval systems (Fox and Shaw, 1994). Specifically, we combine the text-based and image-based metrics by summing their relatedness figures (SUM) and by calculating their F-measure (F1) defined as the harmonic mean of the two input metrics. Because the similarity scores are differently distributed across various methods, we apply a normalization step within each metric to assert the same lower and upper-bound prior to the combination: $Score_{norm} = (Score_{original} - Score_{min})/(Score_{max} - Score_{min})$.

For each dataset and metric, we obtain the Spearman rank correlation of the automatically generated similarity scores with the ground-truths by human subjects.

6 Discussion

The results in Table 1 show that our image-based method can be an effective metric on its own, scoring a competitive Spearman correlation of 0.851 on the MC10 dataset, and 0.820 on the RG18 dataset. Perhaps not surprisingly, these two datasets consists mainly of words such as car, $forest$, $bird$, $furnace$, which are *picturable*, concrete entities that possess distinctive and unambiguous visual representations. Its performance, however, degrades on the WS56 dataset with a somewhat low correlation rating of 0.404, possibly due to the presence of more broadly defined words lacking a visual identity (e.g., $equipment$ in the word pair $phone-equipment$),

Regardless of the performance of the individual image-based metric, the hybrid image-text approach improves over the standalone text-based metric in almost all cases, and this holds for both knowledge-based and corpus-based methods. These results are encouraging, as they suggest that image-based approaches can be effectively used to improve even basic tasks in natural language processing such as word relatedness.

While we are aware that the limited coverage of ImageNet restricts the applicability of this hybrid image-text method to word relatedness, the continued growth of this resource should provide alleviation. Future work will also consider a comparison of multi-way combinations between knowledge-based, corpus-based and image-based metrics for further advancement of the state-of-the-art.

7 Related Work

Recently, some attention has been given to modelling synergistic relationships between the semantics of words and images (Leong and Mihalcea, 2011; Bruni et al., 2011). The research that is most closely related to ours is the work of (Feng and Lapata, 2010), where it has been shown that it is possible to combine visual representations of word meanings into a joint bimodal representation constructed by using probabilistic generative latent topic models. Unlike our approach, however, (Feng and Lapata, 2010) relied on a news corpus where images and words in a document are assumed to be generated by a set of latent topics, rather than a lexical resource such as ImageNet. While they provided a proof-of-concept that using the visual modality leads to an improvement over their purely text-based model (an increase of Spearman correlation of 0.071 on a subset of WordSim353 dataset), no attempt has been made to evaluate the image-based models independently, or to combine image models with previously proposed knowledge-based and corpus-based measures of relatedness.

Abstract

The world of E-commerce is expanding, posing a large arena of products, their descriptions, customer and professional reviews that are pertinent to them. Most of the product attribute extraction techniques in literature work on structured descriptions using several text analysis tools. However, attributes in these descriptions are limited compared to those in customer reviews of a product, where users discuss deeper and more specific attributes. In this paper, we propose a novel supervised domain independent model for product attribute extraction from user reviews. The user generated content contains unstructured and semi-structured text where conventional language grammar dependent tools like parts-of-speech taggers, named entity recognizers, parsers do not perform at expected levels. We used Wikipedia and Web to identify product attributes from customer reviews and achieved $F_1 score$ of 0.73.

1 Introduction

The online retail market is growing immense, offering millions of products for customers. The products are generally described in terms of a few set of attributes. Such product attributes are mined from the descriptions to represent the product in a structured manner.

Often descriptions deal with generic attributes. For example, specific attributes like power consumption, pulsator, load, spin-dry effectiveness, noise, water usage, water leakage, etc for a product like washing machine cannot be correctly found in descriptions. On the other hand, customers express their opinions in the form of reviews. The opinions expressed are in terms of attributes they like and dislike but not always in terms of those attributes that are provided by the retailer for that particular product. Hence mining the attributes about which the customers discuss can be really helpful for retailers as well as for other customers.

Mining product attributes from customer reviews can lead retailers to fetch and group other products that are having similar specific attributes and forecast more precisely. Hence many retailers are trying to enrich their product knowledge bases with these domain specific and product specific attributes. Attribute extraction from reviews is also useful in tasks like review summarization, product rating, sales agent assessment, opinion mining of reviews, product recommendation systems, customer relationship management, customer satisfaction analysis, customer profiling, etc.

On the customers' side, they are prone to seek the opinions of other customers who actually used the product or bought it from a retailer website. They ask for unbiased evaluation of a product by leveraging information from multiple reviews, although each individual review can be subjective in nature. Therefore a person is more interested to read a featured review than overall reviews like "the product is really great, awesome!" or "this is the greatest product I have ever seen!!!" or simply the product rating.

Consider an unstructured customer review on the product

LG Electronics Flatron L1920P monitor:

> Excellent *picture* quality.. videoz are in *HD*.. no complaintz from me. Never had any trouble with gamez.. Paid WAAAAY to much for it at the time th0.. it sellz now fer like a third the *price* I paid.. heheh.. oh well....the fact that I didn't wait a year er so to buy a bigger *model* for half the price.. most likely from a different *store*.. ..not namin any namez th0.. *cough*BBHOSEDMe*cough*

The italicized terms are some product attributes discussed in this review. Our aim is to extract such attributes automatically. The reviews act as good sources in supplying such product specific attributes.

Mining attributes from customer reviews is a challenging task as they mostly comprise of user generated content. The text in such user generated content is low in natural language grammar, structure, formality. It often hinders the performance of natural language processing tools like parts of speech tagging, parsing and named entity recognition.

By this motivation, we have designed a novel framework that can extract attributes of a product with out making use of any natural language tools but treating the text as 'Bag Of words' and using the knowledge of Wikipedia.

2 Related Work

A good amount of research had been put into product attribute extraction in recent years. But the focus was laid in extraction of attributes from product descriptions and a little was done in extracting the same or more specific attributes from user reviews. Much of the existing work focuses on whole review classification and overall opinion extraction.

Work related to word order occurrences where product attributes are believed to exist as noun phrases was already contributed (Justeson and Katz, 1995; Daille, 1996). But it (Hu and Liu, 2006; Hu and Liu, 2004; Liu et al., 2005) was shown that using noun phrases tend to produce too many non-terms (low precision), while using reoccurring phrases misses many low frequency

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1408–1412,
Chiang Mai, Thailand, November 8 – 13, 2011.

terms, terms with variations, and terms with only one word. Their work presents the identification of product attributes with the help of Parts-Of-Speech(POS) tags and the occurrence of adjectives. But in most of the cases when free format reviews are considered, the POS taggers do not function at the expected level as grammar is not guaranteed in user generated text.

Efforts like training noun phrase recognizer model (Raju et al., 2009) to extract attributes from product descriptions worked well on structured text, but when tested did not work on unstructured text and long reviews.

The major extraction problem that has been studied extensively is the named entity extraction. We tried extracting product attributes from a set of reviews which consist of incomplete sentences and short phrases (using the technique given by (Liu et al., 2005)), but the results are not consistent. The reason we believe is that, in most of the cases product attribute terms do not have indicators (like beginning with capitalization of letters) as in the scenario of customer reviews which consequently result in named entity recognition failure.

3 Attribute extraction

For any given product, our approach to attribute extraction involves:

1. Collection of customer reviews of the given product.
2. Filter out stop words.
3. Compute features that we have defined, for the remaining words.
4. Identification of possible attribute words using classification model trained on these features.

Support vector machines (SVMs), are a set of related supervised learning methods for classification and regression analysis which are used to facilitate our model. The features on which our system has been trained are explained in the following sections.

3.1 Most Frequent Items-MFI

Words related to topics that are discussed more occur at high frequencies in any given text. In general people discuss about the attributes of a product in their reviews frequently. The 'Most Frequent Items' feature boosts the importance of attribute words by their frequency of occurrence in customer reviews.

The set of words $\{z_1, z_2, z_3, ...z_m\}$ used for this feature are obtained from customer reviews of a given product after stop word removal is done. For any word z_i the 'Most Frequent Items' feature is computed by

$$MFI(z_i) = \frac{Freq(z_i)}{\sum_{j=1}^{m} Freq(z_j)}$$

$Freq(z_i)$ gives total number of occurrences of z_i in reviews of a given product.

3.2 Context Relation using Wikipedia - CR

To understand a context or to identify a context, we need the set of keywords that portray the context. So, we assume that any context C can be expressed as $C = \{t_1, t_2, t_3, ...t_n\}$ where 't_i' are the related keywords dealt in C.

The product forms the context in customer reviews. People talk about the product and its attributes in their reviews. Its attributes and other highly related things belong to the set of keywords of the context.

The CR feature is about identifying the list of related keywords mentioned in customer reviews that can be found in Wikipedia. We start with identifying all words that have been discussed in reviews of a given product in Wikipedia and then proceed with calculating the most semantically related words among them.

When we make judgments about semantic relatedness between any two words, we draw huge amount of background knowledge about the concepts that these words represent. Hence, any trial to state the semantic relatedness between different words automatically also needs to do the same. One can use hand-crafted lexical structures like thesauri and taxonomies, or statistical analysis of large corpora to process the semantic decisions automatically (Milne, 2007). The limiting factors of such techniques when carried across domains are the background knowledge, precision, scalability and scope. With more than a 18 million articles and thousands of volunteers all over the world, Wikipedia which is a growing massive repository of knowledge, is the best alternative when targeted by such limitations.

We explore Wikipedia's link structure, category structure, article titles, and page types from the static and latest pages-articles xml dump[1] of Wikipedia. We only need Wikipedia's structure rather than it's full textual content. We have created SQL database, tables to store and access the page titles and articles fast, which has been suggested and explored already (Milne and Witten, 2009). We map a word in customer reviews to a Wikipedia article if the word is contained in that Wikipedia article title. We call such words as *Wikipedia words* and if cannot be mapped, we refer them as *Non-Wikipedia words* in later sections of this paper. A word can be mapped to all its homonyms in Wikipedia. For instance the word 'bank' can refer to 'river bank' or a 'savings bank' in Wikipedia. To disambiguate and identify the correct possible article mappings for a given word, we need to first disambiguate words which may possibly contain mappings in more than one domain. To address this, we used a method (Milne and Witten, 2009) where articles for unambiguous words are used to disambiguate the ambiguous words.

Computing semantic relatedness between two words that are mapped to Wikipedia, is equal to finding the semantic relatedness between articles in Wikipedia to which these words refer. And to do this, the best known way is to compute the relation from the links to these articles in Wikipedia (Medelyan et al., 2008; Milne, 2007).
The relation between two Wikipedia articles x and y is given by

$$Relation_{x,y} = 1 - \frac{max(log|A|, log|B|) - log|A \cap B|}{T - min(log|A|, log|B|)}$$

Here A and B are the set of articles which link to the articles x and y respectively, T is the total number of Wikipedia articles, $A \cap B$ is their overlap. Thus for every *Wikipedia word*, we find the semantic relatedness to all other such words. Context relatedness feature (CR) of a word is computed as the sum of its similarity

[1] `http://dumps.wikimedia.org/enwiki/`

scores with all other such words in the context which is then normalized by the total number of such words. Therefore for a Wikipedia words set $\{x_1, x_2, x_3, ...x_k\}$, semantic relatedness of x_i to the context is given by

$$CR_{x_i} = \frac{\sum_{\substack{j=1 \\ j \neq i}}^{K} Relation_{x_i,x_j}}{k}$$

The applicability of CR feature is justified in terms of high scalability and the ever growing knowledge of Wikipedia.

For *Non-Wikipedia words* $\{y_1, y_2, y_3, ...y_l\}$ in the product reviews, the CR feature is modified as the average of all CR feature values for $Wikipedia\ words$, from reviews of that particular product. Hence the CR value for any non-Wikipedia word y_i is uniformly given as

$$CR_{y_i} = \frac{\sum_{j=1}^{k} CR_{x_j}}{k}$$

where x_j is a Wikipedia word.

3.3 Role of surrounding window - SW

We have taken into account the surrounding text of 't' Wikipedia words to the left and right of a given Wikipedia word to examine its role in identifying an attribute. As some topics arise and eventually diminish in a small window of discussion, the situation motivates us to consider the relation with the surrounding text as a classification feature in identifying product attributes.

This feature can help in identifying sub-attributes (attributes of attributes). The sub-attributes may not seem related when overall context is considered, but they are relevant when limited contexts in which they occur are considered.

Suppose if there are p instances of Wikipedia word x_i in the reviews. The relation of x_i with the surrounding text is computed as

$$SW_{x_i} = \frac{\sum_{\substack{j=-t \\ j \neq i}}^{t} Relation_{x_i,x_j}}{(k)(N)(p)}$$

Where N is the total number of words in customer reviews of a given product. The window length t is arbitrarily taken as $\frac{N}{20}$. "-t" means t words to the left of x_i and vice-versa.

The SW feature for the non-Wikipedia words is uniformly given as average of all SW feature values of Wikipedia words from reviews.

$$SW_{y_i} = \frac{\sum_{j=1}^{k} SW_{x_j}}{k}$$

3.4 Web search engine reference-WR

As there are words that cannot be mapped to Wikipedia, we may loose a few trivial attributes in the candidate selection stage. To boost such words we use knowledge on the Web. The WR feature measures the association of a particular word from customer reviews of a product with that product on the Internet.

We have used Bing search API[2] to compute WR for a word. WR value for a word z_i is given by

$$WR_{z_i} = \frac{Res(z_i, P)}{S_N}$$

$Res(Z_i, P)$ is the number of instances where the word z_i and the product name P both occur within the text snippets given as search results by the search engine. This frequency is normalized by the total number of search results S_N that are taken into account.

4 Experiments and Evaluation

We have trained our system with the above features using SVM. We have evaluated our system against two popular datasets of reviews, the Reviews-9-products dataset (Ding et al., 2008) and the Customer Reviews dataset (Hu and Liu, 2004). These datasets have been used for the opinion mining tasks and referred by several other publications[3]. They were annotated manually in terms of product attributes. These annotations consists of trivial words, terminologies, and concepts. The datasets contain customer reviews of products from different domains of Amazon[4].

Experiments are carried out at two levels. First, crucial features are tested to know their respective performance, and then the complete combination of features is tested. To train our model we used $Reviews-9-products$ dataset and for testing $CustomerReviews$ dataset is used. Similarly we have also done testing on $Reviews-9-products$ dataset by generating the training data from $CustomerReviews$ dataset.

We have considered MFI feature as baseline for this approach. The reason is that MFI is intuitive due to the fact that people when discussing about a product mention the attributes a good number of times in their reviews.

$$Precision = \frac{No.\ of\ Attributes\ Identified\ correctly}{No.\ of\ words\ Identified\ as\ Attributes}$$

and the recall is given by

$$Recall = \frac{No.\ of\ Attributes\ Identified\ correctly}{No.\ of\ Attributes\ Actually\ Annotated}$$

4.1 Product attribute extraction using Wikipedia

When we have tested our Wikipedia based features CR, SW along with the baseline feature MFI, we encountered a low recall but a good average precision of approximately 88%. The reason behind this low recall is that trivial words and some verbs cannot be mapped to Wikipedia. For example, for the *DiaperChamp* product listed in Table 1 the annotated attributes like $bang-for-the-buck, deal, looking, filelimit, cost-effective, works, pull, assemble, costlier, clean, safer$, *etc.*, cannot be correctly linked to the articles of

Table 1: Performances of different combinations of features

Product Name	Annotated Attributes	CR,SW,MFI		CR,SW,MFI,WR	
		Candidates Selected	Attributes Identified	Candidates Selected	Attributes Identified
Diaper Champ	68	16	14	57	45
Canon G3	106	30	25	93	70
Hitachi router	82	14	11	79	66
Canon S100	99	26	23	91	73
Nokia 6600	147	48	44	112	85
MicroMP3	196	41	35	133	102
Nikon coolpix 4300	76	16	13	54	46
ipod	92	23	10	85	66
Creative Labs Nomad Jukebox Zen Xtra 40GB	186	47	43	157	122
norton	107	24	23	94	73
Linksys Router	85	24	18	79	52
Apex AD2600 Progressive-scan DVD player	115	24	19	90	79
Canon PowerShot SD500	70	13	12	63	52
Nokia 6610	111	35	31	92	74

Table 2: Overall scores

Feature combination	Recall	Precision	F-score
Baseline(MFI)	0.112	0.603	0.189
CR, SW, MFI	0.202	**0.878**	0.328
CR, SW, MFI, WR	**0.666**	0.802	**0.727**

Wikipedia. To rule out such discrepancies we can use an ontology like Wordnet. But it adds a lot of noise. The statistics of the identified attributes from both datasets are shown in Table 1 and their collective precision, recall and f-score values are given in Table 2.

4.2 Product attribute extraction using Wikipedia & Web

The web based feature WR when combined with other features increased recall of our system.

We can clearly see that the combination of all the four features which include Wikipedia based features and other frequency, web based features has performed the best in terms of f-score. The increase in recall is due to gain in knowledge using WR. The fall in precision can be explained by the boosting of insignificant words in search results.

In Table 1, the given products *Diaper Champ* and *ipod* belong to the most divergent domains. For *Diaper Champ* our model identified 45 out of 68 annotated attributes where as for *ipod*, it identified 66 out of 92 annotated attributes. Similarly for the product *Apex AD2600 Progressive-scan DVD player*, it identified 79 out of 115 attributes. This shows that the recall is approximately equal across the products which is an evidence that the model does not depend on the domain of a product.

5 Conclusion and Future Work

In this paper, we presented a domain independent approach for automatic discovery of product attributes from user reviews. Our work has highlighted the possibility of providing an incremental learning capability for an extraction system. The performance scores of our system show that it is a good design to apply Wikipedia to carve out product attributes from customer reviews. Our contribution is in leveraging information and in getting assistance from greater knowledge sources like Wikipedia and world wide web when doing tasks across domains while discarding all the help from language tools.

In this work we have trained and tested our system over products that belong to different domains but interestingly found it works uniform for all the products. In future we want to test our model extensively across domains and explore new methodologies for generic attribute extraction. We would like to extend the model for sentiment analysis on product attributes mined from reviews. Our future research work also include testing our system using other machine learning techniques (like CRF) and to consider more baselines for evaluation. As we did not make use of any natural language processing tools, this work can be extended to any other language with little changes in the preprocessing stage.

Finding Problem Solving Threads in Online Forum

Zhonghua Qu and **Yang Liu**
The University of Texas at Dallas
{qzh,yangl}@hlt.utdallas.edu

Abstract

Online forum is an important source that people use to find answers to questions. Most search engines simply retrieve "relevant" threads, but those are not necessarily good threads in terms of providing quality answers. In this paper we propose a two-step approach to classify online forum threads according to their informativeness in terms of question answering. We use statistical models to first categorize posts inside a thread. Then, a variety of features including post level information and other meta-data information are used to classify the thread. We show promising results using the online support forum data we have collected.

1 Introduction

Online forums often contain useful information, such as answers to questions. When people use search engines to search the forum for answers, the returned threads can be of very low quality in terms of providing informative answers. Some threads are either long conversations without any final conclusive answers or contain answers that do not work. This is especially the case in technical forums. There has been some work on extracting information from online forums. For example, Cong et al. (Cong et al., 2008) used labeled sequential patterns to detect question sentences in online forums. Ding et al. (Ding et al., 2008) used Conditional Random Fields to extract context of questions for answer detection. Huang et al. (Huang et al., 2007) used SVM to automatically extract and rank title-reply pairs from online discussion forums for chatbot knowledge. These previous studies provide a relatively good foundation for answer finding and extraction. In online environments like mailing list or forums, question answering is carried out in conversations. In this paper we take advantage of the structure of conversation and language cues to answer a basic yet important question: Does the thread actually solve the problem?

We will make use of the conversation within the thread to determine how users think of the answers. To classify the usefulness of a thread, we propose a two-step approach using statistical models. First we classify the posts inside a thread into different categories (e.g., problem description, solution, feedback). Different models using both content and contextual information are evaluated. Then, we develop features generated from the post categories together with forum meta-data to classify a thread's usefulness. In our collection of forum threads, we show that our proposed methods achieve good results, significantly better than the rule-based baseline.

2 Data Collection and Annotation

We created our own data collection and annotation.[1] We crawled 20,000 threads from an active online forum (Oracle database support forum – general section). As an initial study, we selected 200 threads randomly and asked two annotators to label the threads and posts in them. The two annotators are computer science students with adequate knowledge to understand the content of those posts. For thread level annotation, we asked the annotators to label the thread based on whether they think it solves the problem and to what extent. We did not give annotators detailed instructions, but rather let them read the threads and make their own judgment. Each thread is given a score from 1 to 5, 1 being least helpful and 5 being most helpful. In the 200 threads we used, 50 have a usefulness score of 1, 19 with 2, 7 with 3, 61 with 4, and 83 with a score of 5. The distribution has a U

[1] Please contact the authors for data sharing.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1413–1417,
Chiang Mai, Thailand, November 8 – 13, 2011.

shape – many threads are annotated as absolutely solved the problem (usefulness of 5), or absolutely not helpful at all (usefulness of 1). This also shows that the confidence of annotators is very high.

Another annotation we performed is for the posts inside each thread. We defined four classes for the posts based on their main purpose. The categories and brief explanation for them are shown in Table 1, along with the number of posts for each category. Note that sentences inside a post may have different purposes, however, we instructed the annotators to label it with its main purpose. The post classes are very imbalanced in the annotated corpus. The feedback classes account for only about 10% of all the posts, while the majority classes are problems and solutions.

Post category	Description	number
Problem	Ask a question or ask for answer clarification.	399
Solution	Give answers/clarifications to previous questions.	557
Good Feedback	State that the problem is solved.	78
Bad Feedback	State that the answer did not solve the problem.	18

Table 1: Annotated categories for posts inside threads.

Table 2 shows the Kappa statistics on thread and post annotation using 20 threads that we randomly selected and let both annotators label them. For the thread annotation agreement, we use binary labels – usefulness greater than 3 is considered as 1, and usefulness less than 3 is considered as 0. The Kappa scores are very reasonable, suggesting that humans do not have much trouble with this task definition.

Classes	Kappa Coefficient
Thread Usefulness	0.93
Post - Problem	0.86
Post - Solution	0.70
Post - Good Feedback	0.93

Table 2: Kappa statistics between two annotators for thread and post category annotation.

3 Approaches

For the ultimate goal of classifying how likely a thread provides a good solution (its usefulness), we propose to use a two-step approach. First we determine the categories for the posts, then we classify the threads using information from the first step along with other information.

3.1 Post Level Classification

We use the content of a post as well as its context for post classification. First we used Naive Bayes classifier with a bag-of-word model for post classification. Naive Bayes classifiers have been proved to be robust and perform well in document classification. After performing tokenization using space, we use the top 600 words from the training set as the dictionary.[2] Each post is thus represented by a feature vector of tokens that appear in the dictionary. We use binary features for these words. This has been shown to perform better than using word frequency information for many classification tasks. We use the implementation of multinomial Naive Bayes classifier provided by Weka (Hall et al., 2009).

We expect that posts in a thread, like turns in dialogs, are very dependent on the context. For example, a "problem description" post is more likely to be followed by "solution" posts than a "feedback" one. People are more likely to give "feedback" after some "answers" are provided rather after a "question" is asked. Hence we evaluate using an HMM for this post categorization task, in order to take advantage of context information. Figure 1 shows a first order HMM for this setup.

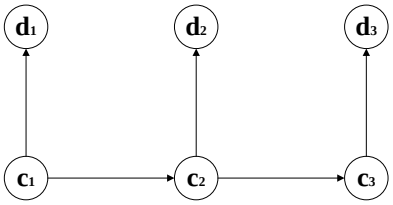

Figure 1: Illustration of HMM for post categorization. An observation d_i is a post, and c_i corresponds to its category.

The generative process is as follows. The category of current post is generated according to a multinomial distribution $P(c_i|c_{i-1})$ conditioned on its previous post category. Then, given the category of current post, words in the post are generated according to multinomial distribution $P(d_i|c_i)$ based on the post's category.

The problem can be formulated to find the most likely state sequence C (post categories) given all

[2]We varied the dictionary size, but observed performance degradation.

the words in all the posts D. The posterior probability of C given D is:

$$\begin{aligned} P(C|D) &= P(c_1, .., c_n|d_1, .., d_n) \\ &\propto P(d_1, .., d_n|c_1, .., c_n) \times P(c_1, .., c_n) \\ &= \prod_{i=1}^{n} P(d_i|c_i) \times P(c_i|c_{i-1}) \end{aligned} \quad (1)$$

The last equation is due to the first order HMM assumption where a post document is only dependent on its category (in a generative process), and a post category is only dependent on its previous category. For parameters in this HMM, the transition probabilities are estimated from the training set, similar to training a bigram language model (LM) for the post categories.

It is possible to use an n-gram language model to model the generation of text in posts given its category. However, since our data set is rather small, there is a data sparsity issue for these n-gram LMs. Hence, we only use a unigram-like model for a subset of the words (same as those in the Naive Bayes model), and each word is represented in binary form: whether or not it appeared.

In practice, when combining the state transition probabilities and emission probabilities, we use a weighting factor γ that is determined empirically. This is needed because the two scores are in different scales and contribute to the final hypothesis differently.

3.2 Thread Level Classification

The second step in our system is thread level classification, where the system determines whether a thread is useful or not. Using our annotated threads, we grouped them into binary classes: useful when the label is equal to or greater than 3; and not useful otherwise. We use a variety of features for thread level classification. Table 3 lists all the features we use for thread classification.

Since the post level classifier is optimized for the classification accuracy for that particular task, its hypotheses might not be optimal for subsequent thread classification. For example, if a post "looks" like both a "good feedback" and a "problem", we may prefer "good feedback" to "problem" since the former is more related to our final decision for the thread usefulness. To achieve this, we adjust the priors in the post classification process for different categories. We found that by increasing the prior for "good feedback" by 1.5 times, the final performance is improved – even though the classification precision decreases, the improved recall seems to be helping.

Name	Description
num_solution	The number of solution posts
feedback_p	Number of positive feedbacks
num_prob_sol	Times of back and forth between problem and solutions
author_post	Number of posts posted by author
author_postend	How far the author's last post is from the end
length	Length of a thread (measured using number of posts)

Table 3: Features used for thread level classification. 'Author' means the user who first posted the problem and started the thread.

We use a maximum entropy model for thread classification. This classifier is chosen because of its good performance in many language processing tasks, as well as our own preliminary experiments when comparing to other classifiers including decision trees and SVMs.

4 Experiments

4.1 Post Level Classification Results

We performed leave-one-out-cross-validation (using threads as the units) for post classification. Table 4 shows the results using different methods. We developed a rule-based baseline system for this task. Posts containing typical question words like "what","where" are classified as "problem" posts. Those containing cue words for positive feedbacks, like "thanks", "solved", and having length of less than 50 words are classified as "positive feedback" posts. The rest are classified as solutions.

The results shown in the table include the F_1 score for 3 individual post categories: problem (F-P), solution (F-S), and good feedback (F-F), as well as the micro averaged F_1 score. Here we ignored the classification results for "bad feedback" category since it is not very useful in later thread classification.

We can see that the basic Naive Bayes (NB) classifier can achieve reasonable performance already. It is significantly better than the baseline. This shows that lexicon features (bag-of-word model) are strong and reliable in classifying post type. We also tried using an SVM (with linear kernels) for post level classification, but its performance is worse than the Naive Bayes clas-

Method	F_{micro}	F_1-P	F_1-S	F_1-F
Baseline: rule	44.58	49.59	46.53	18.58
NB	77.57	76.81	85.52	28.57
HMM	83.17	83.21	87.75	36.04

Table 4: Post classification results using different methods. Results are the F-measures for problem, solution, and good feedback categories, and the overall performance.

sifier. After using context information through HMM, post level classification performance increased substantially. There is consistent improvement for all the categories. In particular, there is a relatively larger gain for the "feedback" class, which we expect may have a great impact on subsequent thread level classification. This performance gain using HMM demonstrates that contextual information is useful and HMM can well model such information (e.g., an 'answer' post is likely to follow a 'problem' one). We also increased HMM to higher order in order to model the transitions using more previous post categories, but found there is no additional improvement. In fact, it is slightly worse than using the first order HMM. This can be explained by either that the long distance relationship is not very crucial for this task, or more likely that we do not have a large training set to learn high order transition information reliably.

In general, we can see that the classifiers perform relatively well for the majority categories, such as problems and solutions. However, for minority classes, e.g., "feedback" (that is only 9.8% among all the posts), the classifiers are not able to learn well. We also observe that many "problem" types are classified as "solutions". This may be explained by two reasons. First, problem description posts use very similar vocabulary as solution posts. Second, there are more solution posts in the training data.

4.2 Thread Level Classification Results

For thread level classification, we use a binary setup, useful vs. not. We used leave-one-out-cross-validation for the 200 labeled threads. Inside each fold, first we use the training set to train the post level classifiers. Then we relabel all the posts in the training set as well as in the testing set with the classifier just trained to obtain the post category hypotheses. After the post level labeling, we extract features for thread classification as described in Section 3. We then train the maximum entropy classifier and test it for the final classification of threads. We use the precision, recall, and F_1 score as the evaluation metrics. Results are shown in Table 5. For a comparison, we also show the performance when using reference post labels for both training and test sets (last row). This is expected to give an upper bound performance regarding the use of post level information for thread classification.

Post Classifier	Precision	Recall	F_1
Baseline: rule	68.50	97.16	80.35
NB	78.21	86.52	82.15
HMM	79.14	91.32	84.97
Ref	84.62	93.62	88.89

Table 5: Thread level binary classification results using features extracted from output of different post level classifiers.

We can see from Table 5 that in general thread classification results depend heavily on the performance of post level classification. HMM achieves the best performance. Using reference post category shows the upper bound of how post level classification could affect thread level classification. We also evaluated using the reference post tags in training the thread classifier, and automatic tags for testing, but that did not perform as well as using automatically obtained tags for both training and testing, suggesting a matched training and testing condition is better. Overall we achieved very good performance – an F_1 score of about 85% using HMM for post categorization. This is a promising result given that we have a quite small data set for training.

5 Conclusion

In this paper, we described a two-step classification approach to determine whether a thread is helpful to users seeking solutions. We perform post level classification in the first step, then use the generated post tag information with other global features for thread level classification. We showed in the experiment that our approach worked well in a technical support online forum. For future work, we plan to use joint optimization for the two tasks. In addition, instead of using predefined categories for posts, we may derive post categories automatically from the corpus that suit better for the thread classification task.

Abstract

A learner's language data of speaking, writing, listening, and reading have been compiled for a learner corpus in this study. The language data consist of linguistic output and language processing. Linguistic output refers to data of pronunciation, sentences, listening comprehension rate, and reading comprehension rate. Language processing refers to processing time and learners' self-judgment of their difficulty of processing in speaking, listening, and reading and the fluency of their writing. This learner corpus will contribute to making the language learning process more clearly visible.

1 Introduction

Learner corpora have contributed to second language acquisition (SLA) research. For instance, SLA research using learner corpora examines learners' proficiency on the basis of what vocabularies/grammars learners actually use (Tono 2009, among others). Thus, most learner corpora are compiled of linguistic outputs that learners produce in speaking and/or writing.

In order to enhance SLA research, a learner corpus should be compiled of a learner's language data of the four modalities (speaking; listening; writing; reading). Language data of each modality are further classified into two types: linguistic output and language processing data. Language output data consist of linguistic objects that learners produce. Language processing data indicate how they produce linguistic outputs. Thus, we have eight types of language data that are useful for the SLA research on the development of learners' proficiency (Hinkel 2010, Segalowitz 2003). Among these eight types of language data, the previous studies (Granger et al. 2009, Izumi et al. 2004, Meurers et al. 2010, Wen et al. 2008) compiled the language output data of speaking, writing, and reading for constructing a learner corpus. See Section 2 for further detail. On the other hand, the other previous studies (Zechner & Bejar 2006, Arthur 1979, Hirai 1999, Kotani et al. 2010, Chang 2010) compiled the language processing data not for constructing a learner corpus but for examining learners' performance. See Section 3 for further detail. Thus, there is a shortage of language output data of listening, and furthermore we have to construct a learner corpus that integrates all these eight types of data. Hereafter, we refer to this corpus as I(ntegrated)-Learner Corpus. In order to construct I-Learner Corpus, we have compiled data of linguistic output and language processing of the four modalities when learners actually use the target language, which in this study is English.

2 Background

Written data are compiled in the International Corpus of Learner English (ICLE) (Granger et al. 2009). The written data are taken from essays written by learners of English as a foreign language (EFL). ICLE consists of learners' essays (approximately 500 words long) and learner information, but has no error tags.

Spoken data are compiled in the National Institute of Information and Communication Technology Japanese Learner English (NICT JLE) Corpus (Izumi et al. 2004). The spoken data are obtained by transcribing one-to-one interviews of EFL learners whose native language is Japanese. The NICT JLE Corpus includes error tags and reference data spoken by native speakers, but has no sound data for phonetic/phonological analyses.

Both spoken and written data are compiled in the Spoken and Written Corpus of Chinese

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1418–1422,
Chiang Mai, Thailand, November 8 – 13, 2011.

Learners (SWECCL) (Wen et al. 2008). The spoken data of SWECCL consist of both sound data and transcription data of retelling, monologues, and role plays. This corpus also includes three years' worth of longitudinal data.

Read data are compiled in the Task-based Corpus (Meurers et al. 2010). This corpus consists of written answers for text comprehension questions. Since written answers for text comprehension questions can demonstrate both learners' reading and writing proficiency, the Task-based Corpus is taken as a learner corpus that integrates written and read data.

3 Corpus design

Table 1 summarizes the design criteria of the I-Learner Corpus on attributes of learners and those of language. The criteria follow the attributes of a learner corpus (Granger 2007).

		Attributes
Age		18 years old and older
Sex		male, female
Mother tongue		Japanese
Level		beginner, intermediate, advanced
Learning context		EFL
Experience		36 months or more
Modality		spoken (S), written (W), listened (L), read (R)
Medium	**S, L, R**	news broadcast
	W	question answering, description
Genre		expository language use
Topic	**S, L, R**	general news topic/topic related to university life
	W	learning profiles, daily events
Technicality		general
Task setting		paid task, no dictionary

Table 1. Design criteria.

The target learners are EFL learners of university students whose native language is Japanese. In Japan, students study English at least three years in junior high school.

The modality of language data covers spoken, written, listened, and read data. Spoken, listened, and read data are taken from news broadcast. Written data are taken from question answering and picture description. The genre is expository contexts in daily-life language use. Though there are other contexts such as academic/professional contexts, these contexts contain more non-linguistic aspects. Thus, we chose daily-life contexts in order to minimize non-linguistic aspects such as background knowledge. Hence, the topics in news broad cast are general news topic and the ones related to university life. The topic of writing covers learners' learning profiles and daily events.

We basically use the compiling procedure stated in the previous studies reviewed in Section 2. Following the Task-based Corpus (Meurers et al. 2010), we compile read and listened data from answers to comprehension questions.

Although the comprehension-question-based procedure is suitable for compiling comprehension rate of a whole text or that of some part(s) of a text, it unfits for compiling comprehension rate at a sentence level. Of course, it is possible to compile comprehension rate at the sentence level by preparing comprehension questions for each sentence, but this is just not realistic. However, we have to compile read and listened data at the sentence level just like for spoken and written data.

Our solution of this problem is to compile language processing. It is reported that language performance can be evaluated on the basis of language processing: speaking performance (Zechner & Bejar 2006), writing performance (Arthur 1979), listening performance (Hirai 1999), and reading performance (Kotani et al. 2010, Chang 2010). An advantage of language processing is the possibility to measure at the sentence level. In addition, language processing (speaking speed) is compiled in native speaker corpora (Braun 2006, Gut 2009). Hence, we compile data of both language processing and linguistic output across the four modalities.

Language processing has two parts. One is the processing time how long a learner takes for linguistic output. The other is the judgment how difficult a learner judges processing in speaking, listening, and reading to be and how fluent a learner judges his or her writing to be. Table 2 lists the data to be stored in the I-Learner Corpus.

	Linguistic Output	**Language Processing**
Speaking	sound output	time, difficulty
Writing	sentence output	time, fluency
Listening	comprehension rate	difficulty
Reading	comprehension rate	time, difficulty

Table 2. Data specification.

Spoken data of the I-Learner Corpus consist of recordings of oral reading (linguistic output), and oral reading time and a learner's judgment of pronunciation difficulty on a five-point scale (1: Very Easy, 2: Easy, 3: Moderate, 4: Difficult, 5:

Very Difficult) (language processing). In addition to learners' data, we prepare reference sound data read by native speakers.

Written data of the I-Learner Corpus consist of sentences of question answering, sentences of picture description (linguistic output), writing time, and a learner's judgment of his or her fluency on a five-point scale (language processing).

Listened data of the I-Learner Corpus consist of comprehension rate (linguistic output) and a learner's judgment of listening difficulty (language processing).

Read data of the I-Learner Corpus consist of the comprehension rate (linguistic output), reading time, and a learner's judgment of reading difficulty on a five-point scale (language processing).

4 Data compiling

4.1 Procedures

Data compiling proceeded in the following order: listening task, reading task, speaking task, and writing task.

In the listening task, learners listened to four news articles that were read by native speakers of English sentence-by-sentence using a data collecting tool described in Section 4.4. Learners judged listening difficulty of a sentence after listening to it. When learners finished listening to an article, they answered five comprehension questions on the data collecting tool. Learners could listen to a sentence only once.

Listened data are often gathered in a situation where learners listen to sentences in an article from start to finish without a stop. However, learners in this study listened to a news article sentence-by-sentence in order to report their judgments for listening difficulty.

In the reading task, learners silently read four news articles sentence-by-sentence using the data collecting tool. Learners judged reading difficulty of a sentence after reading it. When learners finished reading an article, they answered five comprehension questions. Learners could not read a sentence again nor use a dictionary.

Read data are often taken in a situation where learners see a news article as a whole. However, learners in this study read a news article sentence-by-sentence so that processing time and their judgments of reading difficulty could be kept track of.

In the speaking task, learners read aloud four news articles sentence-by-sentence using the data collecting tool. Learners judged pronunciation difficulty of a sentence after reading it aloud. Learners had no comprehension questions in the speaking task, because the speaking task and the reading task used the same articles in order for learners to grasp the contents of the articles before reading aloud.

Spoken data are often taken from utterances in actual discourse (Izumi et al. 2004). However, we chose an oral reading task in which learners read the same sentences, because we can directly compare phonetic/phonological properties between learners.

The writing task had two sub-tasks. In the first, learners wrote answers for twenty questions on their profiles. In the second, learners wrote sentences describing four pictures of a series of events on the data collecting tool. Learners were instructed to write at least five sentences for a picture. In both tasks, learners judged the fluency of a sentence after writing it. Learners could not rewrite a sentence after moving on to another sentence nor use a dictionary.

Although written data are often taken from essays (Granger et al. 2009), we chose question answering and picture description in order to minimize the non-linguistic aspects. While essay writing depends on logical, analytical, and critical thinking, learners can answer profile questions and describe pictures without depending too much on non-linguistic skills as long as questions and pictures are simple enough.

4.2 Participants

Ninety EFL learners took part in the data compiling (48 Male, 42 Female: mean age 21.6 years old, ranging from 19–40 years old). They were university students in Tokyo, Japan. Their practical experience ranged 53 months to 216 months. The learners were paid for their participation.

The learners submitted scores of the Test of English for International Communication (TOEIC) taken within a year before the data started to be compiled. On the basis of the TOEIC scores, they were classified into three proficiency levels: beginner (N=30, TOEIC score range, 280-495), intermediate (N=30, TOEIC score range, 500-725), and advanced (N=30, TOEIC score range, 730-985) levels.

4.3 Materials

The following are questions for learner profiles in the writing task: "Which languages do you speak and read, and how well?" "What language did you learn?" (Ehrman 1996, Eignor et al.

1998). Pictures (Figure 3) described in the writing task were cited from Hughes (2003).

Figure 3. Pictures for description.

News articles used in the speaking, listening, and reading tasks were taken from Voice of America (VOA) (http://www.voanews.com). The length of articles was approximately 350 words (within plus/minus 5%). Each article had five comprehension questions that were made by the authors following question formats (Nation & Malarcher 2007).

These articles had two difficulty levels. Low-difficulty articles were taken from Special English program developed for learners of English, e.g., "Grading Grades." These articles are written in short, simple sentences that contain only one idea, and the sentences consist of a core vocabulary of 1500 words without idiomatic expressions. Low-difficulty articles were limited to the topic "studying in the U.S." High-difficulty articles were taken from VOA editorials that present differing points of view on a wide variety of issues, e.g., "Educating Marginalized Children."

4.4 Data compiling devices

The data collecting tool that learners used presents a sentence on a computer screen in the speaking and reading tasks. This tool keeps track of processing time for a sentence in the speaking, writing, and reading tasks. This tool provides comprehension questions and saves answers in the listening and reading tasks. In the writing task, this tool presents a question/a picture, and provides a blank space in which to write a sentence. The tool further keeps scores (1-5) of sentence difficulty/fluency judged by a learner in all the tasks.

In addition to this data collecting tool, the following devices were used. In the listening task, learners listened to audio files of news articles with headphones. In the speaking task, each learner reads aloud news articles in a recording booth. The recording booth is a sound-attenuated chamber (1700mm, 1900mm, 2100mm (approximately WDH)). A learner sat on a chair at a desk. The oral reading was recorded using a unidirectional electric-condenser microphone on a solid-state stereo. The sampling rate used was 44.1KHz, and quantization was set to 16 bits.

5 Application of the corpus

One application of the I-Learner Corpus is to use the corpus data as a language resource for examining learners' performances across multiple modalities, because the I-Learner Corpus includes linguistic output and language processing of the four modalities. This examination will reveal whether a learner's proficiencies in these modalities have developed equally. It will also enable us to examine how learners' proficiency develops from beginner to advanced levels, because the I-Learner corpus includes data of learners at these levels. These linguistic analyses constitute an important part of the I-Learner Corpus.

Another application is to use the corpus data as training data for a machine learning algorithm to construct an automatic evaluation method for learners' performances of the four modalities. When this automatic evaluation method and the data compiling devices are implemented in a computer-assisted language learning (CALL) system, the CALL system becomes able to compile learners' data. The CALL system can add new corpus, especially, longitudinal data if learners use the system for a certain period.

6 Conclusion

This paper described data compiling for constructing an I-Learner Corpus, a learner corpus that is compiled of data of linguistic output and of language processing of the four modalities. The I-Learner Corpus enables us to examine learners' performances in more detail and serves as a language resource for a learner model that predicts learners' performance.

A future work is to provide annotation data such as error information of pronunciation and written sentences. Another work is to enlarge corpus data by adding data of learners with different native languages.

Mining the Sentiment Expectation of Nouns Using Bootstrapping Method

Abstract

We propose an unsupervised bootstrapping method to generate a new type of affect knowledge base: the sentiment expectation of nouns (e.g., "high salary" is desirable while "high price" is usually undesirable, because people have opposite sentiment expectation towards "salary" and "price"). A bootstrapping framework is designed to retrieve patterns that might be used to express complaints from the Web. The sentiment expectation of a noun could be automatically predicted with the output patterns. We evaluate the retrieved patterns and show that our method yields good results. Also, they are applied to improve both sentence and document level sentiment analysis results.

1 Introduction

In recent years, sentiment analysis has attracted considerable attention in the NLP community due to its wide applications. The task is mining positive and negative opinions from text and an in-depth review of its literature can be found in Pang and Lee (2008). Previous work on this problem falls into three groups: opinion mining of documents, sentiment classification of sentences and polarity prediction of words. Sentiment analysis both at document and sentence level rely heavily on word level.

The most frequently explored task at the word level is to determine the sentiment orientation (SO) of words or word senses in the lexicon. While adjectives and verbs are often considered, the sentiment classification of nouns still poses a challenge. This paper aims at identifying people's sentiment expectation towards a noun, even though the noun itself does not carry polarity. We propose three categories of sentiment expectation (SE) of nouns: positive expectation nouns (Pn), negative expectation nouns (Nn) and neutral. For example, "工资|salary" is a Pn, as "high salaries" is desirable for most people. Also, the noun "价格|price" describes an object that is generally neutral, but it is a Nn, as most people in most cases expect that the product prices become lower.

There are several significances lying in this study. First, the SE of noun reflects world knowledge about an object, which is not readily available in existing semantic resources. This knowledge is useful in determining the context dependent SO of adjectives or verbs. For example, "*high* salary" is desirable while "*high* price" is undesirable. Also, "*receive* money" will probably impart positive state onto its patient while "*receive* hepatitis" will impart negative state onto its patient. Second, our method requires very little human supervision.

We introduce an unsupervised bootstrapping approach. Our system is initialized with a very small seed set of nouns, and then iterates between (a) retrieving a set of *complaint patterns* (*CPs*) - lexico-syntactic patterns such as "<n> is a little a" [1] that tend to occur only in people's complaints - from search engine snippets and (b) using the acquired patterns to determine the SE of new nouns.

The rest of this paper is organized as follows: The related work is discussed in Section 2. In Sections 3,

[1] In this paper, <n> represents a noun and a represents an adj.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1423–1427,
Chiang Mai, Thailand, November 8 – 13, 2011.

we present our bootstrapping method. In Section 4, we conduct evaluation experiments at both sentence and document level sentiment analysis. The paper is concluded in Section 5.

2 Related Work

Bootstrapping and pattern-based methods have been shown to be very effective in previous information extraction research (Riloff, 1996; Riloff and Jones, 1999; Ravichandran and Hovy, 2002; Thelen and Riloff, 2002; Riloff et al., 2003; Mooney and Bunescu, 2005; Wiebe and Mihalcea, 2006; Kozareva et al., 2008). These previous works derive patterns that reveal direct relationship between two words or the property of the word. Though similar in methodology, we focused on patterns that express an implicit relationship between the target noun and the opinion-bearing adjective.

There has been a large body of work on automatic SO prediction of words (Hatzivassiloglou and McKeown, 1997; Turney and Littman, 2003; Kim and Hovy, 2004; Esuli and Sebastiani, 2006), but unfortunately they did not consider the SE of nouns in their research and regarded most of the nouns as "neutral". Recently, some studies try to disambiguate the context dependent SO of adjectives (e.g. distinguish between "the battery life is very *long*" and "it takes a *long* time to focus") (Ding et al., 2008). They infer the context dependent SO by inferring with intra-sentence conjunction rule. Our task is more challenging as we have no global or domain information. Thus our method could be applied to isolated phrase or sentence and is domain independent. Wu and Wen (2010) present the first algorithm for retrieving SE of nouns automatically but the results critically depends on access to a high quality, carefully chosen collection of CPs.

3 Our Approach

Our main insight is to make use of CPs [2], which co-occur frequently with the target noun and the adjective that is opposite to the noun's SE. E.g. people might say "工资有点低| salary is a little low" but seldom say "工资有点高| salary is a little high". Utilizing this property, we try to (a) extract patterns like "$<\ n\ >$ is a little a" from snippets returned queries like "工资低|salary low";[3] (b) Use SVM to determine the SE of new nouns with page counts based features. E.g. "价格有点低| price is a little low" obtains 1080 hits while "价格有点高| price is a little high" obtains 19400 hits.

Input: Noun_Pool = $\{Pn, Nn\}$, A = $\{Pa, Na\}$;
Output: CP_Pool = {N CPs}; $i = 0$;
Bootstrapping
1. Candi_CP_Pool $\leftarrow$ patterns extracted from snippets. For each pattern p,
$score(p) = TScore\ (p.CPFreq, p.WPFreq)$
2. CP_Pool = the N patterns with the highest score in Candi_CP_Pool. If CP_Pool remains unchanged for two succeeding loops or if $i > K$, stop bootstrapping.
3. Candi_Noun_Pool = Extract new nouns from snippets.
4. Train SVM with CP_Pool. Training set $\leftarrow$ Noun_Pool, testing set $\leftarrow$ Candi_Noun_Pool
For each noun n, the feature vector $F_i = TScore($ $\sum_{a \in Na} Hits(p_i(n,a))$, $\sum_{a \in Pa}\ Hits(p_i(n,a)))$, $i = 1, ..., N$.
5. Add the nouns with the largest posterior probability and the smallest posterior probability to Pn and Nn respectively.
6. $i = i + 1$, Go to Step 1.

Table 1: The Whole Bootstrapping Process.

We use a bootstrapping method to automatically discover CPs and predict sentiment expectation of nouns (Table 1). In iteration phase 1, with a few seed nouns, the candidate CPs are retrieved from search engine snippets. We rank these CPs according to their ability to express SE. In iteration phase 2, we infer the sentiment expectation of a noun by mining the Web with CPs. The SVM is trained to classify positive expectation nouns and negative expectation nouns.

Initiation: The bootstrapping begins with a seed noun set Noun_Pool = $\{Pn,\ Nn\}$={{"工资|salary"}, {"价格|price"}}, and an adjective set A. A is grouped into two sets: positive-like adjectives (Pa) and negative-like adjectives (Na):

[2] Wish patterns (WP), which are usually used in people's praises and wishes, might also serve our purpose (Goldberg et. al., 2009). But using the Web as a corpus, we found that the CPs are much easier to be retrieved than WPs. Thus we will just focus on CPs in this paper and leave WPs for future work.

[3] We use Baidu as our search engine in this paper, `http://baidu.com.cn`

(1) Pa = {大|large, 多|many, 高|high, 厚|thick, 深|deep, 重|heavy}
(2) Na = {小|small, 少|few, 低|low, 薄|thin, 浅|shallow, 轻|light}

Phase 1. Extract CPs from Snippets: For each snippet returned by the query "$n\ a$" $\in Noun\_Pool$: A, extracts word n-grams after word segmentation. We select n-grams which contain exactly one <n> and one a. Counts the frequency of a pattern p appears as a CP (where $(<\ n\ >, a) \in (Pn, Na) or (Nn, Pa)$) and the frequency of p appears as a WP (where $(<\ n\ >, a) \in (Nn, Na) or (Pn, Pa)$). Finally, we adopt T-Score to measure the confidence with which we can assert whether this pattern is a CP (Step 1 in Table 1). The top ranking N patterns are selected as CPs experimentally.

Phase 2. Determine the SE of new nouns: We create a feature vector F using the harvested CPs for each noun. The two-class support vector machine (SVM) is trained to find the optimal combination of the page counts-based features (Step 4 in Table 1). We define the SE of a noun as the posterior probability (converted from SVM output with a sigmoid function (J. Platt., 2000)) that they belong to the positive expectation noun class. Then the nouns with the largest and smallest probability are added to the Noun_Pool.

4 Evaluation

4.1 Direct Evaluation

We examine the harvested CPs directly to determine whether they are actually CPs or not. Our evaluation metric is the precision of the output CPs at each bootstrapping iteration. We recruited two Chinese speakers to label them as "being CP", "not CP" or "hard to decide".

Figure 1 plots the number of correctly retrieved CPs in the output at each iteration. Clearly, we see general substantial improvement along with the bootstrapping process, although the increases level off in later iterations. As the number of the output CPs increases, there are more patterns that are labeled as "hard to decide", but some of these patterns could still serve our purpose. E.g., "因<n><a>|because <n>is <a>" and "我<n><a>|my <n>is <a>", as people often post their problems and complaints on Web. These patterns may serve as possible indicators of the presence of a noun and the reversed expectation adjective, regardless of whether they are actually restricted in negative contexts.

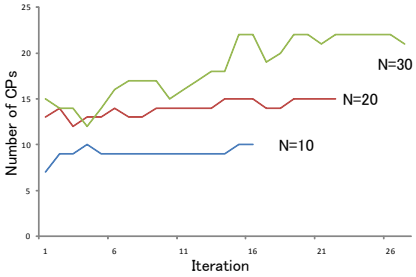

Figure 1: Number of CPs in results returned by the bootstrapping method at each iteration. N is the number of output patterns. Items labeled as "hard to decide" are not included.

The top ranked 10 CPs are of high quality. The manually chosen patterns in Wu and Wen (2010) have been successfully retrieved. This shows that our method yields good results. The 10 CPs and the nouns added in the bootstrapping process are listed below:

CPs: <n>有点a | <n> is a little a, <n>太a | <n> is too a, <n>是不是太a | isn't <n> too a, <n>实在太a | <n> is really too a, 解决<n> a | solve a <n>, <n> a怎么办| <n> is a, what should I do, 嫌<n>a | hate a <n>, 因<n> a | because <n> is a, <n>过a |<n> is too a

Pn: 空间|room, 素质|quality，水平|level，效率|efficiency，内存|PC memory，收入|income，孩子|children，时间|time

Nn: 要求|requirement, 压力|pressure，成本|cost，风险|risk，问题|problem，花费|expense，代价|cost，房价|house price，损失|lost

4.2 Sentiment Analysis at Sentence Level

We apply the SE of nouns to predict the SO of sentiment ambiguous adjectives, which is SemEval-2010 Task 18 (Wu and Jin, 2010).

Data: We use the benchmark dataset of SemEval-2010 Task 18. The task consists of 14 sentiment ambiguous adjectives (SAA) (devided to Pa and Na sets same as in Section 3), which are all high-frequency words in Mandarin Chinese. Each of the 2917 sentences in the dataset contains a target noun and a SAA.

Methods: The SO of SAA can be determined by the target noun in noun-adjective phrases. If the SAA has the same polarity as the SE of noun, then the SAA has positive sentiment; if the SAA has the op-

posite polarity to the SE of noun, the SAA has negative sentiment.

Results: Compared with the other 16 systems that participated in Task 18, our system ranks fifth and is substantially better than baseline (Table 2). Note that all the top ranked 11 systems are supervised or incorporate manually built library. Our system also outperforms Wu and Wen (2010), indicating our bootstrapping method works better than the manually selected patterns.

	Micro Acc.	**Macro Acc.**
Our Method	77.63	79.52
Wu & Wen	75.83	71.67
Baseline	61.20	62.37

Table 2: The scores on SemEval-2010 Task 18.

4.3 Sentiment Analysis at Document Level

We also investigated the impact of recognizing SE of nouns and CPs on the sentiment classification of product reviews. SAAs are frequently used in product reviews and could be sentiment disambiguated by the SE of nouns. Also, CPs usually indicate the speaker is complaining and unsatisfied with the product (i.e. negative reviews). For example, "按键设计太紧密| keyboards are designed *too* close" and "价格偏贵| It is *a little* expensive".

Data: Following the work of Wan (2008) and Wan (2009), we selected the same dataset[4]. The dataset of Wan (2008) contains 886 Chinese product reviews. The dataset of Wan (2009) contains another 1000 unlabeled Chinese product reviews. We manually annotated these product reviews with positive or negative polarity labels. We use both these two datasets as our test set, which includes 1886 reviews. In order to examine the impact of recognizing SE of nouns, we extracted the files that contain the following strings, where the nouns are modified by SAAs in most cases:

(3) noun+adjective (adjective∈SAA)
noun+adverb+adjective
noun+adverb+adverb+adjective.

We obtained 449 files (SAA-set for short), up to 24% of the overall data.

Methods: The baseline method is the same algorithm with Wan (2008). The semantic orientation value for a review is computed by summing the polarity values of all words in the review, making use of both the word polarity defined in the positive and negative lexicons and the contextual valence shifters defined in the negation and intensifier lexicons. We also use the same parameter setting and the same sentiment lexicon [5].

Our method: (a) Add the disambiguation of SO of SAAs to the algorithm. When a word ∈ SAA, compute its SO with our method in Section 4.2, rather than using its prior polarity specified in the sentiment lexicon. (b) Use the CPs as indicators of negative comments. If any CP appears in a review, then it is judged as negative SO.

Results: Our method obviously outperforms the baseline by 12.16% in f-score and 17.02% in accuracy (on SAA-set, see Table 3). The improvement in recall is especially obvious. The results also indicate using more CPs could bring further improvement.

		Base line	SE N=10	SE N=20	SE N=30
Pos.	Pre.	65.69	81.93	83.44	85.28
	Rec.	76.40	74.16	76.40	75.96
	F	70.16	79.07	79.77	80.35
Neg.	Pre.	87.43	84.35	84.53	83.77
	Rec.	60.96	88.05	89.24	90.24
	F	71.83	86.16	86.82	86.89
Total	MacroF	70.98	82.46	83.14	83.49
	Acc.	66.90	83.46	83.92	84.15

Table 3: The sentiment classification results at document level. SE denotes our method. N is the number of CPs.

5 Conclusions

This paper presents an unsupervised bootstrapping method to retrieve the sentiment expectation of nouns from the Web. We utilize the predicted SE of nouns in determining the SO of sentiment ambiguous adjectives. For the sentiment analysis at sentence level, our method achieves promising result that is significantly better than baseline and comparable to the supervised methods. For the sentiment analysis at document level, our method also achieves obvious improvement in performance, which validates the effectiveness of our approach.

An Analysis of Questions in a Q&A Site Resubmitted Based on Indications of Unclear Points of Original Questions

Masahiro Kojima and **Yasuhiko Watanabe** and **Yoshihiro Okada**
Ryukoku University, Seta, Otsu, Shiga, 520-2194, Japan
t10m101@mail.ryukoku.ac.jp, {watanabe, okada}@rins.ryukoku.ac.jp

Abstract

In this study, we analyzed how answerers indicated unclear points in questions, and how questioners modified and resubmitted their questions based on indications of unclear points.

1 Introduction

In these days, many of us use question and answer (Q&A) sites where we share our problems and get solutions of them. For example, about 3.11 million questions were submitted to Yahoo! chiebukuro [1] from April/2004 to October/2005. Because of this large numbers of questions, questioners had better submit questions which give enough information to answerers. However, it is difficult to make good questions. For example, in Yahoo! chiebukuro, we often found unclear questions (e.g. Q1 in Figure 1) and their answers where answerers indicated unclear points of the questions (e.g. A1 in Figure 1).

(Q 1) I cannot access a web page which I could read yesterday. What should I do?

(A 1) Show URL.

In (A 1), the answerer pointed out that the questioner did not describe important information to answer the question: URL. Unclear questions may decrease chances of getting good answers. As a result, it is important to investigate supporting methods of making clear questions. One idea is to indicate unclear points of questions, as the questioner of (A 1) did. In order to obtain helpful knowledge and develop a help system for making clear questions, it is important to analyze

- how answerers indicated unclear points in questions, and
- how questioners modified and resubmitted their questions based on indications of unclear points in their original questions.

[1] Yahoo Answers in Japan. http://chiebukuro.yahoo.co.jp

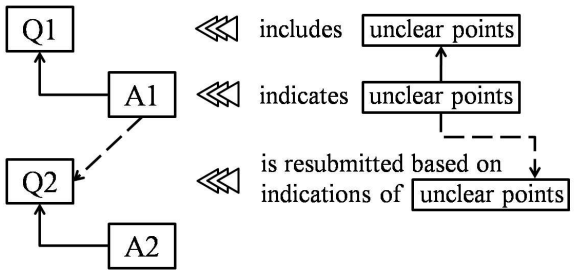

Figure 1: An example of a resubmitted question based on the indication of unclear points in the original question.

Our approach differs from previous analyses on Yahoo! Answers (Su et al., 2007) (Adamic et al., 2008). In this study, we used the data of Yahoo! chiebukuro for observation and examination. The data of Yahoo! chiebukuro was published by Yahoo! JAPAN via National Institute of Informatics in 2007 [2]. This data consists of about 3.11 million questions and 13.47 million answers which were posted on Yahoo! chiebukuro from April/2004 to October/2005.

2 Types of indication of unclear points in questions and modification of questions

2.1 Types of indication of unclear points in questions

We observed answers submitted to PC category of Yahoo! chiebukuro and found the following five types of indication of unclear points in questions (Table 1).

TYPE (A1-1) Answerers wanted detailed accounts of what questioners did.

(Q 2) I got a warning from Symantec. How do I extend the software license.

(A 2) Did you buy an extension key?

[2] http://research.nii.ac.jp/tdc/chiebukuro.html

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1428–1431,
Chiang Mai, Thailand, November 8 – 13, 2011.

Table 1: Types of indication of unclear points in questions

TYPE	indication of unclear points in questions
A1-1	detailed accounts of what questioners did
A1-2	detailed accounts of what happened
A1-3	detailed accounts of conditions
A1-4	information other than (A1-1), (A1-2), and (A1-3)
A1-5	unhelpful solution

TYPE (A1-2) Answerers wanted detailed accounts of what happened.

(Q 3) When I try to maximize my IE window, it is positioned about 2cm below from the top of the screen! What should I do?

(A 3) What's there? blank?

TYPE (A1-3) Answerers wanted detailed accounts of conditions. For example, the indication of (A 1) is classified into this type.

TYPE (A1-4) Answerers wanted detailed accounts of information which were not asked in answers of TYPE (A1-1), (A1-2), and (A1-3).

(Q 4) I don't know the connection type. What should I do?

(A 4) Which connection type do you want to know?

TYPE (A1-5) Answerers submitted solutions, however, they were not helpful to solve questioners' problems. In these cases, answerers did not indicate unclear points of questions. However, we think these unhelpful solutions are one type of indication of unclear points of questions. This is because these unhelpful solutions often made questioners aware of unclear points of their questions. For example, the answerer of (A 5) showed one solution with detailed instruction. The questioner of (Q 5) tried to solve his/her problem according to the instruction and found the solution was unhelpful.

(Q 5) Windows XP crashed. How do I boot my computer?

(A 5) Just put a recovery disc into CD/DVD drive. And restart your PC.

(Q 6) Windows XP crashed. I put a recovery disc into CD drive, but my PC didn't work. How do I boot my computer?

Table 2: Types of modification of questions based on indication of unclear points

TYPE	modification of questions
Q2-1	added explanation based on the indication
Q2-2	added explanation based on other information
Q2-3	described the solution was unhelpful
Q2-4	asked about unknowns in the indication
Q2-5	resubmitted in disregard of the indication

2.2 Types of modification of questions

We observed resubmitted questions in PC category of Yahoo! chiebukuro and found the following five types of modification of questions (Table 2).

TYPE (Q2-1) Questioners added explanations based on the indications of unclear points to their questions and resubmitted them. In this type, it is likely that answerers asked about what questioners knew or could find out easily.

(Q 7) How do I reset my iMac to default settings, except IE and Outlook settings.

(A 7) Show the versions of OS, IE, and Outlook Express.

(Q 8) How do I reset my iMac to default settings, except IE and Outlook settings. My mac OS is version 9 and both IE and Outlook are version 5.

TYPE (Q2-2) Questioners added explanations based on information other than the indications to their questions and resubmitted them. In this type, it is also likely that answerers asked about what questioners knew or could find out easily.

(Q 9) Can I boot my XP PC with Windows 98 HDD?

(A 9) Did you install 98 first? You cannot boot your PC by using Windows 98 if your primary OS is XP.

(Q 10) Can I boot my XP PC with Windows 98 HDD? I don't want to set up a dual boot system. I want to know my PC gets in trouble when I boot it with Win 98 HDD.

TYPE (Q2-3) In resubmitted questions, questioners described that solutions received from answerers were unhelpful to solve their questions. For example, in (Q 6), the questioner described the solution received from the answerer of (A 5) was unhelpful to solve his/her problem. In this type, it

is likely that answerers showed one solution which questioners did not know.

TYPE (Q2-4) In resubmitted questions, questioners asked about unknown points in the indication received from answerers. For example, the questioner of (Q 11) received one solution and got the key to solve his/her problem: module deletion. However, he/she did not know it and submitted (Q 12) for requesting detailed information about it.

(Q 11) I removed all macros from my excel file. Then, whenever I open the file, excel asks me if I want to enable/disable macros. How do I stop it?

(A 11) Open visual basic editor and delete the module.

(Q 12) I removed all macros from my excel file. Then, whenever I open the file, excel asks me if I want to enable/disable macros. I want to stop it. The module should be deleted by using visual basic editor. But, how do I do it?

TYPE (Q2-5) Questioners resubmitted almost the same questions as they had. They did not mentioned any kinds of information received from answerers. For example, in (Q 14), the questioner did not mention any kinds of information described in (A 14) although he/she selected (A 14) as a best answer.

(Q 13) My optical mouse is faulty. The cursor sometimes freezes. Is it end of life?

(A 13) Look the back side and remove dust gathered around the red light.

(Q 14) My optical mouse is faulty. The cursor sometimes freezes. Is it end of life?

3 Extraction of original and resubmitted questions and their answers from Yahoo! chiebukuro

We intended to extract

- original questions which included unclear points (e.g. Q1 in Figure 1),
- answers which indicated unclear points in the original questions (e.g. A1 in Figure 1),
- resubmitted questions based on the indications of unclear points in the original questions (e.g. Q2 in Figure 1), and
- answers to the resubmitted questions

from PC category of Yahoo! chiebukuro in the next way.

step 1 extract an answer which indicated unclear points in a question (e.g. A1 in Figure 1). This kind of answer can be extracted by using a method based on machine learning techniques (Isogai et al., 2009).

step 2 extract the question which had the answer extracted in step 1 (e.g. Q1 in Figure 1). This question is regarded as an original question.

step 3 extract the first question submitted by the questioner after he/she received the answer extracted in step 1.

step 4 examine whether the questions extracted in step 1 and step 3 met one of the following conditions:

- they shared more than 10 content words when both of them consisted of more than 20 content words, or
- they shared more than 5 content words.

When one of the conditions was satisfied, the question extracted in step 3 is regarded as a resubmitted question (e.g. Q2 in Figure 1).

step 5 extract the answers to the resubmitted question extracted in step 4 (e.g. A2 in Figure 1).

4 Experimental results

We applied our method described in section 3 to 171848 questions and 474687 answers which were submitted to PC category of Yahoo! chiebukuro from April/2004 to October/2005, and extracted 4271 cases of questions and their answers. Among them, we selected 200 cases randomly and found 133 cases of them where

- an original question (e.g. Q1 in Figure 1),
- the answer which indicated unclear points in the original questions (e.g. A1 in Figure 1),
- the resubmitted questions based on the indication of unclear points in the original questions (e.g. Q2 in Figure 1), and
- the answers to the resubmitted questions (e.g. A2 in Figure 1)

were extracted adequately. We observed these 133 cases and show

Table 3: The results of the analyses: (1) how answerers indicated unclear points in original questions (A1-1, 2, 3, 4, and 5), (2) how questioners utilized indications in answers when they resubmitted their questions (Q2-1, 2, 3, 4, and 5). The numbers in parentheses are the numbers of best answers.

(a) 122 cases where questioners obtained good answers.

	A1-1	A1-2	A1-3	A1-4	A1-5	total
Q2-1	5 (5)	15 (14)	21 (16)	4 (4)	10 (10)	55 (49)
Q2-2	0 (0)	1 (1)	1 (1)	7 (6)	6 (4)	15 (12)
Q2-3	1 (1)	0 (0)	0 (0)	0 (0)	18 (14)	19 (15)
Q2-4	1 (1)	4 (3)	0 (0)	0 (0)	12 (10)	17 (14)
Q2-5	0 (0)	4 (4)	1 (1)	1 (1)	10 (8)	16 (14)
total	7 (7)	24 (22)	23 (18)	12 (11)	56 (46)	122 (104)

(b) 11 cases where questioners did not obtain good answers.

	A1-1	A1-2	A1-3	A1-4	A1-5	total
Q2-1	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)
Q2-2	0 (0)	0 (0)	0 (0)	1 (1)	0 (0)	1 (1)
Q2-3	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)
Q2-4	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)
Q2-5	0 (0)	2 (1)	2 (1)	1 (1)	5 (4)	10 (7)
total	0 (0)	2 (1)	2 (1)	2 (2)	5 (4)	11 (8)

1. whether questioners obtained good solutions or useful clues by resubmitting their questions, especially, when they added explanations based on indications to their questions.
2. how answerers indicated unclear points in questions.
3. whether questioners gave good evaluations to answerers who indicated unclear points of their questions.
4. how questioners utilized indications of unclear points of their original questions when they resubmitted their questions.

Table 3 shows the results of these analyses.

First, we examined whether questioners obtained good solutions or useful clues by resubmitting their questions. As shown in Table 3, there were 26 cases where questioners resubmitted TYPE (Q2-5) questions (questions resubmitted in disregard of indications), and then, 16 of these 26 cases where questioners obtained good solutions or useful clues. On the other hand, there were 107 cases where questioners resubmitted TYPE (Q2-1), (Q2-2), (Q2-3), and (Q2-4) questions, in other words, they accepted indications from answerers and modified their questions. Then, there were 106 of these 107 cases where questioners obtained good solutions or useful clues. As a result, questioners can increase their chances to obtain good solutions or useful clues when they accepted indications from answerers and modified their questions.

Secondly, we examined how answerers indicated unclear points in questions. As shown in Table 3, TYPE (A1-5) answer (unhelpful solution) was the most common answer. As a result, questioners had chances to recognize unclear points in their questions even if they received unhelpful solutions.

Thirdly, we examined whether questioners gave good evaluations to answerers who indicated unclear points of their questions. As shown in Table 3, there were 112 cases (84%) where questioners gave good evaluations to answerers who indicated unclear points of their questions. On the other hand, in PC category of Yahoo! chiebukuro, 474687 answers were submitted and 171848 of them (36%) were received good evaluations. As a result, many questioners gave good evaluations to answerers who indicated unclear points of their questions.

Finally, we examined how questioners utilized indications of unclear points of their original questions when they resubmitted their questions. In this experiment, there were 107 cases where questioners resubmitted TYPE (Q2-1), (Q2-2), (Q2-3), and (Q2-4) questions, in other words, they accepted indications from answerers and modified their questions. Then, there were 17 of these 107 cases where questioners resubmitted TYPE (Q2-4) questions, in other words, they had unknown points in indications received from answerers and needed to ask about what they were. In other 90 cases, questioners resubmitted TYPE (Q2-1), (Q2-2), and (Q2-3) questions, in other words, they knew or could find out easily what answerers indicated. As a result, just to indicate unclear points in questions is useful to make good questions.

Abstract

Information need is an important factor in question retrieval. This paper proposes a method to diversify the results of question retrieval in term of types of information needs. *CogQTaxo*, a question hierarchy is leveraged to represent users' information needs cognitively from three linguistic levels. Based on a prediction model of question types, three factors, i.e., scores of IR model, question type similarity and question type novelty are linearly combined to re-rank the retrieved questions. Preliminary experimental results show that the proposed method enhances the question retrieval performance in information coverage and diversity.

1 Introduction

Most current question retrieval system attempts to fetch questions semantically similar to the query question (Jeon et al, 2005), together with the accepted answers from a large question-answer pair archive. Previous works focus on reducing the lexicon gap between the query question and retrieved questions (Cao et al, 2010) or recognize the single question type, i.e., the type of information needs(*infoNeed*s) in the query, and confine the types of retrieved questions to be the same as the query (Lytinen and Tomuro, 2002). Normally, the retrieved questions are ranked according to the semantic similarity to the query question.

However, Taylor (1962) argues that the user may fail to express his *infoNeed*s fully in the question. Besides, given different contextual situations, users may have different intentions, which lead to different *infoNeed*s for the same question (Small and Strzalkowski, 2008).

For an example question q_1, "which bank provides the best credit card?", if the user wants to confirm the bank he knows, the name of the bank is enough for an answer; while the user plans to open a credit card account, he may want to obtain detailed descriptions and comparisons between credit card services of different banks in addition to a single bank name. Furthermore, a play-it-safe user may expect the information source of the answer to be of authority or expertise, while a casual user may expect it to be commonsense that anyone can answer.

Considering these requirement, the following two questions q_2 and q_3 should be provided to the user under a certain context. Nevertheless, such *infoNeed*s are not given explicitly in the q_1.

q_2: Which bank should I choose for credit card, Citi Bank and Bank of America?

q_3: How to choose credit card?

As can be observed, the three questions have different types, which are *entity*, *alternative* and *method*, respectively (Diekema et al, 2003). Apparently, the single-dimensional question taxonomies employed at present are insufficient to model those aspects of users' *infoNeed*s (Pomerantz, 2005). Thus, more comprehensive question taxonomy is needed. The question retrieval results should also be diversified accordingly to fulfill these implicit and context-dependent *infoNeeds*, thus making the results more comprehensive for average users.

Present works (Clark et al, 2009; Santos et al, 2010) mainly target on search result diversification for short queries instead of questions. Their focus is to mine the different interpretations of ambiguous queries or navigations for a broad-sense query. Achananuparp et al. (2010) attempted to diversify the aspects of the answer to complex questions, while they also focus on the short information nuggets returned by search engines.

Based on our knowledge, no previous work has been done on the results diversification for question retrieval. In this paper, we utiliz *CogQTaxo*, a multi-dimensional question taxonomy to model both the explicit and implicit

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1432–1436,
Chiang Mai, Thailand, November 8 – 13, 2011.

*infoNeed*s of questions. Based on this, we propose an algorithm to diversify the results of question retrieval in terms of *infoNeed* types. The comparative experimental results show that the proposed algorithm enhances the information coverage and diversity of retrieved questions.

2 *CogQTaxo* - Three Dimensional Question Taxonomy

CogQTaxo is proposed by Zhang et al (2010). It is a framework of three-dimensional question taxonomy by using different levels of linguistic analysis (syntactic, semantic and pragmatic) as the classification criteria.

Let T_i (i=1,2,3) denotes the *i*th dimension of *CogQTaxo*, then:

1. T_1 represents the surface information need (*surfaceIN*), which corresponds to the conventional definition of question types (*QuesTs)*. A question can has one definite type in *surfaceIN*; 14 types are defined for *surfaceIN*, namely *location, person, time, quantity, thing, alternative, definition, comparison, description, procedure, reason, yesNo, abstractEnity* and *other*.

2. T_2 represents implicit information needs (*implicitIN*). *QuesTs* in this dimension are the same as in *surfaceIN*. Nevertheless, it represents the *infoNeeds* which are not expressed explicitly in the question, yet are required to fill the user's information gap. A question has at least one type in *implicitIN*.

3. T_3 represents users' pragmatic expectations (*pragmaticE*) from the answer. Four binary-valued pragmatic aspects are currently considered: (1) *Specification*: whether the question contains detailed specific information as the context; (2) *Knowledge source*: whether the question requires commonsense or expertise to answer; (3) *Temporal constraint*: whether the answer is time sensitive, i.e., whether the answer should be constraint to a time-frame; (4)*Subjectivity Orientation*: whether the information in the expected answer is subjective-oriented or objective-oriented.

A prediction model is built by Zhang et al (2010) to recognize the types of a question in each dimension of *CogQTaxo*. In this study, *CogQTaxo* is employed to diversify the *infoNeeds* in the results of question retrieval.

3 Diversification Algorithm for Question Retrieval Result

According to the definition of *CogQTaxo*, the three dimensions have different functions in user *infoNeeds* fulfillment, in which *surfaceIN* is fundamental and indispensable from the answer. *implicitIN* provides supportive information and helps to make the answer coverage more comprehensive. Therefore, we use *surfaceIN* and *implicitIN* to diversify the types of *infoNeeds* in retrieval results. The predicted *QuesT* sets in these two dimensions are merged into an extended one, in which the *QuesT*s are equally weighted at present. Meanwhile, the third dimension in *CogQTaxo*, *pragmaticE*, adds pragmatic constraints to the former two.

As displayed in figure 1, our question diversification algorithm is given as follows:

For a input question *p*, the question retrieval system will:

Step 1: Question analysis: The content words (nouns, verbs and adjectives) are extracted from *p* as the question content. Types of *p* in line with *CogQTaxo* are recognized automatically by using the model proposed in (Zhang et al, 2010).

Step 2: Question retrieval: retrieve relevant questions with the information retrieval (IR) model by using question content as the query. The relevance score is denoted as *IRScore*, which is normalized by the highest score of retrieved questions for *p*.

Step 3: Question Reranking with *QuesT* Similarity: Similar to (Lytinen and N. Tomuro, 2002) and (Cao et al, 2010), this step considers the relevance of *QuesT* between *p* and *q* for result ranking. Nevertheless, the question taxonomy deployed here is multi-dimensional. For each question *q* in the retrieved question set, $T_i Score$ is defined as the *QuesT* set distance between *p* and *q* in the *i*th dimension of *CogQTaxo*, i=1, 2, 3. It is calculated by MASI (Passonneau, 2006). Since we

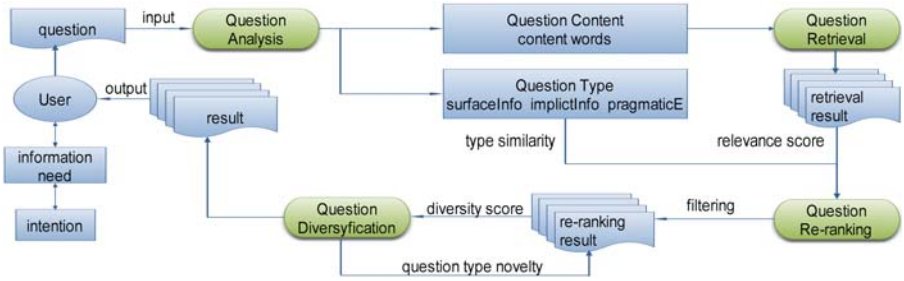

Figure 1 Diversification Procedure of Question Retrieval Results

merge T_1 with T_2, the retrieved results are re-ranked by *rerankScore*, which is defined as:

$$rerankScore = (1 - l_{1+2} - l_3) * IRScore + l_{1+2} * T_{1+2}Score + l_3 * T_3Score$$

where $l_{1+2}, l_3 \in [0,1], l_{1+2} + l_3 \in [0,1]$.

Result questions with the *rerankScore* lower than a threshold λ are filtered.

Step 4: Question *infoNeed*s diversification: This step employs a greedy algorithm to add one question with the largest *infoNeed*s novelty into the final returned question list in each iteration.

Suppose m questions are left in the result set after step 3, we denote *DiverseList* as the list of r questions re-ranked by diversity. For a question q in the m-r remaining result questions, its *QuesTs* novelty is defined as:

$$Novelty(T) = avg(\sum \frac{1}{e^{df_{type_j}+1}}),\ \exists\, type_j \in T_{1+2}^q \cap T_{1+2}^p,$$

where df_{typej} is the frequency of $type_j \in T_{1+2}^q \cap T_{1+2}^p$ in *DiverseList*.

Then *diverseScore* is computed as follows:

$$diversScore = (1-w) * rerankScore + w * Novelty(T),\ 0 \le w \le 1.$$

The question with the highest *diversScore* value is added to *DiverseList*[1].

Repeat Step 4 until the *DiverseList* with top n ($m \ge n$) questions are returned to the user.

4 Experiment and Discussion

4.1 Dataset and Experimental Setup

Questions with accepted answers are collected from the Yahoo! Knowledge portal and Baidu Zhidao portal, respectively. After removing redundancy and invalid questions, more than 1,380,000 postings are obtained [2] postings are obtained. The title of the posting is used as the question, while the accepted response is regarded as the answer.

100 questions chosen randomly as the query questions, the other questions are indexed to build the question retrieval system. Only the content words of questions are indexed. In the experiment, we used three IR model, namely Okapi BM25 model, Vector space model and language model, respectively, in which BM25 outperforms. Therefore, only the performance achieved by BM25 is reported in the rest of this section.

Relevance set: The relevance set of the 100 query questions are built by judging the content relevance between the query and the results regardless of the *infoNeed*s. Poolings among the top 10 results by the evaluated methods are conducted. Finally, 2258 relevant questions are collected.

Information need annotation: Three annotators annotate the *QuesT*s of the 100 query questions individually, by following the same instruction as Zhang et al (2010). In this way, three different *infoNeeds* sets of the query questions are generated. The algorithm performance is evaluated on each *infoNeeds* set separately, while the average performance is reported.

Evaluation criteria: We use *MAP_IA*, *MRR_IA* and *P@K_IA* designed by Agrawal et al (2009) as the evaluation metrics. These metrics are originally defined as the weighted arithmetic mean of performance of each subtopic of a query. In this paper, we substitute the subtopics of a query into the potential types of a question. At present we consider all of *QuesT*s as equally weighted. For example, the formula of *MAP_IA* is as follows:

$$MAP\_IA = \frac{\sum_{QuesT_i \in T_1 \cup T_2} W_i MAP(QuesT_i)}{(|T_1| + |T_2|)}$$

Furthermore, the relevance judgment in those metrics between question p and q is not simply bi-

[1] The reported experimental results are derived by l_{1+2}=0.2, l_3 =0.2, w=0.4, λ=0.5, which are obtained in a pilot experiment using 20 randomly selected test queries.

[2] Data used in this paper can be downloaded from Http://qa.haitianyuan.com/cogQTaxo.html

Table 2 Question retrieval results are listed for the query "Which stock is good to buy?", using BM25 as the retrieval model.

Predicted question type : entity/ description procedure alternative	
BM25 model	BM25 model with question type diversity
Which stock is good to buy?	Which stock is good to buy?
Which stock is good recently?	Which stock is good recently?
Which stock should I buy recently?	What characteristics good stocks have?
Recommend some good stocks to me.	How to identify a good stock?
Is there any good stock to buy?	Which stocks should I buy; good recommendations will be highly rewarded.

Table 3 Information needs diversification performance of the evaluated methods.

	Retrive_M	*Pop_Div*	*SurfaceIN_M*	*implicitIN_M*	*PragmaticE_M*	*LinearC*	*Bow_Div*	*Predict_Div*
MRR_IA	0.343	0.526	0.375	0.371	0.347	0.390	**0.527**	**0.529**
MAP_IA	0.114	0.140	0.138	0.134	0.120	**0.149**	0.058	**0.164**
P_IA @1	0.181	0.211	0.239	0.237	0.213	**0.245**	0.245	**0.262**
P_IA@5	0.192	0.197	0.218	0.215	0.205	**0.230**	0.106	**0.244**

nary valued, as either relevant or not; it is replaced by the similarity between p and q in *pragmaticE*. As mentioned before, *pragmaticE* add pragmatic constraints to the other two dimensions of *infoNeed*s.

$$infoNeed\_relevance(q) = \begin{cases} T_3 Score, & \text{if } relevance(q) = 1 \\ 0, & \text{if } relevance(q) = 0 \end{cases}$$

Evaluated question diversification methods: (1) ***Retrieve_M***: only using the IR model; (2) ***Pop_Div***: Instead of using the *QuesT* prediction model built by (Zhang et al, 2000), the *QuesT*s with the highest relative frequency (larger than 10%), i.e., the most popular *QuesT*s in the top 200 retrieved results by *Retrieve_M* are used as the potential type of *infoNeeds* of the query question; (3) ***SurfaceIN_M***, ***implicitIN_M***, ***PragmaticE_M***: using each of the three dimensions of *CogQTaxo* in the diversification algorithm, individually; (4) ***LinearC***: The first three steps of the diversification algorithm, i.e., without the diversification iteration step; (5) ***Bow_Div***: treating the question as bag-of-words, follows the same procedure without Step 3 in section 3, and only considers the novelty of content words in result questions in Step 4; (6) ***Predict_Div***: the complete proposed diversification algorithm.

4.2 Experimental Results

Table 2 illustrates the top 5 search results of query "Which stock is good to buy?" using *Retrive_M* and *Predict_Div*, respectively. As can be seen, the *infoNeed*s in questions retrieved by *Predict_Div* are more diverse than those retrieved by *Retrive_M*.

Table 3 lists the *infoNeed*s diversification performance achieved by each method, respectively. It is observed that *Predict_Div* outperforms. It is also shown that performance of *Bow_Div* is comparable with *Predict_Div* in *MRR_IA* and *P_IA @1*; however, it is even inferior to *Retrieve_M* in *MAP_IA* and *P_IA @5*. This indicates that the naïve bag-of-word baseline is unable to recall diverse *infoNeed*s of the query, and even deteriorates the performance. *Pop_Div* and *Predict_Div* are comparable in *MRR_IA*. However, in terms of other metrics, *LinearC* and *Predict_Div* are consistently at the top 2 ranks. The reason is that since the predicted types of a question are already diversified by *CogQTaxo*, incorporating it into question re-ranking already enables us to diversify the *infoNeeds* in the results implicitly. Therefore, the explicit diversification step enhances the performance further.

One deficit of the evaluation framework is that the *infoNeed*s of questions in the relevance set are predicted automatically instead of manually annotated; this may result in a bias towards our proposed algorithm. However, since the training set of the question classifier is manually annotated. Thus, it reflects the real user *infoNeed*s distribution. It is assumed that the automatic prediction can also reflect real user *infoNeed*s to some extent. More detailed analysis will be conducted later to examine this problem.

5 Conclusion

This paper proposes a method to diversify the results of question retrieval in term of types of information needs. Comparison results show that the proposed method improves the information need coverage and diversity in retrieved questions.

Beyond Normalization: Pragmatics of Word Form in Text Messages

Abstract

Non-standard spellings in text messages often convey extra pragmatic information not found in the standard word form. However, text message normalization systems that transform non-standard text message spellings to standard form tend to ignore this information. To address this problem, this paper examines the types of extra pragmatic information that are conveyed by non-standard word forms. Empirical analysis of our data shows that 40% of non-standard word forms contain emotional information not found in the standard form, and 38% contain additional emphasis. This extra information can be important to downstream applications such as text-to-speech synthesis. We further investigated the automatic detection of non-standard forms that display additional information. Our empirical results show that character level features can provide important cues for such detection.

1 Introduction

Text message conversations are often filled with non-standard word spellings. While some of these are unintentional misspellings, many of them are purposely produced. One commonly acknowledged reason that text message authors intentionally use non-standard word forms is to reduce the amount of time it takes to type the message, or the amount of space the message occupies.

This phenomenon has motivated the text message normalization task (Aw et al., 2006), which attempts to replace non-standard spelling and symbols by their standard forms. The normalization task is potentially critical for applications involving text messages, such as text-to-speech synthesis.

However, one important aspect that is overlooked when performing normalization is the use of non-standard word forms to express additional information such as emotion or emphasis. For instance, consider the following text message conversation:

A: They won the game!

B: Yesssss

The intent of the utterance by person B seems clear: he wishes to show that he is happy about the event described by person A. If the non-standard form *Yesssss* was normalized to the standard form *yes*, the intent conveyed by the utterance would be ambiguous; it could suggest that person B is happy about this turn of events, or he is indifferent, or he could simply be acknowledging that he already knows this fact. By using the non-standard form instead of the standard one, Person B communicated his excitement to A.

As shown in the above example, text message users often employ these non-standard forms to display extra pragmatic information that is not easily displayed otherwise. However, because normalization is only concerned about converting non-standard spellings to standard forms, it has the potential to remove this important pragmatic information.

To address this problem and to better understand some of the pragmatics of non-standard spellings in text messages, we conducted an initial investigation. In this study, we investigate the prevalence of non-standard spelling for the purpose of displaying information not captured in the standard word form. We also investigate the non-standard word form style associated with extra information and make a first attempt at identifying whether a non-standard form holds extra pragmatic information.

2 Related Work

There are two main areas of related work: text normalization and affective text classification. Because it may be unclear how non-standard forms should be read aloud, the field of text-to-speech synthesis has long been interested in text normalization. Sproat et. al. (2001) study several different corpora and identify several types of non-standard word, including several seen frequently in text message data, such as misspelling, abbreviation, and "funny spellings". More recent work (Zhu et al., 2007) has employed conditional random fields in an attempt to handle word normalization simultaneously with several related problems such as detecting sentence and paragraph boundaries.

Several different approaches have been proposed for normalization of text messages specifically, including those motivated by machine translation (Aw et al., 2006) and spell-checking (Choudhury et al., 2007). Most recently, Pennell and Liu (2010) use handcrafted rules as classification features to normalize SMS terms that contain character deletion, with a focus on normalization for text-to-speech systems. A few hybrid approaches (Kobus et al., 2008; Beaufort et al., 2010) and an unsupervised approach (Cook and Stevenson, 2009) have also been investigated. All of these methods assume that the normalized form is functionally equivalent to the non-standard form found in the text; none address the potential existence of extra information in the non-standard form.

Affective text classification attempts to identify the type or polarity of emotion that is expressed by the text, without the aid of extra linguistic cues such as gesture or prosody. Kao et. al. (2009) survey the field and divide approaches into 3 categories: 1) keyword based approaches (Bracewell, 2008), 2) learning-based approaches (Alm et al., 2005; Yang et al., 2007; Binali et al., 2010), and 3) hybrid approaches (Wu et al., 2006; Agarwal et al., 2009). Although there has been some recognition of the effect that non-standard word forms play in emotion detection (Zhang et al., 2006), the primary feature sources for emotion detection systems has been at the word and sentence level (Quan and Ren, 2010). To our knowledge, no previous work has focused on the role non-standard word form plays in conveying emotional and other pragmatic information in text messages.

Figure 1: Example dialogue from our corpus

3 Empirical Analysis

3.1 Data Set

In order to access whether non-standard word forms have additional pragmatic information, it is necessary to study these forms in their original dialogue context. Because no currently available text message dataset contains messages in context, we collected our own. The website "Damn You Autocorrect"[1] posts screenshots of short text message conversations that contain mistakes produced by automatic spelling correction systems. To create an initial dataset, 1190 text message conversations were transcribed. A sample dialogue is shown in Figure 1.

The speech bubbles originating from the left of the image in Figure 1 are produced by one participant, while those originating from the right are produced by the other. The dialogue shown contains several examples of non-standard spelling. The non-standard form *lookin* drops the letter *g* from the end of the morpheme *ing*, a technique commonly used in informal writing. Two other non-standard spellings, *hiii* and *goooooood* exemplify the use of letter repetition. This dialogue also includes the common texting slang term *lol*.

Since we are interested in studying the presence of extra information in non-standard word forms, we must first identify word forms that contain non-standard spelling. To create a set of non-standard word forms, we used the CMU pronouncing dictionary[2] as a vocabulary set and selected all tokens that were out of our vocabulary. Those tokens that were simply legitimate words in the lexicon, such as proper names or obscure terms not in our dictionary, were manually removed. This left us with a data set of 764 non-standard word tokens.

[1] www.damnyouautocorrect.com

[2] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

3.2 Survey

To assess which word forms displayed extra pragmatic information, we created a short survey that asked users of Amazon Mechanical Turk[3] to determine whether this form contained information not present in the standard form. Survey participants were given the word in context and asked to answer the following four questions:

1. "What is the standard form of this word?"
2. "What type of emotion, if any, is provided by the spelling used that is not provided by the standard form?" (Choose from the following: none, fear, suprise, happiness, disgust, sadness, anger, other)
3. "What other information, if any, is provided by the spelling used that is not provided by the standard form?" (Choose from the following: friendliness/closeness, emphasis, other, none)
4. "Why do you think the writer chose to use the modified spelling instead of the standard form?" (Choose from the following: wanted to display extra information, wanted to save time or space, made an unintentional mistake, other)

Three separate annotators were asked to examine each word form. The observed agreement between any two annotators was around 80% for a given question. For our analysis, we consider a case in which 2 or more annotators agreed as the gold standard. Cases in which no annotators agreed were thrown out, judged separately for each question[4].

3.3 Analysis Results

Figure 2 shows the results of question 2. The emotions used include the six basic emotions (Ekman, 1993) often used in affective text literature. If several emotions were displayed, annotators were asked to pick the emotion that was displayed most strongly. As shown, 5 of the 6 emotions were present in our corpus, with only fear being absent. Although many forms did not contain extra emotion, a full 40% of them did. When additional emotional information was present, it was most commonly positive; happiness was by far the most common emotion displayed.

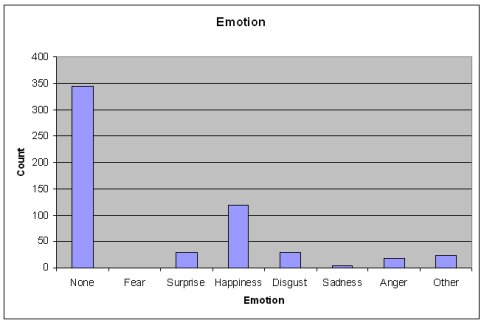

Figure 2: Distribution of forms containing emotion not present in normalized form

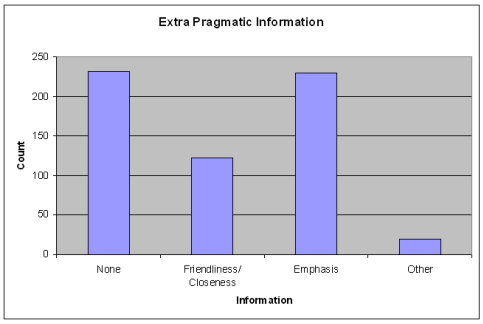

Figure 3: Distribution of forms containing additional information not present in normalized form

Figure 3 shows the results of question 3. Although it was again common for no extra information to be present, cases in which non-standard forms were used to emphasize a word were nearly as common, appearing in 38% of our instances. The use of non-standard forms to express emphasis appears to be widespread in text messaging data. This is an important finding, especially relevant to text-to-speech research. Additionally, Figure 3 suggests that another common usage of non-standard forms, found in 20% of our data, is to display a sense of kinship with the reader through subtle expressions of friendliness or closeness.

Results for question 4 are shown in Figure 4. Wanting to display extra information was perceived as a primary reason why text message authors chose a non-standard spelling. This seems to suggest that, in choosing non-standard word forms, expressiveness is a primary concern for text message writers.

Overall, the results in the figures suggest that the need for greater expressiveness is a paramount reason why text message writers choose non-

[3] mturk.amazon.com

[4] This accounts for the difference in total instances between Figures 2, 3, and 4

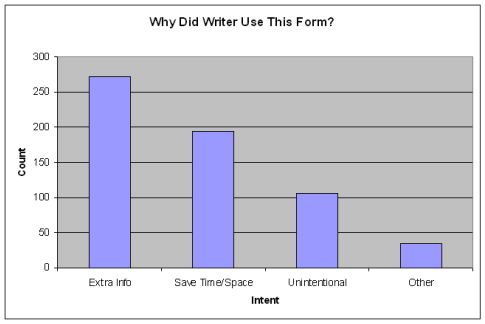

Figure 4: Perceived intent of text message author

standard spellings. It is thus relevant for text message normalization systems to consider the intent of the writer in producing a non-standard form, to ensure that the intended meaning is not lost. This leads to the question of whether an automated system can accurately recognize words that carry extra pragmatic information. In the next section, we take an initial look at this problem.

4 Automatic Identification of Words with Extra Information

We model the task of identifying whether a non-standard word form is intended to display extra information as a binary classification task. All instances that were marked by annotators as having some form of emotion or extra information were considered to be positive instances.

We drew features from three sources for our classification: character level features, punctuation features, and positional features. Because we are focused on classifying the emotional or pragmatic content of the word and not the utterance, we restrict our feature set to only features that pertain the to the word itself.

Character level features. Our feature set focused primarily on character level features. Several features focused on identifying the type of abbreviation used. Features indicating whether the word contained the same letter repeated more than twice, the maximum number of times a letter was repeated in the word, and whether deletion of repeated characters produced an in-vocabulary word were used to detect cases of word elongation. Edit distance from the closest word using only insertions was used as an indicator of word shortening and truncation. One additional feature recorded whether the non-standard form was longer than the normalized form. Features were also included to detect whether the non-standard form contained concatenated words or contained numbers or non-alphanumeric characters. Whether or not a word was written in all capital letters was also observed.

Punctuation features. Punctuation features capture some information beyond that of the word form. The punctuation features detected whether the word was followed by a comma, period, question mark, exclamation point, or emoticon.

Positional features. Positional features were the most discourse dependent features examined. These features indicated whether the word was the first, last, or only word in the current message.

Classification was performed using an SVM classifier. Ten-fold cross validation was performed. The results are shown in Table 1. A majority class baseline suggests that classification is not trivial; although many instances carry extra information, many do not. As shown, the use of character level feature alone achieves above baseline performance of 72.4% ($p < 0.01$). Adding additional features on top of this does not result in an increase in performance.

	Accuracy
Baseline	59.5%
Character Level Features Only	72.4%
Character Level + Punctuation	72.3%
All Features	72.4%

Table 1: Classification of word forms by the presence of added information

5 Conclusion

The analysis presented in this paper shows that non-standard word forms contain additional pragmatic information not present in the standard form. Some of the main functions of this extra information include the expression of emphasis, happiness, and friendliness. It is important that text message normalization systems recognize and address this fact, as it is relevant for downstream applications such as text-to-speech synthesis.

Additionally, this work introduced the problem of identifying whether a non-standard text messaging form was intended to display pragmatic information beyond that of the base form. Our initial investigation showed that above baseline performance could be achieved, but that the problem was non-trivial and required further study. Future work is needed to more robustly address this problem, as well as more closely examine the relationship between non-standard spellings and individual types of emotional and other pragmatic information.

Abstract

The challenging issues of discourse relation recognition in Chinese are addressed. Due to the lack of Chinese discourse corpora, we construct a moderate corpus with human-annotated discourse relations. Based on the corpus, a statistical classifier is proposed, and various features are explored in the experiments. The experimental results show that our method achieves an accuracy of 88.28% and an F-Score of 63.69% in four-class classification and achieves an F-Score of 93.57% in the best case.

1 Introduction

A discourse relation is the way that two successive arguments logically connected. Recognizing discourse relations attracts much attetions in recent years due to many potential applications. In the annotation scheme of Penn Discourse Treebank 2.0 (PDTB-2.0), the first level of discourse relations includes four classes such as *Temporal*, *Contingency*, *Comparison*, and *Expansion* (Prasad et al., 2008).

The first challenge of discourse relation recognition is the lack of corpus. To construct a discourse corpus has several difficulties. First, the definition of discourse is unclear and varied over different areas. Thus, finding the clear boundary of a discourse argument is a vexing problem by itself. Second, the relationship between arguments is often difficult to decide and inherently subjective. Thus, the annotation and the evaluation are problematic and labor-intensive.

In recent years, the study of discourse relation recognition is growing in the English domain rapidly. One of the reasons is the availability of English corpora with discourse annotations. The two most popular discourse corpora are the Rhetorical Structure Theory Discourse Treebank (RSTDT) (Carlson et al., 2001) and PDTB-2.0. Both of them are based on the Wall Street Journal corpus with human-annotated discourse information. The PDTB-2.0 consists of 36,592 pairs of successive arguments and is tagged with three classes, including *Implicit*, *Explicit*, and *AltLex*, and with the relation types at three levels. Based on these corpora, a number of aspects on discourse relation are explored in these years.

Compared to the English corpora, there is still no Chinese discourse corpus worldwide available. For this reason, the dataset is the first challenge encountered in the study of Chinese discourse relation recognition. To address this issue in this work, we construct a moderate Chinese discourse corpus as a starting point. A supervised statistical classifier is trained and tested on this data set to deal with the problem. Various features are extracted from the corpus and evaluated in the experiments.

The rest of this paper is organized as follows. First, we review the related work in Section 2. In Section 3, the Chinese discourse relation problem is illustrated. Our corpus and the details on the annotation work are presented in Section 4. In Section 5, the method and the features are introduced. The experimental results are discussed in Section 6, and we conclude this paper in Section 7.

2 Related Work

Pitler and Nenkova (2009) reported an explicit discourse relation recognizer that achieves an accuracy of 94.15%. On the other hand, the implicit discourse relation recognition is much more challenging than the explicit one. The implicit discourse relation recognition is to predict the relation of two successive arguments without connectives. In the work of Marcu and Echihabi (2002), the dataset for implicit discourse relation

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1442–1446,
Chiang Mai, Thailand, November 8 – 13, 2011.

detection is automatically derived from explicit samples by removing the connectives. Though this approach is efficient to obtain a large corpus, the pseudo implicit corpus does not exactly capture the property in the real world.

Based on PDTB, in which the argument pairs are distinguished between implicit and explicit, Pitler et al. (2009) and Lin et al. (2009) addressed the task of real implicit discourse relation recognition. In the work of Pitler et al., the implicit discourse relation detection achieves an average accuracy of 62.78% for four-class classification. In the work of Lin et al., the implicit discourse relations are classified into 11 types (selected from the second level tagging in PDTB), and their classifier achieves an accuracy of 40.2%.

From the other aspect, the semi-supervised approach is explored to deal with some relations that are rare in the corpus (Hernault et al., 2010).

3 The Discourse Relation in Chinese

In this work, we adopt the top level classes of PDTB to deal with the Chinese materials.

When two arguments are temporally related, they form a *Temporal* relation. There are two subtypes of Temporal relation, ordered in time (*Asynchronous*, as defined in PDTB-2.0 annotation manual[1]) and overlapped (*Synchronous*). For example, the events in the two arguments in (S1) occur sequentially in time. The event in the second argument happened after the event in the first argument.

(S1) 他首先證實傅爾和中谷義雄的理論。'He first confirmed the theory of Voll and Yoshio Nakatani.'

其次，他發現經絡不僅是電流的良導體，也是電磁波的良導體。 'Second, he found that the meridian is not only a good conductor of current, but also a good conductor of electromagnetic waves.'

The *Contingency* relation talks about the situation that the event in one of the arguments casually affects the event in the other argument. In Chinese, the typical compound connective of Contingency is '因為…，所以…' ('Because…, …'). In sample (S2), the event '颱風來襲' is the cause, and the event '學生停課在家' is its result. Such a relation is defined in PDTB-2.0 as *Cause*, a subtype of Contingency. In sample (S3), the connective '因為…，所以…' is removed. Obviously, the relation between the two clauses is still Contingency. This situation is similar to the case of implicit relation in English.

(S2) 因為颱風來襲，所以學校停止上課。 'Because of the typhoon struck, the school has broken up.'

(S3) 颱風來襲，學校停止上課。 'The typhoon struck; the school has broken up.'

Condition is another typical subtype of Contingency. Condition relation between two arguments specifies the situation in which the event in one argument is conditioned on the event in the other argument.

Comparison is used to show the difference between two arguments. A subtype of Comparison is *Contrast*, where the two arguments share a common predicate or property, and their difference is highlighted.

Expansion, the most common relation, either expands the information for one argument in the other one or continues the narrative flow. In sample (S4), the second argument expands the information to the first argument.

(S4) 伏爾泰是啟蒙運動的領導者，一位偉大的思想家。 'Voltaire is the leader of the Enlightenment, a great thinker.'

除此之外，他也是著作等身的作家。 'In addition, he is also a prolific writer.'

Some words that are usually used as marks to indicate the discourse relations are given in Table 1 for reference.

Relations	Sample Marks
Temporal	同時 (at the same time) 之前 (before)
Contingency	因為 (because) 所以 (therefore) 如果 (if)
Comparison	然而 (however) 雖然 (although) 相反的 (in contrast)
Expansion	而且 (furthermore) 也 (also) 或者 (or) 例如 (for example) 除了 (in addition)

Table 1. Chinese Discourse Relations

4 Dataset

To deal with the problem of Chinese discourse relation recognition, we firstly construct a corpus for training and testing. The corpus is based on Sinica Treebank 3.1. Total 81 articles are randomly selected from the Sino and Travel sets.

The first issue we encountered is how to segment an article into arguments. In other words, the issue concerns the determination of the argument boundaries. In PDTB, both the boundaries of arguments and the type of discourse relations are annotated by human. In this data set, an argument is not always a sentence. That is, it may be a clause. Sometimes it may be composed of a number of sentences. However, to annotate in such a way is costly and time-consuming. For convenience, we regard an argument as a sentence in this work. A sentence is defined to be a sequence of words ended by a full-stop, a question mark, or an exclamation mark.

In this way, each article is segmented into sentences and shown to three annotators. An annotator assigns one of four discourse relations to each pair of successive sentences. Under this scheme, the annotators regard a sentence as a discourse unit and determine how successive sentences relate to each other. Finally, the majority among the three labels are taken. In the case of ties, an additional annotator will be involved in the final labeling.

The shortage of this annotation scheme is that the samples of Contingency are very rare. In Chinese, the Contingency relation usually occurs inside a sentence. In sample (S3), the two arguments of Contingency, i.e., "因為颱風來襲" and "所以學校停止上課", are two clauses within a single sentence. For this reason, only 94 inter-sentence Contingency relations are tagged in our corpus.

The statistics of the corpus are shown in Table 2. Due to the genre of the Sino and the Travel is descriptive writings, the major relation among the corpus is Expansion.

5 Method

The multi-class support vector machine (SVM) is utilized as our classifier[2]. Due to the unbalance distribution among the four relations, we duplicate the samples of Temporal, Contingency, and Comparison in the training sets proportionally to derive balanced training data.

[2] http://svmlight.joachims.org/svm_multiclass.html

5.1 Features

Length (*Len*): This feature includes the word counts of the first argument, the second argument, the first clause in the first argument, the last clause in the first argument, the first clause in the second argument, and the last clause in the second argument.

***Punctuation* (*Pun*):** The punctuations which end the first and the second arguments are regarded as features. The possible punctuation is a full-stop, a question mark, or an exclamation mark.

***Connective* (*Connect*):** Similar to the connectives in English, some words are usually used as discourse relation marks in Chinese. We prepare a dictionary that contains 319 single words and 489 word pairs. The number of matching words (word-pairs) and their corresponding relation types are considered as features.

***Shared Word* (*SW*):** The number of words shared in the first and the second arguments is considered as a feature. Besides, the common hypernyms shared in both arguments are also counted.

***Word*:** The bags of words in the first argument, in the second argument, and in the first clause of the second argument are considered.

***Part-of-Speech* (*POS*):** The bags of POS in the first argument, in the second argument, and in the first clause of the second argument.

***Hypernym* (*Hyper*):** The bags of hypernym words in the first argument, in the second argument, and in the first clause of the second argument are considered.

***Collocated Word* (*CW*):** Collocated words are the frequent word pairs mined from the training set. The first word and the second word in the pair come from the first argument and the second argument, respectively.

***Number*:** The binary features capture if the dates, the times, the periods, and the numbers exist in the arguments.

6 Experiments

The experimental results for the four relation types are shown in Tables 3, 4, 5, and 6, respectively and the overall performance is given in Table 7. All the performances are evaluated by 5-fold cross-validation.

In general, no single feature is efficient for all the types. For Temporal relation, the feature *Number* contributes the highest recall to capture most candidates. The precision of using single feature only is no more than 25%.

Source	#Articles	#Sentence Pairs	Temporal (#, %)	Contingency (#, %)	Comparison (#, %)	Expansion (#, %)
Sino	27	1594	(104, 6.52)	(51, 3.20)	(156, 9.79)	(1283, 80.49)
Travel	54	1487	(63, 4.24)	(43, 2.89)	(51, 3.43)	(1330, 89.44)
Total	81	3081	(167, 5.42)	(94, 3.05)	(207, 6.72)	(2613, 84.81)

Table 2. Dataset Statistics

Comparatively, the model using all the features achieves a precision of 60.22%. In other words, these features are complementary for recognizing the Temporal relation. The performance is relatively poor for Contingency relation identification. As discussed in Section 4, our annotation does not capture the intra-sentence Contingency relation, thus the most representative examples of Contingency are lost.

The feature *Connect* achieves the highest recall of 70.53% for Comparison relation labeling. The feature *Word*, which achieves a recall of 70.05%, has the similar identification capability. With all the features, an F-Score of 61.24% is achieved.

Expansion is the largest class among the four types. The performance of this type is much better than that of the other three types. Our classifier achieves an F-Score of 93.57% for Expansion.

The performance in macro average is shown in Table 7. Overall, our classifier trained with all features achieves an F-Score of 63.69% and an accuracy of 88.28%.

7 Conclusion

In this work, we address the issue of discourse relation recognition in Chinese. A moderate corpus sampled from Sinica Treebank 3.1 is labeled with discourse relations. The top-level classes used in PDTB are adopted in the data annotation. The SVM classifier trained with various features recognizes the relations between successive arguments automatically. As a result, our classifier achieves an accuracy of 88.28% and an F-Score of 63.69%. In the best case, our classifier achieves an F-Score of 93.57% for the recognition of Expansion relation.

Abstract

Recent research usually models POS tagging as a sequential labeling problem, in which only local context features can be used. Due to the lack of morphological inflections, many tagging ambiguities in Chinese are difficult to handle unless consulting larger contexts. In this paper, we try to improve Chinese POS tagging by using long-distance dependencies produced by a statistical dependency parser. Experimental results show that, despite error propagation, the syntactic features can significantly improve the tagging accuracy from 93.88% to 94.41% ($p < 10^{-5}$). Detailed analysis shows that these features are helpful for ambiguous pairs like {NN,VV} and {DEC,DEG}.[1]

1 Introduction

Part-of-speech (POS) tagging is a necessary and important step for many natural language tasks, for example, named entity recognition, parsing and sentence boundary detection. In the current literature, POS tagging is treated as a typical sequence labeling problem, to which many models have been successfully applied, such as maximum-entropy (Ratnaparkhi, 1996), conditional random fields (CRF) (Lafferty et al., 2001) and perceptron (Collins, 2002). To facilitate fast decoding, these models make the Markovian independence assumption that the current tag depends on one or two previous tags. In addition, they can merely consider local context features, e.g. two words in both sides of the focus word. This works quite well for English, because inflections are useful and strong clues for POS tags. However, due to the lack of morphological inflections, Chinese POS tagging has proven to be much more challenging than English. With a typical sequential labeling model such as Conditional Random Fields (CRF), the tagging accuracy is about 97% for English, while less than 94% for Chinese (Huang et al., 2009).

NN-VV ambiguities are one of the most notorious difficulties for Chinese POS tagging. Figure 1 gives two examples. We can see that the POS tagger can effortlessly assign the right tags to both "development" and "develop" in the English side. However, it is very difficult in the Chinese side since no word form inflection is available and the context features may be too sparse or uninformative. However, the introduction of long-distance dependencies can largely reduce this difficulty. In the upper example of Figure 1, the coordinate relation between "贸易/NN" and "发展" is a strong clue to "发展/NN". In the lower example of Figure 1, it is also easy to tag "发展" as "VV" if its coordination with "维护/VV" is known.

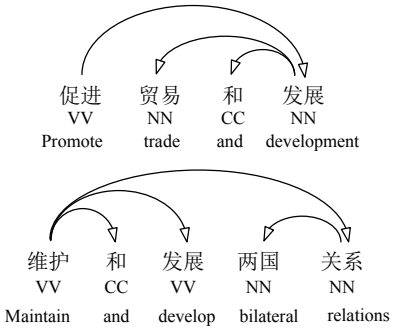

Figure 1: Examples of NN-VV ambiguities with dependency structures. The focus word is "发展".

As far as we know, there has been few research that tries to improve POS tagging with dependency

*Correspondence author: tliu@ir.hit.edu.cn

[1]DEG and DEC are the two POS tags for the frequently used auxiliary word "的" (dē, of) in Chinese. The associative "的" is tagged as DEG, such as "父亲/father 的 眼睛/eyes (eyes of the father)"; while the one in a relative clause is tagged as DEC, such as "他/he 取得/made 的 进步/progress (progress that he made)".

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1447–1451,
Chiang Mai, Thailand, November 8 – 13, 2011.

parsing . The reason for this may be three-fold. Firstly, POS tags are indispensable features for dependency parsing since pure lexical features lead to severe sparseness problem. Therefore, POS tagging is traditionally considered as a supporting task for dependency parsing. Secondly, Chinese dependency parsing performs not well. The accuracy is about 85% when gold-standard POS tags are given, and quickly drops to about 79% when using automatically assigned POS tags. Therefore, error propagation may be an obstacle to research on this idea. Thirdly, inefficiency of syntactic parsing may be another concern. However, we believe that this problem can be relieved in the case of dependency parsing, since efficient cubic-time or even linear-time parsing models have been proposed for dependency parsing (McDonald, 2006; Nivre and Hall, 2005).

In this paper, we propose several kinds of syntactic features based on the output of a statistical dependency parser. And we use these features to enhance a traditional POS tagging model so that long-distance information can be explored. Experimental results show that this effort is rewarding, and the tagging accuracy is significantly improved. Detailed error analysis confirms the usefulness of these syntactic features.

2 Baseline POS Taggers

Given an input sentence $\mathbf{x} = w_1...w_n$, we denote its *POS tag sequence* by $\mathbf{t} = t_1...t_n$, where $t_i \in \mathcal{T}$, $1 \leq i \leq n$, and $\mathcal{T}$ is the POS tag set. The goal of POS tagging is to find the highest-scoring sequence:

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} \mu(\mathbf{x}, \mathbf{t})$$

We implement two baseline taggers, i.e., a Perceptron-based tagger and a CRF-based tagger. As a linear model, Perceptron defines the score of a tag sequence to be

$$\mu(\mathbf{x}, \mathbf{t}) = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{t})$$

where $\mathbf{f}(\mathbf{x}, \mathbf{t})$ refers to the feature vector and $\mathbf{w}$ is the corresponding weight vector. We use standard *averaged perceptron* to learn the weight vector (Collins, 2002).

As a probabilistic model, CRF defines the probability of a sequence to be

$$\mu(\mathbf{x}, \mathbf{t}) = P(\mathbf{t}|\mathbf{x}) = \frac{e^{\mathbf{w}\cdot\mathbf{f}(\mathbf{x},\mathbf{t})}}{\sum_{\mathbf{t}'} e^{\mathbf{w}\cdot\mathbf{f}(\mathbf{x},\mathbf{t}')}}$$

We adopt the *exponentiated gradient* algorithm to learn the weight vector (Collins et al., 2008).

For POS tagging features $\mathbf{f}(\mathbf{x}, \mathbf{t})$, we follow the work of Zhang and Clark (2008a). Besides standard *POS unigram* ($\underline{w_i\ t_i}$), *bigram* ($\underline{t_{i-1}\ t_i}$) and *trigram* ($\underline{t_{i-2}\ t_{i-1}\ t_i}$) features, they explore many features composed of Chinese characters, such as $\underline{c_{i,0}\ t_i}$ and $\underline{c_{i,-1}\ t_i}$, where $c_{i,0}$ and $c_{i,-1}$ denote the start and end characters of w_i. These character-based features are very helpful for tagging accuracy. Due to space limitation, we refer to Zhang and Clark (2008a) for the complete feature description. In order to distinguish these features from our proposed syntactic features, we refer to them as the *basic features* and denote them as $\mathbf{f}_b(\mathbf{x}, \mathbf{t})$. Given $\mathbf{w}$, we adopt the Viterbi algorithm to get the optimal tagging sequence.

3 POS Tagging with Syntactic Features

The framework of our method is shown in Figure 2. Given an input sentence $\mathbf{x}$, we first use the CRF-based model to produce a tagging sequence $\mathbf{t}^C$. Then, based on $\mathbf{t}^C$, we use a statistical dependency parser to obtain the syntactic tree $\mathbf{d}^A$. Finally, both $\mathbf{t}^C$ and $\mathbf{d}^A$ are used as additional features in the enhanced Perceptron-based model. We use Perceptron to build our model because it is competitive to CRF in tagging accuracy but requires much less training time. During training phase, we adopt the 10-fold cross validation strategy to produce both $\mathbf{t}^C$ and $\mathbf{d}^A$ for the training set.

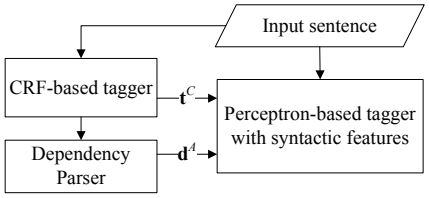

Figure 2: Framework of our method.

Based on a guide POS sequence $\mathbf{t}'$ ($\mathbf{t}^C$ in this paper) and a syntactic tree $\mathbf{d}$, we propose three kinds of features, as shown in Table 1. Our use of guide POS Features $\mathbf{f}_g(\mathbf{x}, \mathbf{t}', \mathbf{t})$ is mainly inspired by *stacked learning*, in which results of the first-level predicator are used to guide the second (Cohen and de Carvalho, 2005; Nivre and McDonald, 2008; Martins et al., 2008).

Syntactic features $\mathbf{f}_s(\mathbf{x}, \mathbf{d}, \mathbf{t})$ explore features related with the head and children of the focus word. Syntactic features with guide POS tags

Guide POS Features: $\mathbf{f}_g(\mathbf{x}, \mathbf{t}', \mathbf{t})$		Syntactic Features: $\mathbf{f}_s(\mathbf{x}, \mathbf{d}, \mathbf{t})$		Syntactic Features with Guide POS: $\mathbf{f}_{sg}(\mathbf{x}, \mathbf{t}', \mathbf{d}, \mathbf{t})$			
$t'_i\ t_i$	$t'_{i-1}\ t'_i\ t_i$	$\#lc(i)\ t_i$	$w_{h(i)}\ t_i$	$\#lc(i)\ t'_i\ t_i$	$\#rc(i)\ t'_i\ t_i$	$t'_{h(i)}\ t_i$	$t'_i\ d(i)\ t_i$
$t'_{i-1}\ t_i$	$t'_i\ t'_{i+1}\ t_i$	$w_{lc(i,k)}\ t_i$	$d(i)\ t_i$	$t'_{lc(i,k)}\ t'_i\ t_i$	$t'_{rc(i,k)}\ t'_i\ t_i$	$t'_{h(i)}\ t'_i\ t_i$	$t'_{h(i)}\ d(i)\ t_i$
$t'_{i+1}\ t_i$	$t'_{i-1}\ t'_{i+1}\ t_i$	$\#rc(i)\ t_i$	$w_{h(i)}\ d(i)\ t_i$	$t'_{lc(i,k)}\ t_i$	$t'_{rc(i,k)}\ t_i$	$t'_{h(i)}\ w_i\ t_i$	$t'_{h(i)}\ t'_i\ d(i)\ t_i$
$t'_i \sim \mathbf{f}_b(\mathbf{x})$	$t'_{i-1}\ t'_i\ t'_{i+1}\ t_i$	$w_{rc(i,k)}\ t_i$	$w_i\ d(i)\ t_i$				$t'_{h(i)}\ w_i\ d(i)\ t_i$

Table 1: Feature templates for our enhanced Perceptron-based tagger. $\mathbf{t}'$ denotes a guide POS sequence, which is $\mathbf{t}^C$ in this paper. $t'_i \sim \mathbf{f}_b(\mathbf{x})$ means that we concatenate t'_i and each feature in $\mathbf{f}_b(\mathbf{x}, \mathbf{t})$ to obtain a new one. $h(i)$ denotes the index of the head of i in the syntactic tree $\mathbf{d}$; while $d(i)$ means the distance and direction of the dependency $h(i) \rightarrow i$. $\#lc(i)$ means the number of left-side children of i, and $lc(i, k)$ is the index of the k^{th} left child of i. Analogously, $\#rc(i)$ and $rc(i, k)$ considers right-side children of i.

$\mathbf{f}_{sg}(\mathbf{x}, \mathbf{t}', \mathbf{d}, \mathbf{t})$ further make use of the POS tags of the head and children of the focus word. The effectiveness of these features will be examined in the experiments.

4 Experiments and Analysis

The Penn Chinese Treebank 5.1 (CTB5) is used as the labeled data (Xue et al., 2005). We follow the setup of Duan et al. (2007) and split CTB5 into training (secs 001-815 and 1001-1136), development (secs 886-931 and 1148-1151), and test (secs 816-885 and 1137-1147) sets. Head-finding rules are used to turn the bracketed sentences into dependency structures (Zhang and Clark, 2008b).

We adopt the second-order graph-based model of McDonald and Pereira (2006) for our statistical dependency parser. Its time complexity for decoding is $O(n^3)$. On the test set, its parsing accuracy is 85.01% when using gold-standard POS tags, and is 78.82% when using automatic POS tags produced by the baseline CRF tagger.

4.1 Main Results

Table 2 gives the final results. The first row contains two baseline tagging models which only use the basic features $\mathbf{f}_b(\mathbf{x}, \mathbf{t})$. We can see that the Perceptron-based and CRF-based models achieve comparable accuracies.

From the results in the second row, we can find that using guide POS features only modestly (but significantly) improve the accuracy. This model can be regarded as the integrated model of both Perceptron-based and CRF-based models.

In the third row, we explore syntactic features based on gold-standard trees and aim to find out the usefulness of syntactic features without error propagation. Obviously, correct syntactic features can greatly help resolve tagging ambiguities. Using all the features leads to the best accuracy.

Method	Token	Known	Unknown
Perceptron with $\mathbf{f}_b(\mathbf{x}, \mathbf{t})$	93.82	94.65	81.32
CRF with $\mathbf{f}_b(\mathbf{x}, \mathbf{t})$	93.88	94.70	81.51
+$\mathbf{f}_g(\mathbf{t}^C)$	94.02	94.84	81.67
+$\mathbf{f}_s(\mathbf{d}^G)$	96.02	96.85	83.51
+$\mathbf{f}_s(\mathbf{d}^G)$+$\mathbf{f}_{sg}(\mathbf{t}^C, \mathbf{d}^G)$	96.19	96.99	84.27
+$\mathbf{f}_s(\mathbf{d}^G)$+$\mathbf{f}_{sg}(\mathbf{t}^C, \mathbf{d}^G)$+$\mathbf{f}_g(\mathbf{t}^C)$	**96.26**	**97.05**	**84.37**
+$\mathbf{f}_s(\mathbf{d}^A)$	94.06	94.91	81.44
+$\mathbf{f}_s(\mathbf{d}^A)$+$\mathbf{f}_{sg}(\mathbf{t}^C, \mathbf{d}^A)$	**94.41**	**95.26**	81.67
+$\mathbf{f}_s(\mathbf{d}^A)$+$\mathbf{f}_{sg}(\mathbf{t}^C, \mathbf{d}^A)$+$\mathbf{f}_g(\mathbf{t}^C)$	94.37	95.20	**81.95**

Table 2: Tagging accuracy on the test set (%). $\mathbf{t}^C$ denotes the tagging sequence of the baseline CRF model. $\mathbf{d}^G$ refers to the gold-standard tree; while $\mathbf{d}^A$ denotes the automatically parsed tree. Note that we omit $\mathbf{x}$ and $\mathbf{t}$ in $\mathbf{f}_{s/g/sg}(.)$ for brevity.

In the fourth row, we examine our method in the realistic scenario. The syntactic tree is automatically produced by the parser trained on the training set. The accuracy improvement is modest but significant when only adding pure syntactic features $\mathbf{f}_s(\mathbf{x}, \mathbf{d}^A, \mathbf{t})$ ($p < 0.01$).[2] Using syntactic features with guide POS tags, i.e., $\mathbf{f}_{sg}(\mathbf{x}, \mathbf{t}^C, \mathbf{d}^A, \mathbf{t})$, can boost the accuracy by a large margin. Compared with the baseline models, the improvement is significant ($p < 10^{-5}$). Then, adding guide POS features $\mathbf{f}_g(\mathbf{x}, \mathbf{t}^C, \mathbf{t})$ slightly decreases the accuracy, but somehow improves the accuracy of unknown words.

4.2 Error Analysis

To find out how the syntactic features help tagging, we conduct detailed error analysis through comparing the results of different models, as shown in Table 3. We choose the most frequent error pat-

[2]We adapt Dan Bikel's randomized parsing evaluation comparator to do significant test for POS tagging. http://www.cis.upenn.edu/~bikel/software.html

terns made by the baseline CRF-based model, and presents them in descending order of frequency.

error pattern	CRF	Gold Parse	Auto Parse
VV → NN	456	-197	-15
NN → VV	341	-180	-30
DEC → DEG	227	-222	-66
NR → NN	224	+1	-5
DEG → DEC	191	-187	-57
JJ → NN	135	+10	0
NN → NR	84	-3	0
NN → JJ	63	0	+1

Table 3: The number of error patterns made by different models. An error pattern "X → Y" means that the focus word, whose true tag is 'X', is assigned a tag 'Y'. "CRF" refers to the baseline CRF-based model. "Gold Parse" and "Auto Parse" are two perceptron-based models augmented with syntactic features, and correspond to the best models in the third and fourth rows of Table 2, respectively. The signed numbers in the last two columns present the change of error number.

From the column of "Gold Parse" we can see that using correct syntactic features can greatly reduce the errors for ambiguous pairs {NN, VV} and {DEC, DEG}. Especially, nearly all ambiguities of {DEC, DEG} are correctly resolved.However, syntactic features are not helpful for ambiguities like {NN,NR} and {NN,JJ}. One common characteristic of these two pairs are that the two POS tags play similar roles from syntactic view. In other words, their syntactic contexts are usually similar, which naturally explains why the gold-standard syntactic features fail to help. In contrast, "NN" and "VV" (or "DEC" and "DEG") usually have completely different syntactic structures. This demonstrates that our proposed syntactic features are very effective.

Using automatic syntactic features still help resolve {NN, VV} and {DEC, DEG}. However, the error reduction is much less than that of using correct parse trees, which is obviously due to error propagation. Likewise, the errors over {NN, NR} and {NN,JJ} are not influenced.

5 Related Work

Recently, extensive research on Chinese POS tagging has been done. Tseng et al. (2005) enhance the tagging accuracy of unknown words by using rich morphological features. Huang et al. (2009) improve a bigram HMM POS tagger by latent annotation and self-training. Several methods are proposed to handle joint word segmentation and POS tagging of Chinese (Jiang et al., 2008; Zhang and Clark, 2008a; Kruengkrai et al., 2009).

The most closely related work to our approach is the one of Huang et al. (2007), which also explores syntactic features to boost the tagging accuracy. In stead of directly using syntactic features in a discriminative POS tagger, they adopt the RankBoost-based algorithm to rerank the N-best output of a sophisticated HMM tagger (Collins and Koo, 2005). As a discriminative model, the reranker can make use of rich features including morphological features, word/tag n-grams and syntactic features. Another difference from our work is that their syntactic tree is produced by the constituent parser of Charniak (2000) which jointly solves POS tagging and parsing. In this way, they might obtain higher-quality syntactic features since error propagation can be alleviated to some extent. Their reranking approach lead to an improvement of about 1% in tagging accuracy over the HMM tagger. In this paper, we propose another way to incorporate long-distance information for POS tagging. In another perspective, our approach may be more promising in real applications, since dependency parsing is simpler and potentially more efficient than constituent parsing.

6 Conclusions

In this paper, we show that the accuracy of a discriminative sequential POS tagger can be substantially improved by exploring syntactic features. We also show that the syntactic features can help resolve ambiguities like {NN,VV} and {DEC,DEG}, which are difficult to handle when only local contexts are considered. In the future, we will investigate joint POS tagging and dependency parsing models to further improve tagging accuracy.

Abstract

In this paper we explore the effect of self-training on Hindi dependency parsing. We consider a state-of-the-art Hindi dependency parser and apply self-training by using a large raw corpus. We consider two types of raw corpus, one from same domain as of training and testing data and the other from different domain. We also do an experiment, where we add small gold-standard data to the training set. Comparing these experiments, we show the impact of adding small, but gold-standard data to training data versus large, but automatically parsed data on Hindi parser.

1 Introduction

Parsing morphologically rich free-word-order languages like Czech, Hindi, Turkish, etc., is a challenging task. Unlike English, most of the parsers for such languages have adopted the dependency grammatical framework. It is well known that for these languages, dependency framework is better suited (Shieber, 1985; Mel'čuk, 1988, Bharati et al., 1995). Due to the availability of annotated corpora in recent years, data driven dependency parsing has achieved considerable success. In spite of availability of annotated treebanks, state-of-the-art parsers for these languages have not reached the performance obtained for English (Nivre et al., 2007a). Frequently stated reasons for low performance are small treebank size, complex linguistic phenomenon, long distance dependencies, and non-projective structures (Nivre et al., 2007a; Nivre et al., 2007b; Bharati et al., 2008).

In this paper, we try to address the problem of small treebank size. We have lots of unannotated data. One way to increase treebanks' size is to manually annotate this data. But it is very time consuming task. Other way is to automatically parse this data and consider highly reliable parses. But, what criteria should be used for extracting reliable parses is a really challenging task. In this paper, we explore a bootstrapping technique called self training and see its impact on dependency parsing accuracy. We consider a state-of-the-art Hindi dependency parser and analyze its performance using self-training. We consider two types of raw corpus, one from the same domain as of training and testing data and the other from a different domain. We also show the impact of adding small, but gold-standard data to training data versus large, but automatically parsed data on Hindi dependency parsing.

The paper is arranged as follows. In section 2, we describe the related work in this field. In section 3, we present the current state-of-the-art of Hindi dependency parser. Section 3, talks about different experiments conducted and presents the results. We conclude with possible future work in section 4.

2 Related Work

In this section, we briefly describe major works on bootstrapping using statistical parsers.

Steedman et al. (2003) did experiments to show that raw data can be used to improve the performance of statistical parsers by bootstrapping. Although their main focus was on co-training between two statistical parsers, they have also performed self-training for each parser but the results are not that promising with self-training. They have also done cross-genre experiments to show that co-training is beneficial even when the seed set was from a different domain compared to the raw data.

Reichart and Rappoport (2007) also perform similar cross-genre experiments to improve the quality of their parser and to adapt the parser to a different domain. They have also reported significant reduction in annotation cost and amount of work because only small amount of manually annotated seed data was used.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1452–1456,
Chiang Mai, Thailand, November 8 – 13, 2011.

McClosky et al. (2006) used a two phase parser-reranker system for self-training using readily available raw data. In their approach, instead of adding the raw data in steps, they have added the entire data in one go. They have reported significant improvement in accuracy over the previous state-of-the-art accuracy for Wall Street Journal parsing. They have also performed sentence length analysis to show that there is a general improvement in intermediate-length sentences, but no improvement at the extremes.

All the above mentioned works are on phrase structure parsing of English. There is an attempt at exploring usefulness of large raw corpus for dependency parsing by Chen et al. (2008). They could achieve considerable improvement over baseline for Chinese using only high confident edges instead of entire sentences. In our work the focus is dependency parsing of Hindi. We also explore how domain and quality of data affects the parser performance.

3 Hindi Dependency Parsing

In ICON 2009 and 2010, two tools contests were held that focused on Indian Language dependency parsing (Husain, 2009; Husain et al., 2010). In these contests, rule-based, constraint based, statistical and hybrid approaches were explored towards building dependency parsers for Hindi. In 2009 contest, given the gold standard chunk heads, the task was to find dependencies between them. But in 2010 contest, given words with gold features like part-of-speech (POS) and morph information, the task was to find word level dependency parse. Table 1, gives the basic statistics about the data.

Type	*Sentences*	*Words*	*Average Sentence Length*
Training	2,972	64632	22.69
Development	543	12617	23.28
Testing	320	6589	20.59

Table 1: Hindi ICON 2010 data statistics

3.1 Baseline (State-of-the-art) System

We consider the best system (Kosaraju et al., 2010) in ICON 2010 tools contest as the starting point. Kosaraju et al. (2010) used MaltParser (Nivre et al., 2007b) and achieved 94.5% Unlabeled Attachment Score (UAS) and 88.6% Labeled Attachment Score (LAS). They could achieve this using *liblinear* learner and *nivre-standard* parsing algorithm. But, as mentioned above, POS and other features used in this system were gold standard. The only available system which uses automatically extracted features and does complete word level parsing for Hindi is Ambati et al. (2010). Though both Ambati et al. (2010) and Kosaraju et al. (2010) used MaltParser, the data used is the subset of the one used by the latter and the parser settings were slightly different.

Taking training data and parser settings of Kosaraju et al. (2010) and automatic features similar to Ambati et al. (2010), we developed a parser and evaluated it on the ICON 2010 tools contest test data. We could achieve LAS of 77.9% and UAS of 86.5% on test set. This is the state-of-the-art system for Hindi dependency paring using automatic features. We consider this system as our baseline and try to explore self-training technique.

System	**UAS**	**LAS**	**LS**
1) Ambati et. al. (2010); automatic features	85.5%	75.4%	78.9%
2) Kosaraju et. al. (2010); gold features	94.5%	88.6%	90.0%
3) Kosaraju et. al. (2010) + automatic features	**86.5%**	**77.9%**	**81.7%**

Table 2: Comparison of different systems

4 Experiments and Analysis

We have modified the Malt parser used in baseline system so that it gives a confidence value for each arc-decision taken. We have taken the average confidence value for all the arcs in the sentence to be the confidence value of a sentence. This system was first trained on ICON 2010 tools contest training data for Hindi. The model generated was then used to parse the large raw corpus. The output sentences were then sorted in descending order based on their scores.

In the self-training experiments, in each iteration, we have added 1000 sentences from the sorted output generated above, to the training data and re-trained the parser. The resulting model was then used to parse the test data.

Hindi data released in ICON-2010 tools contest is a portion of large treebank (Bhatt et al., 2009), which is under development. This is a news corpus taken from well-known Hindi news daily. Self-training experiments were performed using two types of data: one from the same news domain (in-domain) and another from a different domain (out-of-domain).

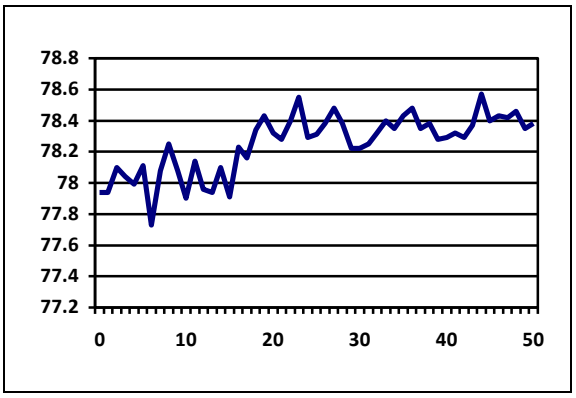

Figure 1a. Self training in-domain (LAS)

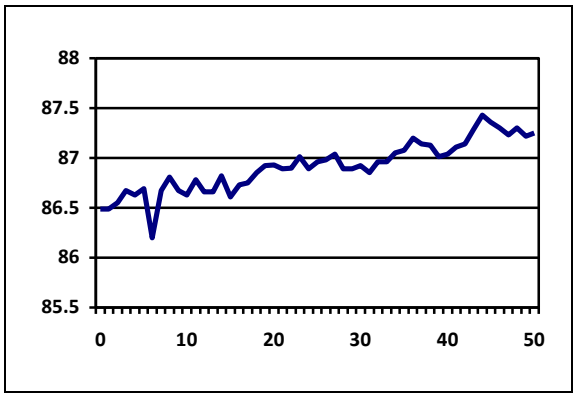

Figure 1b. Self training in-domain (UAS)

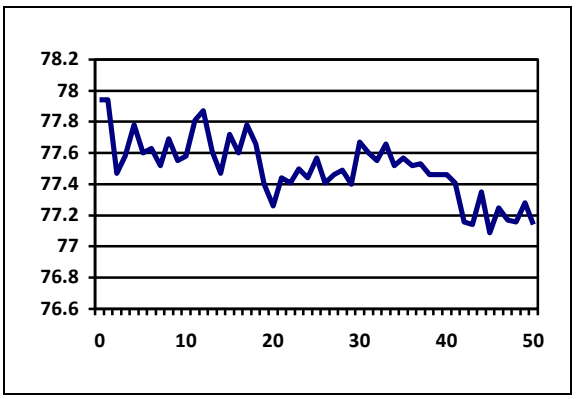

Figure 2a. Self training out-of-domain (LAS)

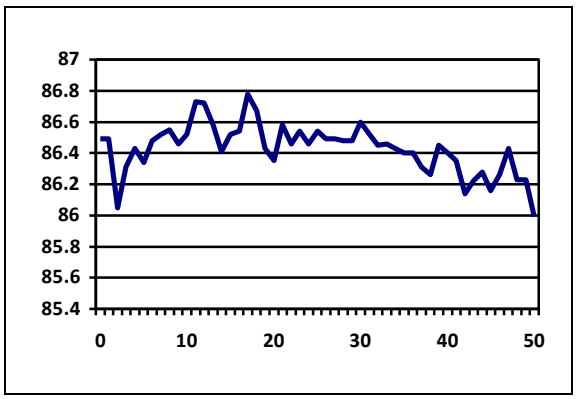

Figure 2b. Self training out-of-domain (UAS)

4.1 Self training: In-domain

We have taken raw news corpus of about 108,000 sentences. As a first step, we have cleaned the data. In this process, we removed the repeated sentences, and very large sentences (>100 words per sentence). Using the above mentioned approach of self-training, we added top 1000 sentences one by one to the training data. Performance of the resulting system on test data for the first 50 iterations is shown in Figures 1a and 1b. After 50 iterations, there was steady drop in the accuracy of the system. This could be because of less confidence values of the sentences after 50th iteration. As the confidence values are low, major arcs in these sentences might be wrong. As a result, these sentences were giving negative impact on the parser performance. There were slight fluctuations in the initial iteration and peeked at 23rd iteration. At this iteration, accuracy of 78.6% LAS and 86.9% UAS was achieved. With this data, we could achieve 0.7% and 0.4% improvement in LAS and UAS respectively over the baseline.

4.2 Self training: Out-of-domain

In this experiment, raw data of a domain different from the actual training, and testing data was used for self-training. For this purpose, we have taken raw non-news corpus of about 700,000 sentences. Major part of this data is from tourism domain. Similar to in-domain data, we first cleaned the data. Apart from repeated, and very large, there were a few non-Hindi sentences. We also removed them during the process of cleaning. Using the above mentioned approach of self-training (see section 4), we added top 1000 sentences one by one to the training data. Performance of the resulting system on test data for the first 50 iterations is shown in Figures 2a and 2b. After 50 iterations, there was sharp drop in the accuracy of the system. There isn't any improvement in LAS over the baseline. But in case of UAS after initial fluctuations, accuracy peeked at 17th iteration. At this iteration, accuracy of 77.8% LAS and 86.8% UAS was observed. We could achieve an improvement of 0.3% in UAS, but a decrement 0.1% in LAS.

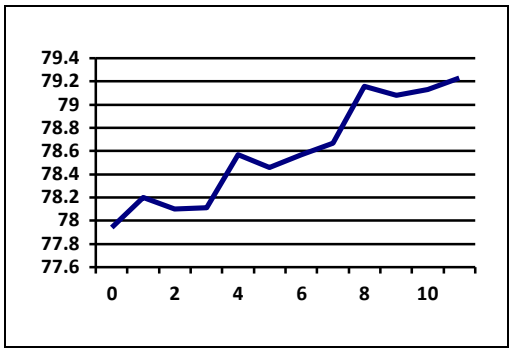

Figure 3a. Gold-standard data (LAS)

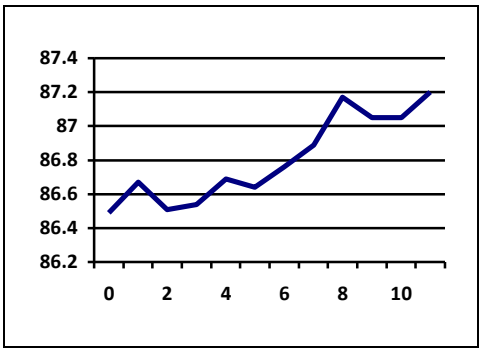

Figure 3b. Gold-standard data (UAS)

4.3 Gold-Standard Data

In the previous two experiments (sections 4.1 and 4.2), we have taken large amount of raw data from same and different domains and applied self-training technique. In both these experiments, impact of large automatically annotated data was observed. In this experiment, we shall observe the impact of small but, gold-standard data. We have taken the development data of ICON 2010 tools contest. We have divided the data into sets of 50 sentences and added one by one similar to above experiments. We could achieve the accuracy of 79.2% LAS and 87.2% UAS at the final iteration. With this gold standard data, we could achieve an improvement of 0.7% in UAS and 1.3% in LAS.

4.4 Analysis

Table 3, gives the summary comparing all the experiments performed. "*" mark in the table shows that, accuracy is statistically significant over the baseline. Significance is calculated using McNemar's test ($p <= 0.05$) made available with MaltEval (Nilsson and Nivre, 2008).

System	UAS	LAS	LS
1) Baseline System	86.5%	77.9%	81.7%
2) In-domain self-training	87.0%*	78.6%*	82.3%*
3) Out-of-domain self-training	86.8%	77.8%	81.6%
4) Gold-Standard Data	**87.2%***	**79.2%***	**82.9%***

Table 2. Summary of Experiments.

We could achieve significant improvement in the accuracy when the raw data is from the same domain. But, when the data is from different domain, we haven't seen any significant increase in the performance. This clearly shows the importance of domain of the training data. One can get better accuracies when training data is similar to testing data. As expected, adding gold-standard data outperformed both the self-training experiments. Our experiments show that gold-standard data is the best solution for improving the parser performance. When this is not possible, raw data from same domain seems to be a better option.

Interesting observation is that even when gold data is being added, there isn't steady increase. Slight drop was observed when some sentences are added. This clearly shows that nature of the sentences being added to training data is very important. Currently, criterion being used to extract reliable sentences from automatically parsed ones is average confidence score given by the parser. We are considering all the nodes in the sentences for calculating confidence score of sentence. It was shown by Ambati et al. (2010) that accuracy for intra-chunk dependencies is pretty high and that of inter-chunk dependencies is low. We can explore considering sentences with high confidence scores for inter-chunk nodes, rather than average score considering all the nodes. We can also explore considering only high confidence nodes rather than entire sentence, similar to works of Chen et al. (2008) and Mannem and Dara (2011).

5 Conclusions and Future Work

We explored the effect of self-training on Hindi dependency parsing. We showed the impact of adding small, but gold-standard data to training data versus large, but automatically parsed data on Hindi dependency parsing.

We are planning to explore the importance of co-training technique also using another parser like MSTParser, as the parser can learn new information in case of co-training. We did experiments on Hindi. There are several other languages like Telugu, Bangla etc. for which annotated data is less but large amount of raw corpus is available. We are also planning to explore the importance of self-training and co-training techniques for parsing these languages.

Reduction of Search Space to Annotate Monolingual Corpora

Prajol Shrestha **Christine Jacquin** **Beatrice Daille**

{prajol.shrestha;christine.jacquin;beatrice.daille}@univ-nantes.fr

Abstract

Monolingual corpora which are aligned with similar text segments (paragraphs, sentences, etc.) are used to build and test a wide range of natural language processing applications. The drawback wanting to use them is the lack of publicly available annotated corpora which obligates people to make one themselves. The annotation process is a time consuming and costly task. This paper describes a new corpus-based measure to significantly reduce the search space for a faster and easier manual annotation process for monolingual corpora. This measure can be used in making alignments on different types of text segments. The performance of this measure is evaluated on a manually annotated paragraph corpus, whose alignments are freely available, with promising results.

1 Introduction

In the field of Natural Language Processing (NLP), annotated monolingual corpora are used to build and test a wide range of applications such as information retrieval, summarization, plagiarism detection, dictionary building and so on. With a number of applications to be built, the field of NLP requires a wide range of monolingual corpus with different annotations on different level of text segments. Our focus is on the fast and easy way of aligning short text segments based on similarity. These annotations are usually done manually by annotators as done by Hatzivassiloglou et al. (1999) where a corpus with alignments between similar short texts are created by two or more annotators who look at each possible short text pair independently and analyse them to make a decision on whether each pair should be aligned as similar or not. Finally, the annotators discuss the disagreements between their annotations and come to an agreement with reasoning. A corpus containing n number of short texts will generate $\frac{n(n-1)}{2}$ number of short text pairs for comparing similarities which becomes a tedious and time consuming task even if a corpus contains a few hundred of short texts. For example, the corpus we use consists of 239 paragraphs, explained in section 3.1, generating a total of 28,441 text pairs to compare.

There are few publicly available annotated corpus, some are manually annotated like the TDT corpus[1] for topic detection and tracking and the METER corpus (Gaizauskas et al., 2001) for detection of text reuse and some are automatically annotated like the PAN-PC-10 (Barrón-Cedeño et al., 2010) for plagiarism detection and the MSRPC (Dolan and Brockett, 2005) for paraphrase detection. Annotating a corpus automatically is easier and faster than manual annotation but they have a major limitation which allows the corpus to include only a subset of the problem which prevents the corpus to represent many of the naturally occurring instances. This limitation in turn might cause some incompleteness issues on the applications built on it as mentioned by Barrón-Cedeño et al. (2010) and Dolan and Brockett (2005). To reduce this effect of coverage in a corpus, annotations on corpus are done manually.

We propose manual annotation to be done in two phases. At first, the number of pairs to compare are reduced and then manual annotation is done. We present a corpus-based measure to automatically reduce the search space for manual annotation making the annotation process faster and easier. We evaluate this measure using a manually annotated paragraph corpus[2], created by reducing the search space manually.

2 Search Space Reduction

In this section, we show how we reduce the search space manually to find similar short texts (e.g. thematic segments, paragraphs, sentences) and present a measure to automatize this manual process. Similarity is a vague concept and its definition depends on the application for which it is intended. The most general intuition of similarity is that, two short texts are similar if they have something in common (Lin, 1998). This intuition includes paraphrases, reused text, plagiarized text and so on as similar texts. Each application specifies what commonality is required to call it similar and we believe our reduction of search space will be useful for all the application based on this general intuition of similarity. This reduction of search space is the first phase towards manual annotation. This phase produces *candidate* similar pairs which is a subset of the total short text pairs within which all the actual similar pairs are present. The number of candidate similar pairs will be less than the total number of short text pairs which allows many annotators in the second phase to efficiently annotate the small set of text pairs manually in less human hours.

The manual reduction of search space is done by going through all the possible short text pairs and selecting the candidate similar pairs using a criteria which states that: each short text in a candidate similar pair consists at least one common entity (Shrestha, 2011a). This criteria for selection theoretically guarantees that all the actual similar pairs will be present in the candidate similar pairs because for two short texts to be similar they must have at least one entity in common. The entities that we use are noun, noun phrase, and transitive verb (Loberger and Shoup, 2009). Two entities are said to be common when they both have the same meaning or in other words share the same concept for example, the entities 'crashed', 'rammed into a wall', 'fatal impact' can all be mapped to the concept 'crashed' and the entities 'Prince Charles', 'heir to the British throne' can be mapped to the concept 'Prince Charles'. The context within the short text also helps to identify the concept that the entity represents.

The selection of candidate similar pairs is easier and faster because the analysis of the pairs is not required unlike when selecting actual similar pairs. This manual reduction is used while building the paragraph corpus for evaluation. As this phase is done manually, the annotator can remove a selected candidate similar pair if a decision of it not being useful can be taken easily and without any doubt to further reduce the search space.

2.1 Short text Vector Space Measure (SVSM)

We present a corpus-based measure called Short text Vector Space Measure (SVSM) (Shrestha, 2011b) based on Vector Space Model (VSM) (Salton et al., 1975) to reduce the search space. SVSM assigns a value to each text pair and text pairs having a value greater than a threshold is considered as candidate similar pairs. For simplicity reasons, we explain the method using sentences. For each sentence a sentence vector is created from term vectors. Given a corpus C of n sentences and m unique terms, the term vector, $\vec{t_j}$, for term t_j is a vector created with n number of possible dimensions where each dimension represents a unique sentence. The presence of the term in a sentence is indicated by its sentence id and the term's inverse document frequency, idf, here a document is a sentence, as shown below:

$$\vec{t_j} = [(S_1, idf_j), (S_5, idf_j), ..., (S_i, idf_j)]$$

where S_i is the sentence id where the term t_j is present, $i \in 1, .., n$ and idf_j is the idf value of term t_j. This term vector is a reduced vector space representation where sentences that do not contain the term is absent which saves space. The dimension of the matrix formed by term vectors can be further reduced using Latent Semantic Analysis (Deerwester et al., 1990) or Principle Component Analysis (Jolliffe, 1986) but are not used here. Once we have the term vectors we can create sentence vectors by adding the term vectors of the terms present in that sentence. For a sentence consisting of terms $t_1, t_2, .., t_k$, the dimension, d_i, of the sentence vector corresponding to the sentence S_i will be:

$$d_i = \Sigma_{j=1;t_j \in S_i}^{k} idf_j$$

where idf_j is the idf value of the term j and $i \in 1, .., n$. This term vector shows the different senses that the term may have. Here, the sense of the term means the idea with which it can be related to. Our assumption is that sentences are independent to each other making each sentence presenting a unique idea and therefore, each term present in a sentence is related to this idea. This assumption like the assumption of VSM (Wong et al., 1987) is unrealistic but the effect of this assumption can

-William and Harry, with their father Prince Charles and their grandmother Queen Elizabeth, are thought likely to remain in seclusion at Balmoral Castle in Scotland until Saturday's ceremony. -The royal family remained at Balmoral in Scotland Tuesday, with reports that Charles and his younger son Prince Harry went for a walk in the afternoon. It was not clear when they would return to London.
-Dodi Al Fayed's father, Harrods Department Store owner Mohammed Al Fayed, arrived here immediately after learning of his son's death. -Bernard Dartevelle, a lawyer for Mohamed Al Fayed, Dodi Fayed's wealthy businessman father and also the owner of the Hotel Ritz, said the revelation "changes absolutely nothing." He spoke of an "ambience of harassment" created around Diana and Fayed by the constant presence of paparazzi.

Table 1: Examples of similar and dissimilar paragraph pairs. The first block consists of a similar paragraph pair whereas the second block consists of a dissimilar paragraph pair.

be reduced using clustering techniques like hierarchical clustering (Han and Kamber, 2006) to group sentences that give the same idea or in other words similar sentences.

This method is similar to the method of Kaufmann (2000) using lexical cohesion but includes more information which are i) the importance of each term using its idf; ii) the co-occurrence of terms by adding up the idf value in term vectors while creating sentence vectors; and iii) the distribution of term along various sentences as the dimensions of the sentence vector is equal to the number of sentences present in the corpus. Using these sentence vectors we can now compute the similarity value between two sentences using the cosine similarity measure (Barron-Cedeno et al., 2009). In this method, other types of short text can be used in place of sentences.

3 Experiments and Results

3.1 Corpus

The corpus used for experiments was made from 12 articles on the same topic, the death of Diana, from the Linguistic Data Consortium's (LDC) North American News Text Corpus (LDC Catalog number: LDC95T21). The articles contain newswire text from three different news services which were published within two consecutive days. The articles contained 239 paragraphs, each of which contains more than 10 non stopwords, which produces 28,441 paragraph pairs for comparisons.

3.2 Manual Alignment

We have manually aligned 28,441 paragraph pairs from the corpus based on similarity. The alignment was done in two phases as explained in section 1. The first phase was performed by one annotator who selected 3,418 candidate similar paragraph pairs from a total of 28,441 paragraph pairs which took about 71 hours of work.

The second phase was done manually by two annotators who independently selected similar pairs from the candidate pairs. The similarity definition given to the annotators is an intuitive definition which states that two paragraphs are similar if one of the main information that the paragraph conveys is common. This definition is slightly different from the definition given by Shrestha (2011a) based on sub-topics. There exist few definitions on text similarity but they are all specific to the size of the text segment (Barzilay, 2003) or entities within the sentences (Hatzivassiloglou and Klavans, 2001) which make them unsuitable for a general text similarity definition. In Table 1, we present a positive and a negative example to further explain the definition. The first block presents a positive example whose main information in common is that the royal family will remain at Balmoral Castle. The paragraph pair in the second block is not similar even though the information about Dodi's father is a businessman is common because the main information conveyed by the paragraphs is different. We used kappa statistics (Carletta, 1996; Cohen, 1960) to evaluate the annotations made by the annotators in the second phase. Kappa statistics is defined as $k = \frac{P_A - P_E}{1 - P_E}$ where, in our case P_A=0.959, which is the probability of two annotators agreeing in practice and P_E=0.918, which is the expected probability of the two annotators agreeing, and k=0.5, indicating a moderate agreement (Artstein and Poesio, 2008). The error between the annotators is about 5% due to the intuitive definition of similarity. The annotators jointly resolved annotation disagreements between them by reasoning.

The second phase produced 144 similar paragraph pairs and took about 20 hours for both annotators. The total time that took to annotate the corpus manually was about 91 hours. If we had directly tried to find the actual similar paragraph

Table 2: Rec. (Recall) and Retri. (Retrieved pairs) of methods CS, SVSM, and stem overlap according to T (Threshold).

pairs without phase one, with an assumption that the time taken per paragraph pair (≈21 sec) is the same as in the second phase, it would take about 166 hours. The total time saved is 75 hours of work.

3.3 Automatic Selection of Candidate Pairs

The manual alignment method is still time consuming and difficult as manual effort has to be done. SVSM, presented in section 2.1, is used to reduce the search space for annotators. Its performance is compared with stem overlap (Overlap) and cosine similarity measure (CS) with TF*IDF as weights (Salton and McGill, 1983). For each method, stop-words were removed and the remaining words were stemmed using the snowball stemmer[3]. We decide a paragraph pair is a candidate similar pair if the value given by a method exceeds a threshold. Table 2 shows the performance based on recall compared to the manually selected actual similar pairs of section 3.2 and the number of retrieved paragraph pairs by each method on the total paragraph pairs at different thresholds.

If we look at the table, the best result with 100% Recall is given by CS and Overlap methods with 15,415 retrieved pairs but still this is a large number. Using automatic methods, we would like to optimize our threshold so that we can reduce the retrieved paragraph pairs as much as possible without losing much of the actual similar paragraph pairs. According to the optimization issue SVSM is the best among the three methods at threshold 0.3 with 3009 retrieved paragraph pairs almost equal to the manually selected candidate pairs and with a recall of 93.06%. Another property we would like in a method for automatic reduction of search space is the slow rate of decrease in recall making sure with a small variation of threshold the recall will not have a drastic change. The rate of decrease in recall is shown in Figure 1 where four highest varying recall are plotted for each method. These values are boldfaced in Table 2. From Figure 1 we can see that SVSM is the method that has the most gradual decrease in recall making it the most suitable method for automatic reduction of search space. CS on the other hand is the least suitable with a sharp decrease in recall showing that similarity measures based only on term overlap is not suitable to find similar short text as discussed by Abdalgader (2011). Using this method at the threshold 0.3 we can reduce the time for manual annotation to about 17.5 hours (3009x21) with a loss of about 10 similar paragraph pairs only.

[3]http://snowball.tartarus.org/

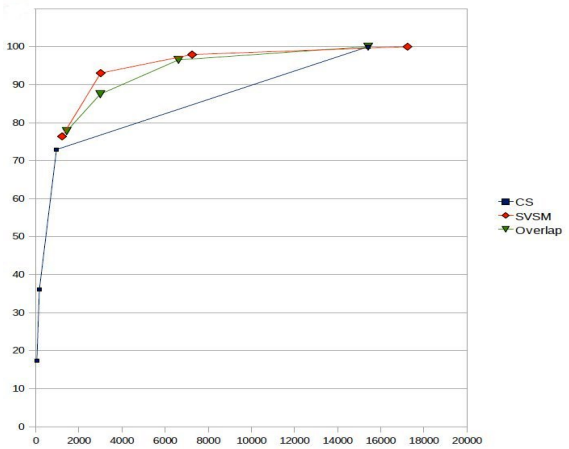

Figure 1: The rate of decrease in recall as the retrieved paragraph decreases.

4 Conclusion and Future Work

We present an automatic method using SVSM to reduce the total number of paragraph pairs from which actual similar paragraph pairs are manually selected. Using the manual method we reduced the 28,441 total paragraph comparisons to only 3,418 paragraph comparisons from which 144 paragraph pairs were aligned as similar. This shows that 99.5% of the effort in selecting the similar paragraph is wasted in terms of the difference between the end number of aligned paragraph pairs and the total initial pairs. Using the manual method we were able to save 75 hours of human work which can be further increased to 148.5 hours by using the automatic method in expense of few similar pairs. In future, the reliability of the threshold will be tested on other corpus and the present manually annotated corpus will be populated with more manually selected similar paragraph pairs using the automatic method.

Toward a Parallel Corpus of Spoken Cantonese and Written Chinese

John Lee
The Halliday Centre for Intelligent Applications of Language Studies
Department of Chinese, Translation and Linguistics
City University of Hong Kong
jsylee@cityu.edu.hk

Abstract

We introduce a parallel corpus of spoken Cantonese and written Chinese. This sentence-aligned corpus consists of transcriptions of Cantonese spoken in television programs in Hong Kong, and their corresponding Chinese (Mandarin) subtitles. Preliminary evaluation shows that the corpus reflects known syntactic differences between Cantonese and Mandarin, facilitates quantitative analyses on these differences, and already reveals some phenomena not yet discussed in the literature.

1 Introduction

While standard Chinese, also known as Mandarin or Putonghua, is served by an ever-expanding set of linguistic resources[1], its various dialects have received relatively little attention. The use of these Chinese dialects, however, is as widespread as many other national languages. For example, Cantonese is spoken by more than 52 million people, mostly in southern China and overseas Chinese communities.

Although considered the "most widely known and influential variety of Chinese other than Mandarin" (Matthews & Yip, 1994), Cantonese currently has rather limited linguistic resources. This paucity may be due to its unofficial status, as opposed to Mandarin, which is the official language of China. Furthermore, as a primarily spoken language, it does not traditionally have any standard written form. This paper presents the first parallel corpus of transcribed Cantonese speech and its equivalent written Mandarin. The corpus is expected to be useful for language learners, linguists and developers of natural language processing applications.

The corpus provides students with authentic, parallel examples of sentences in both languages, which are not mutually intelligible. Native speakers of Cantonese must learn Mandarin for use in writing and official communication; conversely, many Mandarin speakers living in Hong Kong also want to learn Cantonese.

The corpus also serves as a repository for linguistic research. In particular, it facilitates research in comparative grammar, by lending statistical evidence, and potentially demonstrating exceptions or other differences yet unnoticed.

Finally, it can be exploited as training material for natural language processing systems, such as cross-lingual spoken document retrieval (Meng & Hui, 2001), and especially machine translation (MT) systems. For example, MT systems may be trained to automatically generate Chinese subtitles for Cantonese television programs, as has been done for Scandinavian languages (Volk et al., 2010).

2 Previous Work

Cantonese grammar has been well studied (Matthews & Yip, 1994; Cheung, 2007), and a few monolingual corpora for Cantonese have been compiled (Lee & Wong, 1998; Leung & Law, 2001; Wong, 2006). While the present corpus may also be used simply as Cantonese data, its primary contribution is as parallel data between Cantonese and Mandarin.

The main difference between Cantonese and Mandarin is in phonology and vocabulary; indeed, various bilingual dictionaries and lexical comparisons are already available (Zhang & Yang, 2008). In terms of syntax, although the "grammatical structure is similar in most major respects", the differences are not insignificant (Ouyang, 1993). So far, there have been few

[1] For example, (Chen et al., 1996), (Xue et al., 2005), and (Tsou & Kwong, 2006), among many others

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 1462–1466,
Chiang Mai, Thailand, November 8 – 13, 2011.

studies on direct comparisons between the grammars of Cantonese and Mandarin (Ouyang 1993; Liang 1996), none of which was conducted on a large-scale, empirical methodology using naturally occurring Cantonese speech. This corpus is intended to lay the foundation for this direction of research.

3 Corpus

We motivate the design principles of the corpus (section 3.1), then describe how the corpus was constructed and processed (section 3.2).

3.1 Choice of material

The material of the corpus comes from television programs, including news and dramas, broadcast on a Cantonese channel in Hong Kong (see Table 1). All have Mandarin subtitles, which we aligned to the transcription of the Cantonese that was simultaneously spoken. The corpus contains 4,135 pairs of such "sentences", with a total of 36,775 characters in Mandarin, and 39,192 in Cantonese.

The choice of these sources of material follows considerations on two main issues: register variations, and speech and translation quality. Cantonese has a wide range of registers, from formal to colloquial. The formal register closely resembles Mandarin, and diverges significantly from the colloquial; this divergence is in fact a topic of active research in its own right. For any contrastive studies between Cantonese and Mandarin, a corpus balanced between formal and colloquial registers would be desirable. Thus, the TV drama provides the colloquial register; the news program contributes mostly to the formal register with the speeches of the anchor and reporters, but also some colloquial register with those of the spontaneous interviewees.

With the exception of these spontaneous interviews, all materials consist of pre-planned speech. They are thus largely free of false starts, sentence fragments, repairs, repetitions and other errors, which would have led to a considerable amount of spurious word alignments. This is an important advantage, as the parallel corpus will be used for word-level comparative studies.

The Mandarin subtitles, professionally translated, are in general of high quality. However, they are sometimes condensed, likely due to constraints posed by speech timing and screen size (Prokopidis, 2008).

3.2 Corpus construction

The Mandarin side of the corpus comes from subtitles, which consist of characters only; in contrast, the Cantonese side mixes orthographic transcriptions (characters) with a small number of phonetic transcriptions and English. Phonetic transcriptions, conforming to the Jyutping standard, are used when the Cantonese morpheme does not traditionally correspond to any standard Chinese characters. Code-mixing between English and Cantonese is not infrequent, and the English words are preserved in these cases.

Sentence-final particles in Cantonese, such as 啦 *la*, present a challenge for orthographic transcription. "Many of the particles differ only in tone and in nuance of meaning. Given that there is little uniformity of representation in relation to these particles", they are written as the same form in (Leung & Law, 2001). We also follow this practice.

The metadata records both the name and the category of the speaker. Speakers in the drama are always assigned as the "Character" category; those in the news are assigned one of four, namely "Anchor", "Reporter", "Live Reporter", or "Interviewee". "Anchor" and "Reporter" are considered to belong to the formal register, and all others, to the colloquial. Overall, about 60% of the corpus belongs to the colloquial.

Automatic word segmentation was performed on the Mandarin sentences (Chang et al., 2008). A subset of these words was then manually aligned to their Cantonese counterparts to facilitate a preliminary investigation, which will be reported in the next section.

TV Program	Size
六點半新聞報道 "TVB News at Six-Thirty" (2011)	*Time*: 5 episodes x 20 min *Length (chars)*: 19,069 Mandarin; 20,900 Cantonese
溏心風暴之家好月圓 "Moonlight Resonance" (2008)	*Time*: 2 episodes x 45 min *Length (chars)*: 17,706 Mandarin; 18,292 Cantonese

Table 1. The source material of the corpus comes from two TV programs, news (top) and drama (bottom).

4 Evaluation

The usefulness of the corpus may be gauged in two ways. First, it should reflect known differences between Mandarin and Cantonese (section

4.1), and those between formal and colloquial registers in Cantonese (section 4.2). Secondly, it should not only corroborate, but also contribute new information to previous studies. For this second goal, we give examples in three specific areas, namely the plural marker for personal nouns (section 4.3), agentless passives (section 4.4), and possessive constructions (section 4.5). In what follows, 'CL' refers to "classifier" and "PL" to "plural".

4.1 Coverage of Grammatical Differences

One of the most detailed comparative study between Mandarin and Cantonese to-date is (Ouyang, 1993), which lists 18 major differences. Table 2 lists some of these[2].

To investigate the degree to which the corpus exhibits known grammatical differences the two languages, we search for examples for each of the 18 differences in the corpus. Out of these 18 differences, 15 are found. The three differences for which no examples exist are the following. The first is concerned with word order involving the gender marker of animals. For example, The marker *gong* precedes the animal in Mandarin 公鷄 *gong ji* 'rooster', but its Cantonese equivalent *gung* follows the animal, as in 鷄公 *gai gung* 'rooster'. The second deals with word order in a negated resultative verb when the direct object is a personal pronoun. In Mandarin, the pronoun is always placed after the two-character verb, but in Cantonese it may be placed between as an infix. For example, 我 *ngo* 'I' is placed between the resultative verb 打贏 *daa-jeng* 'beat' in the sentence 你打我唔贏 'you did not beat me'. Finally, the third is the use of 過 *gwo* as a dative marker in Cantonese verbs of giving, e.g., 話過你知 'tell *gwo* you know' "tell you". This marker is normally omitted in contemporary Cantonese spoken in Hong Kong.

In summary, the corpus reflects well the known grammatical differences between the two languages as set out in (Ouyang, 1993). Two of the missing differences deal with rather specific constructions, and the third is no longer valid for the Hong Kong variety of the language.

Modal verbs: verbs such as 能 *neng* is used in Mandarin, vs. the 得 *dak* construction in Cantonese
能 忍耐 就真的 不是 人 了 忍 **得** 嗰個都 唔係 人 嚟㗎 'can' 'tolerate' 'can' 'not' 'man' 'No man can tolerate [that]'
Plural marker of personal nouns: Suffix 們 *men* for Mandarin, prefix 啲 *di* for Cantonese
你要 照顧 **弟妹 們** 你要 睇住 **啲 細** 㗎 'you should' 'take care' PL 'young' PL 'You should take care of your younger siblings'
Double objects: different word orders
那 你 **給 我 一個地址** 咁一係 你 **俾 個地址 我** 呀 'you' 'give' 'me' 'address' 'me' 'Please give me an address'
Predicative adjectives: the adjective may be placed in front of the topic in Cantonese
她 **年紀 這麼大** 演秦香蓮? 佢 **咁大 年紀** 演秦香蓮呀? 'she' 'so big' 'age' 'so big' 'She is so old, can she still play Chin Xianglian?'
Comparison of quantities: the adjective 多 *do* is placed after the verb in Cantonese
多 補 半天假 **補 多** 半日假 'more' 'compensate' 'more' 'half-day holiday' 'compensate for another half-day holiday'
Comparison of adjectives: different word orders
保管得 **比** 你的容貌 還 **好** keep 得 **好 過** 你個樣喎 'keep' 'good' 'compare' 'your face' 'more' 'good' 'keep [one's face] in better conditions'
Use of Numerals: Certain numerals can be omitted in Cantonese in large numbers
我 出夠 **一 萬 五 千** 我 出夠 **萬 五** 'I' 'pay' 'one' '10000' '5' 'thousand' 'I pay 15000'

Table 2. Grammatical differences between Cantonese and Mandarin listed in (Ouyang, 1993). In the example sentences, Mandarin is placed on top and Cantonese at the bottom, with their words roughly aligned. A total of 18 differences are discussed in (Ouyang, 1993); please see footnote 2 for the rest.

[2] For lack of space, we describe here briefly the other differences, and refer the interested reader to (Ouyang, 1993). They include: the lack of distinction in Cantonese between inclusive and exclusive "we"; the use of the *dak* construction with 有 you 'have', and in the negated resultative verbs, both impossible in Mandarin; the use of 去 *heoi* 'go' in Cantonese without a preceding 到 *dou* 'arrive', as in Mandarin; the reduplication of verbs and adjectives in yes/no questions; and finally, the distinctive use of a number of particles in Cantonese, including the assertive particles 嚟㗎 *lai-gaa* in copular sentences; the delimitative particle 吓 *haa*, and the verbal particle 過 *gwo* for repetition.

4.2 Coverage of Register Differences

It has been observed that "almost any Mandarin grammatical pattern can be used in Cantonese and be understood, but such locutions are often not idiomatic" (Ramsey, 1987), and in general formal Cantonese is closer to Mandarin. These remarks are corroborated by our corpus. In the formal portion of the corpus, 30% of the Cantonese sentences are identical to the Mandarin; whereas in the colloquial portion, only 4% are.

Modality also highlights the differences in registers. To express modality, Mandarin typically uses modal verbs such as 可以 *ke-yi* or 能夠 *neng-gou* 'may'. While Cantonese has its equivalents *ho-ji* and *nang-gau*, in many contexts it is more idiomatic to employ syntactic constructions with 得 *dak* and 到 *dou*. The former indicates potential, and can mean possibility or permission; the latter is a verbal particle. Both can also be used in Mandarin, but much less frequently.

A comparison between the formal and colloquial registers again confirms their known differences (Matthews & Yip, 1994) and provides some quantitative evidence. In the colloquial register, there were 88 instances of *ke-yi* and *neng-gou* and their respective abbreviated forms; 27% of these instances were spoken in Cantonese with the *dak* or *dou* construction. In contrast, in the 23 instances of the same modal words in the formal register, neither *dak* nor *dou* appear.

4.3 Plural marker for personal nouns

Although not mentioned in the list of (Ouyang, 1993), it is well known that Mandarin uses the suffix 們 *men* to mark personal nouns as plural, while Cantonese has the analogous suffix 哋 *dei* for personal pronouns, and the classifier 啲 *di* for other nouns (Matthew & Yip, 1994). Our corpus shows, however, two additional details.

First, the Cantonese suffix may be omitted. For example, in the noun phrase 你兩個 *nei loeng go* 'you two CL', the suffix *dei* is expected to mark 'you' as plural but is missing. These omissions all occur in the colloquial register.

Second, besides *dei* and *di*, the classifier 班 *baan* 'group' can also serve as the plural marker. For example, 孩子們 *hai-zi-men* 'child PL' 'children' is equivalent to 班細路 *baan-sai-lou* 'group child' 'children'. These also were observed exclusively in the colloquial register. This classifier is also used for the vocative case. In Mandarin, *men* is used in vocative plural, but the Cantonese *di* itself will not do. Instead, both the plural 'you' and *baan* are prefixed before the personal noun, as in 你哋班師奶 *nei dei baan si naai* 'you PL group wife' 'O you wives'.

4.4 Agentless passive

Both Cantonese and Mandarin mark passives with the word 被 bei, followed by the agent. If the agent unknown, it can be simply dropped in Mandarin, but in Cantonese the "generic" agent 人 *jan* 'person' must still be supplied.

Of the 16 sentences with passives, 9 are agentless in Mandarin. As for their Cantonese counterparts, 7 conform to the normal practice using *jan*, but the other two are agentless. These latter may be considered a form of "Mandarinism", i.e., usage that is not ungrammatical, but atypical of Cantonese speech. As expected, one of these occurs in the formal portion of the corpus; the other, in the colloquial, turns out to be a read speech in the drama.

4.5 Possessive constructions

Mandarin uses the possessive marker 的 *de*, whose Cantonese counterpart is 嘅 *ge*. In Cantonese, the marker may be omitted when expressing kinship or a "close" and "inalienable" link (Matthews & Yip, 1994; Pacioni 1998), as in 佢哋老豆 *keoi-dei lou-dau* 'they father' 'their father', without *ge* in between 'they' and 'father'.

The corpus shows, on the one hand, that this phenomenon extends to other nouns such as 佢心願 *sam jyun* 'wish'. On the other hand, for some expressions of kinship, the marker is not simply omitted but replaced by a classifier, such as 我個仔 *ngo-go-zai* 'I CL son' 'my son'. The number of syllables may be a determining factor.

5 Conclusion

We have presented the first large-scale parallel corpus of transcribed spoken Cantonese and written Chinese. Have shown its coverage of grammatical differences between the two languages, and its potential in corroborating and adding to known issues, we plan to further exploit it for quantitative studies in comparative grammars.

Abstract

The limitations of keyword-only approaches to information retrieval were recognized since the early days, specially in cases where different but closely-related words are used in the query and the relevant document. Query expansion techniques like pseudo-relevance feedback rely on the target document set in order to bridge the gap between those words, but they might suffer from topic drift. This paper explores the use of knowledge-based semantic relatedness in order to bridge the gap between query and documents. We performed query expansion, with positive effects over some language modeling baselines.

1 Introduction

The potential pitfalls of keyword retrieval have been noted since the earliest days of Information Retrieval (IR). Keyword retrieval proves ineffective when different but closely-related words are used in the query and the relevant document. The use of different words creates a lexical gap between the query and the document.

In order to bridge the gap, IR has resorted to distributional semantic models. Most research concentrated on Query Expansion (QE) methods, which typically analyze term co-occurrence statistics in the corpus and/or in the highest scored documents in order to select terms for expanding the query terms (Manning et al., 2009). The work presented here is complementary, in that we explore QE, but we use an approach based on semantic relatedness instead of distributional methods.

In a closely related work, (Agirre et al., 2010) proposed a WordNet-based document expansion method using random walks: given a document, a random walk algorithm over the WordNet graph, inspired in (Agirre et al., 2009b), ranks concepts closely related to the words in the document. Note that the method can return concepts which are not explicitly mentioned in the document. The highest ranking concepts were then selected to expand the document.

In this work, we explore an alternative method to exploit relatedness, query expansion, so we thus run the relatedness algorithm over the queries and we expand the queries. We adopt a language modeling framework to implement the query likelihood and pseudo-relevance feedback baselines, as well as our relatedness-based query expansion method.

In order to test the performance of our method we selected several datasets with different domains, topic typologies and document lengths. Given the relevance among the community using WordNet-related methods, we selected the Robust-WSD dataset from CLEF (Agirre et al., 2009a), which is a typical ad-hoc dataset on news. As we think that our method is specially relevant for short queries and/or short documents, we also selected the Yahoo! Answers dataset, which contains questions and answers as phrased by real users on diverse topics (Surdeanu et al., 2008), and ResPubliQA, a paragraph retrieval task on European Union laws organized at CLEF (Peñas et al., 2009).

The results show that our method provide improvements in all three datasets, when compared to the query likelihood baseline, and that they compare favorably to pseudo-relevance feedback in two datasets.

The paper is structured as follows. We first briefly introduce related work. We then mention the random walk model for query expansion. The design of the experiments is presented in Section 4. Section 5 shows our results, and, finally, Section 6 presents the conclusions.

2 Related Work

Query expansion methods analyze user query terms and incorporate related terms automatically (Voorhees, 1994). They are usually divided into local and global methods.

Local methods adjust a query relative to the documents that initially appear to match the query (Manning et al., 2009). Pseudo-relevance Feedback (PRF) is one of the most widely used expansion methods (Rocchio, 1971; Xu and Croft, 1996). This method assumes top-ranked documents to be relevant (and sometimes, also that low-ranked documents are irrelevant), and selects additional query terms from the top-ranked documents.

Global methods are techniques for expanding query terms without checking the results returned by the query. These methods analyze term co-occurrence statistics in the entire corpus or use external knowledge sources to select terms for expansion (Manning et al., 2009). For example, techniques using Word Sense Disambiguation (WSD) techniques and synonyms from WordNet have been used for query expansion with some success (Voorhees, 1994; Liu et al., 2005).

The query expansion method proposed in this paper is a global expansion technique based on WordNet, but in contrast to the previous work based on WordNet, it does not perform WSD and adds related words beyond synonyms.

(Agirre et al., 2010) is the work which is closest to ours. They use the same WordNet-based relatedness method in order to expand documents, following the BM25 probabilistic method for IR, obtaining some improvements, specially when parameters had not been optimized. In contrast to their work, we investigate methods to apply relatedness to query expansion, and we compare the results with pseudo-relevance feedback. Besides, we found that a language modeling (Ponte and Croft, 1998) approach to IR combined with inference networks (Turtle and Croft, 1991) offered more flexibility for query expansion.

Our work stems from the use of random walks over the WordNet graph to compute the relatedness between pairs of words (Hughes and Ramage, 2007). In this work a single word was input to the random walk algorithm, obtaining the probability distribution over all WordNet synsets. The similarity of two words was computed as the similarity of the distributions of each word. In later work, (Agirre et al., 2009b) tested different configurations of the graph, and obtained the best results for a WordNet-based system, comparable to the results of a distributional similarity method which used a crawl of the entire web. The same authors later released their UKB software, which is the one we use here.

3 Relatedness-based Query Expansion (RQE)

The key insight of our model is to expand the query with related words according to the background information in WordNet (Fellbaum, 1998), which provides generic information about general vocabulary terms.

In contrast with previous work using WordNet, we select those concepts that are most closely related to the query as a whole. To this end, we follow the approach in (Agirre et al., 2010), which, based on random walks over the graph representation of WordNet concepts and relations, obtains concepts related to the documents. We use the same settings and implementation for the graph algorithm, which is publicly available[1]. Details are omitted here due to lack of space, please refer to (Agirre et al., 2010).

In order to select the expansion terms, we choose the top N highest scoring concepts, and get all the words that lexicalize the given concept. We explored several values of N, and tune it in order to get the optimum value, as discussed in Section 4. For instance, given a query like "*What is the lowest speed in miles per hour which can be shown on a speedometer?*", our method suggests related terms like *vehicle*, *distance* and *mph*.

Our retrieval model runs queries which contain the original terms of the query and the expansion terms. Documents are ranked by their probability of generating the whole expanded query (Q_{RQE}), which is given by:

$$P_{RQE}(Q_{RQE} \mid \Theta_D) = P(Q \mid \Theta_D)^w P(Q' \mid \Theta_D)^{1-w} \quad (1)$$

where w is the weight given to the original query and Q' is the expansion of query Q.

The query likelihood probability is estimated following the multinomial distribution:

$$P(Q \mid \Theta_D) = \prod_{i=1}^{|Q|} P(q_i \mid \Theta_D)^{\frac{1}{|Q|}} \quad (2)$$

[1] http://ixa2.si.ehu.es/ukb/

where q_i is a query term of query Q and $|Q|$ is the length of Q. And following the Dirichlet smoothing (Zhai and Lafferty, 2001) we have

$$P(q_i \mid \Theta_D) = \frac{tf_{q_i D} + \mu \frac{tf_{q_i C}}{|C|}}{|D| + \mu} \quad (3)$$

where $tf_{q_i D}$ and $tf_{q_i C}$ are the frequency of the query term q_i in the document D and the entire collection, respectively, and μ is the smoothing free parameter.

The probability of generating the expansion terms is defined as

$$P(Q' \mid \Theta_D) = \prod_{q'_i}^{|Q'|} P(q'_i \mid \Theta_D)^{\frac{w_i}{W}} \quad (4)$$

where q'_i is a expansion term, $W = \sum_{i=1}^{|Q'|} w_i$ and w_i is the weight we give to a expansion term, which we can see as the relatedness between the original query Q and the expansion term, and is computed as

$$w_i = P(q' \mid Q) = \sum_{j=1}^{N} P(q' \mid c_j) P(c_j \mid Q) \quad (5)$$

where c is a concept returned by the expansion algorithm, N is the number of concepts we chose for the expansion, $P(q' \mid c_j)$ is estimated using the sense probabilities estimated from Semcor (i.e. how often the query term q' occurs with sense c_j), and $P(c_j \mid Q)$ is the similarity weight that the mentioned expansion algorithm assigned to c_j concept.

4 Experiments

In order to test the performance of our method we selected several datasets with different domains, topic typologies and document lengths. Table 1 shows some statistics for each.

The first is the English dataset of the **Robust-WSD** task at CLEF 2009 (Agirre et al., 2009a), a typical ad-hoc dataset on news. This dataset has been widely used among the community interested on WSD and WordNet-related methods. The documents in the Robust-WSD comprise news collections from LA Times 94 and Glasgow Herald 95.

The **Yahoo! Answers** corpus is a subset of a dump of the Yahoo! Answers web site, where people post questions and answers, all of which are public to any web user willing to browse them

	docs	length	q. train	q. test	length
Robust	166,754	532	150	160	8.6
Yahoo!	89,610	104	1,000	30,000	11.7
ResPubliQA	1,379,011	20	100	500	12.2

Table 2: Optimal values in each dataset for free parameters.

(Surdeanu et al., 2008). The document set was created with the best answer of each question (only one for each question). We use the dataset as released by its authors[2].

The other collection is the English dataset of **ResPubliQA** exercise at the Multilingual Question Answering Track at CLEF 2009 (Peñas et al., 2009). The exercise is aimed at retrieving paragraphs that contain answers to a set of 500 natural language questions.

Our experiments were performed using the Indri search engine (Strohman et al., 2005), which is a part of the open-source Lemur toolkit[3].

To determine whether the query expansion model we developed is useful to improve retrieval performance, we set up a number of experiments in which we compared our expansion model with other retrieval approaches. We used two baseline retrieval approaches for comparison purposes. One of the baselines is the default query likelihood (**QL**) language modeling method implemented in the Indri search engine. The other one is pseudo-relevance feedback (**PRF**) using a modified version of Lavrenko's relevance model (Lavrenko and Croft, 2001), where the final query is a weighted combination of the original and expanded queries, analogous to Eq. 1. As in our own model presented in the previous section, we chose the Dirichlet smoothing method for the baselines. We consider **QL** and **PRF** to be strong, reasonable baselines.

All the methods have several free parameters. The PRF model has three: number of documents (d) and terms (t), and w (cf. Eq. 1). The RQE

Table 3: Results of all methods. Δ columns show relative improvement with respect to QL or PRF.

model has two parameters: w (cf. Eq.. 1) and N the number of concepts for the expansion (Eq. 5). In addition, all methods use Dirichlet smoothing, which has a smoothing parameter μ. We used the train part of each dataset to tune all these parameters via a simple grid-search. The μ parameter was tested on the [100,1200] range for ResPubliQA and Yahoo! and [100,2000] for Robust, with increments of 100. The w parameter ranged over [0,1] with 0.1 increments. The d parameter ranged over [2,50] and the t and N in the range [1,200] (we tested 10 different values in the respective ranges). The parameter settings that maximized mean average precision for each model and each collection are shown in Table 2.

5 Results

Our main results are shown in Table 3. The main evaluation measure for Robust is Mean Average Precision (MAP), as customary. In two of the datasets (Yahoo! and ResPubliQA), there is a single correct answer per topic, and therefore we use Mean Reciprocal Rank (MRR). We also report Mean Precision at ranks 5 and 10 (P@5 and P@10). GMAP is also included (we will introduce and mention it afterwards). Statistical significance was computed using Paired Randomization Test (Smucker et al., 2007). In the tables throughout the paper, we use * to indicate statistical significance at 90% confidence level, ** for 95% and *** for 99%.

QL and PRF. The first two columns in Table 3 shows the results for QL and PRF and the performance difference between them. The results for PRF are mixed. It is very effective in the Robust dataset, with dramatic improvements, specially in MAP. All differences are statistical significant, except for P@5. In Yahoo! the improvement is small in MRR and P@10, without statistical significance, but P@5 is lower. In ResPubliQA the results are bad, with statistical significant degradation in MRR.

RQE. Continuing rightwards with Table 3, the following columns show the results for RQE, together with its difference with respect to QL and PRF. Note that figures in bold mean the best performance for each metric. It can be seen that, although RQE is not effective for Robust, it is the best method for Yahoo! and ResPubliQA. Moreover, the improvements over QL, and also over PRF, for Yahoo! are all statistical significant.

PRF is known to perform well for some topics and datasets but not for others. Table 3 includes results for the geometrical mean, GMAP (Robertson, 2006), in the Robust dataset, as it is not relevant in the other datasets. GMAP tries to promote systems which are able to perform well for all topics, in contrast to systems that perform better in some but worse in others. The figures show that RQE approximate the performance of PRF, showing that it perform better for difficult topics.

Combining PRF and RQE. In a preliminary experiment, we added the expansion terms produced both by RQE and PRF, obtaining a **MAP of 37.67** in the Robust collection, the best result. We would like to explore the potential for combination further in the future.

6 Conclusions

Motivated by the recent success of knowledge-based methods in word similarity and relatedness tasks (Agirre et al., 2009b), we explored a generic method to improve IR results using WordNet-based query expansion, and compared it to baseline query likelihood and pseudo-relevance feedback methods.

Our results on a diverse range of ad-hoc datasets with different domains, topic typologies and document lengths show that our method improves over a query likelihood baseline in all three datasets, while Pseudo Relevance Feedback is beneficial in only two datasets. Our method compares favorably to PRF in two datasets, and, in a preliminary experiment, the combination of PRF and our method yielded the best results in the third dataset.

In the future, we would like to analyze the differences between PRF and our method, and explore further combinations. We would also like to use our method on domains where large lexical resources are available, such as UMLS (Humphreys et al., 1998) and linked data repositories

Abstract

Word Sense Disambiguation (WSD) is one of the fundamental natural language processing tasks. However, lack of training corpora is a bottleneck to construct a high accurate all-words WSD system. Annotating a large-scale corpus by experts costs enormous time and financial resources. Human Computation is a novel idea for integrating human resources behind the Web, which has been wasted, to solve practical problems that are difficult for computers. Based on human computation, we design a confirmation code system, which can not only distinguish between human beings and computers (the function of normal confirmation code system), but also annotate WSD corpora. The preliminary experimental result shows that the proposed method can annotate large-scale and high-quality WSD corpora within a short time. To the best of our knowledge, this is the first attempt to use confirmation code in natural language processing for corpora acquisition.

1 Introduction

It is a common phenomenon that a word has multiple senses in natural languages. The aim of word sense disambiguation (WSD) is to identify the correct senses of ambiguous words according to their surrounding contexts. WSD is a basic task of natural language processing. The state-of-the-art in WSD is dominated by supervised machine learning methods where a model is trained to recognize word senses in a given context based on various features. Although it is important to use powerful machine learning algorithms, latest studies have found that large-scale and high-quality corpora are more important for WSD (Agirre and Edmonds, 2006). Therefore, building such corpora is key challenge to be addressed.

Currently, corpora are created mainly through manual annotation by expert annotators. However, the cost of annotating a necessary size of corpora is prohibitive. Consequently, in the research field of WSD, some common ambiguous words are sampled and then annotated with a necessary amount of examples. The sampling method promotes the research in WSD algorithms. However, these algorithms are difficult to be used in practical applications due to lack of large-scale corpora in which all ambiguous words are annotated. For example, SemCor[1] corpus contains WSD annotation of about 250,000 words sampled from a subset of the Brown corpus. However, for most of the ambiguous words, the number of examples is still too small to train a high performance all-words WSD model. The best performance of Senseval-3 English all-words evaluation task (Snyder and Palmer, 2004) is only about 65%.

Semi-supervised methods have been applied to build large-scale corpora, such as bootstrapping (Yarowsky, 1995). However, the quality of corpora built with such methods is not high enough to train accurate WSD models. Therefore, the methods are not feasible to be used in practice.

Crowdsourcing is an "online, distributed problem-solving and production model. (Brabham, 2008)" A benefit of this distributed model is that a job can be shared amongst a wide variety of demographics, where such diversity would be difficult to obtain otherwise. Previous research has demonstrated the successful application of crowdsourcing in a variety of natural language processing areas including relevance evaluation (Alonso et al., 2008), machine

translation (Ambati et al., 2010), and language processing (Callison-Burch and Dredze, 2010). However, the submissions of crowdsourcing are always needed to review to separate the legitimate work from the rest. Additionally, the crowdworkers are always motivated by money. These increase the extra cost of time and finance.

Human Computation is a novel method for collecting corpora (von Ahn, 2007). In this method, a computer asks a person or a large group of people to solve a problem, and then collects, interprets, and integrates their solutions. The methods of human computation include interactive online games, confirmation code, and so on. For instance, reCAPTCHA (von Ahn et al., 2008) system is a kind of confirmation code, also called CAPTCHA (Completely Automated Public Turing test to tell Computers and Humans Apart). Confirmation code systems are widely used on the Web as security measures to prevent automatic programs from abusing online services by asking a question that computers cannot yet answer. In reCAPTCHA, to pass the confirmation stage, users must input the content of word images from scanned old books. Two scanned word images are shown to a user at the same time. The system knows the content of one word and does not know the other. If the user wants to pass the confirmation stage, he must input the correct content of the known word. Because the user does not know which word the system knows, he has to input the contents of both words. Thus, once the confirmation function is successfully achieved, the content of the unknown word can be obtained. Finally, reCAPTCHA helps to digitize plenty of old books that an optical character recognition (OCR) cannot decipher.

Different from crowdsourcing, human computation does not need to review the results again nor pay users. The method can take advantage of a larger range of people. However, human computation methods are rarely used in natural language processing tasks. The main reason is that natural language processing tasks are usually very complex. It is difficult to design an appropriate game and also be annotated by normal users. Seemakurty et al. (2010) designed a game which helps to collect WSD corpora. The game chooses two participants randomly and then shows a sentence to them. The two users are asked to input as many synonyms of the same ambiguous word in the sentence as possible within a limited period of game round time. Once there are identical input words by them, they are awarded scores and then a synonym of the ambiguous word is obtained. Based on these synonyms, the correct sense of the ambiguous word can be recognized. However, a big problem is how to attract a considerable number of users. In addition, it needs long time to collect these synonyms[2]. More seriously, the game can be cheated under some extreme circumstances, e.g., when all users just input the same words, or we use a robot to input all words in a dictionary quickly.

In this paper, we are inspired by the idea of reCAPTCHA system and propose a confirmation code based method to annotate WSD corpora with low cost. The method can help to collect large-scale and high-quality corpora within a short time. Preliminary experimental result shows that the method can achieve 80.65% accuracy on an annotated WSD corpus which is close to the inter-rater agreement of the corpus. It only needs about 8 to 10 seconds to annotate an example by a person.

2 System Description

A WSD confirmation code includes two questions. Each question consists of a sentence and a highlighted ambiguous word in the sentence. All senses of the ambiguous word are provided as optional answers. The system only knows the answer for one of the two questions, which is named as *known* question and the other is *unknown* question. A user needs to choose a word sense for each ambiguous word. The user can pass the confirmation stage if and only if his answer to the known question is correct. Like in reCAPTCHA, users do not know which one is known question. They must choose each word sense carefully in order to pass confirmation stage. Therefore, they provide the correct sense for the ambiguous word of unknown question. If WSD confirmation code system is widely used by lots of Web sites, we can easily collect large-scale corpora.

The data flow chart of the WSD confirmation code system is shown in Figure 1. ① two questions are randomly selected from known and unknown question databases respectively. ② the two questions are asked to a user and the user needs to answer them. ③ once the user's answer is correct,

[2]In their work, a game round is to be set 30 seconds, i.e. it needs 30 seconds to annotate the sense of an ambiguous word at least.

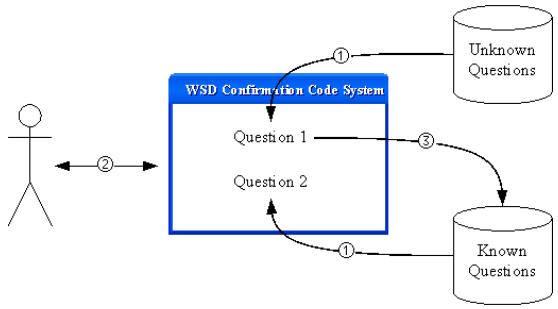

Figure 1: The data flow chart of WSD confirmation code system

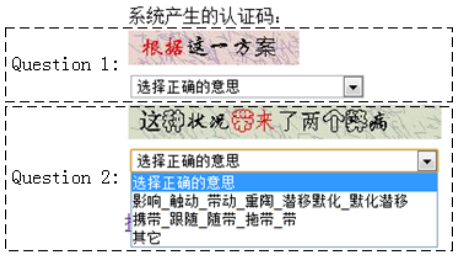

Figure 2: An example of WSD confirmation code system. Here, the two sentences are "根据这一方案 (according to the scheme)" and "这种状况带来了两个弊端 (this situation brings two drawbacks)" respectively. The two ambiguous words are "根 据 (according to)" and "带 来 (bring)". Here, "带来" has two senses: "影响 触动 · · · (influence)" and "携带 跟随 · · · (bring)". Because of the incompleteness of the thesaurus, there are some words whose senses cannot be found. Therefore, we add a "其它 (other)" option for every word since the current word sense does not belong to any of above options. The other Chinese sentences in the example instruct the users how to use the system. "系统产生的验证码" means "The confirmation codes provided by the system" and "选择正确的意思" means "Please choose the correct word sense".

i.e. it is equal to the answer of known question, he can pass the confirmation stage. Then we can know the answer of the unknown question, which becomes a new known question and can be added into the known question database. Otherwise, the confirmation stage cannot be passed and the user has to answer another pair of questions.

The known question is used to distinguish between human beings and computers, i.e. this is the function of commonly used confirmation code. Usually, it is either impossible or less possible for a computer to automatically choose correct answers. In order to further prevent automatic WSD programs from passing the confirmation stage, we convert original sentences into images with randomly distorted background and font. This method makes it impossible to recognize the contents of the original sentences and to do WSD automatically. If users correctly annotate the known word sense, the system can assume that they are human and gain confidence that they can also annotate the other word sense correctly.

Figure 2 shows an example of WSD confirmation code[3]. Sentences are in image forms and the target ambiguous words are highlighted with red font. The senses of these ambiguous words are shown in pull-down menus.

In order to improve the consistency of the final corpora, we allow each example to be annotated more than once. Then, a voting method can be used to determine the final word sense.

3 Experiment

3.1 Experimental Data

To evaluate the correctness of the corpus annotated by our WSD confirmation code method, we built a trial system and took advantage of an annotated Chinese all-words WSD corpus consisting of about 10,000 sentences containing about 200,000 words sampled from Chinese news documents. In these words, there are about 78,800 ambiguous words and all of which have been annotated with their corresponding senses by human experts. Among them, we randomly set 5,000 words as unknown questions and remaining as known.

3.2 Thesaurus

We use WordMap (Che et al., 2010) as a thesaurus to represent word senses. There are more than 100,000 Chinese words in WordMap. Each word sense belongs to a tree node with five levels. There are 12 top level nodes, such as "entity" and "human beings". There are about 100 second, 15,000 third, and more fourth and fifth level nodes. Under the fifth level nodes, there are some synonyms which have the same word sense. For instance, the word "材料" has two senses which are represented by five level nodes as follows:

1. 物 (entity) → 统称 (common name) → 物资 (goods) → 物资 (goods) → 材料 (material)

[3]In this paper, we use Chinese as an example. However, the method is not restricted to specific language.

# of times an example is annotated	# of annotated examples	# of correct annotated examples	Acc.
Random			41.01%
1	2,387	1,609	67.41%
≥2	336	271	80.65%

Table 1: Comparison of Experimental Results

2. 人 (human beings) → 才识 (ability) → 俊杰 (hero) → 人才 (talents) → 人才 (talents)

We can see that the two word senses belong to two top level nodes "物 (entity)" and "人 (human beings)" respectively. In each sense, the concept becomes more and more specific as the level increases.

However, the above sense representation method is not suitable to be shown as word sense options directly since it is too abstract to be understood by normal users. Therefore, we use synonyms of each word sense to represent the word sense. For instance, the synonyms of the two senses of the word "材料" are "材质 生料 质料 (materials)" and "人才 佳人 才子 奇才 天才 (talents)" respectively. Then we show these synonyms to the users for better understanding of the word sense.

3.3 Preliminary Results

We invited 20 volunteers to test the system. We collected 2,723 examples which passed the confirmation successfully. Table 1 shows the comparison of the experimental results.

From Table 1, we can see that when an example is annotated once, the accuracy (67.41%) is much higher than the random sense selection (41.01%)[4]. This tells us that the human efforts have a positive effect on the annotation. However, the accuracy is still not high enough and this can be attributed to volunteers' lack of experience in WSD. They maybe make mistakes. The accuracy, along with an increase of the annotation times, is improved. When an example is annotated more than once, the accuracy reaches 80.65% and is close to the inter-rater agreement (83.84%) of the original corpus.

On average, it needs about 8 to 10 seconds for a person to successfully input a WSD confirmation code. It is faster than common confirmation code systems (with six to eight randomly characters), which need 13.51 seconds on average (von Ahn et al., 2008). This is not surprising, because choosing an answer is faster than inputting some characters. So, in practice, the WSD confirmation code system can be adopted without reducing the quality of user experience.

[4]In WordMap, there are 2.44 senses for each ambiguous word on average. Therefore, the accuracy of random selection is 41.01%.

4 Conclusion and Future Work

To address the lack of WSD corpora, we propose a human computation based method. When users successfully input a confirmation code, they annotate a WSD example incidentally. The preliminary experiments show that the novel method can annotate large-scale and high-quality WSD corpora within a short time. As far as we know, there is no work done to annotate natural language processing corpora with confirmation code.

In the future, we plan to improve the annotation speed and reduce the complexity of confirmation process by showing two sentences with the same ambiguous words. Thus, users can easily compare the two sentences. More importantly, they only need to read the options once, which can save confirmation time further. We also can use unsupervised clustering method which determines senses that are very similar and displays only one of the alternatives. Secondly, we will apply this method to other languages. Our method is general enough and can be applied to any languages as long as the language has a thesaurus and some initial WSD corpora. Of course, a particular language WSD confirmation code system can only be used in Web sites of the same language because it is difficult for a normal user to perform WSD task on the foreign language that they are unfamiliar with. Thirdly, we can apply this method to other natural language processing tasks which need corpora acquisition such as co-reference resolution, named entity recognition, and parsing. Finally, we will use the corpora annotated by the confirmation code method to train a more effective WSD model.
