Message from the General Chair

Welcome to New Orleans and to NAACL HLT 2018 – the biggest NAACL to date. Natural Language Processing and Computational Linguistics is constantly growing and changing with a constant flow of new methods and topics. Every year also sees an even more exciting and diverse research community, with a steadily increasing number researchers, companies both large and small, and a vibrant community of practitioners and students who are excited at the prospect of taking on the newest challenges of the discipline. This year's NAACL HLT conference reflects what an exciting time this is for our field, and highlights the vibrancy and vitality of our community.

I feel extremely lucky to be able to work with a fantastic program committee, especially the two extremely dedicated, creative and resourceful program chairs: Amanda Stent and Heng Ji. Their innovations include a new review form, intended to elicit higher quality reviews, the opportunity for authors to review the reviewers, the Test-of-Time awards, and a program where poster and demo sessions run consistently in parallel to the oral sessions, in order to allow the conference to reflect the ever increasing diversity of research topics and the corresponding volume of accepted papers. I am especially excited about the new Test-of-Time papers award session, and hope to see this new innovation become a regular part of ACL conferences.

We have named the Test-of-Time award in memory of Aravind Joshi, who left us this year, after having a huge lifetime impact on our community. We will always remember him for his gentle conversational style, sharp focus, interest in linguistic, computational and mathematical properties of language, and his lifetime commitment to mentoring women in NLP. I feel extremely lucky to have been one of his Ph.D. students.

This year we also introduced an industrial track, with the aim of featuring papers that focus on scalable, interpretable, reliable and customer facing methods for industrial applications of Natural Language Processing. The idea of having such a track was proposed by Yunyao Li who strongly advocated for it: this proposal was then discussed and approved by the NAACL board. After that, it was all go, with an incredible amount of work to promote and organize it by the industrial track chairs: Jennifer Chu-Carroll, Yunyao Li and Srinivas Bangalore.

The overall program looks amazing and reflects the cooperative way that everyone on the committee worked together. What a team! I am so grateful for getting to be a part of this community of people, and I really appreciate the enthusiasm and attention to detail reflected in their hard work: Amanda Stent and Heng Ji (program chairs); Jennifer Chu-Carroll, Yunyao Li and Srinivas Bangalore (industrial track chairs); Ying Lin (website chair); Marie Meteer and Jason Williams (workshop co-chairs); Mohit Bansal and Rebecca Passonneau (tutorial co-chairs); Yang Liu, Tim Paek, and Manasi Patwardhan (demo co-chairs); Chris Callison-Burch and Beth Hockey (Family-Friendly Program Co-Chairs) Stephanie Lukin and Meg Mitchell (publication co-chairs); Jonathan May (handbook chair); Silvio Ricardo Cordeiro, Shereen Oraby, Umashanthi Pavalanathan, and Kyeongmin Rim (student cochairs) along with Swapna Somasundaran and Sam Bowman (Faculty Advisors) for the student research workshop; Lena Reed (student volunteer coordinator); Kristy Hollingshead, Kristen Johnson, and Parisa Kordjamshidi (local sponsorships and exhibits cochairs); Yonatan Bisk and Wei Xu (publicity and social media chairs); David Yarowsky and Joel Tetreault (treasurers) and Alexis Palmer and Jason Baldridge (the NAACL international Sponsorship Team). Also thanks to Rich at SoftConf for his speedy response to questions and his willingness to help us innovate with our new review form. And thanks to Julia Hockenmaier and the whole NAACL Executive Board for always being willing to consult on any issue.

The program highlights three keynote speakers in the main track: Dilek Hakkani-Tür, Kevin Knight, and Charles Yang. We also have two keynote speakers in the industry track: Mari Ostendorf and Daniel Marcu. These talks promising to be interesting across a range of issues from language acquisition in

children to the commercial possibilities of conversational agents. The industry track will also feature two panels, one on careers in industry (as compared to academia) and the other on ethics in NLP. The program also includes six tutorials featuring topics of current interest and sources of innovation in the field. We have sixteen workshops plus the student research workshop: some of these workshops have become events in themselves with many of them repeated each year. We will also have plenary sessions for the outstanding paper awards and the new Test-Of-Time papers award session.

Any event of this scale can only happen with the the hard work of a wonderful group of people. I especially want to thank the NAACL board for being willing to consult on a range of different issues and Priscilla Rasmussen for taking care of all the millions of details that need to be looked after every single day to make sure the logistical aspects of the conference come together. I want to especially thank Priscilla for her hard work and creativity organizing our social event: we first will go to Mardi Gras World to see the world of wonders created each year for the Mardi Gras. From there we go to the river, to the dockside River City Plaza and River City Ballroom for New Orleans' famous cuisine and libations and dancing to live Zydeco, funk, soul and R&B.

ACL has been working for several years to increase diversity at our conferences and in our community. So, taking inspiration from ACL 2017, we aimed to make NAACL family friendly, by providing childcare at the conference, and encouraging people to bring their families to the social events and breakfasts. Diversity can also be a consequence of the support for students to attend the conference that we receive from the NSF, CRA-CCC and CRA-W: this subsidizes student travel to the student research workshop as well as their registration and ACL memberships. When combined with the support we are able to give to our student volunteers, we aim to make it possible for students from all over the world to come to the conference and be part of our community. We also decided, in consultation with the NAACL board, to provide subsidies to the Widening NLP workshop, which is only being held for the second time at this year's NAACL (last year called the Women in NLP workshop). These subsidies enable participation from students and young researchers from developing countries to attend the conference.

I am grateful to our sponsors for their generous contributions, which add so much to what we can do at the conference. Our Diamond sponsors are Bloomberg, Google, and Toutiao AI Lab (ByteDance). The Platinum sponsor is Amazon. The Gold Sponsors are Ebay, Grammarly, IBM Research, KPMG, Oracle, Poly AI, Tulane University, Capital One and Two Sigma. The Silver sponsors are Nuance and Facebook, and the Bronze sponsors are iMerit and USC/ISI.

Finally, there are many more people who through their hard work and dedication have contributed to make this conference a success: the area chairs, workshop organizers, tutorial presenters, student mentors, and reviewers. And of course you all, the attendees without whom there would be no conference: you are the life and spirit of the conference and the NAACL community. I hope you all have a fun and exciting time at NAACL HLT 2018!

NAACL HLT 2018 General Chair
Marilyn Walker, University of California Santa Cruz

Message from the Program Co-Chairs

We welcome you to New Orleans for the 16th Annual Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (NAACL HLT 2018)! We had three primary goals for NAACL HLT 2018: construct a great program; manage the integrity and quality of the publication process; and ensure broad participation.

Construct a great program: NAACL HLT 2018 does have a great program, thanks to all of you! We will have three exciting keynotes, from Charles Yang, Kevin Knight and Dilek Hakkani-Tür. 331 research track papers (205 long, 125 short), accepted following peer review, will be presented[1]. Four of these papers have been identified as outstanding papers, and one will be named best paper. We will also feature a "Test of Time" session with retrospectives (from the authors) on three influential papers from ACL venues. We thank the committees who nominated and voted on these paper awards.

The main program at NAACL HLT 2018 also includes 16 TACL paper presentations, 20 demos, a student research workshop and an industry track. Keynotes from both the research and industry tracks are plenary. In a change from previous years of NAACL HLT, and motivated by EMNLP 2017, poster and oral presentation sessions will be held in parallel during the day. All posters are grouped thematically (including posters from the industry track and student research workshop and demos) and assigned to poster sessions so as to not be against oral presentation sessions with the same theme.

Manage the integrity and quality of the publication process: To manage load, we decided that each area chair should be responsible for no more than 30 submissions and that reviewers should be responsible for reviewing no more than 3 submissions. To help reviewers, we and the ACL program co-chairs constructed a more structured review form, with questions related to the new ACL guidelines on publication and reviewing, as well as to contribution types, experimental methods (thank you, Bonnie Webber!), software and handling of data.

We recruited an excellent group of 72 area chairs; we thank them for their leadership, and for nominating and voting on outstanding papers, outstanding reviewers and test of time papers. 1372 individuals reviewed papers for the conference (as program committee members, ad hoc reviewers or secondary reviewers); all but 49 reviewers had no more than 3 submissions to review overall, and the 49 reviewers who took on a heavier load did so voluntarily. We thank all our reviewers, especially the ad-hoc reviewers who provided last minute reviews and the outstanding reviewers identified by the area chairs.

Submissions were assigned to area chairs and reviewers using a combination of area chair expertise, Toronto Paper Matching System (TPMS) scores and reviewer bids. Both long and short paper submissions received 3 reviews each. Long paper authors had an opportunity to respond to reviews. Accept/reject suggestions were made by area chairs working in small groups of 2-3 and discussing with reviewers as necessary; final decisions were made by the program chairs. Where there was disagreement or discussion, one area chair wrote a short meta review that was shared with the authors.

This year, if the authors of a NAACL HLT 2018 submission and the author of a review for that submission both consented, then we will include the review in a review corpus to be released jointly with the program chairs of ACL, Iryna Gureyvich and Yusuke Miyao. We also asked authors of accepted papers to upload the source code for their papers. Both of these corpora will be released in the coming months.

The health of our field as a science is dependent on a scalable peer review process, which in turn depends on (a) conscientious effort from a broad pool of expert reviewers, and (b) tools, processes and policies that can structure and facilitate reviewing. As a field we are at a breaking point: we are growing rapidly,

[1]We received 1122 research track submissions (664 long, 458 short). 33 were rejected without review and 85 were withdrawn by the authors either before, during or after review.

with corresponding heavy load on experienced reviewers; and we lack good tools to manage the process. Peer review involves several tasks that we, as NLP researchers, ought to be uniquely qualified to address, including expertise sourcing, network analysis and text mining. We have written a proposal with other members of the ACL community about ways the ACL can improve our peer review infrastructure. We have also written a collection of "how to" documents that we will pass on to future conference organizers.

Ensure broad participation: To ensure broad participation, we recruited program committee members using a similar method to that used for NAACL HLT 2016: we invited anyone who had published repeatedly in ACL sponsored venues, who had a PhD or significant experience in the field spanning more than 5 years, and whose email address was up to date in START. We thank Dragomir Radev for giving us a list of names from the ACL anthology.

We also kept a blog where we discussed and attempted to "demystify" each stage of the publication process. This blog can be found at the conference website, `http://naacl2018.org`. We are very grateful to the researchers who wrote guest blog posts, including Justine Cassell, Barbara Plank, Preslav Nakov, Omer Levy, Gemma Boleda, Emily Bender, Nitin Madnani, David Chiang, Kevin Knight, Dan Bikel and Joakim Nivre.

On our blog, we reported on the diversity of our area chair, reviewer and author pools in terms of years of experience, affiliation type and geography, and gender. We will include these details in our report to the NAACL Executive Committee. We hope that future years' chairs will make similar reports.

The excellence of the overall NAACL HLT 2018 program is thanks to all the chairs and organizers. We especially thank the following people: Margaret Mitchell and Stephanie Lukin, the publication chairs; Jonathan May, the handbook chair; Yonatan Bisk and Wei Xu, the publicity and social media chairs; Ying Lin, the tireless website chair; and Marilyn Walker, the NAACL HLT 2018 general chair. We thank the chairs of NAACL HLT 2016 and ACL 2017 for their informative blogs, and the program chairs of NAACL HLT 2016, Owen Rambow and Ani Nenkova, for their advice. We thank the program co-chairs of ACL 2018, Iryna Gurevych and Yusuke Miyao, who have been very collaborative on matters related to reviewing. We thank Shuly Winter, who helped fix a serious START bug. We thank Julia Hockenmaier and the NAACL Executive Committee for their support. We are grateful for the professional work of Rich Gerber and his colleagues at SoftConf (START), and of Priscilla Rasmussen from the ACL.

It has been an enormous privilege for us to see the scientific advances that will be presented at this conference. We would like to close with some advice for you, the conference attendees.

- The presenters have made valuable contributions to our science; their oral, poster and demo presentations are worth your time and attention.
- Talk to some people you haven't previously met. They may be your future collaborators!
- You can follow the conference on social media; we have a conference app and website where we will post any updates to the program, and our twitter handle is @naaclhlt.
- This event is run by a professional organization with a code of conduct[2]. If you observe or are the recipient of unprofessional behavior, you may contact any current member of the ACL or NAACL Executive Committees, the NAACL HLT general chair (Marilyn Walker), us (the program chairs), or Priscilla Rasmussen (acl@aclweb.org). We will hold your communications in strict confidence and consult you before taking any action.

We look forward to a wonderful conference!

NAACL HLT 2018 Program Co-Chairs
Heng Ji, RPI
Amanda Stent, Bloomberg

Organizing Committee

General Chair

Marilyn Walker, University of California, Santa Cruz

Program Co-Chairs

Heng Ji, Rensselaer Polytechnic Institute
Amanda Stent, Bloomberg

Industry Track Co-Chairs

Srinivas Bangalore, Interactions
Jennifer Chu-Carroll, Elemental Cognition
Yunyao Li, IBM

Demonstration Co-Chairs

Yang Liu, University of Texas at Dallas
Tim Paek, Apple
Manasi Patwardhan, Tata Consultancy Services Research, India

Student Research Workshop Co-Chairs

Chairs:

Silvio Ricardo Cordeiro, Aix-Marseille Université
Shereen Oraby, University of California, Santa Cruz
Umashanthi Pavalanathan, Georgia Institute of Technology
Kyeongmin Rim, Brandeis University

Faculty Advisors:

Swapna Somasundaran, ETS Princeton
Sam Bowman, New York University

Workshop Co-Chairs

Marie Meteer, Brandeis University
Jason Williams, Microsoft Research

Tutorial Co-Chairs

Mohit Bansal, University of North Carolina
Rebecca Passonneau, Pennsylvania State University

Publications Co-Chairs

Stephanie Lukin, U.S. Army Research Laboratory
Margaret Mitchell, Google

Handbook Chair

Jonathan May, University of Southern California Information Sciences Institute

Local Arrangements Chair

Priscilla Rasmussen, ACL

Family-Friendly Program Co-Chairs

Chris Callison-Burch, University of Pennsylvania
Beth Hockey, Intel

International Sponsorships Co-Chairs

Alexis Palmer, University of North Texas
Jason Baldridge, Google

Local Sponsorships and Exhibits Co-Chairs

Kristy Hollingshead, Florida Institute for Human & Machine Cognition
Kristen Johnson, Purdue University
Parisa Kordjamshidi, Tulane University / Florida Institute for Human and Machine Cognition

Publicity and Social Media Co-Chairs

Yonatan Bisk, University of Washington
Wei Xu, Ohio State University

Website Chair

Ying Lin, Rensselaer Polytechnic Institute

Student Volunteer Coordinator

Lena Reed, University of California, Santa Cruz

Program Committee, Research Track

Area Chairs

Cognitive Modeling/Psycholinguistics
- Morteza Dehghani, University of Southern California
- Kristy Hollingshead, Institute for Human & Machine Cognition

Dialogue and Interactive Systems
- Yun-Nung (Vivian) Chen, National Taiwan University
- Gabriel Skantze, KTH Royal Institute of Technology

Discourse and Pragmatics
- Jacob Eisenstein, Georgia Institute of Technology
- Junyi (Jessy) Li, University of Texas at Austin
- Annie Louis, University of Edinburgh
- Yi Yang, Bloomberg

Generation
- Dimitra Gkatzia, Edinburgh Napier University
- Shashi Narayan, University of Edinburgh
- Michael White, Ohio State University

Information Extraction
- Mausam, Indian Institute of Technology Delhi
- Dan Bikel, Google
- Chia-Hui Chang, National Central University
- Bonan Min, BBN
- Aurélie Névéol, CNRS

Marius Pasca, Google
Hinrich Schütze, Ludwig Maximilian University of Munich
Avirup Sil, IBM Research AI
Michael Strube, HITS gGmbH

Machine Learning for NLP

Chris Dyer, Google DeepMind
Ozan Irsoy, Bloomberg
Tie-Yan Liu, Microsoft Research
Raymond Mooney, University of Texas at Austin

Machine Translation

Marine Carpuat, University of Maryland
Kyunghyun Cho, New York University
Daniel Marcu, Amazon
Taro Watanabe, Google
Deyi Xiong, Soochow University

NLP Applications

Jinho Choi, Emory University
Joel Tetreault, Grammarly

Phonology, Morphology and Word Segmentation

Jennifer Foster, Dublin City University
Barbara Plank, University of Groningen

Question Answering

Eugene Agichtein, Emory University
Hannaneh Hajishirzi, University of Washington
Idan Szpektor, Google

Semantics

Yoav Artzi, Cornell University
Mona Diab, George Washington University
Kevin Duh, Johns Hopkins University
Jonathan May, University of Southern California
Preslav Nakov, Qatar Computing Research Institute
Roi Reichart, Technion - Israel Institute of Technology

Outstanding Papers

For NAACL HLT 2018 we recognize four outstanding research track papers (one of these will be named best paper). These four papers were selected by a committee composed of Joyce Chai (Michigan State University), Michael Collins (Columbia University), Jennifer Foster (Dublin City University), Smaranda Muresan (Columbia University) and Joel Tetreault (Grammarly; chair), all NAACL HLT 2018 area chairs with no conflicts with the candidate outstanding papers. The nine candidate papers were selected by the program chairs from nineteen papers nominated by the area chairs. These papers will be presented in a plenary session on the last day of the conference. Congratulations to the authors!

- *Deep Contextualized Word Representations*, by Matthew Peters, Mark Neumann, Mohit Iyyer, Matt Gardner, Christopher Clark, Kenton Lee and Luke Zettlemoyer
- *Learning to Map Context-Dependent Sentences to Executable Formal Queries*, by Alane Suhr, Srinivasan Iyer and Yoav Artzi
- *Neural Text Generation in Stories using Entity Representations as Context*, by Elizabeth Clark, Yangfeng Ji and Noah A. Smith
- *Recurrent Neural Networks as Weighted Language Recognizers*, by Yining Chen, Sorcha Gilroy, Andreas Maletti, Jonathan May and Kevin Knight

Test of Time Papers

For NAACL HLT 2018 we recognize three influential and inspiring Computational Linguistics (CL) papers which were published between 2002-2012 at the Association for Computational Linguistics (ACL) conferences (including ACL, NAACL, EACL, EMNLP and CONLL), workshops and journals (including TACL and CL), to recognize research that has had long-lasting influence until today, including positive impact on a subarea of CL, across subareas of CL, and outside of the CL research community. These papers may have proposed new research directions and new technologies, or released results and resources that have greatly benefit the community. Nineteen candidate test of time papers were nominated by our area chairs. Separate votes on these papers were held separately by two committees: an expert award committee consisting of all ACL and NAACL general chairs and program chairs and NAACL board members from 2013-2018 who did not have a conflict with the nominated papers, and a community award committee consisting of the 1000 authors who have published the most papers at ACL venues and who did not have a conflict with the nominated papers. These papers will be re-presented by the authors in a plenary session on the second day of the conference. Congratulations to the authors!

- *BLEU: a Method for Automatic Evaluation of Machine Translation*, by Kishore Papineni, Salim Roukos, Todd Ward and Wei-Jing Zhu
- *Discriminative Training Methods for Hidden Markov Models: Theory and Experiments with Perceptron Algorithms*, by Michael Collins
- *Thumbs up?: Sentiment Classification using Machine Learning Techniques*, by Bo Pang, Lillian Lee and Shivakumar Vaithyanathan

Keynote Talk: Why 72?

Charles Yang
University of Pennsylvania

Biography
Charles is a Professor of Linguistics, Computer Science, and Psychology at the University of Pennsylvania and directs the Program in Cognitive Science. He has spent a long time to work out the tricks children use to learn languages and is now ready to try them out on machines. His most recent book, The Price of Linguistic Productivity, is the winner of the 2017 LSA Leonard Bloomfield award.

Keynote Talk: The Moment When the Future Fell Asleep

Kevin Knight
University of Southern California / Information Sciences Institute

Biography
Kevin is a professor of computer science at the University of Southern California and fellow of the Information Sciences Institute. He is a 2014 fellow of the ACL for foundational contributions to machine translation, to the application of automata for NLP, to decipherment of historical manuscripts, to semantics and to generation.

Keynote Talk: Google Assistant or My Assistant? Towards Personalized Situated Conversational Agents

Dilek Hakkani-Tür
Google Research

Abstract
Interacting with machines in natural language has been a holy grail since the beginning of computers. Given the difficulty of understanding natural language, only in the past couple of decades, we started seeing real user applications for targeted/limited domains. More recently, advances in deep learning based approaches enabled exciting new research frontiers for end-to-end goal-oriented conversational systems. However, personalization (i.e., learning to take actions from users and learning about users beyond memorizing simple attributes) remains a research challenge. In this talk, I'll review end-to-end situated dialogue systems research, with components for situated language understanding, dialogue state tracking, policy, and language generation. The talk will highlight novel approaches where dialogue is viewed as a collaborative game between a user and an agent in the presence of visual information. The situated conversational agent can be bootstrapped using user simulation (crawl), improved through interactions with crowd-workers (walk), and iteratively refined with real user interactions (run).

Biography
Dilek is a research scientist at Google Research Dialogue Group and has previously held positions at Microsoft Research, ICSI, and AT&T Labs – Research. She is a fellow of the IEEE and of ISCA. Her research interests include conversational AI, natural language and speech processing, spoken dialogue systems, and machine learning for language processing.

Table of Contents

Conference Program

June 2

07:30–08:45 Breakfast

08:45–09:00 Welcome from the Chairs

09:00–10:00 Keynote (sponsored by Toutiao AI Lab)

Why 72?
Charles Yang, University of Pennsylvania

10:00–10:30 Morning Coffee

10:30–11:30 Information Extraction 1

10:30–10:48 *Label-Aware Double Transfer Learning for Cross-Specialty Medical Named Entity Recognition*
Zhenghui Wang, Yanru Qu, Liheng Chen, Jian Shen, Weinan Zhang, Shaodian Zhang, Yimei Gao, Gen Gu, Ken Chen and Yong Yu

10:48–11:06 *Neural Fine-Grained Entity Type Classification with Hierarchy-Aware Loss*
Peng Xu and Denilson Barbosa

11:06–11:24 *Joint Bootstrapping Machines for High Confidence Relation Extraction*
Pankaj Gupta, Benjamin Roth and Hinrich Schütze

June 2 (continued)

10:30–11:30 Phonology, Morphology and Word Segmentation 1

10:30–10:48 *A Deep Generative Model of Vowel Formant Typology*
Ryan Cotterell and Jason Eisner

10:48–11:06 *Fortification of Neural Morphological Segmentation Models for Polysynthetic Minimal-Resource Languages*
Katharina Kann, Jesus Manuel Mager Hois, Ivan Vladimir Meza Ruiz and Hinrich Schütze

11:06–11:24 *Improving Character-Based Decoding Using Target-Side Morphological Information for Neural Machine Translation*
Peyman Passban, Qun Liu and Andy Way

10:30–11:30 Speech 1

10:30–10:48 *Parsing Speech: a Neural Approach to Integrating Lexical and Acoustic-Prosodic Information*
Trang Tran, Shubham Toshniwal, Mohit Bansal, Kevin Gimpel, Karen Livescu and Mari Ostendorf

10:48–11:06 *Tied Multitask Learning for Neural Speech Translation*
Antonios Anastasopoulos and David Chiang

11:06–11:24 *Please Clap: Modeling Applause in Campaign Speeches*
Jon Gillick and David Bamman

June 2 (continued)

10:30–12:00 Discourse and Pragmatics 1

Attentive Interaction Model: Modeling Changes in View in Argumentation
Yohan Jo, Shivani Poddar, Byungsoo Jeon, Qinlan Shen, Carolyn Rose and Graham Neubig

Automatic Focus Annotation: Bringing Formal Pragmatics Alive in Analyzing the Information Structure of Authentic Data
Ramon Ziai and Detmar Meurers

Dear Sir or Madam, May I Introduce the GYAFC Dataset: Corpus, Benchmarks and Metrics for Formality Style Transfer
Sudha Rao and Joel Tetreault

Improving Implicit Discourse Relation Classification by Modeling Inter-dependencies of Discourse Units in a Paragraph
Zeyu Dai and Ruihong Huang

10:30–12:00 Generation 1

A Deep Ensemble Model with Slot Alignment for Sequence-to-Sequence Natural Language Generation
Juraj Juraska, Panagiotis Karagiannis, Kevin Bowden and Marilyn Walker

A Melody-Conditioned Lyrics Language Model
Kento Watanabe, Yuichiroh Matsubayashi, Satoru Fukayama, Masataka Goto, Kentaro Inui and Tomoyasu Nakano

Discourse-Aware Neural Rewards for Coherent Text Generation
Antoine Bosselut, Asli Celikyilmaz, Xiaodong He, Jianfeng Gao, Po-Sen Huang and Yejin Choi

Natural Answer Generation with Heterogeneous Memory
Yao Fu and Yansong Feng

Query and Output: Generating Words by Querying Distributed Word Representations for Paraphrase Generation
Shuming Ma, Xu Sun, Wei Li, Sujian Li, Wenjie Li and Xuancheng Ren

Simplification Using Paraphrases and Context-Based Lexical Substitution
Reno Kriz, Eleni Miltsakaki, Marianna Apidianaki and Chris Callison-Burch

June 2 (continued)

Zero-Shot Question Generation from Knowledge Graphs for Unseen Predicates and Entity Types
Hady Elsahar, Christophe Gravier and Frederique Laforest

10:30–12:00 NLP Applications 1

Automated Essay Scoring in the Presence of Biased Ratings
Evelin Amorim, Marcia Cançado and Adriano Veloso

Content-Based Citation Recommendation
Chandra Bhagavatula, Sergey Feldman, Russell Power and Waleed Ammar

Looking Beyond the Surface: A Challenge Set for Reading Comprehension over Multiple Sentences
Daniel Khashabi, Snigdha Chaturvedi, Michael Roth, Shyam Upadhyay and Dan Roth

Neural Automated Essay Scoring and Coherence Modeling for Adversarially Crafted Input
Youmna Farag, Helen Yannakoudakis and Ted Briscoe

QuickEdit: Editing Text & Translations by Crossing Words Out
David Grangier and Michael Auli

Tempo-Lexical Context Driven Word Embedding for Cross-Session Search Task Extraction
Procheta Sen, Debasis Ganguly and Gareth Jones

June 2 (continued)

11:30–12:30 Machine Learning 1

11:30–11:48 *Zero-Shot Sequence Labeling: Transferring Knowledge from Sentences to Tokens*
Marek Rei and Anders Søgaard

11:48–12:06 *Variable Typing: Assigning Meaning to Variables in Mathematical Text*
Yiannos Stathopoulos, Simon Baker, Marek Rei and Simone Teufel

11:30–12:30 Information Extraction 2

11:30–11:48 *Learning beyond Datasets: Knowledge Graph Augmented Neural Networks for Natural Language Processing*
Annervaz K M, Somnath Basu Roy Chowdhury and Ambedkar Dukkipati

11:48–12:06 *Comparing Constraints for Taxonomic Organization*
Anne Cocos, Marianna Apidianaki and Chris Callison-Burch

11:30–12:30 Machine Translation 1

11:30–11:48 *Improving Lexical Choice in Neural Machine Translation*
Toan Nguyen and David Chiang

11:48–12:06 *Universal Neural Machine Translation for Extremely Low Resource Languages*
Jiatao Gu, Hany Hassan, Jacob Devlin and Victor O.K. Li

12:06–12:24 *Classical Structured Prediction Losses for Sequence to Sequence Learning*
Sergey Edunov, Myle Ott, Michael Auli, David Grangier and Marc'Aurelio Ranzato

June 2 (continued)

12:30–14:00 Lunch

14:00–15:00 Industry Track Keynote

15:00–15:30 Afternoon Coffee

15:30–17:00 Machine Learning 2

15:30–15:48 *Deep Dirichlet Multinomial Regression*
Adrian Benton and Mark Dredze

15:30–17:00 Social Media and Computational Social Science 1

15:30–15:48 *Microblog Conversation Recommendation via Joint Modeling of Topics and Discourse*
Xingshan Zeng, Jing Li, Lu Wang, Nicholas Beauchamp, Sarah Shugars and Kam-Fai Wong

15:48–16:06 *Before Name-Calling: Dynamics and Triggers of Ad Hominem Fallacies in Web Argumentation*
Ivan Habernal, Henning Wachsmuth, Iryna Gurevych and Benno Stein

15:30–17:00 Vision, Robotics and Other Grounding 1

15:30–15:48 *Scene Graph Parsing as Dependency Parsing*
Yu-Siang Wang, Chenxi Liu, Xiaohui Zeng and Alan Yuille

15:48–16:06 *Learning Visually Grounded Sentence Representations*
Douwe Kiela, Alexis Conneau, Allan Jabri and Maximilian Nickel

16:06–16:24 *Comparatives, Quantifiers, Proportions: a Multi-Task Model for the Learning of Quantities from Vision*
Sandro Pezzelle, Ionut-Teodor Sorodoc and Raffaella Bernardi

16:24–16:42 *Being Negative but Constructively: Lessons Learnt from Creating Better Visual Question Answering Datasets*
Wei-Lun Chao, Hexiang Hu and Fei Sha

June 2 (continued)

15:30–17:00 Semantics 1

Abstract Meaning Representation for Paraphrase Detection
Fuad Issa, Marco Damonte, Shay B. Cohen, Xiaohui Yan and Yi Chang

attr2vec: Jointly Learning Word and Contextual Attribute Embeddings with Factorization Machines
Fabio Petroni, Vassilis Plachouras, Timothy Nugent and Jochen L. Leidner

Can Network Embedding of Distributional Thesaurus Be Combined with Word Vectors for Better Representation?
Abhik Jana and Pawan Goyal

Deep Neural Models of Semantic Shift
Alex Rosenfeld and Katrin Erk

Distributional Inclusion Vector Embedding for Unsupervised Hypernymy Detection
Haw-Shiuan Chang, Ziyun Wang, Luke Vilnis and Andrew McCallum

Mining Possessions: Existence, Type and Temporal Anchors
Dhivya Chinnappa and Eduardo Blanco

Neural Tensor Networks with Diagonal Slice Matrices
Takahiro Ishihara, Katsuhiko Hayashi, Hitoshi Manabe, Masashi Shimbo and Masaaki Nagata

Post-Specialisation: Retrofitting Vectors of Words Unseen in Lexical Resources
Ivan Vulić, Goran Glavaš, Nikola Mrkšić and Anna Korhonen

Unsupervised Learning of Sentence Embeddings Using Compositional n-Gram Features
Matteo Pagliardini, Prakhar Gupta and Martin Jaggi

June 2 (continued)

15:30–17:00 Sentiment Analysis 1

Learning Domain Representation for Multi-Domain Sentiment Classification
Qi Liu, Yue Zhang and Jiangming Liu

Learning Sentence Representations over Tree Structures for Target-Dependent Classification
Junwen Duan, Xiao Ding and Ting Liu

Relevant Emotion Ranking from Text Constrained with Emotion Relationships
Deyu Zhou, Yang Yang and Yulan He

Solving Data Sparsity for Aspect Based Sentiment Analysis Using Cross-Linguality and Multi-Linguality
Md Shad Akhtar, Palaash Sawant, Sukanta Sen, Asif Ekbal and Pushpak Bhattacharyya

SRL4ORL: Improving Opinion Role Labeling Using Multi-Task Learning with Semantic Role Labeling
Ana Marasović and Anette Frank

17:00–18:30 NLP Applications 2

17:00–17:18 *Approaching Neural Grammatical Error Correction as a Low-Resource Machine Translation Task*
Marcin Junczys-Dowmunt, Roman Grundkiewicz, Shubha Guha and Kenneth Heafield

17:18–17:36 *Robust Cross-Lingual Hypernymy Detection Using Dependency Context*
Shyam Upadhyay, Yogarshi Vyas, Marine Carpuat and Dan Roth

17:36–17:54 *Noising and Denoising Natural Language: Diverse Backtranslation for Grammar Correction*
Ziang Xie, Guillaume Genthial, Stanley Xie, Andrew Ng and Dan Jurafsky

June 2 (continued)

17:00–18:30 Question Answering 1

17:00–17:18 *Self-Training for Jointly Learning to Ask and Answer Questions*
Mrinmaya Sachan and Eric Xing

17:18–17:36 *The Web as a Knowledge-Base for Answering Complex Questions*
Alon Talmor and Jonathan Berant

17:36–17:54 *A Meaning-Based Statistical English Math Word Problem Solver*
Chao-Chun Liang, Yu-Shiang Wong, Yi-Chung Lin and Keh-Yih Su

17:00–18:30 SRW Highlights

June 3

07:45–08:45 Breakfast

08:45–09:00 Announcements

09:00–10:00 Keynote 2 (sponsored by Google)

The Moment When the Future Fell Asleep
Kevin Knight, University of Southern California / Information Sciences Institute

June 3 (continued)

10:00–10:30 Morning Coffee

10:30–11:30 Cognitive Modeling and Psycholinguistics 1

10:30–10:48 *Fine-Grained Temporal Orientation and its Relationship with Psycho-Demographic Correlates*
Sabyasachi Kamila, Mohammed Hasanuzzaman, Asif Ekbal, Pushpak Bhattacharyya and Andy Way

10:48–11:06 *Querying Word Embeddings for Similarity and Relatedness*
Fatemeh Torabi Asr, Robert Zinkov and Michael Jones

10:30–11:30 Summarization 1

10:30–10:48 *Semantic Structural Evaluation for Text Simplification*
Elior Sulem, Omri Abend and Ari Rappoport

10:48–11:06 *Entity Commonsense Representation for Neural Abstractive Summarization*
Reinald Kim Amplayo, Seonjae Lim and Seung-won Hwang

11:06–11:24 *Newsroom: A Dataset of 1.3 Million Summaries with Diverse Extractive Strategies*
Max Grusky, Mor Naaman and Yoav Artzi

10:30–11:30 Semantics 2

10:30–10:48 *Polyglot Semantic Parsing in APIs*
Kyle Richardson, Jonathan Berant and Jonas Kuhn

11:06–11:24 *Neural Models of Factuality*
Rachel Rudinger, Aaron Steven White and Benjamin Van Durme

June 3 (continued)

10:30–12:00 Information Extraction 3

Accurate Text-Enhanced Knowledge Graph Representation Learning
Bo An, Bo Chen, Xianpei Han and Le Sun

Acquisition of Phrase Correspondences Using Natural Deduction Proofs
Hitomi Yanaka, Koji Mineshima, Pascual Martínez-Gómez and Daisuke Bekki

Automatic Stance Detection Using End-to-End Memory Networks
Mitra Mohtarami, Ramy Baly, James Glass, Preslav Nakov, Lluís Màrquez and Alessandro Moschitti

Collective Entity Disambiguation with Structured Gradient Tree Boosting
Yi Yang, Ozan Irsoy and Kazi Shefaet Rahman

DeepAlignment: Unsupervised Ontology Matching with Refined Word Vectors
Prodromos Kolyvakis, Alexandros Kalousis and Dimitris Kiritsis

Efficient Sequence Learning with Group Recurrent Networks
Fei Gao, Lijun Wu, Li Zhao, Tao Qin, Xueqi Cheng and Tie-Yan Liu

FEVER: a Large-scale Dataset for Fact Extraction and VERification
James Thorne, Andreas Vlachos, Christos Christodoulopoulos and Arpit Mittal

Global Relation Embedding for Relation Extraction
Yu Su, Honglei Liu, Semih Yavuz, Izzeddin Gur, Huan Sun and Xifeng Yan

Implicit Argument Prediction with Event Knowledge
Pengxiang Cheng and Katrin Erk

Improving Temporal Relation Extraction with a Globally Acquired Statistical Resource
Qiang Ning, Hao Wu, Haoruo Peng and Dan Roth

Multimodal Named Entity Recognition for Short Social Media Posts
Seungwhan Moon, Leonardo Neves and Vitor Carvalho

June 3 (continued)

Nested Named Entity Recognition Revisited
Arzoo Katiyar and Claire Cardie

Simultaneously Self-Attending to All Mentions for Full-Abstract Biological Relation Extraction
Patrick Verga, Emma Strubell and Andrew McCallum

Supervised Open Information Extraction
Gabriel Stanovsky, Julian Michael, Luke Zettlemoyer and Ido Dagan

10:30–12:00 Tagging, Chunking, Syntax and Parsing 1

Embedding Syntax and Semantics of Prepositions via Tensor Decomposition
Hongyu Gong, Suma Bhat and Pramod Viswanath

From Phonology to Syntax: Unsupervised Linguistic Typology at Different Levels with Language Embeddings
Johannes Bjerva and Isabelle Augenstein

Monte Carlo Syntax Marginals for Exploring and Using Dependency Parses
Katherine Keith, Su Lin Blodgett and Brendan O'Connor

Neural Particle Smoothing for Sampling from Conditional Sequence Models
Chu-Cheng Lin and Jason Eisner

Neural Syntactic Generative Models with Exact Marginalization
Jan Buys and Phil Blunsom

Noise-Robust Morphological Disambiguation for Dialectal Arabic
Nasser Zalmout, Alexander Erdmann and Nizar Habash

Parsing Tweets into Universal Dependencies
Yijia Liu, Yi Zhu, Wanxiang Che, Bing Qin, Nathan Schneider and Noah A. Smith

Robust Multilingual Part-of-Speech Tagging via Adversarial Training
Michihiro Yasunaga, Jungo Kasai and Dragomir Radev

June 3 (continued)

Universal Dependency Parsing for Hindi-English Code-Switching
Irshad Bhat, Riyaz A. Bhat, Manish Shrivastava and Dipti Sharma

What's Going On in Neural Constituency Parsers? An Analysis
David Gaddy, Mitchell Stern and Dan Klein

11:30–12:30 Machine Learning 3

11:30–11:48 *Deep Generative Model for Joint Alignment and Word Representation*
Miguel Rios, Wilker Aziz and Khalil Simaan

12:06–12:24 *Learning Word Embeddings for Low-Resource Languages by PU Learning*
Chao Jiang, Hsiang-Fu Yu, Cho-Jui Hsieh and Kai-Wei Chang

11:30–12:30 Social Media and Computational Social Science 2

11:30–11:48 *Exploring the Role of Prior Beliefs for Argument Persuasion*
Esin Durmus and Claire Cardie

11:48–12:06 *Inducing a Lexicon of Abusive Words – a Feature-Based Approach*
Michael Wiegand, Josef Ruppenhofer, Anna Schmidt and Clayton Greenberg

12:06–12:24 *Author Commitment and Social Power: Automatic Belief Tagging to Infer the Social Context of Interactions*
Vinodkumar Prabhakaran, Premkumar Ganeshkumar and Owen Rambow

June 3 (continued)

11:30–12:30 Vision, Robotics and Other Grounding 2

12:30–14:00 Lunch

14:00–15:00 Industry Track Keynote

15:00–15:30 Afternoon Coffee

15:30–17:00 Text Mining 1

15:30–15:48 *Comparing Automatic and Human Evaluation of Local Explanations for Text Classification*
Dong Nguyen

15:48–16:06 *Deep Temporal-Recurrent-Replicated-Softmax for Topical Trends over Time*
Pankaj Gupta, Subburam Rajaram, Hinrich Schütze and Bernt Andrassy

16:06–16:24 *Lessons from the Bible on Modern Topics: Low-Resource Multilingual Topic Model Evaluation*
Shudong Hao, Jordan Boyd-Graber and Michael J. Paul

16:24–16:42 *Explainable Prediction of Medical Codes from Clinical Text*
James Mullenbach, Sarah Wiegreffe, Jon Duke, Jimeng Sun and Jacob Eisenstein

June 3 (continued)

15:30–17:00 Semantics 3

15:30–15:48 *A Broad-Coverage Challenge Corpus for Sentence Understanding through Inference*
Adina Williams, Nikita Nangia and Samuel Bowman

15:48–16:06 *Filling Missing Paths: Modeling Co-occurrences of Word Pairs and Dependency Paths for Recognizing Lexical Semantic Relations*
Koki Washio and Tsuneaki Kato

16:06–16:24 *Specialising Word Vectors for Lexical Entailment*
Ivan Vulić and Nikola Mrkšić

16:24–16:42 *Cross-Lingual Abstract Meaning Representation Parsing*
Marco Damonte and Shay B. Cohen

15:30–17:00 Tagging, Chunking, Syntax and Parsing 2

15:30–15:48 *Sentences with Gapping: Parsing and Reconstructing Elided Predicates*
Sebastian Schuster, Joakim Nivre and Christopher D. Manning

15:48–16:06 *A Structured Syntax-Semantics Interface for English-AMR Alignment*
Ida Szubert, Adam Lopez and Nathan Schneider

16:06–16:24 *End-to-End Graph-Based TAG Parsing with Neural Networks*
Jungo Kasai, Robert Frank, Pauli Xu, William Merrill and Owen Rambow

16:24–16:42 *Colorless Green Recurrent Networks Dream Hierarchically*
Kristina Gulordava, Piotr Bojanowski, Edouard Grave, Tal Linzen and Marco Baroni

June 3 (continued)

15:30–17:00 Machine Learning 4

Diverse Few-Shot Text Classification with Multiple Metrics
Mo Yu, Xiaoxiao Guo, Jinfeng Yi, Shiyu Chang, Saloni Potdar, Yu Cheng, Gerald Tesauro, Haoyu Wang and Bowen Zhou

Early Text Classification Using Multi-Resolution Concept Representations
Adrian Pastor López Monroy, Fabio A. González, Manuel Montes, Hugo Jair Escalante and Thamar Solorio

Multinomial Adversarial Networks for Multi-Domain Text Classification
Xilun Chen and Claire Cardie

Pivot Based Language Modeling for Improved Neural Domain Adaptation

Abstract

We study the problem of named entity recognition (NER) from electronic medical records, which is one of the most fundamental and critical problems for medical text mining. Medical records which are written by clinicians from different specialties usually contain quite different terminologies and writing styles. The difference of specialties and the cost of human annotation makes it particularly difficult to train a universal medical NER system. In this paper, we propose a label-aware double transfer learning framework (La-DTL) for cross-specialty NER, so that a medical NER system designed for one specialty could be conveniently applied to another one with minimal annotation efforts. The transferability is guaranteed by two components: (i) we propose label-aware MMD for feature representation transfer, and (ii) we perform parameter transfer with a theoretical upper bound which is also label aware. We conduct extensive experiments on 12 cross-specialty NER tasks. The experimental results demonstrate that La-DTL provides consistent accuracy improvement over strong baselines. Besides, the promising experimental results on non-medical NER scenarios indicate that La-DTL is potential to be seamlessly adapted to a wide range of NER tasks.

1 Introduction

The development of hospital information system and medical informatics drives the leverage of various medical data for a more efficient and intelligent medical care service. Among many kinds of medical data, electronic health records (EHRs) are one of the most valuable and informative data as they contain detailed information about the patients and the clinical practices. EHRs are essential to many intelligent clinical applications, such as hospital quality control and clinical decision support systems (Wu et al., 2015). Most of EHRs are recorded in an unstructured form, i.e., natural language. Hence, extracting structured information from EHRs using natural language processing (NLP), e.g., named entity recognition (NER) and entity linking, plays a fundamental role in medical informatics (Zhang and Elhadad, 2013). In this paper, we focus on medical NER from EHRs, which is a fundamental task and is widely studied in the research community (Nadeau and Sekine, 2007; Uzuner et al., 2011).

In practice, the difficulty of building a universally robust and high-performance medical NER system lies in the variety of medical terminologies and expressions among different departments of specialties and hospitals. However, building separate NER systems for so many specialties comes with a prohibitively high cost. The data privacy issue further discourages the sharing of the data across departments or hospitals, making it more difficult to train a canonical NER system to be applied everywhere. This raises a natural question: if we have sufficient annotated EHRs data in one *source* specialty, can we distill the knowledge and transfer it to help training models in a related *target* specialty with few annotations? By transferring the knowledge we can achieve higher performance in target specialties with lower annotation cost and bypass the data sharing concerns. This is commonly referred to as *transfer learning* (Pan and Yang, 2010).

Current state-of-the-art transfer learning methods for NER are mainly based on deep neural networks, which perform an end-to-end training to distill sequential dependency patterns in the natural language (Ma and Hovy, 2016; Lample et al., 2016). These transfer learning methods include (i) feature representation transfer (Peng and Dredze, 2017; Kulkarni et al., 2016), which normally lever-

*Weinan Zhang is the corresponding author.

Proceedings of NAACL-HLT 2018, pages 1–15
New Orleans, Louisiana, June 1 - 6, 2018.

ages deep neural networks to learn a close feature mapping between the source and target domains, and (ii) parameter transfer (Murthy et al., 2016; Yang et al., 2017), which performs parameter sharing or joint training to get the target-domain model parameters close to those of the source-domain model. To the best of our knowledge, there is no previous literature working on transfer learning for NER in the medical domain, or even in a larger scope, i.e., medical natural language processing.

In this paper, we propose a novel NER transfer learning framework, namely label-aware double transfer learning (La-DTL): (i) We leverage bidirectional long-short term memory (Bi-LSTM) network (Graves and Schmidhuber, 2005) to automatically learn the text representations, based on which we perform a label-aware feature representation transfer. We propose a variant of maximum mean discrepancy (MMD) (Gretton et al., 2012), namely label-aware MMD (La-MMD), to explicitly reduce the domain discrepancy of feature representations of tokens with the same label between two domains. (ii) Based on the learned feature representations from Bi-LSTM, two conditional random field (CRF) models are performed for sequence labeling for source and target domain separately, where parameter transfer learning is performed. Specifically, an upper bound of KL divergence between the source and target domain's CRF label distributions is added over the emission and transition matrices across the source and target CRF models to explore the shareable parts of the parameters. Both (i) and (ii) have a label-aware characteristic, which will be discussed later. We further argue that label-aware characteristic is crucial for transfer learning in sequence labeling problems, e.g., NER, because only when the corresponding labels are matched, can the "similar" contexts (i.e. feature representation) and model parameters be efficiently borrowed to improve the label prediction.

Extensive experiments are conducted on 12 cross-specialty medical NER tasks with real-world EHRs. The experimental results demonstrate that La-DTL provides consistent accuracy improvement over strong baselines, with overall 2.62% to 6.70% absolute F1-score improvement over the state-of-the-art methods. Besides, the promising experimental results on other two non-medical NER scenarios indicate that La-DTL has the potential to be seamlessly adapted to a wide range of NER tasks.

2 Related Works

Named Entity Recognition (NER) is fundamental in information extraction area which aims at automatic detection of named entities (e.g., person, organization, location and geo-political) in free text (Marrero et al., 2013). Many high-level applications such as entity linking (Moro et al., 2014) and knowledge graph construction (Hachey et al., 2011) could be built on top of an NER system. Traditional high-performance approaches include conditional random fields models (CRFs) (Lafferty et al., 2001), maximum entropy Markov models (MEMMs) (McCallum et al., 2000) and hidden Markov models (HMMs). Recently, many neural network-based models have been proposed (Collobert et al., 2011; Chiu and Nichols, 2016; Ma and Hovy, 2016; Lample et al., 2016), in which few feature engineering works are needed to train a high-performance NER system. The architecture of those neural network-based models are similar, where different neural networks (LSTMs, CNNs) at different levels (char- and word-level) are applied to learn feature representations, and on top of neural networks, a CRF model is employed to make label predictions.

Transfer Learning distills knowledge from a source domain to help create a high-performance learner for a target domain. Transfer learning algorithms are mainly categorized into three types, namely instance transfer, feature representation transfer and parameter transfer (Pan and Yang, 2010). Instance transfer normally samples or reweights source-domain samples to match the distribution of the target domain (Chen et al., 2011; Chu et al., 2013). Feature representation transfer typically learns a feature mapping which projects source and target domain data simultaneously onto a common feature space following similar distributions (Zhuang et al., 2015; Long et al., 2015; Shen et al., 2017). Parameter transfer normally involves a joint or constrained training for the models on source and target domains, usually introduce connections between source target parameters via sharing (Srivastava and Salakhutdinov, 2013), initialization (Perlich et al., 2014), or inter-model parameter penalty schemes (Zhang et al., 2016).

Transfer Learning for NER Training a high-performance NER system requires expensive and

time-consuming manually annotated data. But sufficient labeled data is critical for the generalization of an NER system, especially for neural network-based models. Thus, transfer learning for NER is a practically important problem. The first group of methods focuses on sharing model parameters but they differ in the training schemes. He and Sun (2017) proposed to train the parameter-shared model with source and target data jointly, while the learning rates for sentences from source domain are re-weighted by the similarity with target domain corpus. Yang et al. (2017) proposed a family of frameworks which share model parameters in hierarchical recurrent networks to handle cross-application, cross-lingual, and cross-domain transfer in sequence labeling tasks. Differently, Lee et al. (2017) first trained the model with source domain data and then fine-tuned the model with little annotated target domain data.

Domain adaptation method has been well studied in NER scenarios such as using distributed word representations (Kulkarni et al., 2016) and leveraging rule-based annotators (Chiticariu et al., 2010). Multi-task learning has also been studied to improve performance in multiple NER tasks by transferring meaningful knowledge from other tasks (Collobert et al., 2011; Peng and Dredze, 2016). To take the advantages of both domain adaptation and multi-task learning, Peng and Dredze (2017) proposed a multi-task domain adaptation model.

3 Preliminaries

This section briefly introduces bidirectional LSTM, conditional random field and maximum mean discrepancy, which are the building blocks of our transfer learning framework.

Bidirectional LSTM Recurrent neural networks (RNNs) are widely used in NLP tasks for their great capability to capture contextual information in sequence data. A widely used variant of RNNs is long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), which incorporates input and forget gates to capture both long and short term dependencies. Furthermore, it will be beneficial if we process the sequence in not only a forward but also a backward way. Thus, bidirectional LSTM (Bi-LSTM) was employed in many previous works (Chiu and Nichols, 2016; Ma and Hovy, 2016; Lample et al., 2016) to capture bidirectional information in a sequence. More specifically, for token $\mathbf{x}_t$ (embedding vector) at timestep t in sequence $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n)$, the θ_b-parameterized Bi-LSTM recurrently updates hidden vectors $\mathbf{h}_t^{\rightarrow} = G^f_{\theta_b}(\mathbf{X}, \mathbf{h}_{t-1}^{\rightarrow})$ and $\mathbf{h}_t^{\leftarrow} = G^b_{\theta_b}(\mathbf{X}, \mathbf{h}_{t+1}^{\leftarrow})$ produced by a forward LSTM and a backward one, respectively. Then we concatenate $\mathbf{h}_t^{\rightarrow}$ and $\mathbf{h}_t^{\leftarrow}$ to $\mathbf{h}_t$ as the final hidden vector produced by Bi-LSTM:

$$\mathbf{h}_t = \mathbf{h}_t^{\rightarrow} \oplus \mathbf{h}_t^{\leftarrow}.$$

The representations learned from Bi-LSTM for sequence $\mathbf{X}$ is thus denoted as $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$.

Conditional Random Field The goal of NER is to detect named entities in a sequence $\mathbf{X}$ by predicting a sequence of labels $\mathbf{y} = (y_1, y_2, ..., y_n)$. Conditional random field (CRF) is widely used to make joint labeling of the tokens in a sequence (Lafferty et al., 2001).

Recently, Lample et al. (2016) proposed to build a CRF layer on top of a Bi-LSTM so that the automatically learned feature representation $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$ of the sequence can be directly fed into the CRF for sequence labeling. For a sequence of labels $\mathbf{y}$, given the hidden vector sequence $\mathbf{H}$, we define its θ_c-parametrized score function $s_{\theta_c}(\mathbf{H}, \mathbf{y})$ as:

$$s_{\theta_c}(\mathbf{H}, \mathbf{y}) = \sum_{i=1}^{n} \mathbf{E}_{i,y_i} + \sum_{i=1}^{n-1} \mathbf{A}_{y_i, y_{i+1}},$$

where $\mathbf{E}$ is the emission score matrix of size $n \times m$ (m is the number of unique labels), and is computed by $\mathbf{E} = \mathbf{HW}$ where $\mathbf{W}$ is the label emission parameter matrix; $\mathbf{A}$ is the label transition parameter matrix; thus $\theta_c = \{\mathbf{W}, \mathbf{A}\}$. We then define the conditional probability of label sequence $\mathbf{y}$ given $\mathbf{H}$ by a softmax over all possible label sequences in set $\mathcal{Y}(\mathbf{H})$ as:

$$\begin{aligned} p_{\theta_c}(\mathbf{y}|\mathbf{H}) &= \exp\{s_{\theta_c}(\mathbf{H}, \mathbf{y})\}/Z(\mathbf{H}) \\ &= \exp\{s_{\theta_c}(\mathbf{H}, \mathbf{y})\} \Big/ \sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{H})} \exp\{s_{\theta_c}(\mathbf{H}, \mathbf{y}')\}, \end{aligned} \quad (1)$$

where θ_c is omitted for simplification in the following part. The training objective in the CRF layer is to maximize the log-likelihood $\max_{\theta_c} \log p(\mathbf{y}|\mathbf{H})$. In the label prediction phase, we give the output label sequence $\mathbf{y}^*$ with the highest conditional probability $\mathbf{y}^* = \arg\max_{\mathbf{y}' \in \mathcal{Y}(\mathbf{H})} p(\mathbf{y}'|\mathbf{H})$ by dynamic programming (Sutton et al., 2012).

Maximum Mean Discrepancy Maximum Mean Discrepancy (Gretton et al., 2012) is a non-

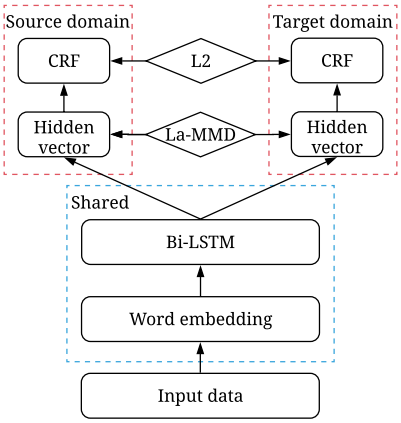

Figure 1: La-DTL framework overview: embedding and Bi-LSTM layers are shared across domains, predictors in red (upper) boxes are task-specific CRFs, with label-aware MMD and L2 constraints to perform feature representation transfer and parameter transfer.

parametric test statistic to measure the distribution discrepancy in terms of the distance between the kernel mean embeddings of two distributions p and q. The MMD is defined in particular function spaces that witness the difference in distributions

$$\text{MMD}(\mathcal{F}, p, q) = \sup_{f \in \mathcal{F}} (\mathbb{E}_{x \sim p}[f(x)] - \mathbb{E}_{y \sim q}[f(y)]).$$

By defining the function class $\mathcal{F}$ as the unit ball in a universal Reproducing Kernel Hilbert Space (RKHS), denoted by $\mathcal{H}$, it holds that $\text{MMD}[\mathcal{F}, p, q] = 0$ if and only if $p = q$. And then given two sets of samples $X = \{x_1, ..., x_m\}$ and $Y = \{y_1, ..., y_n\}$ independently and identically distributed (i.i.d.) from p and q on the data space $\mathcal{X}$, the empirical estimate of MMD can be written as the distance between the empirical mean embeddings after mapping to RKHS

$$\text{MMD}(X, Y) = \left\| \frac{1}{m} \sum_{i=1}^{m} \phi(x_i) - \frac{1}{n} \sum_{j=1}^{n} \phi(y_j) \right\|_{\mathcal{H}}, \quad (2)$$

where $\phi(\cdot) : \mathcal{X} \to \mathcal{H}$ is the nonlinear feature mapping that induces $\mathcal{H}$.

4 Methodology

In this section, we present a label-aware double transfer learning (La-DTL) framework and discuss its rationale.

4.1 Framework Overview

Figure 1 gives an overview of La-DTL for NER. From bottom up, each input sentence is converted into a sequence of embedding vectors, which are then fed into a Bi-LSTM to sequentially encode contextual information into fixed-length hidden vectors. The embedding and Bi-LSTM layers are shared among source/target domains. With label-aware maximum mean discrepancy (La-MMD) to reduce the feature representation discrepancy between two domains, the hidden vectors are directly fed into source/target domain specific CRF layers to predict the label sequence. We use domain constrained CRF layers to enhance the target domain performance.

More formally, let $\mathcal{D}_s = \{(\mathbf{X}_i^s, \mathbf{y}_i^s)\}_{i=1}^{N^s}$ be the training set of N^s samples from the source domain and $\mathcal{D}_t = \{(\mathbf{X}_i^t, \mathbf{y}_i^t)\}_{i=1}^{N^t}$ be the training set of N^t samples from the target domain, with $N^t \ll N^s$. Bi-LSTM encodes a sentence $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n)$ to hidden vectors $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$. We occasionally use $\mathbf{H}(\mathbf{X})$ to denote the corresponding hidden vectors when feeding $\mathbf{X}$ into the Bi-LSTM. CRF decodes hidden vectors $\mathbf{H}$ to a label sequence $\hat{\mathbf{y}} = (\hat{y}_1, \hat{y}_2, ..., \hat{y}_n)$. Our goal is to improve label prediction accuracy on the target domain $\mathcal{D}_t$ by utilizing the knowledge from the source domain $\mathcal{D}_s$:

$$\begin{aligned} p(\mathbf{y}|\mathbf{X}) =& p(\mathbf{y}|\mathbf{H}(\mathbf{X})), \\ \log p(\mathbf{y}|\mathbf{H}) =& \sum_{i=1}^{n} \mathbf{E}_{i,y_i} + \sum_{i=1}^{n-1} \mathbf{A}_{y_i,y_{i+1}} - \log Z(\mathbf{H}). \end{aligned} \quad (3)$$

Thus training a transferable model $p(\mathbf{y}|\mathbf{X})$ requires both $\mathbf{H}(\mathbf{X})$ and $p(\mathbf{y}|\mathbf{H})$ to be transferable.

We use share word embedding and Bi-LSTM by approaching the feature representation distributions $p(\mathbf{h}|\mathcal{D}_s)$ and $p(\mathbf{h}|\mathcal{D}_t)$, i.e., the distributions of Bi-LSTM hidden vectors at each timestep of the sentences from the source and target domains respectively. The rationale behind it lies on the insufficiency of labeled target data. Even though LSTM has high capacity, its generalization ability highly relies on viewing "sufficient" data. Otherwise, LSTM is very likely to overfit the data. Training on both source and target data, the Bi-LSTM is expected to learn feature representations with high quality. Yosinski et al. (2014) provided a justification of this solution that sharing bottom layers is promising for transfer learning in practice.

With the sentences projected onto the same hidden space, the conditional distribution $p(\mathbf{h}^s|\mathcal{D}_s)$ and $p(\mathbf{h}^t|\mathcal{D}_t)$, however, may be distant because

LSTM hidden vectors contain contextual information which is different across domains. In order to reduce source/target discrepancy, we refine MMD (Gretton et al., 2012) with label constraints, i.e., label-aware MMD (La-MMD). Using La-MMD, the source/target hidden states are pushed to similar distributions to make the feature representation $\mathbf{H}(\mathbf{X})$ transfer feasible.

Based on the hidden vectors from Bi-LSTM, we adopt independent CRF layers for each domain. The rationale lies in the hypotheses that (i) the target domain predictor can better capture target data distribution which could be very unique; (ii) a good predictor trained on the source domain directly could be leveraged to assist the target domain predictor without directly borrowing the source domain training data to bypass the data privacy issue. With respect to the emission and transition score matrices $\sum \mathbf{E}_{i,y_i}$ and $\sum \mathbf{A}_{y_i,y_{i+1}}$, we adopt an upper bound between source/target domains, which helps the target domain predictor to be guided by the source domain predictor. Thus $p(\mathbf{y}|\mathbf{H})$ is also transferable.

There are also other transfer methods, including fine-tuning, sharing parameter directly (without constraints) (He and Sun, 2017; Lee et al., 2017; Yang et al., 2017), etc. However, simply sharing models may dismiss target specific instances.

4.2 Learning Objective

The learning objective is to minimize the following loss $\mathcal{L}$ with respect to parameters $\mathbf{\Theta} = \{\theta_b, \theta_c\}$:

$$\mathcal{L} = \mathcal{L}_c + \alpha\, \mathcal{L}_{\text{La-MMD}} + \beta\, \mathcal{L}_p + \gamma\, \mathcal{L}_r,$$

where $\mathcal{L}_c$ is the CRF loss, $\mathcal{L}_{\text{La-MMD}}$ is the La-MMD loss, $\mathcal{L}_p$ is the parameter similarity loss on CRF layers, and $\mathcal{L}_r$ is the regularization term, with α, β, γ as hyperparameters to balance loss terms.

The CRF loss is our ultimate objective predicting the label sequence given the input sentence, i.e., we minimize the negative log-likelihood of training samples from both source/target domains:

$$\mathcal{L}_c = -\frac{\varepsilon}{N^s}\sum_{i=1}^{N^s}\log p(\mathbf{y}_i^s|\mathbf{H}_i^s) - \frac{1-\varepsilon}{N^t}\sum_{i=1}^{N^t}\log p(\mathbf{y}_i^t|\mathbf{H}_i^t),$$

where $\mathbf{H}$ are hidden vectors obtained from Bi-LSTM, ε is the balance coefficient. The La-MMD loss $\mathcal{L}_{\text{La-MMD}}$ and parameter similarity loss $\mathcal{L}_p$ are discussed in Section 4.3 and 4.4, respectively. The regularization term is to generally control overfitting:

$$\mathcal{L}_r = \|\theta_b\|_2^2 + \|\theta_c\|_2^2.$$

We will provide the model convergence and hyperparameter study in Section 5.1.

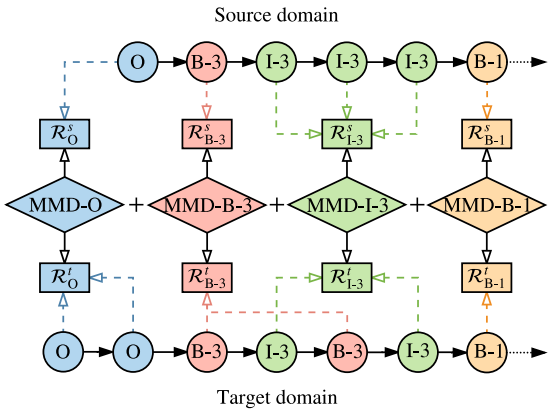

Figure 2: Illustration for La-MMD. MMD-y is computed between two domains' hidden representations with the same ground truth label y. A linear combination is then applied to each label-wise MMD to form La-MMD and the coefficient is set as $\mu_y = 1$.

4.3 Bi-LSTM Feature Representation Transfer

To learn transferable feature representations, the maximum mean discrepancy (MMD) which measures the distance between two distributions, has been widely used in domain adaptation scenarios (Long et al., 2015; Rozantsev et al., 2016). Almost all these works focus on reducing the *marginal* distribution distance between different domain features in an unsupervised manner to make them indistinguishable. However, considering a word is not evenly distributed conditioning on different labels, it may result in that the discriminative property of features from different domains may not be similar, which means that close source and target samples may not have the same label. Different from previous works, we propose label-aware MMD (La-MMD) in Eq. (5) to explicitly reduce the discrepancy between hidden representations with the same label, i.e., the linear combination of the MMD for each label. For each label class $y \in \mathcal{Y}_v$, where $\mathcal{Y}_v$ is the set of matched labels in two domains, we compute the squared population MMD between the hidden representations of source/target samples with the same label y:

$$\text{MMD}^2(\mathcal{R}_y^s, \mathcal{R}_y^t) = \frac{1}{(N_y^s)^2} \sum_{i,j=1}^{N_y^s} k(\mathbf{h}_i^s, \mathbf{h}_j^s) + \frac{1}{(N_y^t)^2} \sum_{i,j=1}^{N_y^t} k(\mathbf{h}_i^t, \mathbf{h}_j^t) - \frac{2}{N_y^s N_y^t} \sum_{i,j=1}^{N_y^s, N_y^t} k(\mathbf{h}_i^s, \mathbf{h}_j^t), \quad (4)$$

where $\mathcal{R}_y^s$ and $\mathcal{R}_y^t$ are sets of hidden representation $\mathbf{h}^s$ and $\mathbf{h}^t$ with corresponding number N_y^s and N_y^t. Eq. (4) can be easily derived by casting Eq. (2) into inner product form and applying $\langle \phi(x), \phi(y) \rangle_{\mathcal{H}} = k(x, y)$ where k is the reproducing kernel function (Gretton et al., 2012). For each label class, we compute the MMD loss in a normal manner. After that, we define the La-MMD loss as:

$$\mathcal{L}_{\text{La-MMD}} = \sum_{y \in \mathcal{Y}_v} \mu_y \cdot \text{MMD}^2(\mathcal{R}_y^s, \mathcal{R}_y^t), \quad (5)$$

where μ_y is the corresponding coefficient. The illustration of La-MMD is shown in Figure 2.

Once we have applied this La-MMD to our representations learned from Bi-LSTM, the representation distribution of instances with the same label from different domains should be close. Then the standard CRF layer which has a simple linear structure takes these similar representations as input and is likely to give a more transferable label decision for instances with the same label.

4.4 CRF Parameter Transfer

Simply sharing the CRF layer is non-promising when source/target data are diversely distributed. According to probability decomposition in Eq. (3), in order to transfer on source/target CRF layers, more specifically, $p(\mathbf{y}|\mathbf{H})$, we reduce the KL divergence from $p^t(\mathbf{y}|\mathbf{H})$ to $p^s(\mathbf{y}|\mathbf{H})$. But directly reducing $D_{\text{KL}}(p^s(\mathbf{y}|\mathbf{H})||p^t(\mathbf{y}|\mathbf{H}))$ is intractable, we tend to reduce its upper bound:

$$\begin{aligned} & D_{\text{KL}}(p^s(\mathbf{y}|\mathbf{H})||p^t(\mathbf{y}|\mathbf{H})) \\ =& \sum_{\mathbf{y} \in \mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H}) \log(\frac{p^s(\mathbf{y}|\mathbf{H})}{p^t(\mathbf{y}|\mathbf{H})}) \\ =& -H(p^s(\mathbf{y}|\mathbf{H})) - \sum_{\mathbf{y} \in \mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H}) \log p^t(\mathbf{y}|\mathbf{H}) \\ \leq& c(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2)^{\frac{1}{2}}, \end{aligned} \quad (6)$$

where $H(\cdot)$ is the entropy of distribution $(\cdot)$ and c is a constant. The detailed proof is provided in Appendix A.1. Since $c(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2)$ is the upper bound of $D_{\text{KL}}(p^s(\mathbf{y}|\mathbf{H})\|p^t(\mathbf{y}|\mathbf{H}))$,

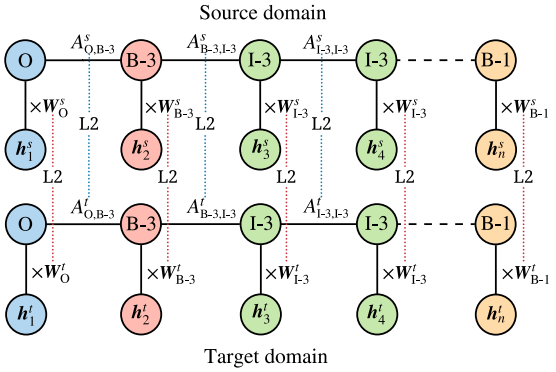

Figure 3: Illustration for CRF parameter transfer.

we conduct CRF parameter transfer by minimizing

$$\mathcal{L}_p = \|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2.$$

It turns out that a similar regularization term is applied in our CRF parameter transfer method and the regularization framework (RF) for domain adaptation (Lu et al., 2016). However, RF is proposed to generalize the feature augmentation method in (Daume III, 2007), and these two methods are only discussed from a perspective of the parameter. There is no guarantee that two models having similar parameters yields similar output distributions. In this work, we discuss the model behavior in CRF conditions, and we successfully prove that two CRF models having similar parameters (in Euclidean space) yields similar output distributions. In another word, our method guarantees transferability in the model behavior level, while previous works are limited in parameter level.

The CRF parameter transfer is illustrated in Figure 3, which is also label-aware since the L2 constraint is added over parameters corresponding to the same label in two domains, e.g., $\mathbf{W}_O^s$ and $\mathbf{W}_O^t$.

4.5 Training

We train La-DTL in an end-to-end manner with mini-batch AdaGrad (Duchi et al., 2011). One mini-batch contains training samples from both domains, otherwise the computation of $\mathcal{L}_{\text{La-MMD}}$ can not be performed. During training, word (and character) embeddings are fine-tuned to adjust real data distribution. During both training and decoding (testing) of CRF layers, we use dynamic programming to compute the normalizer in Eq. (1) and infer the label sequence.

5 Experiments

In this section, we evaluate La-DTL[1] and other baseline methods on 12 cross-specialty NER problems based on real-world datasets. The experimental results show that La-DTL steadily outperforms other baseline models in all tasks significantly. We also conduct further ablation study and robustness study. We evaluate La-DTL on two more non-medical NER transfer tasks to validate its general efficacy over a wide range of applications.

5.1 Cross-Specialty NER

Datasets We collected a Chinese medical NER (*CM-NER*) corpus for our experiments. This corpus contains 1600 de-identified EHRs of our affiliated hospital from four different specialties in four departments: Cardiology (500), Respiratory (500), Neurology (300) and Gastroenterology (300), and the research had been reviewed and approved by the ethics committee. Named entities are annotated in the BIOES format (Begin, Inside, Outside, End and Single), with 30 types in total. The statistics of *CM-NER* is shown in Table 1.

Baselines The following methods are compared. For a fair comparison, we implement La-DTL and baselines with the same base model introduced in (Lample et al., 2016) but with different transfer techniques.

- **Non-transfer** uses the target domain labeled data only.
- **Domain mask** and **Linear projection** belong to the same framework proposed by Peng and Dredze (2017) but have different implementations at the projection layer, which aims to produce shared feature representations among different domains through a linear transformation.
- **Re-training** is proposed by Lee et al. (2017), where an artificial neural networks (ANNs) is first trained on the source domain and then re-trained on the target domain.
- **Joint-training** is a transfer learning method proposed by Yang et al. (2017) where different tasks are trained jointly.
- **CD-learning** is a cross-domain learning method proposed by He and Sun (2017), where each source domain training example's learning rate is re-weighted.

Experimental Settings We use 23,217 unlabeled clinical records to train the word embeddings (word2vec) at 128 dimensions using skip-gram model (Mikolov et al., 2013). The hidden state size is set to be 200 for word-level Bi-LSTM. We evaluate La-DTL for cross-specialty NER with *CM-NER* in 12 transfer tasks, results shown in Table 2. For each task, we take the whole source domain training set $\mathcal{D}_s$ and 10% sentences of the target domain training set $\mathcal{D}_t$ as training data. We use the development set in target domain to search hyper-parameters including training epochs. We then take the models to make the prediction in target domain test set and use F1-score as the evaluation metric. Statistical significance has been determined using a randomization version of the paired sample t-test (Cohen, 1995).

Results and Discussion From the results of 12 cross-specialty NER tasks shown in Table 2, we find that La-DTL outperforms all the strong baselines in all the 12 cross-specialty transfer learning tasks, with 2.62% to 6.70% F1-score lift over state-of-the-art baseline methods. Meanwhile, Linear projection and Domain mask (Peng and Dredze, 2017) do not perform as good as other three baselines, which may be because such linear transformation methods are likely to weaken the representations. While other three baseline methods all share the whole model between source/target domains but differ in the training schemes and performance.

To better understand the transferability of La-DTL, we also evaluate three variants of La-DTL: La-MMD, CRF-L2, and MMD-CRF-L2. La-MMD and CRF-L2 have the same networks and loss function as La-DTL but with different building blocks: La-MMD has $\beta = 0$, while CRF-L2 has $\alpha = 0$. In MMD-CRF-L2, we replace La-MMD loss $\mathcal{L}_{\text{La-MMD}}$ in La-DTL with a vanilla MMD loss:

$$\mathcal{L}_{\text{MMD}} = \text{MMD}^2(\mathcal{R}^s, \mathcal{R}^t),$$

Table 2: Results (F1-score %) of 12 cross-specialty medical NER tasks. C, R, N, G are short for the department of Cardiology, Respiratory, Neurology, and Gastroenterology, respectively. † indicates La-DTL outperforms the 6 baselines significantly ($p < 0.05$).

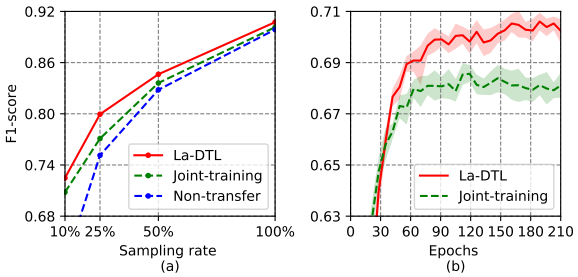

Figure 4: (a) F1-score of La-DTL, Joint-training and Non-transfer method in C→R task with different sampling rate. (b) The learning curve of La-DTL and Joint-training in C→R task.

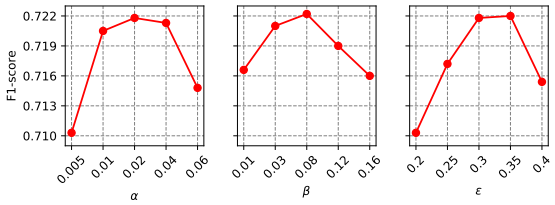

Figure 5: Hyperparameter study for α, β, and ε.

where $\mathcal{R}^s$ and $\mathcal{R}^t$ are sets of hidden representation from source and target domain. Results in Table 2 show that: (i) Using La-MMD alone does achieve satisfactory performance since it outperforms the best baseline Joint-training (Yang et al., 2017) in 7 of 12 tasks. And it has a significant improvement over Domain mask and Linear projection methods (Peng and Dredze, 2017), which indicates that using La-MMD to reduce the domain discrepancy of feature representations in sequence tagging tasks is promising. (ii) CRF-L2 is also a promising method when transferring between NER tasks, and it improves the La-MMD method significantly when these two methods are combined to form La-DTL. (iii) Label-aware characteristic is important in sequence labeling problems because there is an obvious performance drop when La-MMD is replaced with a vanilla MMD in La-DTL. But MMD-CRF-L2 still has very competitive performance compared to all the baseline methods. This shows positive empirical evidence that transferring knowledge at both Bi-LSTM feature representation level and CRF parameter level for NER tasks is better than transferring knowledge at only one of these two levels, as discussed in Section 4.1.

Robustness to Target Domain Data Sparsity We further study the sparsity problem (target domain) of La-DTL in C→R task comparing to Joint-training (Yang et al., 2017) and Non-transfer method. We evaluate La-DTL with different data volume (sampling rate: 10%, 25%, 50%, 100%) on the target domain training set. Results are shown in Figure 4(a). We observe that La-DTL outperforms Joint-training and Non-transfer results under all circumstances, and the improvement of La-DTL is more significant when the sampling rate is lower.

To show La-DTL's convergence and significant improvement over Joint-training, we repeat the 10% sampling rate experiment for 10 times with 10 random seeds. The F1-score on the target domain development set for two methods with a 95% confidence interval is shown in Figure 4(b) where La-DTL outperforms Joint-training method significantly.

Hyperparameter Study We study the influence of three key hyperparameters in La-DTL: α, β, and ε in C→R task with 10% target domain sampling rate. We first apply a rough grid search for the three hyperparameters, and the result is ($\alpha = 0.02, \beta = 0.03, \varepsilon = 0.3$). We then fix two hyperparameters and test the third one in a finer granularity. The results in Figure 5 indicate that setting $\alpha \in [0.01, 0.04]$ could better leverage La-MMD and further setting $\beta \in [0.03, 0.12]$ and $\varepsilon \in [0.3, 0.4]$ yields the best empirical perfor-

Table 4: Results (F1-score %) of *WeiboNER* transfer. $*$ indicates the result reported in the corresponding reference.

mance. This shows that we need to balance the learning objective of the source and target domains for better transferability.

5.2 NER Transfer Experiment on Non-medical Corpus

To show La-DTL could be applied in a wide range of NER transfer learning scenarios, we make experiments on two non-medical NER tasks. Corpora's details are shown in Table 3.

***WeiboNER* Transfer** Following He and Sun (2017); Peng and Dredze (2017), we transfer knowledge from *SighanNER* (MSR corpus of the sixth SIGHAN Workshop on Chinese language processing) to *WeiboNER* (a social media NER corpus) (Peng and Dredze, 2015). Results in Table 4 show that La-DTL outperforms all the baseline methods in Chinese social media domain.

***TwitterNER* Transfer** Following Yang et al. (2017) we transfer knowledge from CoNLL 2003 English NER (Tjong Kim Sang and De Meulder, 2003) to *TwitterNER* (Ritter et al., 2011). Since the entity types in these two corpora cannot be exactly matched, La-DTL and Joint-training (Yang et al., 2017) can be applied directly in this case while other baselines can not. Because the CRF parameter transfer of La-DTL is label-aware, and Joint-training simply leverages two independent CRF layers. The results are shown in Table 5, where La-DTL again outperforms Joint-training, indicating that La-DTL could be applied seamlessly to transfer learning scenarios with mismatched label sets and languages like English.

Method	F1-score
Non-transfer	34.65
Joint-training (Yang et al., 2017)*	43.24
La-DTL	**45.71**

Table 5: Results (F1-score %) of *TwitterNER* transfer. $*$ indicates the result reported in the corresponding reference.

6 Conclusions

In this paper, we propose La-DTL, a label-aware double transfer learning framework, to conduct both Bi-LSTM feature representation transfer and CRF parameter transfer with label-aware constraints for cross-specialty medical NER tasks. To our best knowledge, this is the first work on transfer learning for medical NER in cross-specialty scenario. Experiments on 12 cross-specialty NER tasks show that La-DTL provides consistent performance improvement over strong baselines. We further perform a set of experiments on different target domain data size, hyperparameter study and other non-medical NER tasks, where La-DTL shows great robustness and wide efficacy. For future work, we plan to jointly perform NER and entity linking for better cross-specialty media structural information extraction.

A Appendix

A.1 Detailed Proof

Recall the bound as in Eq. (6):

Lemma A.1. *$c_1(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2)$ is the upper bound of $(s^s(\mathbf{H}, \mathbf{y}) - s^t(\mathbf{H}, \mathbf{y}))^2$.*

Proof of Lemma A.1. $\otimes$ refers to convolutional product, $\mathbf{H}^W, \mathbf{H}^A$ are mask matrices corresponding to the given hidden vectors $\mathbf{H}$, and c_1 is a constant. We have:

$$
\begin{aligned}
&(s^s(\mathbf{H}, \mathbf{y}) - s^t(\mathbf{H}, \mathbf{y}))^2 \\
=&(\sum_{i=1}^{n} \mathbf{E}^s_{i,y_i} + \sum_{i=1}^{n-1} \mathbf{A}^s_{y_i,y_{i+1}} - \sum_{i=1}^{n} \mathbf{E}^t_{i,y_i} - \sum_{i=1}^{n-1} \mathbf{A}^t_{y_i,y_{i+1}})^2 \\
=&(\mathbf{W}^s \otimes \mathbf{H}^W + \mathbf{A}^s \otimes \mathbf{H}^A - \mathbf{W}^t \otimes \mathbf{H}^W - \mathbf{A}^t \otimes \mathbf{H}^A)^2 \\
=&((\mathbf{W}^s - \mathbf{W}^t) \otimes \mathbf{H}^W + (\mathbf{A}^s - \mathbf{A}^t) \otimes \mathbf{H}^A)^2 \\
\leq&2((\mathbf{W}^s - \mathbf{W}^t) \otimes \mathbf{H}^W)^2 + 2((\mathbf{A}^s - \mathbf{A}^t) \otimes \mathbf{H}^A)^2 \\
=&2(\sum_{i,j} (\mathbf{W}^s - \mathbf{W}^t)_{i,j} \cdot \mathbf{H}^W_{i,j})^2 + 2(\sum_{p,q} (\mathbf{A}^s - \mathbf{A}^t)_{p,q} \cdot \mathbf{H}^A_{p,q})^2 \\
\leq&2(\sum_{i,j} (\mathbf{W}^s - \mathbf{W}^t)^2_{i,j} \cdot \sum_{i,j} (\mathbf{H}^W_{i,j})^2) + 2(\sum_{p,q} (\mathbf{A}^s - \mathbf{A}^t)^2_{p,q} \cdot \sum_{p,q} (\mathbf{H}^A_{p,q})^2) \\
=&2(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 \cdot \|\mathbf{H}^W\|_2^2) + 2(\|\mathbf{A}^s - \mathbf{A}^t\|_2^2 \cdot \|\mathbf{H}^A\|_2^2) \\
\leq&c_1(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2).
\end{aligned}
$$

□

Lemma A.2. *$c(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2)^{\frac{1}{2}}$ is the upper bound of $D_{KL}(p^s(\mathbf{y}|\mathbf{H})||p^t(\mathbf{y}|\mathbf{H}))$.*

Proof of Lemma A.2. With Lemma. (A.1), we set $\varepsilon = (c_1(\|\mathbf{W}^s - \mathbf{W}^t\|_2^2 + \|\mathbf{A}^s - \mathbf{A}^t\|_2^2))^{\frac{1}{2}} \geq 0$ and $c = 2c_1^{\frac{1}{2}}$, and we have:

$$
s^s(\mathbf{H}, \mathbf{y}) - \varepsilon \leq s^t(\mathbf{H}, \mathbf{y}) \leq s^s(\mathbf{H}, \mathbf{y}) + \varepsilon, \tag{7}
$$

$$
\log\{\sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{H})} \exp[s^s(\mathbf{H}, \mathbf{y}')]\} - \varepsilon \leq \log\{\sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{H})} \exp[s^t(\mathbf{H}, \mathbf{y}')]\} \leq \log\{\sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{H})} \exp[s^s(\mathbf{H}, \mathbf{y}')]\} + \varepsilon. \tag{8}
$$

With Eq. (7) and Eq. (8), we can derive

$$
\begin{aligned}
& -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\log p^t(\mathbf{y}|\mathbf{H}) \\
=& -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\log\frac{\exp[s^t(\mathbf{H},\mathbf{y})]}{\sum_{\mathbf{y}'\in\mathcal{Y}(\mathbf{H})}\exp[s^t(\mathbf{H},\mathbf{y}')]} \\
=& -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\big\{s^t(\mathbf{H},\mathbf{y})-\log\{\sum_{\mathbf{y}'\in\mathcal{Y}(\mathbf{H})}\exp[s^t(\mathbf{H},\mathbf{y}')]\}\big\} \\
\leq& -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\big\{s^s(\mathbf{H},\mathbf{y})-\varepsilon-\log\{\sum_{\mathbf{y}'\in\mathcal{Y}(\mathbf{H})}\exp[s^s(\mathbf{H},\mathbf{y}')]\}-\varepsilon\big\} \\
=& -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\big\{\log\frac{\exp[s^s(\mathbf{H},\mathbf{y})]}{\sum_{\mathbf{y}'\in\mathcal{Y}(\mathbf{H})}\exp[s^s(\mathbf{H},\mathbf{y}')]}-2\varepsilon\big\} \\
=& -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\big\{\log p^s(\mathbf{y}|\mathbf{H})-2\varepsilon\big\} \\
=& H(p^s(\mathbf{y}|\mathbf{H}))+2\varepsilon.
\end{aligned}
$$

Finally, we have

$$
\begin{aligned}
& D_{\mathrm{KL}}(p^s(\mathbf{y}|\mathbf{H})||p^t(\mathbf{y}|\mathbf{H})) \\
=& \sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\log(\frac{p^s(\mathbf{y}|\mathbf{H})}{p^t(\mathbf{y}|\mathbf{H})}) \\
=& -H(p^s(\mathbf{y}|\mathbf{H}))-\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{H})} p^s(\mathbf{y}|\mathbf{H})\log p^t(\mathbf{y}|\mathbf{H}) \\
\leq& -H(p^s(\mathbf{y}|\mathbf{H}))+H(p^s(\mathbf{y}|\mathbf{H}))+2\varepsilon \\
=& c(\|\mathbf{W}^s-\mathbf{W}^t\|_2^2+\|\mathbf{A}^s-\mathbf{A}^t\|_2^2)^{\frac{1}{2}}.
\end{aligned}
$$

□

A.2 Case Analysis

In clinical practice, patients with specific diseases would be assigned to different departments, and specialist doctors in their department may pay more attention to the specific disease. When writing a medical chart, these specific diseases and related clinical findings would have a more detailed description. Therefore, some medical terms would have enriched meanings in different departments accordingly. For example, patients with rheumatic heart disease are often treated in the department of Cardiology. The term, "rheumatic", a modifier, describes and limits the type of "heart disease". In English, "rheumatic" is an adjective modifying "heart disease". However, in Chinese, "rheumatic heart disease" can be regarded as two diseases, "rheumatism" and "heart disease". In the department of Cardiology, "rheumatic heart disease" is usually mentioned as a single term. While in other departments, "rheumatism" and "heart disease" are mostly two independent named entities in annotated datasets. As such, it is difficult to train an NER model to capture the relationship between "rheumatism" and "heart disease", and band them as a whole. In the training set of our study, the diagnostic term "rheumatic heart disease" (including synonym) is mentioned for 17 times in Dept. Cardiology, 16 times in Dept. Respiratory, none in Dept. Neurology and 3 times in Dept. Gastroenterology. We use the data from the first 3 departments as source domain training set respectively, and the data from Dept. Gastroenterology as the target domain training set. We test our models on the test set from Dept. Gastroenterology, where "rheumatic heart disease" is mentioned 3 times, and compare the results across models

Disease	Transfer Task	# disease term in source domain training set	# disease term in target domain training set	# disease term in target domain test set	# accurate labeling without transfer	# accurate labeling with transfer
rheumatic heart disease	C→G N→G R→G	17 0 16	0	3	0	3 0 3
pulmonary heart disease	C→G N→G R→G	4 0 24	0	2	0	2 0 2
coronary atherosclerotic heart disease	G→N C→N R→N	5 136 23	0	15	10	3 15 11

Table 6: Case analysis for cross-specialty medical NER tasks. C, R, N, G are short for department of Cardiology, Respiratory, Neurology, and Gastroenterology, respectively.

with/without transfer learning. As expected, models with source training data from Dept. Cardiovascular and Respiration correctly predict all these entities, but the model using source data from Dept. Neurology fails and so does a model without transfer learning.

Patients with pulmonary heart disease were often referred to Dept. Respiratory and Dept. Cardiology. In our training set, "pulmonary heart disease" (including synonym) is labeled for 24 times in Dept. Respiratory and 4 times in Dept. Cardiology. In English, "pulmonary" modified "heart disease". In Chinese, "pulmonary heart disease" contains body structure "lung" and disease name "heart disease". The model trained with the source set from both from department of respiratory and cardiology could correctly recognize the relation between lung and heart disease and predict the entity in the test set from Dept. Gastroenterology.

Similarly, "coronary atherosclerotic heart disease" contains two disease names, "coronary atherosclerosis" and "heart disease". Training model using source set from a department where the terms are enriched could improve the performance of recognizing the whole entity.

A.3 Medical Experiments Details

The 30 entity types for medical domain are: Symptom, Disease, Examination, Treatment, Laboratory index, Products, Body structure, Frequency, Negative word, Value, Trend, Modification, Temporal word, Noun of locality, Degree modifier, Probability, Object, Organism, Location, Person, Pronoun, Privacy information, Accident, Action, Header, Instrument and material, Non-physiological structure, Dosage, Scale, and Preposition.

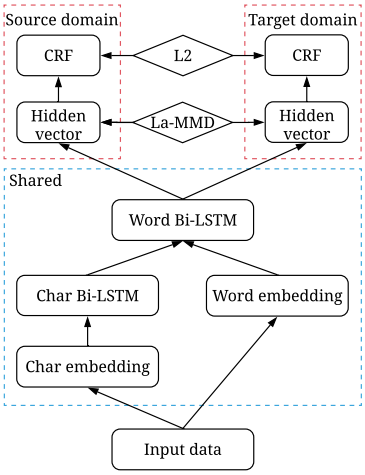

Figure 6: La-DTL framework for language like English.

A.4 Non-medical Experiments Details

WeiboNER Transfer

Both *SighanNER* and *WeiboNER* are annotated in the BIO format (Begin, Inside and Outside), but there is one more entity type (geo-political) in *WeiboNER*. For a fair comparison, we follow Peng and Dredze (2017); He and Sun (2017) to merge geo-political entities and locations in *WeiboNER*, to match different labeling schemes between *WeiboNER* and *SighanNER*. We use the inconsistencies fixed second version of *WeiboNER* data and word embeddings provided by *WeiboNER*'s developers (Peng and Dredze, 2015)[2] in this experiment.

TwitterNER Transfer

To show that La-DTL could be applied in transfer learning for NER scenario with mismatched

[2] https://github.com/hltcoe/golden-horse

named entity types and languages like English, we conduct this experiment transfer from CoNLL 2003 English NER to *TwitterNER*. The four entity types in CoNLL 2003 English NER are LOC, PER, ORG, and MISC. The ten entity types in *TwitterNER* are company, facility, geo-loc, movie, musicartist, other, person, product, sportsteam, and tvshow.

The Joint-training method (Yang et al., 2017) separates the CRF layers for each domain to bypass the label mismatch problem. Since our La-DTL is label-aware, we match four pairs of named entities between two CoNLL 2003 English NER and *TwitterNER*: LOC with geo-loc, PER with person, ORG with company and MISC with other to compute $\mathcal{L}_{\text{La-MMD}}$ and $\mathcal{L}_p$, and leave six named entities unmatched. Following Yang et al. (2017), We leverage char-level Bi-LSTM to generate better word representations, concatenate it with pre-trained word embeddings and feed concatenated embeddings to the word-level Bi-LSTM. The framework used for language like English is illustrated in Figure 6.

We also convert all characters to lowercase and use the same word embeddings provided by Yang et al. (2017)[3]. Also, we concatenate the training set and the development set for both domains and sample the same 10% from *TwitterNER* as (Yang et al., 2017) to be target domain training data. Since Yang et al. (2017) merge training and development set into training data, both Yang et al. (2017) and we report the best performance in the target domain test set.

Abstract

The task of Fine-grained Entity Type Classification (FETC) consists of assigning types from a hierarchy to entity mentions in text. Existing methods rely on distant supervision and are thus susceptible to noisy labels that can be *out-of-context* or *overly-specific* for the training sentence. Previous methods that attempt to address these issues do so with heuristics or with the help of hand-crafted features. Instead, we propose an end-to-end solution with a neural network model that uses a variant of cross-entropy loss function to handle *out-of-context* labels, and hierarchical loss normalization to cope with *overly-specific* ones. Also, previous work solve FETC a multi-label classification followed by ad-hoc post-processing. In contrast, our solution is more elegant: we use public word embeddings to train a single-label that jointly learns representations for entity mentions and their context. We show experimentally that our approach is robust against noise and consistently outperforms the state-of-the-art on established benchmarks for the task.

1 Introduction

Fine-grained Entity Type Classification (FETC) aims at labeling entity mentions in context with one or more specific types organized in a hierarchy (e.g., **actor** as a subtype of **artist**, which in turn is a subtype of **person**). Fine-grained types help in many applications, including relation extraction (Mintz et al., 2009), question answering (Li and Roth, 2002), entity linking (Lin et al., 2012), knowledge base completion (Dong et al., 2014) and entity recommendation (Yu et al., 2014). Because of the high cost in labeling large training corpora with fine-grained types, current FETC systems resort to distant supervision (Mintz et al., 2009) and annotate mentions in the training corpus with *all types* associated with the entity in a knowledge graph. This is illustrated in Figure 1, with three training sentences about entity *Steve Kerr*. Note that while the entity belongs to three fine-grained types (**person**, **athlete**, and **coach**), some sentences provide evidence of only some of the types: **person** and **coach** from **S1**, **person** and **athlete** from **S2**, and just **person** for **S3**. Clearly, direct distant supervision leads to noisy training data which can hurt the accuracy of the FETC model.

One kind of noise introduced by distant supervision is assigning labels that are *out-of-context* (**athlete** in **S1** and **coach** in **S2**) for the sentence. Current FETC systems sidestep the issue by either ignoring *out-of-context* labels or using simple pruning heuristics like discarding training examples with entities assigned to multiple types in the knowledge graph. However, both strategies are inelegant and hurt accuracy. Another source of noise introduced by distant supervision is when the type is *overly-specific* for the context. For instance, example **S3** does not support the inference that Mr. Kerr is either an **athlete** or a **coach**. Since existing knowledge graphs give more attention to notable entities with more specific types, *overly-specific* labels bias the model towards popular subtypes instead of generic ones, *i.e.*, preferring **athlete** over **person**. Instead of correcting for this bias, most existing FETC systems ignore the problem and treat each type equally and independently, ignoring that many types are semantically related.

Besides failing to handle noisy training data there are two other limitations of previous FETC approaches we seek to address. First, they rely on hand-crafted features derived from various NLP tools; therefore, the inevitable errors introduced by these tools propagate to the FETC systems via the training data. Second, previous systems treat FETC as a multi-label classification problem: during type inference they predict a plausibility score for each type, and, then, either classify types

Proceedings of NAACL-HLT 2018, pages 16–25
New Orleans, Louisiana, June 1 - 6, 2018.

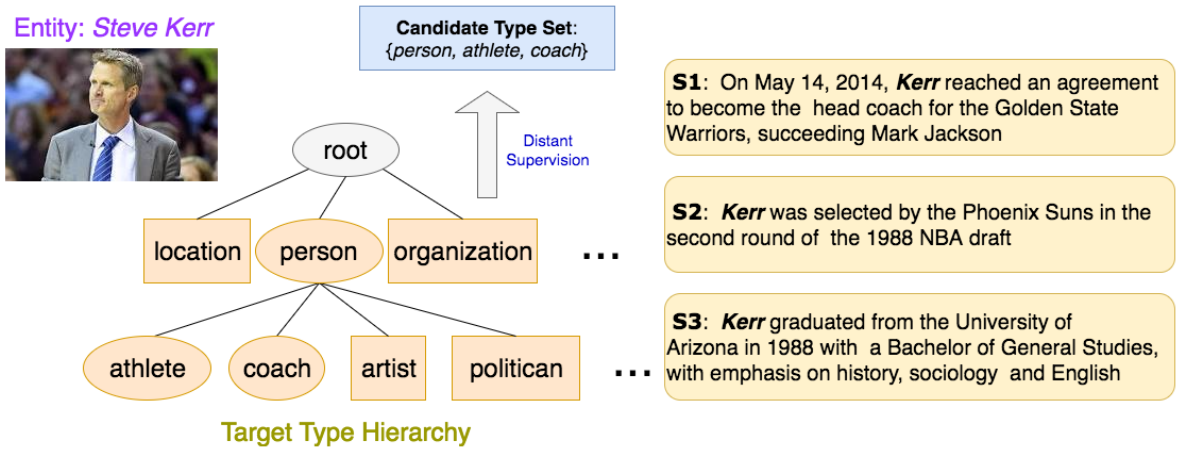

Figure 1: With distant supervision, all the three mentions of *Steve Kerr* shown are labeled with the same types in oval boxes in the target type hierarchy. While only part of the types are correct: **person** and **coach** for **S1**, **person** and **athlete** for **S2**, and just **person** for **S3**.

with scores above a threshold (Mintz et al., 2009; Gillick et al., 2014; Shimaoka et al., 2017) or perform a top-down search in the given type hierarchy (Ren et al., 2016a; Abhishek et al., 2017).

Contributions: We propose a neural network based model to overcome the drawbacks of existing FETC systems mentioned above. With publicly available word embeddings as input, we learn two different entity representations and use bidirectional long-short term memory (LSTM) with attention to learn the context representation. We propose a variant of cross entropy loss function to handle *out-of-context* labels automatically during the training phase. Also, we introduce hierarchical loss normalization to adjust the penalties for correlated types, allowing our model to understand the type hierarchy and alleviate the negative effect of *overly-specific* labels.

Moreover, in order to simplify the problem and take advantage of previous research on hierarchical classification, we transform the multi-label classification problem to a single-label classification problem. Based on the assumption that each mention can only have one *type-path* depending on the context, we leverage the fact that type hierarchies are forests, and represent each *type-path* uniquely by the terminal type (which might not be a leaf node). For Example, *type-path* **root-person-coach** can be represented as just **coach**, while **root-person** can be unambiguously represented as the non-leaf **person**.

Finally, we report on an experimental validation against the state-of-the-art on established benchmarks that shows that our model can adapt to noise in training data and consistently outperform previous methods. In summary, we describe a single, much simpler and more elegant neural network model that attempts FETC "end-to-end" without post-processing or ad-hoc features and improves on the state-of-the-art for the task.

2 Related Work

Fine-Grained Entity Type Classification: The first work to use distant supervision (Mintz et al., 2009) to induce a large - but noisy - training set and manually label a significantly smaller dataset to evaluate their FETC system, was Ling and Weld (2012) who introduced both a training and evaluation dataset FIGER (GOLD). They used a linear classifier perceptron for multi-label classification. While initial work largely assumed that mention assignments could be done independently of the mention context, Gillick et al. (2014) introduced the concept of context-dependent FETC where the types of a mention are constrained to what can be deduced from its context and introduced a new OntoNotes-derived (Weischedel et al., 2011) manually annotated evaluation dataset. In addition, they addressed the problem of label noise induced by distant supervision and proposed three label cleaning heuristics. Yogatama et al. (2015) proposed an embedding-based model where user-defined features and labels were embedded into a low dimensional feature space to facilitate information sharing among labels. Ma et al. (2016) presented a label embedding method that incor-

	Attentive	AFET	LNR	AAA	**NFETC**

Table 1: Summary comparison to related FETC work. FETC systems listed in the table: (1) **Attentive** (Shimaoka et al., 2017); (2) **AFET** (Ren et al., 2016a); (3) **LNR** (Ren et al., 2016b); (4) **AAA** (Abhishek et al., 2017).

porates prototypical and hierarchical information to learn pre-trained label embeddings and adpated a zero-shot framework that can predict both seen and previously unseen entity types.

Shimaoka et al. (2016) proposed an attentive neural network model that used LSTMs to encode the context of an entity mention and used an attention mechanism to allow the model to focus on relevant expressions in such context. Shimaoka et al. (2017) summarizes many neural architectures for FETC task. These models ignore the *out-of-context noise*, that is, they assume that all labels obtained via distant supervision are "correct" and appropriate for every context in the training corpus. In our paper, a simple yet effective variant of cross entropy loss function is proposed to handle the problem of *out-of-context noise*.

Ren et al. (2016a) have proposed AFET, an FETC system, that separates the loss function for *clean* and *noisy* entity mentions and uses label-label correlation information obtained by given data in its parametric loss function. Considering the noise reduction aspects for FETC systems, Ren et al. (2016b) introduced a method called LNR to reduce label noise without data loss, leading to significant performance gains on both the evaluation dataset of FIGER(GOLD) and OntoNotes. Although these works consider both *out-of-context noise* and *overly-specific noise*, they rely on hand-crafted features which become an impediment to further improvement of the model performance. For LNR, because the noise reduction step is separated from the FETC model, the inevitable errors introduced by the noise reduction will be propagated into the FETC model which is undesirable. In our FETC system, we handle the problem induced from *irrelevant noise* and *overly-specific noise* seamlessly inside the model and avoid the usage of hand-crafted features.

Most recently, following the idea from AFET, Abhishek et al. (2017) proposed a simple neural network model which incorporates noisy label information using a variant of non-parametric hinge loss function and gain great performance improvement on FIGER(GOLD). However, their work overlooks the effect of *overly-specific noise*, treating each type label equally and independently when learning the classifiers and ignores possible correlations among types.

Hierarchical Loss Function: Due to the intrinsic type hierarchy existing in the task of FETC, it is natural to adopt the idea of hierarchical loss function to adjust the penalties for FETC mistakes depending on how far they are in the hierarchy. The penalty for predicting **person** instead of **athlete** should less than the penalty for predicting **organization**. To the best of our knowledge, the first use of a hierarchical loss function was originally introduced in the context of document categorization with support vector machines (Cai and Hofmann, 2004). However, that work assumed that weights to control the hierarchical loss would be solicited from domain experts, which is inapplicable for FETC. Instead, we propose a method called hierarchical loss normalization which can overcome the above limitations and be incorporated with cross entropy loss used in our neural architecture.

Table 1 provides a summary comparison of our work against the previous state-of-the-art in fine grained entity typing.

3 Background and Problem

Our task is to automatically reveal the type information for entity mentions in context. The input is a knowledge graph Ψ with schema $\mathcal{Y}_\Psi$, whose types are organized into a type hierarchy $\mathcal{Y}$, and an automatically labeled training corpus $\mathcal{D}$ obtained by distant supervision with $\mathcal{Y}$. The output is a *type-path* in $\mathcal{Y}$ for each named entity mentioned in a test sentence from a corpus $\mathcal{D}_t$.

More precisely, a labeled corpus for entity type classification consists of a set of extracted *entity mentions* $\{m_i\}_{i=1}^N$ (*i.e.*, token spans representing entities in text), the *context* (*e.g.,* sentence, paragraph) of each mention $\{c_i\}_{i=1}^N$, and the *candidate*

type sets $\{\mathcal{Y}_i\}_{i=1}^N$ automatically generated for each mention.

We represent the training corpus using a set of mention-based triples $\mathcal{D} = \{(m_i, c_i, \mathcal{Y}_i)\}_{i=1}^N$.

If $\mathcal{Y}_i$ is free of *out-of-context noise*, the type labels for each m_i should form a single *type-path* in $\mathcal{Y}_i$. However, $\mathcal{Y}_i$ may contain *type-paths* that are irrelevant to m_i in c_i if there exists *out-of-context noise*.

We denote the type set including all terminal types for each *type-path* as the target type set $\mathcal{Y}_i^t$. In the example type hierarchy shown in Figure 1, if $\mathcal{Y}_i$ contains types **person**, **athlete**, **coach**, $\mathcal{Y}_i^t$ should contain **athlete**, **coach**, but not **person**. In order to understand the trade-off between the effect of *out-of-context noise* and the size of the training set, we report on experiments with two different training sets: $\mathcal{D}_{filtered}$ only with triples whose $\mathcal{Y}_i$ form a single *type-path* in $\mathcal{D}$, and $\mathcal{D}_{raw}$ with all triples.

We formulate fine-grained entity classification problem as follows:

Definition 1 *Given an entity mention* $m_i = (w_p, \ldots, w_t)$ $(p, t \in [1, T], p \leq t)$ *and its context* $c_i = (w_1, \ldots, w_T)$ *where* T *is the context length, our task is to predict its most specific type* $\hat{y}_i$ *depending on the context.*

In practice, c_i is generated by truncating the original context with words beyond the context window size C both to the left and to the right of m_i. Specifically, we compute a probability distribution over all the $K = |\mathcal{Y}|$ types in the target type hierarchy $\mathcal{Y}$. The type with the highest probability is classified as the predicted type $\hat{y}_i$ which is the terminal type of the predicted *type-path*.

4 Methodology

This section details our Neural Fine-Grained Entity Type Classification (NFETC) model.

4.1 Input Representation

As stated in Section 3, the input is an entity mention m_i with its context c_i. First, we transform each word in the context c_i into a real-valued vector to provide lexical-semantic features. Given a word embedding matrix W^{wrd} of size $d_w \times |V|$, where V is the input vocabulary and d_w is the size of word embedding, we map every w_i to a column vector $\mathbf{w}_i^d \in \mathbb{R}^{d_w}$.

To additionally capture information about the relationship to the target entities, we incorporate word position embeddings (Zeng et al., 2014) to reflect relative distances between the i-th word to the entity mention. Every relative distance is mapped to a randomly initialized position vector in $\mathbb{R}^{d_p}$, where d_p is the size of position embedding. For a given word, we obtain the position vector $\mathbf{w}_i^p$. The overall embedding for the i-th word is $\mathbf{w}_i^E = [(\mathbf{w}_i^d)^\top, (\mathbf{w}_i^p)^\top]^\top$.

4.2 Context Representation

For the context c_i, we want to apply a non-linear transformation to the vector representation of c_i to derive a context feature vector $h_i = f(c_i; \theta)$ given a set of parameters θ. In this paper, we adopt bidirectional LSTM with d_s hidden units as $f(c_i; \theta)$. The network contains two sub-networks for the forward pass and the backward pass respectively. Here, we use element-wise sum to combine the forward and backward pass outputs. The output of the i-th word in shown in the following equation:

$$h_i = [\overrightarrow{h_i} \oplus \overleftarrow{h_i}] \tag{1}$$

Following Zhou et al. (2016), we employ word-level attention mechanism, which makes our model able to softly select the most informative words during training. Let H be a matrix consisting of output vectors $[h_1, h_2, \ldots, h_T]$ that the LSTM produced. The context representation r is formed by a weighted sum of these output vectors:

$$G = \tanh(H) \tag{2}$$

$$\alpha = softmax(w^\top G) \tag{3}$$

$$r_c = H\alpha^\top \tag{4}$$

where $H \in \mathbb{R}^{d_s \times T}$, w is a trained parameter vector. The dimension of w, α, r_c are d_s, T, d_s respectively.

4.3 Mention Representation

Averaging encoder: Given the entity mention $m_i = (w_p, \ldots, w_t)$ and its length $L = t - p + 1$, the averaging encoder computes the average word embedding of the words in m_i. Formally, the averaging representation r_a of the mention is computed as follows:

$$r_a = \frac{1}{L} \sum_{i=p}^{t} \mathbf{w}_i^d \tag{5}$$

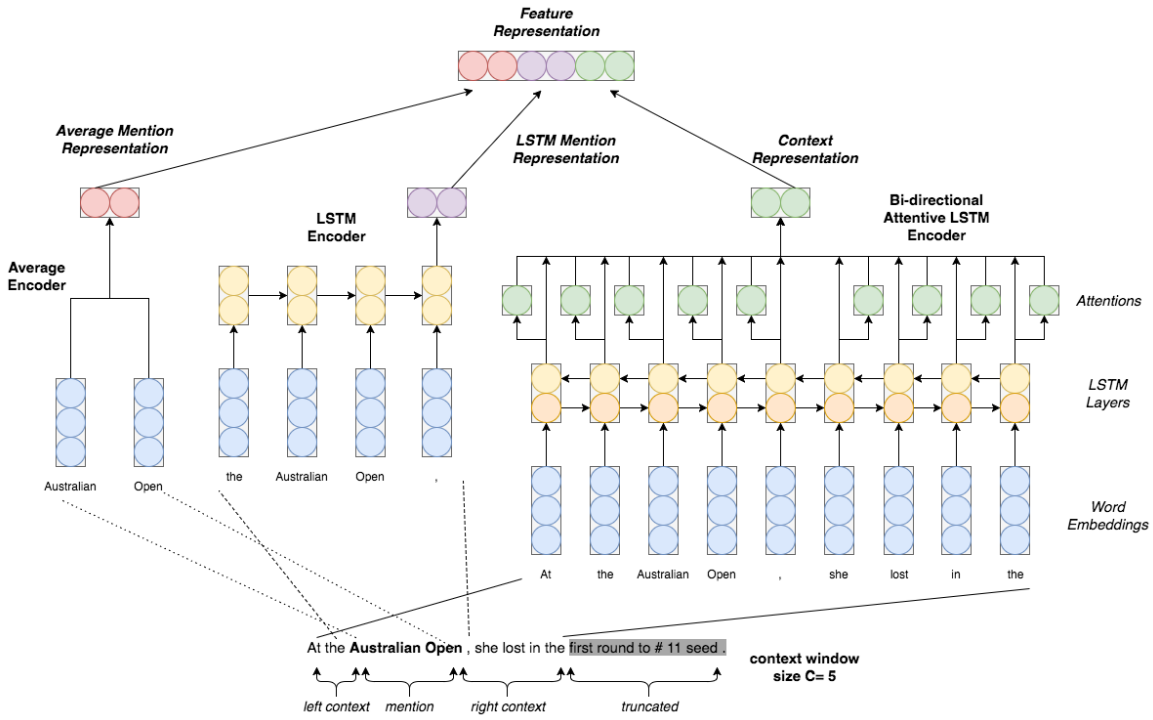

Figure 2: The architecture of the NFETC model.

This relatively simple method for composing the mention representation is motivated by it being less prone to overfitting (Shimaoka et al., 2017).

LSTM encoder: In order to capture more semantic information from the mentions, we add one token before and another after the target entity to the mention. The extended mention can be represented as $m_i^* = (w_{p-1}, w_p, \ldots, w_t, w_{t+1})$. The standard LSTM is applied to the mention sequence from left to right and produces the outputs $h_{p-1}, \ldots, h_{t+1}$. The last output h_{t+1} then serves as the LSTM representation r_l of the mention.

4.4 Optimization

We concatenate context representation and two mention representations together to form the overall feature representation of the input $R = [r_c, r_a, r_l]$. Then we use a softmax classifier to predict $\hat{y}_i$ from a discrete set of classes for a entity mention m and its context c with R as input:

$$\hat{p}(y|m,c) = \text{softmax}(WR + b) \quad (6)$$

$$\hat{y} = \arg\max_y \hat{p}(y|m,c) \quad (7)$$

where W can be treated as the learned type embeddings and b is the bias.

The traditional cross-entropy loss function is represented as follows:

$$J(\theta) = -\frac{1}{N}\sum_{i=1}^{N} \log(\hat{p}(y_i|m_i,c_i)) + \lambda\|\Theta\|^2 \quad (8)$$

where y_i is the only element in $\mathcal{Y}_i^t$ and $(m_i, c_i, \mathcal{Y}_i) \in \mathcal{D}_{filtered}$. λ is an L2 regularization hyperparameter and Θ denotes all parameters of the considered model.

In order to handle data with *out-of-context noise* (in other words, with multiple labeled types) and take full advantage of them, we introduce a simple yet effective variant of the cross-entropy loss:

$$J(\theta) = -\frac{1}{N}\sum_{i=1}^{N} \log(\hat{p}(y_i^*|m_i,c_i)) + \lambda\|\Theta\|^2 \quad (9)$$

where $y_i^* = \arg\max_{y \in \mathcal{Y}_i^t} \hat{p}(y|m_i,c_i)$ and $(m_i, c_i, \mathcal{Y}_i) \in \mathcal{D}_{raw}$. With this loss function, we assume that the type with the highest probability among $\mathcal{Y}_i^t$ during training as the correct type. If there is only one element in $\mathcal{Y}_i^t$, this loss function is equivalent to the cross-entropy loss function. Wherever there are multiple elements, it can filter the less probable types based on the local context automatically.

4.5 Hierarchical Loss Normalization

Since the fine-grained types tend to form a forest of type hierarchies, it is unreasonable to treat every type equally. Intuitively, it is better to predict an ancestor type of the true type than some other unrelated type. For instance, if one example is labeled as **athlete**, it is reasonable to predict its type as **person**. However, predicting other high level types like **location** or **organization** would be inappropriate. In other words, we want the loss function to penalize less the cases where types are related. Based on the above idea, we adjust the estimated probability as follows:

$$p^*(\hat{y}|m,c) = p(\hat{y}|m,c) + \beta * \sum_{t \in \Gamma} p(t|m,c) \quad (10)$$

where Γ is the set of ancestor types along the *type-path* of $\hat{y}$, β is a hyperparameter to tune the penalty. Afterwards, we re-normalize it back to a probability distribution, a process which we denote as *hierarchical loss normalization*.

As discussed in Section 1, there exists *overly-specific noise* in the automatically labeled training sets which hurt the model performance severely. With *hierarchical loss normalization*, the model will get less penalty when it predicts the actual type for one example with *overly-specific noise*. Hence, it can alleviate the negative effect of *overly-specific noise* effectively. Generally, *hierarchical loss normalization* can make the model somewhat understand the given type hierarchy and learn to detect those overly-specific cases. During classification, it will make the models prefer generic types unless there is a strong indicator for a more specific type in the context.

4.6 Regularization

Dropout, proposed by Hinton et al. (2012), prevents co-adaptation of hidden units by randomly omitting feature detectors from the network during forward propagation. We employ both input and output dropout on LSTM layers. In addition, we constrain L2-norms for the weight vectors as shown in Equations 8, 9 and use early stopping to decide when to stop training.

5 Experiments

This section reports an experimental evaluation of our NFETC approach using the previous state-of-the-art as baselines.

	FIGER(GOLD)	OntoNotes

Max hierarchy depth	2	3

Table 2: Statistics of the datasets

5.1 Datasets

We evaluate the proposed model on two standard and publicly available datasets, provided in a pre-processed tokenized format by Shimaoka et al. (2017). Table 2 shows statistics about the benchmarks. The details are as follows:

- **FIGER(GOLD):** The training data consists of Wikipedia sentences and was automatically generated with distant supervision, by mapping Wikipedia identifiers to Freebase ones. The test data, mainly consisting of sentences from news reports, was manually annotated as described by Ling and Weld (2012).

- **OntoNotes:** The OntoNotes dataset consists of sentences from newswire documents present in the OntoNotes text corpus (Weischedel et al., 2013). DBpedia spotlight (Daiber et al., 2013) was used to automatically link entity mention in sentences to Freebase. Manually annotated test data was shared by Gillick et al. (2014).

Because the type hierarchy can be somewhat understood by our proposed model, the quality of the type hierarchy can also be a key factor to the performance of our model. We find that the type hierarchy for FIGER(GOLD) dataset following Freebase has some flaws. For example, **software** is not a subtype of **product** and **government** is not a subtype of **organization**. Following the proposed type hierarchy of Ling and Weld (2012), we refine the Freebase-based type hierarchy. The process is a one-to-one mapping for types in the original dataset and we didn't add or drop any type or sentence in the original dataset. As a result, we can directly compare the results of our proposed model with or without this refinement.

Aside from the advantages brought by adopting the single label classification setting, we can see one disadvantage of this setting based on Table 2. That is, the performance upper bounds of

our proposed model are no longer 100%: for example, the best strict accuracy we can get in this setting is 88.28% for **FIGER(GOLD)**. However, as the strict accuracy of state-of-the-art methods are still nowhere near 80% (Table 3), the evaluation we perform is still informative.

5.2 Baselines

We compared the proposed model with state-of-the-art FETC systems [1]: (1) **Attentive** (Shimaoka et al., 2017); (2) **AFET** (Ren et al., 2016a); (3) **LNR+FIGER** (Ren et al., 2016b); (4) **AAA** (Abhishek et al., 2017).

We compare these baselines with variants of our proposed model: (1) **NFETC(f)**: basic neural model trained on $\mathcal{D}_{filtered}$ (recall Section 4.4); (2) **NFETC-hier(f)**: neural model with hierarichcal loss normalization trained on $\mathcal{D}_{filtered}$. (3) **NFETC(r)**: neural model with proposed variant of cross-entropy loss trained on $\mathcal{D}_{raw}$; (4) **NFETC-hier(r)**: neural model with proposed variant of cross-entropy loss and hierarchical loss normalization trained on $\mathcal{D}_{raw}$.

5.3 Experimental Setup

For evaluation metrics, we adopt the same criteria as Ling and Weld (2012), that is, we evaluate the model performance by strict accuracy, loose macro, and loose micro F-scores. These measures are widely used in existing FETC systems (Shimaoka et al., 2017; Ren et al., 2016b,a; Abhishek et al., 2017).

We use pre-trained word embeddings that were not updated during training to help the model generalize to words not appearing in the training set. For this purpose, we used the freely available 300-dimensional cased word embedding trained on 840 billion tokens from the Common Crawl supplied by Pennington et al. (2014). For both datasets, we randomly sampled 10% of the test set as a development set, on which we do the hyperparameters tuning. The remaining 90% is used for final evaluation. We run each model with the well-tuned hyperparameter setting five times and report their average strict accuracy, macro F1 and micro F1 on the test set. The proposed model was implemented using the TensorFlow framework. [2]

[1]The results of the baselines are all as reported in their corresponding papers.

[2]The code to replicate the work is available at: https://github.com/billy-inn/NFETC

Parameter	FIGER(GOLD)	OntoNotes
lr	0.0002	0.0002
d_p	85	20
d_s	180	440
p_i	0.7	0.5
p_o	0.9	0.5
λ	0.0	0.0001
β	0.4	0.3

Table 4: Hyperparameter Settings

5.4 Hyperparameter Setting

In this paper, we search different hyperparameter settings for FIGER(GOLD) and OntoNotes separately, considering the differences between the two datasets. The hyperparameters include the learning rate lr for Adam Optimizer, size of word position embeddings (WPE) d_p, state size for LSTM layers d_s, input dropout keep probability p_i and output dropout keep probability p_o for LSTM layers [3], L2 regularization parameter λ and parameter to tune hierarchical loss normalization β. The values of these hyperparameters, obtained by evaluating the model performance on the development set, for each dataset can be found in Table 4.

5.5 Performance comparison and analysis

Table 3 compares our models with other state-of-the-art FETC systems on FIGER(GOLD) and OntoNotes. The proposed model performs better than the existing FETC systems, consistently on both datasets. This indicates benefits of the proposed representation scheme, loss function and hierarchical loss normalization.

Discussion about *Out-of-context Noise*: For dataset FIGER(GOLD), the performance of our model with the proposed variant of cross-entropy loss trained on $\mathcal{D}_{raw}$ is significantly better than the basic neural model trained on $\mathcal{D}_{filtered}$, suggesting that the proposed variant of the cross-entropy loss function can make use of the data with *out-of-context noise* effectively. On the other hand, the improvement introduced by our proposed variant of cross-entropy loss is not as significant for the OntoNotes benchmark. This may be caused by the fact that OntoNotes is much smaller than FIGER(GOLD) and proportion of examples without *out-of-context noise* are also higher, as shown in Table 2.

[3]Following TensorFlow terminology.

Model	FIGER(GOLD)			OntoNotes		
	Strict Acc.	Macro F1	Micro F1	Strict Acc.	Macro F1	Micro F1

Table 3: Strict Accuracy, Macro F1 and Micro F1 for the models tested on the FIGER(GOLD) and OntoNotes datasets.

Test Sentence	Ground Truth
S1: ***Hopkins*** said four fellow elections is curious , considering the ...	**Person**
S2: ... for WiFi communications across all ***the SD cards.***	**Product**
S3: A handful of professors in the ***UW*** Department of Chemistry ...	**Educational Institution**
S4: Work needs to be done and, in ***Washington state***, ...	**Province**
S5: ***ASC*** Director Melvin Taing said that because the commission is ...	**Organization**

Table 5: Examples of test sentences in FIGER(GOLD) where the entity mentions are marked as bold italics.

Investigations on *Overly-Specific Noise*: With hierarchical loss normalization, the performance of our models are consistently better no matter whether trained on $\mathcal{D}_{raw}$ or $\mathcal{D}_{filtered}$ on both datasets, demonstrating the effectiveness of this hierarchical loss normalization and showing that *overly-specific noise* has a potentially significant influence on the performance of FETC systems.

5.6 T-SNE Visualization of Type Embeddings

By visualizing the learned type embeddings (Figure 3), we can observe that the parent types are mixed with their subtypes and forms clear distinct clusters without hierarchical loss normalization, making it hard for the model to distinguish subtypes like **actor** or **athlete** from their parent types **person**. This also biases the model towards the most popular subtype. While the parent types tend to cluster together and the general pattern is more complicated with hierarchical loss normalization. Although it's not as easy to interpret, it hints that our model can learn rather subtle intricacies and correlations among types latent in the data with the help of hierarchical loss normalization, instead of sticking to a pre-defined hierarchy.

5.7 Error Analysis on FIGER(GOLD)

Since there are only 563 sentences for testing in FIGER(GOLD), we look into the predictions for all the test examples of all variants of our model. Table 5 shows 5 examples of test sentence. Without hierarchical loss normalization, our model will make too aggressive predictions for S1 with **Politician** and for S2 with **Software**. This kind of mistakes are very common and can be effectively reduced by introducing hierarchical loss normalization leading to significant improvements on the model performance. Using the changed loss function to handle multi-label (noisy) training data can help the model distinguish ambiguous cases. For example, our model trained on $\mathcal{D}_{filtered}$ will misclassify S5 as **Title**, while the model trained on $\mathcal{D}_{raw}$ can make the correct prediction.

However, there are still some errors that can't be fixed with our model. For example, our model cannot make correct predictions for S3 and S4 due to the fact that our model doesn't know that ***UW*** is an abbreviation of *University of Washington* and ***Washington state*** is the name of a province. In addition, the influence of *overly-specific noise* can only be alleviated but not eliminated. Sometimes, our model will still make too aggressive or conservative predictions. Also, mixing up very ambiguous entity names is inevitable in this task.

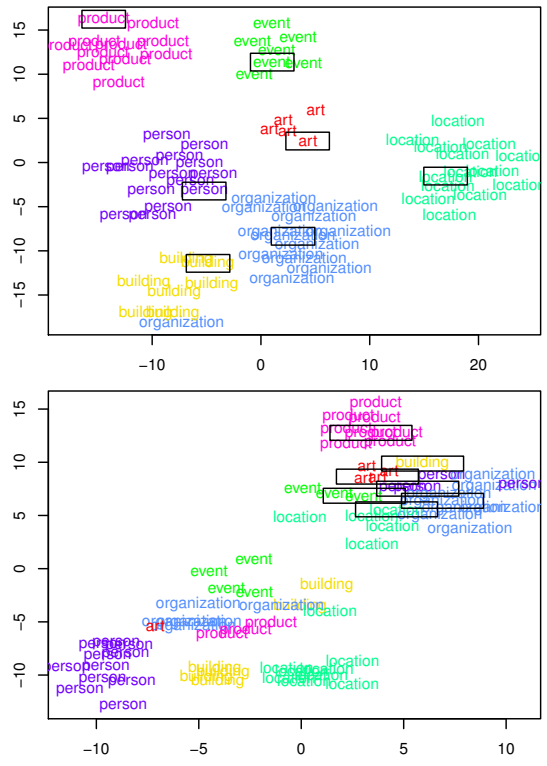

Figure 3: T-SNE visualization of the type embeddings learned from FIGER(GOLD) dataset where subtypes share the same color as their parent type. The seven parent types are shown in the black boxes. The below sub-figure uses the hierarchical loss normalization, while the above not.

6 Conclusion and Further Work

In this paper, we studied two kinds of noise, namely *out-of-context noise* and *overly-specific noise*, for noisy type labels and investigate their effects on FETC systems. We proposed a neural network based model which jointly learns representations for entity mentions and their context. A variant of cross-entropy loss function was used to handle *out-of-context noise*. Hierarchical loss normalization was introduced into our model to alleviate the effect of *overly-specific noise*. Experimental results on two publicly available datasets demonstrate that the proposed model is robust to these two kind of noise and outperforms previous state-of-the-art methods significantly.

More work can be done to further develop hierarchical loss normalization since currently it's very simple. Considering type information is valuable in various NLP tasks, we can incorporate results produced by our FETC system to other tasks, such as relation extraction, to check our model's effectiveness and help improve other tasks' performance. In addition, tasks like relation extraction are complementary to the task of FETC and therefore may have potentials to be digged to help improve the performance of our system in return.

Abstract

Semi-supervised bootstrapping techniques for relationship extraction from text iteratively expand a set of initial seed instances. Due to the lack of labeled data, a key challenge in bootstrapping is semantic drift: if a false positive instance is added during an iteration, then all following iterations are contaminated. We introduce BREX, a new bootstrapping method that protects against such contamination by highly effective confidence assessment. This is achieved by using entity and template seeds jointly (as opposed to just one as in previous work), by expanding entities and templates in parallel and in a mutually constraining fashion in each iteration and by introducing higher-quality similarity measures for templates. Experimental results show that BREX achieves an F_1 that is 0.13 (0.87 vs. 0.74) better than the state of the art for four relationships.

1 Introduction

Traditional semi-supervised bootstrapping relation extractors (REs) such as BREDS (Batista et al., 2015), SnowBall (Agichtein and Gravano, 2000) and DIPRE (Brin, 1998) require an initial set of seed *entity pairs* for the target binary relation. They find occurrences of positive seed entity pairs in the corpus, which are converted into extraction patterns, i.e., *extractors*, where we define an extractor as a cluster of instances generated from the corpus. The initial seed entity pair set is expanded with the relationship entity pairs newly extracted by the extractors from the text iteratively. The augmented set is then used to extract new relationships until a stopping criterion is met.

Due to lack of sufficient labeled data, rule-based systems dominate commercial use (Chiticariu et al., 2013). Rules are typically defined by creating patterns around the entities (entity extraction) or entity pairs (relation extraction). Recently, supervised machine learning, especially deep learning techniques (Gupta et al., 2015; Nguyen and Grishman, 2015; Vu et al., 2016a,b; Gupta et al., 2016), have shown promising results in entity and relation extraction; however, they need sufficient hand-labeled data to train models, which can be costly and time consuming for web-scale extractions. Bootstrapping machine-learned rules can make extractions easier on large corpora. Thus, open information extraction systems (Carlson et al., 2010; Fader et al., 2011; Mausam et al., 2012; Mesquita et al., 2013; Angeli et al., 2015) have recently been popular for domain specific or independent pattern learning.

Hearst (1992) used hand written rules to generate more rules to extract hypernym-hyponym pairs, without distributional similarity. For entity extraction, Riloff (1996) used seed entities to generate extractors with heuristic rules and scored them by counting positive extractions. Prior work (Lin et al., 2003; Gupta et al., 2014) investigated different extractor scoring measures. Gupta and Manning (2014) improved scores by introducing expected number of negative entities.

Brin (1998) developed the bootstrapping relation extraction system DIPRE that generates extractors by clustering contexts based on string matching. SnowBall (Agichtein and Gravano, 2000) is inspired by DIPRE but computes a TF-IDF representation of each context. BREDS (Batista et al., 2015) uses word embeddings (Mikolov et al., 2013) to bootstrap relationships.

Related work investigated adapting extractor scoring measures in bootstrapping entity extraction with either entities or *templates* (Table 1) as seeds (Table 2). The state-of-the-art relation extractors bootstrap with only seed entity pairs and suffer due to a surplus of unknown extractions and the lack of labeled data, leading to low confidence extractors. This in turn leads to to low confidence in the system output. Prior RE sys-

BREE	Bootstrapping Relation Extractor with *Entity pair*
BRET	Bootstrapping Relation Extractor with *Template*
BREJ	Bootstrapping Relation Extractor in Joint learning
type	a named entity type, e.g., `person`
typed entity	a typed entity, e.g., <"Obama",`person`>
entity pair	a pair of two typed entities
template	a triple of vectors ($\vec{v}_{-1}$, $\vec{v}_0$, $\vec{v}_1$) and an entity pair
instance	entity pair and template (types must be the same)
γ	instance set extracted from corpus
i	a member of γ, i.e., an instance
$x(i)$	the entity pair of instance i
$\mathfrak{t}(i)$	the template of instance i
G_p	a set of positive seed entity pairs
G_n	a set of negative seed entity pairs
$\mathfrak{G}_p$	a set of positive seed templates
$\mathfrak{G}_n$	a set of negative seed templates
$\mathcal{G}$	$< G_p, G_n, \mathfrak{G}_p, \mathfrak{G}_n >$
k_{it}	number of iterations
λ_{cat}	cluster of instances (*extractor*)
cat	category of *extractor* λ
λ_{NNHC}	Non-Noisy-High-Confidence extractor (True Positive)
λ_{NNLC}	Non-Noisy-Low-Confidence extractor (True Negative)
λ_{NHC}	Noisy-High-Confidence extractor (False Positive)
λ_{NLC}	Noisy-Low-Confidence extractor (False Negative)

Table 1: Notation and definition of key terms

tems do not focus on improving the extractors' scores. In addition, SnowBall and BREDS used a weighting scheme to incorporate the importance of contexts around entities and compute a similarity score that introduces additional parameters and does not generalize well.

Contributions. **(1)** We propose a *Joint Bootstrapping Machine*[1] (JBM), an alternative to the entity-pair-centered bootstrapping for relation extraction that can take advantage of both entity-pair and template-centered methods to jointly learn extractors consisting of instances due to the occurrences of both entity pair and template seeds. It scales up the number of positive extractions for *non-noisy* extractors and boosts their confidence scores. We focus on improving the scores for *non-noisy-low-confidence* extractors, resulting in higher *recall*. The relation extractors bootstrapped with entity pair, template and joint seeds are named as *BREE*, *BRET* and *BREJ* (Table 1), respectively.

(2) Prior work on embedding-based context comparison has assumed that relations have *consistent syntactic expression* and has mainly addressed synonymy by using embeddings (e.g.,"acquired" – "bought"). In reality, there is *large variation in the syntax* of how relations are expressed, e.g., "MSFT to acquire NOK for $8B" vs. "MSFT earnings hurt by NOK acquisition". We introduce cross-context similarities that compare all parts of the context (e.g., "to acquire" and "acquisition") and show that these perform better (in terms of recall) than measures assuming consistent syntactic expression of relations.

(3) Experimental results demonstrate a 13% gain in $F1$ score on average for four relationships and suggest eliminating four parameters, compared to the state-of-the-art method.

The *motivation* and *benefits* of the proposed JBM for relation extraction is discussed in depth in section 2.3. The method is applicable for both entity and relation extraction tasks. However, in *context of relation extraction*, we call it *BREJ*.

2 Method

2.1 Notation and definitions

We first introduce the notation and terms (Table 1).

Given a relationship like "x acquires y", the task is to extract pairs of entities from a corpus for which the relationship is true. We assume that the arguments of the relationship are typed, e.g., x and y are organizations. We run a named entity tagger in preprocessing, so that the types of all candidate entities are given. The objects the bootstrapping algorithm generally handles are therefore *typed entities* (an entity associated with a type).

For a particular sentence in a corpus that states that the relationship (e.g., "acquires") holds between x and y, a *template* consists of three vectors that represent the context of x and y. $\vec{v}_{-1}$ represents the context before x, $\vec{v}_0$ the context between x and y and $\vec{v}_1$ the context after y. These vectors are simply sums of the embeddings of the corresponding words. A template is "typed", i.e., in addition to the three vectors it specifies the types of the two entities. An *instance* joins an entity pair and a template. The types of entity pair and template must be the same.

The first step of bootstrapping is to extract a set of instances from the input corpus. We refer to this set as γ. We will use i and j to refer to instances. $x(i)$ is the entity pair of instance i and $\mathfrak{t}(\mathrm{i})$ is the template of instance i.

A required input to our algorithm are sets of positive and negative seeds for either entity pairs (G_p and G_n) or templates ($\mathfrak{G}_p$ and $\mathfrak{G}_n$) or both. We define $\mathcal{G}$ to be a tuple of all four seed sets.

We run our bootstrapping algorithm for k_{it} iterations where k_{it} is a parameter.

[1] github.com/pgcool/Joint-Bootstrapping-Machines

A key notion is the similarity between two instances. We will experiment with different similarity measures. The baseline is (Batista et al., 2015)'s measure given in Figure 4, first line: the similarity of two instances is given as a weighted sum of the dot products of their before contexts ($\vec{v}_{-1}$), their between contexts ($\vec{v}_0$) and their after contexts ($\vec{v}_1$) where the weights w_p are parameters. We give this definition for instances, but it also applies to templates since only the context vectors of an instance are used, not the entities.

The similarity between an instance i and a cluster λ of instances is defined as the maximum similarity of i with any member of the cluster; see Figure 2, right, Eq. 5. Again, there is a straightforward extension to a cluster of templates: see Figure 2, right, Eq. 6.

The extractors Λ can be categorized as follows:

$$\Lambda_{NNHC} = \{\lambda \in \Lambda | \underbrace{\lambda \mapsto \Re}_{non-noisy} \wedge \text{cnf}(\lambda, \mathcal{G}) \geqslant \tau_{cnf}\} \quad (1)$$

$$\Lambda_{NNLC} = \{\lambda \in \Lambda | \lambda \mapsto \Re \wedge \text{cnf}(\lambda, \mathcal{G}) < \tau_{cnf}\} \quad (2)$$

$$\Lambda_{NHC} = \{\lambda \in \Lambda | \underbrace{\lambda \nmapsto \Re}_{noisy} \wedge \text{cnf}(\lambda, \mathcal{G}) \geqslant \tau_{cnf}\} \quad (3)$$

$$\Lambda_{NLC} = \{\lambda \in \Lambda | \lambda \nmapsto \Re \wedge \text{cnf}(\lambda, \mathcal{G}) < \tau_{cnf}\} \quad (4)$$

where $\Re$ is the relation to be bootstrapped. The λ_{cat} is a member of Λ_{cat}. For instance, a λ_{NNLC} is called as a *non-noisy-low-confidence* extractor if it represents the target relation (i.e., $\lambda \mapsto \Re$), however with the confidence below a certain threshold (τ_{cnf}). Extractors of types Λ_{NNHC} and Λ_{NLC} are desirable, those of types Λ_{NHC} and Λ_{NNLC} undesirable within bootstrapping.

2.2 The Bootstrapping Machines: BREX

To describe BREX (Figure 1) in its most general form, we use the term *item* to refer to an entity pair, a template or both.

The input to BREX (Figure 2, left, line 01) is a set γ of instances extracted from a corpus and $\mathcal{G}_{\text{seed}}$, a structure consisting of one set of positive and one set of negative seed items. $\mathcal{G}_{\text{yield}}$ (line 02) collects the items that BREX extracts in several iterations. In each of k_{it} iterations (line 03), BREX first initializes the cache $\mathcal{G}_{\text{cache}}$ (line 04); this cache collects the items that are extracted in this iteration. The design of the algorithm balances elements that ensure high recall with elements that ensure high precision.

High recall is achieved by starting with the seeds and making three "hops" that consecutively consider order-1, order-2 and order-3 neighbors

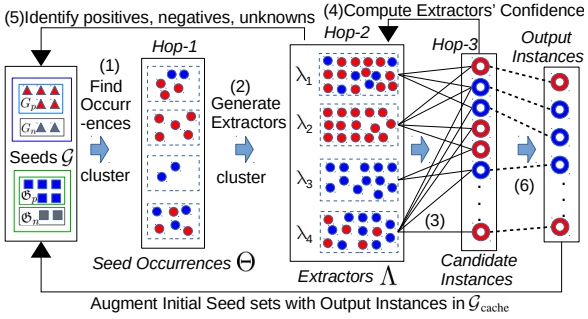

Figure 1: Joint Bootstrapping Machine. The red and blue filled circles/rings are the instances generated due to seed entity pairs and templates, respectively. Each dashed rectangular box represents a cluster of instances. Numbers indicate the flow. Follow the notations from Table 1 and Figure 2.

of the seeds. On line 05, we make the first hop: all instances that are similar to a seed are collected where "similarity" is defined differently for different BREX configurations (see below). The collected instances are then clustered, similar to work on bootstrapping by Agichtein and Gravano (2000) and Batista et al. (2015). On line 06, we make the second hop: all instances that are within τ_{sim} of a hop-1 instance are added; each such instance is only added to one cluster, the closest one; see definition of μ: Figure 2, Eq. 8. On line 07, we make the third hop: we include all instances that are within τ_{sim} of a hop-2 instance; see definition of ψ: Figure 2, Eq. 7. In summary, every instance that can be reached by three hops from a seed is being considered at this point. A cluster of hop-2 instances is named as *extractor*.

High precision is achieved by imposing, on line 08, a stringent check on each instance before its information is added to the cache. The core function of this check is given in Figure 2, Eq. 9. This definition is a soft version of the following hard max, which is easier to explain:

$$\text{cnf}(i, \Lambda, \mathcal{G}) \approx \max_{\{\lambda \in \Lambda | i \in \psi(\lambda)\}} \text{cnf}(i, \lambda, \mathcal{G})$$

We are looking for a cluster λ in Λ that licenses the extraction of i with high confidence. $\text{cnf}(i, \lambda, \mathcal{G})$ (Figure 2, Eq. 10), the *confidence* of a single cluster (i.e., extractor) λ for an instance, is defined as the product of the overall reliability of λ (which is independent of i) and the similarity of i to λ, the second factor in Eq. 10, i.e., $\text{sim}(i, \lambda)$. This factor $\text{sim}(i, \lambda)$ prevents an extraction by a cluster whose members are all distant from the instance – even if the cluster itself is highly reliable.

Algorithm: *BREX*

01 INPUT: γ, $\mathcal{G}_{\text{seed}}$
02 $\mathcal{G}_{\text{yield}} := \mathcal{G}_{\text{seed}}$
03 for k_{it} iterations:
04 $\quad \mathcal{G}_{\text{cache}} := \varnothing$
05 $\quad \Theta := \biguplus(\{i \in \gamma | \text{match}(i, \mathcal{G}_{\text{yield}})\}$
06 $\quad \Lambda := \{\mu(\theta, \Theta) | \theta \in \Theta\}$
07 $\quad$ for each $i \in \bigcup_{\lambda \in \Lambda} \psi(\lambda)$:
08 $\quad\quad$ if check$(i, \Lambda, \mathcal{G}_{\text{yield}})$:
09 $\quad\quad\quad$ add$(i, \mathcal{G}_{\text{cache}})$
10 $\quad \mathcal{G}_{\text{yield}} \cup= \mathcal{G}_{\text{cache}}$
11 OUTPUT: $\mathcal{G}_{\text{yield}}$, Λ

$$\text{sim}(i, \lambda) = \max_{i' \in \lambda} \text{sim}(i, i') \quad (5)$$

$$\text{sim}(i, \mathfrak{G}) = \max_{\mathfrak{t} \in \mathfrak{G}} \text{sim}(i, \mathfrak{t}) \quad (6)$$

$$\psi(\lambda) = \{i \in \gamma | \text{sim}(i, \lambda) \geqslant \tau_{\text{sim}}\} \quad (7)$$

$$\mu(\theta, \Theta) = \{i \in \gamma | \text{sim}(i, \theta) = d \wedge d = \max_{\theta \in \Theta} \text{sim}(i, \theta) \geqslant \tau_{\text{sim}}\} \quad (8)$$

$$\text{cnf}(i, \Lambda, \mathcal{G}) = 1 - \prod_{\{\lambda \in \Lambda | i \in \psi(\lambda)\}} (1 - \text{cnf}(i, \lambda, \mathcal{G})) \quad (9)$$

$$\text{cnf}(i, \lambda, \mathcal{G}) = \text{cnf}(\lambda, \mathcal{G}) \text{sim}(i, \lambda) \quad (10)$$

$$\text{cnf}(\lambda, \mathcal{G}) = \frac{1}{1 + w_n \frac{N_+(\lambda, \mathcal{G}_n)}{N_+(\lambda, \mathcal{G}_p)} + w_u \frac{N_0(\lambda, \mathcal{G})}{N_+(\lambda, \mathcal{G}_p)}} \quad (11)$$

$$N_0(\lambda, \mathcal{G}) = |\{i \in \lambda | x(i) \notin (G_p \cup G_n)\}| \quad (12)$$

Figure 3: BREX configurations

The first factor in Eq. 10, i.e., $\text{cnf}(\lambda, \mathcal{G})$, assesses the reliability of a cluster λ: we compute the ratio $\frac{N_+(\lambda, \mathcal{G}_n)}{N_+(\lambda, \mathcal{G}_p)}$, i.e., the ratio between the number of instances in λ that match a negative and positive gold seed, respectively; see Figure 3, line (i). If this ratio is close to zero, then likely false positive extractions are few compared to likely true positive extractions. For the simple version of the algorithm (for which we set $w_n = 1$, $w_u = 0$), this results in $\text{cnf}(\lambda, \mathcal{G})$ being close to 1 and the reliability measure it not discounted. On the other hand, if $\frac{N_+(\lambda, \mathcal{G}_n)}{N_+(\lambda, \mathcal{G}_p)}$ is larger, meaning that the relative number of likely false positive extractions is high, then $\text{cnf}(\lambda, \mathcal{G})$ shrinks towards 0, resulting in progressive discounting of $\text{cnf}(\lambda, \mathcal{G})$ and leading to *non-noisy-low-confidence* extractor, particularly for a reliable λ. Due to lack of labeled data, the scoring mechanism cannot distinguish between noisy and non-noisy extractors. Therefore, an extractor is judged by its ability to extract more positive and less negative extractions. Note that we carefully designed this precision component to give good assessments while at the same time making maximum use of the available seeds. The reliability statistics are computed on λ, i.e., on hop-2 instances (not on hop-3 instances). The ratio $\frac{N_+(\lambda, \mathcal{G}_n)}{N_+(\lambda, \mathcal{G}_p)}$ is computed on instances that directly match a gold seed – this is the most reliable information we have available.

After all instances have been checked (line 08) and (if they passed muster) added to the cache (line 09), the inner loop ends and the cache is merged into the yield (line 10). Then a new loop (lines 03–10) of hop-1, hop-2 and hop-3 extensions and cluster reliability tests starts.

Thus, the algorithm consists of k_{it} iterations. There is a tradeoff here between τ_{sim} and k_{it}. We will give two extreme examples, assuming that we want to extract a fixed number of m instances where m is given. We can achieve this goal either by setting k_{it}=1 and choosing a small τ_{sim}, which will result in very large hops. Or we can achieve this goal by setting τ_{sim} to a large value and running the algorithm for a larger number of k_{it}. The flexibility that the two hyperparameters k_{it} and τ_{sim} afford is important for good performance.

$$\text{sim}_{\text{match}}(i,j) = \sum_{p\in\{-1,0,1\}} w_p \vec{v}_p(i)\vec{v}_p(j) \quad ; \quad \text{sim}_{cc}^{asym}(i,j) = \max_{p\in\{-1,0,1\}} \vec{v}_p(i)\vec{v}_0(j) \tag{13}$$

$$\text{sim}_{cc}^{sym1}(i,j) = \max\left(\max_{p\in\{-1,0,1\}} \vec{v}_p(i)\vec{v}_0(j), \max_{p\in\{-1,0,1\}} \vec{v}_p(j)\vec{v}_0(i)\right) \tag{14}$$

$$\text{sim}_{cc}^{sym2}(i,j) = \max\left(\left(\vec{v}_{-1}(i) + \vec{v}_1(i)\right)\vec{v}_0(j), \left(\vec{v}_{-1}(j) + \vec{v}_1(j)\right)\vec{v}_0(i), \vec{v}_0(i)\vec{v}_0(j)\right) \tag{15}$$

Figure 4: Similarity measures. These definitions for instances equally apply to templates since the definitions only depend on the "template part" of an instance, i.e., its vectors. (value is 0 if types are different)

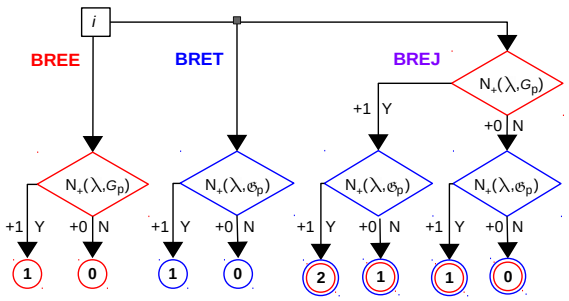

Figure 5: Illustration of Scaling-up Positive Instances. i: an instance in extractor, λ. Y: YES and N: NO

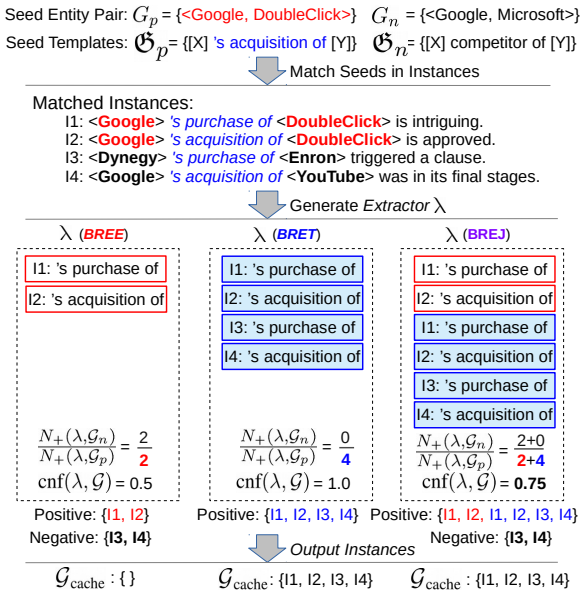

Figure 6: An illustration of scaling positive extractions and computing confidence for a non-noisy extractor generated for *acquired* relation. The dashed rectangular box represents an extractor λ, where λ (BREJ) is *hybrid* with 6 instances. Text segments matched with seed template are shown in italics. Unknowns (bold in black) are considered as negatives. $\mathcal{G}_{cache}$ is a set of output instances where $\tau_{cnf} = 0.70$.

2.3 BREE, BRET and BREJ

The main contribution of this paper is that we propose, as an alternative to entity-pair-centered BREE (Batista et al., 2015), template-centered BRET as well as BREJ (Figure 1), an instantiation of BREX that can take advantage of both entity pairs and templates. The differences and advantages of BREJ over BREE and BRET are:

(1) Disjunctive Matching of Instances: The first difference is realized in how the three algorithms match instances with seeds (line 05 in Figure 3). BREE checks whether the entity pair of an instance is one of the entity pair seeds, BRET checks whether the template of an instance is one of the template seeds and BREJ checks whether the disjunction of the two is true. The disjunction facilitates a higher hit rate in matching instances with seeds. The introduction of a few handcrafted templates along with seed entity pairs allows BREJ to leverage discriminative patterns and learn similar ones via distributional semantics. In Figure 1, the joint approach results in *hybrid* extractors Λ that contain instances due to seed occurrences Θ of both entity pairs and templates.

(2) Hybrid Augmentation of Seeds: On line 09 in Figure 3, we see that the bootstrapping step is defined in a straightforward fashion: the entity pair of an instance is added for BREE, the template for BRET and both for BREJ. Figure 1 demonstrates the hybrid augmentation of seeds via *red* and *blue* rings of *output instances*.

(3) Scaling Up Positives in Extractors: As discussed in section 2.2, a good measure of the quality of an extractor is crucial and N_+, the number of instances in an extractor λ that match a seed, is an important component of that. For BREE and BRET, the definition follows directly from the fact that these are entity-pair and template-centered instantiations of BREX, respectively. However, the disjunctive matching of instances for an extractor with entity pair and template seeds in BREJ (Figure 3 line "(i)") boosts the likelihood of finding positive instances. In Figure 5, we demonstrate computing the count of positive instances

Relationship	*Seed Entity Pairs*	*Seed Templates*

Table 2: Seed Entity Pairs and Templates for each relation. [X] and [Y] are slots for entity type tags.

$N_+(\lambda, \mathcal{G})$ for an extractor λ within the three systems. Observe that an instance i in λ can scale its $N_+(\lambda, \mathcal{G})$ by a factor of maximum 2 in BREJ if i is matched in both entity pair and template seeds. The reliability cnf$(\lambda, \mathcal{G})$ (Eq. 11) of an extractor λ is based on the ratio $\frac{N_+(\lambda,\mathcal{G}_n)}{N_+(\lambda,\mathcal{G}_p)}$, therefore suggesting that the scaling boosts its confidence.

In Figure 6, we demonstrate with an example how the joint bootstrapping scales up the positive instances for a *non-noisy* extractor λ, resulting in λ_{NNHC} for BREJ compared to λ_{NNLC} in BREE.

Due to unlabeled data, the instances not matching in seeds are considered either to be ignored/unknown N_0 or negatives in the confidence measure (Eq. 11). The former leads to high confidences for noisy extractors by assigning high scores, the latter to low confidences for non-noisy extractors by penalizing them. For a simple version of the algorithm in the illustration, we consider them as negatives and set $w_n = 1$. Figure 6 shows the three extractors (λ) generated and their confidence scores in BREE, BRET and BREJ. Observe that the scaling up of positives in BREJ due to BRET extractions (without w_n) discounts cnf$(\lambda, \mathcal{G})$ relatively lower than BREE. The discounting results in λ_{NNHC} in BREJ and λ_{NNLC} in BREE. The discounting in BREJ is adapted for *non-noisy* extractors facilitated by BRET in generating mostly non-noisy extractors due to stringent checks (Figure 3, line "(i)" and 05). Intuitively, the intermixing of non-noisy extractors (i.e., *hybrid*) promotes the scaling and boosts recall.

2.4 Similarity Measures

The before ($\vec{v}_{-1}$) and after ($\vec{v}_1$) contexts around the entities are highly sparse due to large variation in the syntax of how relations are expressed. SnowBall, DIPRE and BREE assumed that the between ($\vec{v}_0$) context mostly defines the syntactic expression for a relation and used weighted mechanism on the three contextual similarities in pairs, sim$_{match}$ (Figure 4). They assigned higher weights to the similarity in between ($p = 0$) contexts, that resulted in lower recall. We introduce attentive (max) similarity across all contexts (for example, $\vec{v}_{-1}(i)\vec{v}_0(j)$) to automatically capture the large variation in the syntax of how relations are expressed, without using any weights. We investigate asymmetric (Eq 13) and symmetric (Eq 14 and 15) similarity measures, and name them as *cross-context attentive* (sim$_{cc}$) similarity.

	ORG-ORG	*ORG-PER*	*ORG-LOC*

3 Evaluation

3.1 Dataset and Experimental Setup

We re-run BREE (Batista et al., 2015) for **baseline** with a set of 5.5 million news articles from AFP and APW (Parker et al., 2011). We use processed dataset of 1.2 million sentences (released by BREE) containing at least two entities linked to FreebaseEasy (Bast et al., 2014). We extract four relationships: *acquired* (ORG-ORG), *founder-of* (ORG-PER), *headquartered* (ORG-LOC) and *affiliation* (ORG-PER) for Organization (ORG), Person (PER) and Location (LOC) entity types. We bootstrap relations in BREE, BRET and BREJ, each with 4 similarity measures using seed entity

	Relationships	$\#out$	P	R	$F1$	$\#out$	P	R	$F1$	$\#out$	P	R	$F1$	$\#out$	P	R	$F1$

pairs and templates (Table 2). See Tables 3, 4 and 5 for the count of candidates, hyperparameters and different configurations, respectively.

Our evaluation is based on Bronzi et al. (2012)'s framework to estimate precision and recall of large-scale RE systems using FreebaseEasy (Bast et al., 2014). Also following Bronzi et al. (2012), we use Pointwise Mutual Information (PMI) (Turney, 2001) to evaluate our system automatically, in addition to relying on an external knowledge base. We consider only extracted relationship instances with confidence scores cnf$(i, \Lambda, \mathcal{G})$ equal or above 0.5. We follow the same approach as BREE (Batista et al., 2015) to detect the correct order of entities in a relational triple, where we try to identify the presence of passive voice using part-of-speech (POS) tags and considering any form of the verb to be, followed by a verb in the past tense or past participle, and ending in the word 'by'. We use GloVe (Pennington et al., 2014) embeddings.

3.2 Results and Comparison with baseline

Table 5 shows the experimental results in the three systems for the different relationships with *ordered* entity pairs and similarity measures (sim$_{match}$, sim$_{cc}$). Observe that BRET (config$_5$) is *precision-oriented* while BREJ (config$_9$) *recall-oriented* when compared to BREE (baseline). We see the number of output instances $\#out$ are also higher in BREJ, therefore the higher recall. The BREJ system in the different similarity configurations outperforms the baseline BREE and BRET in terms of $F1$ score. On an average for the four relations, BREJ in configurations config$_9$ and config$_{10}$ results in $F1$ that is 0.11 (0.85 vs 0.74) and 0.13 (0.87 vs 0.74) better than the baseline BREE.

We discover that sim$_{cc}$ improves $\#out$ and *recall* over sim$_{\text{match}}$ correspondingly in all three systems. Observe that sim$_{cc}$ performs better with BRET than BREE due to *non-noisy* extractors in BRET. The results suggest an alternative to the weighting scheme in sim$_{\text{match}}$ and therefore, the state-of-the-art (sim$_{cc}$) performance with the 3 parameters (w_{-1}, w_0 and w_1) ignored in bootstrap-

τ	k_{it}	$\#out$	P	R	$F1$

Attributes are: number of extractors ($|\Lambda|$), avg number of instances in Λ (AIE), avg Λ score (AES), avg number of noisy Λ (ANE), avg number of non-noisy Λ (ANNE), avg number of Λ_{NNLC} below confidence 0.5 (ANNLC), avg number of positives (AP) and negatives (AN), ratio of AN to AP (ANP). The **bold** indicates comparison of BREE and BREJ with sim_{match}. avg: average

ping. Observe that sim_{cc}^{asym} gives higher recall than the two symmetric similarity measures.

Table 6 shows the performance of BREJ in different iterations trained with different similarity τ_{sim} and confidence τ_{cnf} thresholds. Table 7 shows a comparative analysis of the three systems, where we consider and evaluate the extracted relationship instances at different confidence scores.

3.3 Disjunctive Seed Matching of Instances

As discussed in section 2.3, BREJ facilitates disjunctive matching of instances (line 05 Figure 3) with seed entity pairs and templates. Table 8 shows $\#hit$ in the three systems, where the higher values of $\#hit$ in BREJ conform to the desired property. Observe that some instances in BREJ are found to be matched in both the seed types.

3.4 Deep Dive into Attributes of Extractors

We analyze the extractors Λ generated in BREE, BRET and BREJ for the 4 relations to demonstrate the impact of joint bootstrapping. Table 9 shows the attributes of Λ. We manually annotate the extractors as *noisy* and *non-noisy*. We compute $ANNLC$ and the lower values in BREJ compared to BREE suggest fewer non-noisy extractors with lower confidence in BREJ due to the scaled confi-

	Relationships	$\#out$	P	R	$F1$
BREE	acquired	387	0.99	0.13	0.23
	founder-of	28	0.96	0.09	0.17
	headquartered	672	0.95	0.21	0.34
	affiliation	17516	0.99	0.68	0.80
	avg	4651	0.97	0.28	0.39
BRET	acquired	4031	1.00	0.61	0.76
	founder-of	920	0.97	0.77	0.86

	headquartered	38737	0.61	0.91	**0.73**
	affiliation	33203	0.98	0.81	**0.89**
	avg	26986	0.82	0.88	**0.84**

Table 10: BREX+$\text{sim}_{\text{match}}$:Scores when w_n ignored

dence scores. *ANNE* (higher), *ANNLC* (lower), *AP* (higher) and *AN* (lower) collectively indicate that BRET mostly generates *NNHC* extractors. *AP* and *AN* indicate an average of $N_+(\lambda, \mathcal{G}_l)$ (line " (i)" Figure 3) for positive and negative seeds, respectively for $\lambda \in \Lambda$ in the three systems. Observe the impact of scaling positive extractions (*AP*) in BREJ that shrink $\frac{N_+(\lambda,\mathcal{G}_n)}{N_+(\lambda,\mathcal{G}_p)}$ i.e., *ANP*. It facilitates λ_{NNLC} to boost its confidence, i.e., λ_{NNHC} in BREJ suggested by *AES* that results in higher $\#out$ and recall (Table 5, BREJ).

3.5 Weighting Negatives Vs Scaling Positives

As discussed, Table 5 shows the performance of BREE, BRET and BREJ with the parameter $w_n = 0.5$ in computing extractors' confidence $\text{cnf}(\lambda, \mathcal{G})$(Eq. 11). In other words, config_9 (Table 5) is combination of both weighted negative and scaled positive extractions. However, we also investigate ignoring $w_n(= 1.0)$ in order to demonstrate the capability of BREJ with only scaling positives and without weighting negatives. In Table 10, observe that BREJ outperformed both BREE and BRET for all the relationships due to higher $\#out$ and recall. In addition, BREJ scores are comparable to config_9 (Table 5) suggesting that the scaling in BREJ is capable enough to remove the parameter w_n. However, the combination of both weighting negatives and scaling positives results in the state-of-the-art performance.

3.6 Qualitative Inspection of Extractors

Table 11 lists some of the non-noisy extractors (simplified) learned in different configurations to illustrate boosting extractor confidence $\text{cnf}(\lambda, \mathcal{G})$. Since, an extractor λ is a cluster of instances, therefore to simplify, we show one in-

config$_1$: BREE + sim$_{\text{match}}$	cnf$(\lambda, \mathbf{G})$	config$_5$: BRET + sim$_{\text{match}}$	cnf$(\lambda, \mathbf{G})$	config$_9$: BREJ + sim$_{\text{match}}$	cnf$(\lambda, \mathbf{G})$	config$_{10}$: BREJ + sim$_{cc}^{\text{asym}}$	cnf$(\lambda, \mathbf{G})$

Table 11: Subset of the non-noisy extractors (simplified) with their confidence scores cnf$(\lambda, \mathcal{G})$ learned in different configurations for each relation. $*$ denotes that the extractor was never learned in config$_1$ and config$_5$. † indicates that the extractor was never learned in config$_1$, config$_5$ and config$_9$. [X] and [Y] indicate placeholders for entities.

stance (mostly populated) from every λ. Each cell in Table 11 represents either a simplified representation of λ or its confidence. We demonstrate how the confidence score of a non-noisy extractor in BREE (config$_1$) is increased in BREJ (config$_9$ and config$_{10}$). For instance, for the relation *acquired*, an extractor $\{$*[X] acquiring [Y]*$\}$ is generated by BREE, BRET and BREJ; however, its confidence is boosted from 0.75 in BREE (config$_1$) to 0.95 in BREJ (config$_9$). Observe that BRET generates high confidence extractors. We also show extractors (marked by †) learned by BREJ with sim$_{cc}$ (config$_{10}$) but not by config$_1$, config$_5$ and config$_9$.

3.7 Entity Pairs: Ordered Vs Bi-Set

In Table 5, we use ordered pairs of typed entities. Additionally, we also investigate using entity sets and observe improved recall due to higher $\#out$ in both BREE and BREJ, comparing correspondingly Table 12 and 5 (*baseline* and config$_9$).

4 Conclusion

We have proposed a Joint Bootstrapping Machine for relation extraction (BREJ) that takes advantage of both entity-pair-centered and template-centered approaches. We have demonstrated that the joint approach scales up positive instances that boosts the confidence of NNLC extractors and improves recall. The experiments showed that the cross-context similarity measures improved recall and suggest removing in total four parameters.

A Deep Generative Model of Vowel Formant Typology

Ryan Cotterell and **Jason Eisner**

Department of Computer Science
Johns Hopkins University, Baltimore MD, 21218
{ryan.cotterell,eisner}@jhu.edu

Abstract

What makes some types of languages more probable than others? For instance, we know that almost all spoken languages contain the vowel phoneme /i/; why should that be? The field of linguistic typology seeks to answer these questions and, thereby, divine the mechanisms that underlie human language. In our work, we tackle the problem of vowel system typology, i.e., we propose a generative probability model of which vowels a language contains. In contrast to previous work, we work directly with the acoustic information—the first two formant values—rather than modeling discrete sets of phonemic symbols (IPA). We develop a novel generative probability model and report results based on a corpus of 233 languages.

1 Introduction

Human languages are far from arbitrary; cross-linguistically, they exhibit surprising similarity in many respects and many properties appear to be universally true. The field of linguistic typology seeks to investigate, describe and quantify the axes along which languages vary. One facet of language that has been the subject of heavy investigation is the nature of vowel inventories, i.e., which vowels a language contains. It is a cross-linguistic universal that all spoken languages have vowels (Gordon, 2016), and the underlying principles guiding vowel selection are understood: vowels must be both easily recognizable and well-dispersed (Schwartz et al., 2005). In this work, we offer a more formal treatment of the subject, deriving a generative probability model of vowel inventory typology. Our work builds on (Cotterell and Eisner, 2017) by investigating not just discrete IPA inventories but the cross-linguistic variation in acoustic formants.

The philosophy behind our approach is that linguistic typology should be treated probabilistically and its goal should be the construction of a universal prior over potential languages. A probabilistic approach does not rule out linguistic systems completely (as long as one's theoretical formalism can describe them at all), but it can position phenomena on a scale from very common to very improbable. Probabilistic modeling also provides a discipline for drawing conclusions from sparse data. While we know of over 7000 human languages, we have some sort of linguistic analysis for only 2300 of them (Comrie et al., 2013), and the dataset used in this paper (Becker-Kristal, 2010) provides simple vowel data for fewer than 250 languages.

Formants are the resonant frequencies of the human vocal tract during the production of speech sounds. We propose a Bayesian generative model of vowel inventories, where each language's inventory is a finite subset of acoustic vowels represented as points $(F_1, F_2) \in \mathbb{R}^2$. We deploy tools from the neural-network and point-process literatures and experiment on a dataset with 233 distinct languages. We show that our most complicated model outperforms simpler models.

2 Acoustic Phonetics and Formants

Much of human communication takes place through speech: one conversant emits a sound wave to be comprehended by a second. In this work, we consider the nature of the portions of such sound waves that correspond to vowels. We briefly review the relevant bits of acoustic phonetics so as to give an overview of the data we are actually modeling and develop our notation.

The anatomy of a sound wave. The sound wave that carries spoken language is a function from time to amplitude, describing sound pressure variation in the air. To distinguish vowels, it is helpful to transform this function into a **spectrogram** (Fig. 1) by using a short-time Fourier transform

Proceedings of NAACL-HLT 2018, pages 37–46
New Orleans, Louisiana, June 1 - 6, 2018.

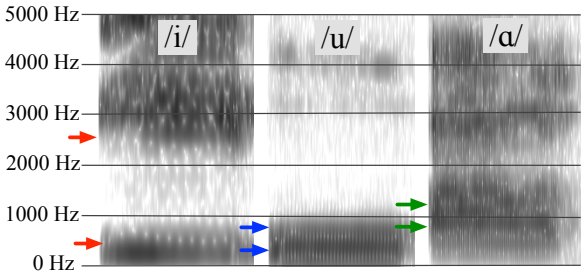

Figure 1: Example spectrogram of the three English vowels: /i/, /u/ and /ɑ/. The x-axis is time and y-axis is frequency. The first two formants F_1 and F_2 are marked in with arrows for each vowel. The figure was made with Praat (Boersma et al., 2002).

(Deng and O'Shaughnessy, 2003, Chapter 1) to decompose each short interval of the wave function into a weighted sum of sinusoidal waves of different frequencies (measured in Hz). At each interval, the variable darkness of the spectrogram indicates the weights of the different frequencies. In phonetic analysis, a common quantity to consider is a **formant**—a local maximum of the (smoothed) frequency spectrum. The fundamental frequency F_0 determines the pitch of the sound. The formants F_1 and F_2 determine the quality of the vowel.

Two is all you need (and what we left out). In terms of vowel recognition, it is widely speculated that humans rely almost exclusively on the first two formants of the sound wave (Ladefoged, 2001, Chapter 5). The two-formant assumption breaks down in edge cases: e.g., the third formant F_3 helps to distinguish the roundness of the vowel (Ladefoged, 2001, Chapter 5). Other non-formant features may also play a role. For example, in tonal languages, the same vowel may be realized with different tones (which are signaled using F_0): Mandarin Chinese makes a distinction between mǎ (*horse*) and má (*hemp*) without modifying the quality of the vowel /a/. Other features, such as creaky voice, can play a role in distinguishing phonemes. We do not explicitly model any of these aspects of vowel space, limiting ourselves to (F_1, F_2) as in previous work (Liljencrants and Lindblom, 1972). However, it would be easy to extend all the models we will propose here to incorporate such information, given appropriate datasets.

3 The Phonology of Vowel Systems

The vowel inventories of the world's languages display clear structure and appear to obey several underlying principles. The most prevalent of these principles are **focalization** and **dispersion**.

Focalization. The notion of focalization grew out of quantal vowel theory (Stevens, 1989). Quantal vowels are those that are phonetically "better" than others. They tend to display certain properties, e.g., the formants tend to be closer together (Stevens, 1987). Cross-linguistically, quantal vowels are the most frequently attested vowels, e.g., the cross-linguistically common vowel /i/ is considered quantal, but less common /y/ is not.

Dispersion. The second core principle of vowel system organization is known as dispersion. As the name would imply, the principle states that the vowels in "good" vowel systems tend to be spread out. The motivation for such a principle is clear—a well-dispersed set of vowels reduces a listener's potential confusion over which vowel is being pronounced. See Schwartz et al. (1997) for a review of dispersion in vowel system typology and its interaction with focalization, which has led to the joint dispersion-focalization theory.

Notation. We will denote the universal set of international phonetic alphabet (IPA) symbols as $\mathcal{V}$. The observed vowel inventory for language ℓ has size n^ℓ and is denoted $V^\ell = \{(v_1^\ell, \mathbf{v}_1^\ell), \ldots, (v_{n^\ell}^\ell, \mathbf{v}_{n^\ell}^\ell)\} \subseteq \mathcal{V} \times \mathbb{R}^d$, where for each $k \in [1, n^\ell]$, $v_k^\ell \in \mathcal{V}$ is an IPA symbol assigned by a linguist and $\mathbf{v}_k^\ell \in \mathbb{R}^d$ is a vector of d measurable phonetic quantities. In short, the IPA symbol v_k^ℓ was assigned as a label for a phoneme with pronunciation $\mathbf{v}_k^\ell$. The ordering of the elements within V^ℓ is arbitrary.

Goals. This framework recognizes that the same IPA symbol v (such as /u/) may represent a slightly different sound $\mathbf{v}$ in one language than in another, although they are transcribed identically. We are specifically interested in how the vowels in a language influence one another's fine-grained pronunciation in $\mathbb{R}^d$. In general, there is no reason to suspect that speakers of two languages, whose phonological systems contain the same IPA symbol, should produce that vowel with identical formants.

Data. For the remainder of the paper, we will take $d = 2$ so that each $\mathbf{v} = (F_1, F_2) \in \mathbb{R}^2$, the vector consisting of the first two formant values, as compiled from the field literature by Becker-Kristal (2006). This dataset provides inventories V^ℓ in the form above. Thus, we do not consider further variation of the vowel pronunciation that

may occur within the language (between speakers, between tokens of the vowel, or between earlier and later intervals within a token).

4 Phonemes versus Phones

Previous work (Cotterell and Eisner, 2017) has placed a distribution over discrete phonemes, ignoring the variation across languages in the *pronunciation* of each phoneme. In this paper, we crack open the phoneme abstraction, moving to a learned set of finer-grained phones.

Cotterell and Eisner (2017) proposed (among other options) using a *determinantal point process* (DPP) over a universal inventory $\mathcal{V}$ of 53 symbolic (IPA) vowels. A draw from such a DPP is a language-specific inventory of vowel *phonemes*, $V \subseteq \mathcal{V}$. In this paper, we say that a language instead draws its inventory from a larger set $\bar{\mathcal{V}}$, again using a DPP. In both cases, the reason to use a DPP is that it prefers relatively diverse inventories whose individual elements are relatively quantal.

While we could in principle identify $\bar{\mathcal{V}}$ with $\mathbb{R}^d$, for convenience we still take it to be a (large) discrete finite set $\bar{\mathcal{V}} = \{\bar{v}_1, \ldots, \bar{v}_N\}$, whose elements we call *phones*. $\bar{\mathcal{V}}$ is a learned cross-linguistic parameter of our model; thus, its elements—the "universal phones"—may or may not correspond to phonetic categories traditionally used by linguists.

We presume that language ℓ draws from the DPP a subset $\bar{V}^\ell \subseteq \bar{\mathcal{V}}$, whose size we call n^ℓ. For each universal phone $\bar{v}_i$ that appears in this inventory $\bar{V}^\ell$, the language then draws an observable language-specific pronunciation $\mathbf{v}_i^\ell \sim \mathcal{N}\left(\boldsymbol{\mu}_i, \sigma^2 I\right)$ from a distribution associated cross-linguistically with the universal phone $\bar{v}_i$. We now have an inventory of pronunciations.

As a final step in generating the vowel inventory, we could model IPA labels. For each $\bar{v}_i \in \bar{V}^\ell$, a field linguist presumably draws the IPA label v_i^ℓ conditioned on all the pronunciations $\{\mathbf{v}_i^\ell \in \mathbb{R}^d : \bar{v}_i \in \bar{V}^\ell\}$ in the inventory (and perhaps also on their underlying phones $\bar{v}_i \in \bar{V}^\ell$). This labeling process may be complex. While each pronunciation in $\mathbb{R}^d$ (or each underlying phone in $\bar{\mathcal{V}}$) may have a preference for certain IPA labels in $\mathcal{V}$, the n^ℓ labels must be drawn jointly because the linguist will take care not to use the same label for two phones, and also because the linguist may like to describe the inventory using a small number of distinct IPA features, which will tend to favor factorial grids of symbols. The linguist's use of IPA features may also be informed by phonological and phonetic processes in the language. We leave modeling of this step to future work; so our current likelihood term ignores the evidence contributed by the IPA labels in the dataset, considering only the pronunciations in $\mathbb{R}^d$.

The overall idea is that human languages ℓ draw their inventories from some universal prior, which we are attempting to reconstruct. A caveat is that we will train our method by maximum-likelihood, which does not quantify our uncertainty about the reconstructed parameters. An additional caveat is that some languages in our dataset are related to one another, which belies the idea that they were drawn independently. Ideally, one ought to capture these relationships using hierarchical or evolutionary modeling techniques.

5 Determinantal Point Processes

Before delving into our generative model, we briefly review technical background used by Cotterell and Eisner (2017). A DPP is a probability distribution over the subsets of a *fixed ground set* of size N—in our case, the set of phones $\bar{\mathcal{V}}$. The DPP is usually given as an L-ensemble (Borodin and Rains, 2005), meaning that it is parameterized by a positive semi-definite matrix $L \in \mathbb{R}^{N \times N}$. Given a discrete base set $\bar{\mathcal{V}}$ of phones, the probability of a subset $\bar{V} \subseteq \bar{\mathcal{V}}$ is given by

$$p(\bar{V}) \propto \det\left(L_{\bar{V}}\right), \tag{1}$$

where $L_{\bar{V}}$ is the submatrix of L corresponding to the rows and columns associated with the subset $\bar{V} \subseteq \bar{\mathcal{V}}$. The entry L_{ij}, where $i \neq j$, has the effect of describing the similarity between the elements $\bar{v}_i$ and $\bar{v}_j$ (both in $\bar{\mathcal{V}}$)—an ingredient needed to model dispersion. And, the entry L_{ii} describes the quality—focalization—of the vowel $\bar{v}_i$, i.e., how much the model wants to have $\bar{v}_i$ in a sampled set independent of the other members.

5.1 Probability Kernel

In this work, each phone $\bar{v}_i \in \bar{\mathcal{V}}$ is associated with a probability density over the space of possible pronunciations $\mathbb{R}^2$. Our measure of phone similarity will consider the "overlap" between the densities associated with two phones. This works as follows: Given two densities $f(x, y)$ and $f'(x, y)$ over $\mathbb{R}^2$, we define the kernel (Jebara et al., 2004) as

$$\mathcal{K}(f, f'; \rho) = \int_x \int_y f(x, y)^\rho f'(x, y)^\rho dx\, dy, \tag{3}$$

$$\prod_{\ell=1}^{M} \Big[p(\mathbf{v}^{\ell,1}, \ldots, \mathbf{v}^{\ell,n^\ell} \mid \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_N, N)\Big] p(\boldsymbol{\mu}_1, \ldots \boldsymbol{\mu}_N \mid N)\, p(N) \tag{2}$$

$$= \prod_{\ell=1}^{M} \left[\sum_{\mathbf{a}^\ell \in A(n^\ell, N)} \left(\prod_{k=1}^{n^\ell} \underbrace{p(\mathbf{v}^{\ell,k} \mid \boldsymbol{\mu}_{a_k^\ell})}_{④} \right) \underbrace{p(\bar{V}(\mathbf{a}^\ell) \mid \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_N, N)}_{③} \right] \underbrace{p(\boldsymbol{\mu}_1, \ldots \boldsymbol{\mu}_N \mid N)}_{②} \underbrace{p(N)}_{①}$$

Figure 2: Joint likelihood of M vowel systems under our deep generative probability model for continuous-space vowel inventories. Here language ℓ has an observed inventory of pronunciations $\{\mathbf{v}^{\ell,k} : 1 \leq k \leq n^\ell\}$, and $a_k^\ell \in [1, N]$ denotes a phone that might be responsible for the pronunciation $\mathbf{v}^{\ell,k}$. Thus, $\mathbf{a}^\ell$ denotes some way to jointly label all n^ℓ pronunciations with distinct phones. We must sum over all $\binom{N}{n^\ell}$ such labelings $\mathbf{a}^\ell \in A(n^\ell, N)$ since the true labeling is not observed. In other words, we sum over all ways $\mathbf{a}^\ell$ of completing the data for language ℓ. Within each summand, the product of factors 3 and 4 is the probability of the completed data, i.e., the joint probability of generating the inventory $\bar{V}(\mathbf{a}^\ell)$ of phones used in the labeling and their associated pronunciations. Factor 3 considers the prior probability of $\bar{V}(\mathbf{a}^\ell)$ under the DPP, and factor 4 is a likelihood term that considers the probability of the associated pronunciations.

with inverse temperature parameter ρ.

In our setting, f, f' will both be Gaussian distributions with means $\boldsymbol{\mu}$ and $\boldsymbol{\mu}'$ that share a fixed spherical covariance matrix $\sigma^2 I$. Then eq. (3) and indeed its generalization to any $\mathbb{R}^d$ has a closed-form solution (Jebara et al., 2004, §3.1):

$$\mathcal{K}(f, f'; \rho) = \tag{4}$$
$$(2\rho)^{\frac{d}{2}} \left(2\pi\sigma^2\right)^{\frac{(1-2\rho)d}{2}} \exp\left(-\frac{\rho||\boldsymbol{\mu} - \boldsymbol{\mu}'||^2}{4\sigma^2}\right).$$

Notice that making ρ small (i.e., high temperature) has an effect on (4) similar to scaling the variance σ^2 by the temperature, but it also results in changing the scale of $\mathcal{K}$, which affects the balance between dispersion and focalization in (6) below.

5.2 Focalization Score

The probability kernel given in eq. (3) naturally handles the linguistic notion of dispersion. What about focalization? We say that a phone is focal to the extent that it has a high score

$$F(\boldsymbol{\mu}) = \exp\left(U_2 \tanh(U_1 \boldsymbol{\mu} + \mathbf{b}_1) + \mathbf{b}_2\right) > 0 \tag{5}$$

where $\boldsymbol{\mu}$ is the mean of its density. To learn the parameters of this neural network from data is to learn which phones are focal. We use a neural network since the focal regions of $\mathbb{R}^2$ are distributed in a complex way.

5.3 The L Matrix

If $f_i = \mathcal{N}(\boldsymbol{\mu}_i, \sigma^2 I)$ is the density associated with the phone $\bar{v}_i$, we may populate an $N \times N$ real matrix L where

$$L_{ij} = \begin{cases} \mathcal{K}(f_i, f_j; \rho) & \text{if } i \neq j \\ \mathcal{K}(f_i, f_j; \rho) + F(\boldsymbol{\mu}_i) & \text{if } i = j \end{cases} \tag{6}$$

Since L is the sum of two positive definite matrices (the first specializes a known kernel and the second is diagonal and positive), it is also positive definite. As a result, it can be used to parameterize a DPP over $\bar{\mathcal{V}}$. Indeed, since L is positive definite and not merely positive semidefinite, it will assign positive probability to *any* subset of $\bar{\mathcal{V}}$.

As previously noted, this DPP does not define a distribution over an infinite set, e.g., the powerset of $\mathbb{R}^2$, as does recent work on continuous DPPs (Affandi et al., 2013). Rather, it defines a distribution over the powerset of a *set of densities with finite cardinality*. Once we have sampled a subset of densities, a real-valued quantity may be additionally sampled from each sampled density.

Algorithm 1 Generative Process

```

for i = 1 to N :
    μ_i ~ 𝒩(0, I) (∈ ℝ^2)                              ②
define L ∈ ℝ^{N×N} via (6)
for ℓ = 1 to M :
    V̄^ℓ ~ DPP(L) (⊆ [1, N]); let n^ℓ = |V̄^ℓ|           ③
    for i ∈ V̄^ℓ :
        ṽ_i^ℓ ~ 𝒩(μ_i, σ^2 I)                          ④
        v_i^ℓ = ν_θ(ṽ_i^ℓ)                             ④
```

6 A Deep Generative Model

We are now in a position to expound our generative model of continuous-space vowel typology. We

generate a set of formant pairs for M languages in a four step process. Note that throughout this exposition, language-specific quantities with be superscripted with an integral language marker ℓ, whereas universal quantities are left unsuperscripted. The generative process is written in algorithmic form in Alg. 1. Note that each step is numbered and color-coded for ease of comparison with the full joint likelihood in Fig. 2.

Step ①: $p(N)$. We sample the size N of the universal phone inventory $\bar{\mathcal{V}}$ from a Poisson distribution with a rate parameter λ, i.e.,

$$N \sim \text{Poisson}\,(\lambda)\,. \tag{7}$$

That is, we do not presuppose a certain number of phones in the model.

Step ②: $p(\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_N)$. Next, we sample the means $\boldsymbol{\mu}_i$ of the Gaussian phones. In the model presented here, we assume that each phone is generated independently, so $p(\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_N) = \prod_{i=1}^{N} p(\boldsymbol{\mu}_i)$. Also, we assume a standard Gaussian prior over the means, $\boldsymbol{\mu}_i \sim \mathcal{N}(\mathbf{0}, I)$.

The sampled means define our N Gaussian phones $\mathcal{N}\left(\boldsymbol{\mu}_i, \sigma^2 I\right)$: we are assuming for simplicity that all phones share a *single* spherical covariance matrix, defined by the hyperparameter σ^2. The dispersion and focalization of these phones define the matrix L according to equations (4)–(6), where ρ in (4) and the weights of the focalization neural net (5) are also hyperparameters.

Step ③: $p(\bar{V}^\ell \mid \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_N)$. Next, for each language $\ell \in [1, \ldots, M]$, we sample a diverse subset of the N phones, via a single draw from a DPP parameterized by matrix L:

$$\bar{V}^\ell \sim \text{DPP}(L), \tag{8}$$

where $\bar{V}^\ell \subseteq [1, N]$. Thus, $i \in \bar{V}^\ell$ means that language ℓ contains phone $\bar{v}_i$. Note that even the size of the inventory, $n^\ell = |\bar{V}^\ell|$, was chosen by the DPP. In general, we have $n^\ell \ll N$.

Step ④: $\prod_{i \in \bar{V}^\ell} p(\mathbf{v}_i^\ell \mid \boldsymbol{\mu}_i)$ The final step in our generative process is that the phones $\bar{v}_i$ in language ℓ must generate the pronunciations $\mathbf{v}_i^\ell \in \mathbb{R}^2$ (formant vectors) that are actually observed in language ℓ. Each vector takes two steps. For each $i \in \bar{V}^\ell$, we generate an underlying $\tilde{\mathbf{v}}_i \in \mathbb{R}^2$ from the corresponding Gaussian phone. Then, we run this vector through a feed-forward neural network $\nu_{\boldsymbol{\theta}}$ with parameters $\boldsymbol{\theta}$. In short:

$$\tilde{\mathbf{v}}_i^\ell \sim \mathcal{N}(\boldsymbol{\mu}_i, \sigma^2 I) \tag{9}$$

$$\mathbf{v}_i^\ell = \nu_{\boldsymbol{\theta}}(\tilde{\mathbf{v}}_i^\ell), \tag{10}$$

where the second step is deterministic. We can fuse these two steps into a single step $p(\mathbf{v}_i \mid \boldsymbol{\mu}_i)$, whose closed-form density is given in eq. (12) below. In effect, step 4 takes a Gaussian phone as input and produces the observed formant vector with an *underlying* formant vector in the middle.

This completes our generative process. We do not observe all the steps, but only the final collection of pronunciations $\mathbf{v}_i^\ell$ for each language, where the subscripts i that indicate phone identity have been lost. The probability of this incomplete dataset involves summing over possible phones for each pronunciation, and is presented in Fig. 2.

6.1 A Neural Transformation of a Gaussian

A crucial bit of our model is running a sample from a Gaussian through a neural network. Under certain restrictions, we can find a closed form for the resulting density; we discuss these below. Let $\nu_{\boldsymbol{\theta}}$ be a depth-2 multi-layer perceptron

$$\nu_{\boldsymbol{\theta}}(\tilde{\mathbf{v}}_i) = W_2 \tanh\left(W_1 \tilde{\mathbf{v}}_i + \mathbf{b}_1\right) + \mathbf{b}_2. \tag{11}$$

In order to find a closed-form solution, we require that (5) be a diffeomorphism, i.e., an invertible mapping from $\mathbb{R}^2 \to \mathbb{R}^2$ where both $\nu_{\boldsymbol{\theta}}$ and its inverse $\nu_{\boldsymbol{\theta}}^{-1}$ are differentiable. This will be true as long as $W_1, W_2 \in \mathbb{R}^{2\times 2}$ are square matrices of full-rank and we choose a smooth, invertible activation function, such as $\tanh$. Under those conditions, we may apply the standard theorem for transforming a random variable (see Stark and Woods, 2011):

$$\begin{aligned} p(\mathbf{v}_i \mid \boldsymbol{\mu}_i) &= p(\nu_{\boldsymbol{\theta}}^{-1}(\mathbf{v}_i) \mid \boldsymbol{\mu}_i)\ \det J_{\nu_{\boldsymbol{\theta}}^{-1}(\mathbf{v}_i)} \\ &= p(\tilde{\mathbf{v}}_i \mid \boldsymbol{\mu}_i)\ \det J_{\nu_{\boldsymbol{\theta}}^{-1}(\mathbf{v}_i)} \end{aligned} \tag{12}$$

where $J_{\nu_{\boldsymbol{\theta}}^{-1}(\mathbf{x})}$ is the Jacobian of the inverse of the neural network at the point $\mathbf{x}$. Recall that $p(\tilde{\mathbf{v}}_i \mid \boldsymbol{\mu}_i)$ is Gaussian-distributed.

7 Modeling Assumptions

Imbued in our generative story are a number of assumptions about the linguistic processes behind vowel inventories. We briefly draw connections between our theory and the linguistics literature.

Why underlying phones? A technical assumption of our model is the existence of a universal set of underlying phones. Each phone is equipped with a probability distribution over reported acoustic measurements (pronunciations), to allow for a single phone to account for multiple slightly different pronunciations in different languages (though never in the same language). This distribution can capture both actual interlingual variation and also random noise in the measurement process.

While our universal phones may seem to resemble the universal IPA symbols used in phonological transcription, they lack the rich featural specifications of such phonemes. A phone in our model has no features other than its mean position, which wholly determines its behavior. Our universal phones are not a substantive linguistic hypothesis, but are essentially just a way of partitioning $\mathbb{R}^2$ into finitely many small regions whose similarity and focalization can be precomputed. This technical trick allows us to use a discrete rather than a continuous DPP over the $\mathbb{R}^2$ space.[1]

Why a neural network? Our phones are Gaussians of spherical variance σ^2, presumed to be scattered with variance 1 about a two-dimensional *latent* vowel space. Distances in this latent space are used to compute the dissimilarity of phones for modeling dispersion, and also to describe the phone's ability to vary across languages. That is, two phones that are *distant* in the latent space can appear in the same inventory—presumably they are easy to discriminate in both perception and articulation—and it is easy to choose which one better explains an acoustic measurement, thereby affecting the other measurements that may appear in the inventory.

We relate this *latent* space to measurable acoustic space by a learned diffeomorphism $\nu_{\boldsymbol{\theta}}$ (Cotterell and Eisner, 2017). $\nu_{\boldsymbol{\theta}}^{-1}$ can be regarded as warping the acoustic distances into perceptual/articulatory distances. In some "high-resolution" regions of acoustic space, phones with fairly similar (F_1, F_2) values might yet be far apart in the latent space. Conversely, in other regions, relatively large acoustic changes in some direction might not prevent two phones from acting as similar or two pronunciations from being attributed to the same phone. In general, a unit circle of radius σ in latent space may be mapped by $\nu_{\boldsymbol{\theta}}$ to an oddly shaped connected region in acoustic space, and a Gaussian in latent space may be mapped to a multimodal distribution.

[1] Indeed, we could have simply taken our universal phone set to be a huge set of tiny, regularly spaced overlapping Gaussians that "covered" (say) the unit circle. As a computational matter, we instead opted to use a smaller set of Gaussians, giving the learner the freedom to infer their positions and tune their variance σ^2. Because of this freedom, this set should not be too large, or a MAP learner may overfit the training data with zero-variance Gaussians and be unable to explain the test languages—similar to overfitting a Gaussian mixture model.

8 Inference and Learning

We fit our model via MAP-EM (Dempster et al., 1977). The E-step involves deciding which phones each language has. To achieve this, we fashion a Gibbs sampler (Geman and Geman, 1984), yielding a Markov-Chain Monte Carlo E-step (Levine and Casella, 2001).

8.1 Inference: MCMC E-Step

Inference in our model is intractable even when the phones $\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_N$ are fixed. Given a language with n vowels, we have to determine which subset of the N phones best explains those vowels. As discussed above, the alignment $\mathbf{a}$ between the n vowels and n of the N phones represents a latent variable. Marginalizing it out is #P-hard, as we can see that it is equivalent to summing over all bipartite matchings in a weighted graph, which, in turn, is as costly as computing the permanent of a matrix (Valiant, 1979). Our sampler[2] is an approximation algorithm for the task. We are interested in sampling $\mathbf{a}$, the labeling of observed vowels with universal phones. Note that this implicitly samples the language's phone inventory $\bar{V}(\mathbf{a})$, which is fully determined by $\mathbf{a}$.

Specifically, we employ an MCMC method closely related to Gibbs sampling. At each step of the sampler, we update our vowel-phone alignment $\mathbf{a}^\ell$ as follows. Choose a language ℓ and a vowel index $k \in [1, n^\ell]$, and let $i = a_k^\ell$ (that is, pronunciation $\mathbf{v}^{\ell,k}$ is currently labeled with universal phone $\bar{v}_i$). We will consider changing a_k^ℓ to j, where j is drawn from the $(N - n^\ell)$ phones that do *not* appear in $\bar{V}(\mathbf{a}^\ell)$, heuristically choosing j in proportion to the likelihood $p(\mathbf{v}^{\ell,k} \mid \boldsymbol{\mu}_j)$. We then stochastically decide whether to keep $a_k^\ell = i$ or set $a_k^\ell = j$ in proportion to the resulting values of the product (4) · (3) in eq. (2).

For a single E-step, the Gibbs sampler "warm-starts" with the labeling from the end of the previous iteration's E-step. It sweeps $S = 5$ times

[2] Taken from Volkovs and Zemel (2012, 3.1).

through all vowels for all languages, and returns S sampled labelings, one from the end of each sweep.

We are also interested in automatically choosing the number of phones N, for which we take the Poisson's rate parameter $\lambda = 100$. To this end, we employ reversible-jump MCMC (Green, 1995), resampling N at the start of every E-step.

8.2 Learning: M-Step

Given the set of sampled alignments provided by the E-step, our M-step consists of optimizing the log-likelihood of the now-complete training data using the inferred latent variables. We achieved this through SGD training of the diffeomorphism parameters $\boldsymbol{\theta}$, the means $\boldsymbol{\mu}_i$ of the Gaussian phones, and the parameters of the focalization kernel $\mathcal{F}$.

9 Experiments

9.1 Data

Our data is taken from the Becker-Kristal corpus (Becker-Kristal, 2006), which is a compilation of various phonetic studies and forms the largest multilingual phonetic database. Each entry in the corpus corresponds to a linguist's phonetic description of a language's vowel system: an inventory consisting of IPA symbols where each symbol is associated with two or more formant values. The corpus contains data from 233 distinct languages. When multiple inventories were available for the same language (due to various studies in the literature), we selected one at random and discarded the others.

9.2 Baselines

Baseline #1: Removing dispersion. The key technical innovation in our work lies in the incorporation of a DPP into a generative model of vowel formants—a continuous-valued quantity. The role of the DPP was to model the linguistic principle of dispersion—we may cripple this portion of our model, e.g., by forcing $\mathcal{K}$ to be a diagonal kernel, i.e., $K_{ij} = 0$ for $i \neq j$. In this case the DPP becomes a Bernoulli Point Process (BPP)—a special case of the DPP. Since dispersion is widely accepted to be an important principle governing naturally occurring vowel systems, we expect a system trained without such knowledge to perform worse.

Baseline #2: Removing the neural network $\nu_{\boldsymbol{\theta}}$. Another question we may ask of our formulation is whether we actually need a fancy neural mapping $\nu_{\boldsymbol{\theta}}$ to model our typological data well. The human perceptual system is known to perform a non-linear transformation on acoustic signals, starting with the non-linear cochlear transform that is physically performed in the ear. While $\nu_{\boldsymbol{\theta}}^{-1}$ is intended as loosely analogous, we determine its benefit by removing eq. (10) from our generative story, i.e., we take the observed formants $\mathbf{v}_k$ to arise directly from the Gaussian phones.

Baseline #3: Supervised phones and alignments. A final baseline we consider is *supervised* phones. Linguists standardly employ a finite set of phones—symbols from the international phonetic alphabet (IPA). In phonetic annotation, it is common to map each sound in a language back to this universal discrete alphabet. Under such an annotation scheme, it is easy to discern, cross-linguistically, which vowels originate from the same phoneme: an /ɪ/ in German may be roughly equated with an /ɪ/ in English. However, it is not clear how consistent this annotation truly is. There are several reasons to expect high-variance in the cross-linguistic acoustic signal. First, IPA symbols are primarily useful for interlinked phonological distinctions, i.e., one applies the symbol /ɪ/ to distinguish it from /i/ in the given language, rather than to associate it with the sound bearing the same symbol in a second language. Second, field linguists often resort to the closest common IPA symbol, rather than an exact match: if a language makes no distinction between /i/ and /ɪ/, it is more common to denote the sound with a /i/. Thus, IPA may not be as universal as hoped. Our dataset contains 50 IPA symbols so this baseline is only reported for $N = 50$.

9.3 Evaluation

Evaluation in our setting is tricky. The scientific goal of our work is to place a bit of linguistic theory on a firm probabilistic footing, rather than a downstream engineering-task, whose performance we could measure. We consider three metrics.

Cross-Entropy. Our first evaluation metric is cross-entropy: the average negative log-probability of the vowel systems in held-out test data, given the universal inventory of N phones that we trained through EM. We find this to be the cleanest method for scientific evaluation—it is the metric of optimization and has a clear interpretation: how surprised was the model to see the vowel systems of held-out, but attested, languages?

The cross-entropy is the negative log of the $\prod \left[\cdots \right]$ expression in eq. (2), with ℓ now rang-

N	metric	DPP+$\nu_{\boldsymbol{\theta}}$	BPP+$\nu_{\boldsymbol{\theta}}$	DPP−$\nu_{\boldsymbol{\theta}}$	Sup.
15	x-ent	540.02	540.05	600.34	✗
	cloze1	5.76	5.76	6.53	✗
	cloze12	4.89	4.89	5.24	✗
25	x-ent	280.47	275.36	335.36	✗
	cloze1	5.04	5.25	6.23	✗
	cloze12	4.76	4.97	5.43	✗
50	x-ent	222.85	231.70	320.05	1610.37
	cloze1	3.38	3.16	4.02	4.96
	cloze12	2.73	2.93	3.04	6.95
57	x-ent	212.14	220.42	380.31	✗
	cloze1	2.21	3.08	3.25	✗
	cloze12	2.01	3.05	3.41	✗
100	x-ent	271.95	301.45	380.02	✗
	cloze1	2.26	2.42	3.03	✗
	cloze12	1.96	2.01	2.51	✗

Table 1: Cross-entropy in nats per language (lower is better) and expected Euclidean-distance error of the cloze prediction (lower is better). The overall best value for each task is bold-faced. The case $N = 50$ is compared against our supervised baseline. The $N = 57$ row is the case where we allowed N to fluctuate during inference using reversible-jump MCMC; this was the N value selected at the final EM iteration.

ing over held-out languages.[3] Wallach et al. (2009) give several methods for estimating the intractable sum in language ℓ. We use the simple harmonic mean estimator, based on 50 samples of $\mathbf{a}^\ell$ drawn with our Gibbs sampler (warm-started from the final E-step of training).

Cloze Evaluation. In addition, following Cotterell and Eisner (2017), we evaluate our trained model's ability to perform a cloze task (Taylor, 1953). Given $n^\ell - 1$ or $n^\ell - 2$ of the vowels in held-out language ℓ, can we predict the pronunciations $\mathbf{v}_k$ of the remaining 1 or 2? We predict $\mathbf{v}_k$ to be $\nu_{\boldsymbol{\theta}}(\boldsymbol{\mu}_i)$ where $i = a_k^\ell$ is the phone inferred by the sampler. Note that the sampler's inference here is based only on the observed vowels (the likelihood) and the focalization-dispersion preferences of the DPP (the prior). We report the expected error of such a prediction—where error is quantified by Euclidean distance in (F_1, F_2) formant space—over the same 50 samples of $\mathbf{a}^\ell$.

For instance, consider a previously unseen vowel system with formant values $\{(499, 2199), (861, 1420), (571, 1079)\}$. A "cloze1" evaluation would aim to predict $\{(499, 2199)\}$ as the missing vowel, given $\{(861, 1420), (571, 1079)\}$, and the fact that $n^\ell = 3$. A "cloze12" evaluation would aim to predict two missing vowels.

[3] Since that expression is the product of both probability distributions and probability densities, our "cross-entropy" metric is actually the sum of both entropy terms and (potentially negative) differential entropy terms. Thus, a value of 0 has no special significance.

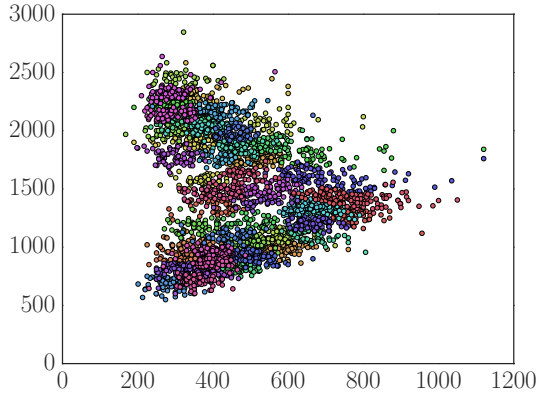

Figure 3: A graph of $\mathbf{v} = (F_1, F_2)$ in the union of all the training languages' inventories, color-coded by inferred phone ($N = 50$).

9.4 Experimental Details

Here, we report experimental details and the hyperparameters that we use to achieve the results reported. We consider a neural network $\nu_{\boldsymbol{\theta}}$ with $k \in [1, 4]$ layers and find $k = 1$ the best performer on development data. Recall that our *diffeomorphism* constraint requires that each layer have exactly two hidden units, the same as the number of observed formants. We consider $N \in \{15, 25, 50, 100\}$ phones as well as letting N fluctuate with reversible-jump MCMC (see footnote 1). We train for 100 iterations of EM, taking $S = 5$ samples at each E-step. At each M-step, we run 50 iterations of SGD for the focalization NN and also for the diffeomorphism NN. For each N, we selected (σ^2, ρ) by minimizing cross-entropy on a held-out development set. We considered $(\sigma^2, \rho) \in \{10^k\}_{k=1}^5 \times \{\rho^k\}_{k=1}^5$.

9.5 Results and Error Analysis

We report results in Tab. 1. We find that our DPP model improves over the baselines. The results support two claims: (i) dispersion plays an important role in the structure of vowel systems and (ii) learning a non-linear transformation of a Gaussian improves our ability to model sets of formant-pairs. Also, we observe that as we increase the number of phones, the role of the DPP becomes more important. We visualize a sample of the trained alignment in Fig. 3.

Frequency Encodes Dispersion. Why does dispersion not always help? The models with fewer phones do not reap the benefits that the models with more phones do. The reason lies in the fact that the most common vowel formants are *already* dispersed. This indicates that we still have not quite modeled the mechanisms that select for good vowel formants, despite our work at the phonetic level; further research is needed. We would prefer a model that explains the *evolutionary motivation* of sound systems as communication systems.

Number of Induced Phones. What is most salient in the number of induced phones is that it is close to the number of IPA phonemes in the data. However, the performance of the phoneme-supervised system is much worse, indicating that, perhaps, while the linguists have the right idea about the *number* of universal symbols, they did not specify the correct IPA symbol in all cases. Our data analysis indicates that this is often due to pragmatic concerns in linguistic field analysis. For example, even if /ɪ/ is the proper IPA symbol for the sound, if there is no other sound in the vicinity the annotator may prefer to use more common /i/.

10 Related Work

Most closely related to our work is the classic study of Liljencrants and Lindblom (1972), who provide a simulation-based account of vowel systems. They argued that minima of a certain objective that encodes dispersion should correspond to canonical vowel systems of a given size n. Our tack is different in that we construct a generative probability model, whose parameters we learn from data. However, the essence of modeling is the same in that we explain *formant* values, rather than discrete IPA symbols. By extension, our work is also closely related to extensions of this theory (Schwartz et al., 1997; Roark, 2001) that focused on incorporating the notion of focalization into the experiments.

Our present paper can also be regarded as a continuation of Cotterell and Eisner (2017), in which we used DPPs to model vowel inventories as sets of discrete IPA symbols. That paper pretended that each IPA symbol had a single cross-linguistic (F_1, F_2) pair, an idealization that we remove in this paper by discarding the IPA symbols and modeling formant values directly.

11 Conclusion

Our model combines existing techniques of probabilistic modeling and inference to attempt to fit the actual distribution of the world's vowel systems. We presented a generative probability model of sets of measured (F_1, F_2) pairs. We view this as a necessary step in the development of generative probability models that can explain the distribution of the world's languages. Previous work on generating vowel inventories has focused on how those inventories were transcribed into IPA by field linguists, whereas we focus on the field linguists' acoustic measurements of how the vowels are actually pronounced.

Acknowledgments

We would like to acknowledge Tim Vieira, Katharina Kann, Sebastian Mielke and Chu-Cheng Lin for reading many early drafts. The first author would like to acknowledge an NDSEG grant and a Facebook PhD fellowship. This material is also based upon work supported by the National Science Foundation under Grant No. 1718846 to the last author.

Abstract

Morphological segmentation for polysynthetic languages is challenging, because a word may consist of many individual morphemes and training data can be extremely scarce. Since neural sequence-to-sequence (seq2seq) models define the state of the art for morphological segmentation in high-resource settings and for (mostly) European languages, we first show that they also obtain competitive performance for Mexican polysynthetic languages in minimal-resource settings. We then propose two novel multi-task training approaches—one with, one without need for external unlabeled resources—, and two corresponding data augmentation methods, improving over the neural baseline for all languages. Finally, we explore cross-lingual transfer as a third way to fortify our neural model and show that we can train one single multi-lingual model for related languages while maintaining comparable or even improved performance, thus reducing the amount of parameters by close to 75%. We provide our morphological segmentation datasets for Mexicanero, Nahuatl, Wixarika and Yorem Nokki for future research.

1 Introduction

Due to the advent of computing technologies to indigenous communities all over the world, natural language processing (NLP) applications for languages with limited computer-readable textual data are getting increasingly important. This contrasts with current research, which focuses strongly on approaches which require large amounts of training data, e.g., deep neural networks. Those are not trivially applicable to *minimal-resource* settings with less than $1,000$ available training examples. We aim at closing this gap for morphological surface segmentation, the task of splitting a word into the surface forms of its smallest meaning-bearing units, its *morphemes*.

Recovering morphemes provides information about unknown words and is thus especially important for polysynthetic languages with a high morpheme-to-word ratio and a consequently large overall number of words. To illustrate how segmentation helps understanding unknown multiple-morpheme words, consider an example in this paper's language of writing: even if the word *unconditionally* did not appear in a given training corpus, its meaning could still be derived from a combination of its morphs *un*, *condition*, *al* and *ly*.

Due to its importance for down-stream tasks (Creutz et al., 2007; Dyer et al., 2008), segmentation has been tackled in many different ways, considering unsupervised (Creutz and Lagus, 2002), supervised (Ruokolainen et al., 2013) and semi-supervised settings (Ruokolainen et al., 2014). Here, we add three new questions to this line of research: (i) Are data-hungry neural network models

*The first two authors contributed equally.

Proceedings of NAACL-HLT 2018, pages 47–57
New Orleans, Louisiana, June 1 - 6, 2018.

applicable to segmentation of polysynthetic languages in minimal-resource settings? (ii) How can the performance of neural networks for surface segmentation be improved if we have only unlabeled or no external data at hand? (iii) Is cross-lingual transfer for this task possible between related languages? The last two questions are crucial: While for many languages it is difficult to obtain the number of annotated examples used in earlier work on (semi-)supervised methods, a limited amount might still be obtainable.

We experiment on four polysynthetic Mexican languages: Mexicanero, Nahuatl, Wixarika and Yorem Nokki (details in §2). The datasets we use are, as far as we know, the first computer-readable datasets annotated for morphological segmentation in those languages.

Our experiments show that neural seq2seq models perform on par with or better than other strong baselines for our polysynthetic languages in a minimal-resource setting. However, we further propose two novel multi-task approaches and two new data augmentation methods. Combining them with our neural model yields up to 5.05% absolute accuracy or 3.40% F1 improvements over our strongest baseline.

Finally, following earlier work on cross-lingual knowledge transfer for seq2seq tasks (Johnson et al., 2017; Kann et al., 2017), we investigate training one single model for all languages, while sharing parameters. The resulting model performs comparably to or better than the individual models, but requires only roughly as many parameters as one single model.

Contributions. To sum up, we make the following contributions: (i) we confirm the applicability of neural seq2seq models to morphological segmentation of polysynthetic languages in minimal-resource settings; (ii) we propose two novel multi-task training approaches and two novel data augmentation methods for neural segmentation models; (iii) we investigate the effectiveness of cross-lingual transfer between related languages; and (iv) we provide morphological segmentation datasets for Mexicanero, Nahuatl, Wixarika and Yorem Nokki.

2 Polysynthetic Languages

Polysynthetic languages are morphologically rich languages which are highly synthetic, i.e., single words can be composed of many individual morphemes. In extreme cases, entire sentences consist of only one single token, whereupon "every argument of a predicate must be expressed by morphology on the word that contains that assigner" (Baker, 2006). This property makes surface segmentation of polysynthetic languages at the same time complex and particularly relevant for further linguistic analysis.

In this paper, we experiment on four polysynthetic languages of the Yuto-Aztecan family (Baker, 1997), with the goal of improving the performance of neural seq2seq models. The languages will be described in the rest of this section.

Mexicanero is a Western Peripheral Nahuatl variant, spoken in the Mexican state of Durango by approximately one thousand people. This dialect is isolated from the rest of the other branches and has a strong process of Spanish stem incorporation, while also having borrowed some suffixes from that language (Vanhove et al., 2012). It is common to see Spanish words mixed with Nahuatl agglutinations. In the following example we can see an intrasentencial mixing of Spanish (*in uppercases*) and Mexicanero:

u|ni|ye MALO – *I was sick*

Nahuatl is a large subgroup of the Yuto-Aztecan language family, and, including all of its variants, the most spoken native language in Mexico. Its almost two million native speakers live mainly in Puebla, Guerrero, Hidalgo, Veracruz, and San Luis Potosi, but also in Oaxaca, Durango, Modelos, Mexico City, Tlaxcala, Michoacan, Nayarit and the State of Mexico. Three dialectical groups are known: Central Nahuatl, Occidental Nahuatl and Oriental Nahuatl. The data collected for this work belongs to the Oriental branch spoken by 70 thousand people in Northern Puebla.

Like all languages of the Yuto-Aztecan family, Nahuatl is agglutinative and one word can consist of a combination of many different morphemes. Usually, the verb functions as the stem and gets extended by morphemes specifying, e.g., subject, patient, object or indirect object. The most common syntax sequence for Nahuatl is SOV. An example word is:

o|ne|mo|kokowa|ya – *I was sick*

Wixarika is a language spoken in the states of Jalisco, Nayarit, Durango and Zacatecas in Central West Mexico by approximately fifty thousand people. It belongs to the Coracholan group of languages within the Yuto-Aztecan family. Wixarika has five vowels {a,e,i,+[1],u} with long and short variants. An example for a word in the language is:

ne|p+|ti|kuye|kai – *I was sick*

Like Nahuatl, it has an SOV syntax, with heavy agglutination on the verb. Wixarika is morphologically more complex than other languages from the same family, because it incorporates more information into the verb (Leza and López, 2006). This leads to a higher number of morphemes per word as can also be seen in Table 3.

Yorem Nokki is part of Taracachita subgroup of the Yuto-Aztecan language family. Its Southern dialect is spoken by close to forty thousand people in the Mexican states of Sinaloa and Sonora, while its Northern dialect has about twenty thousand speakers. In this work, we consider the Southern dialect. The nominal morphology of Yorem

[1]While linguists often use a dashed i (ɨ) to denote this vowel, in practice almost all native speakers use a plus symbol (+). In this work, we choose to use the latter.

Table 2: Number of examples in the final data splits for all languages.

Nokki is rather simple, but, like in the other Yuto-Aztecan languages, the verb is highly complex. Its alphabet consists of 28 characters and contains 8 different vowels. An example verb is:

ko'kore|ye|ne – *I was sick*

3 Morphological Segmentation Datasets

To create our datasets, we make use of both segmentable (i.e., consisting of multiple morphemes) and non-segmentable (i.e., consisting of one single morpheme) words described in books of the collection *Archive of Indigenous Languages* in Mexicanero (Canger, 2001), Nahuatl (Lastra de Suárez, 1980), Wixarika (Gómez and López, 1999), and Yorem Nokki (Freeze, 1989). Statistics about the data in the four languages are displayed in Tables 1, 2 and 3. We include segmentable as well as non-segmentable words into our datasets in order to ensure that our methods can correctly decide against splitting up single morphemes. The phrases in all languages are mostly parallel, such that the corpora are roughly equivalent. Therefore, we can compare the morphology of translated words (cf. Table 3), noticing that the language with most agglutination is Wixarika, with an average rate of 3.25 morphemes per word; the other languages have an average of close to 2.2 morphemes per word. This higher morphological complexity naturally produces data sparsity at the token level. Also, we can notice that Wixarika has more unique words than the rest of our studied languages. However, Nahuatl has with 810 the highest number of unique morphemes.

Final splits. In order to make follow-up work on minimal-resource settings for morphological segmentation easily comparable, we provide predefined splits of our datasets[2]. 40% of the data constitute the test sets. Of the remaining data, we

[2]Our datasets can be found together with the code of our models at `http://turing.iimas.unam.mx/wix/MexSeg`.

use 20% for development and the rest for training. The final numbers of words per dataset and language are shown in Table 2.

4 Neural Seq2seq Models for Segmentation

In the beginning of this section, we will introduce our neural architecture for segmentation. Subsequently, we will first describe our two proposed multi-task training approaches and second our data augmentation methods. Finally, we will elaborate on expected differences between the two.

4.1 Character-Based Encoder-Decoder RNN

Following work on segmentation by Kann et al. (2016) for high-resource settings, our approach is based on the neural seq2seq model introduced by Bahdanau et al. (2015) for machine translation.

Encoder. The first part of our model is a bidirectional recurrent neural network (RNN) which encodes the input sequence, i.e., the sequence of characters of a given word $w = w_1, w_2, \ldots, w_{T_v}$, represented by the corresponding embedding vectors $v_{w_1}, ..., v_{w_{T_v}}$. In particular, our encoder consists of one gated recurrent neural network (GRU) which processes the input in forward direction and a second GRU which processes the input from the opposite side.

Encoding with this bidirectional GRU yields the forward hidden state $\overrightarrow{h}_i = f\left(\overrightarrow{h}_{i-1}, v_i\right)$ and the backward hidden state $\overleftarrow{h}_i = f\left(\overleftarrow{h}_{i+1}, v_i\right)$, for a non-linear activation function f. Their concatenation $h_i = \left[\overrightarrow{h_i}; \overleftarrow{h_i}\right]$ is passed on to the decoder.

Decoder. The second part of our network, the decoder, is a single GRU, defining a probability distribution over strings in $(\Sigma \cup \mathtt{S})^*$, for an alphabet Σ and a separation symbol $\mathtt{S}$:

$$p_{\text{ED}}(c \mid w) = \prod_{t=1}^{T_c} p(c_t \mid c_1, \ldots, c_{t-1}, w). \quad (1)$$

where $p(c_t \mid c_1, \ldots, c_{t-1}, w)$ is computed using an attention mechanism and an output softmax layer over $\Sigma \cup \mathtt{S}$.

A more detailed description of the general attention-based encoder-decoder architecture can be found in the original paper by Bahdanau et al. (2015).

5 Improving Neural Models for Segmentation

5.1 Multi-Task Training

In order to leverage unlabeled data or even random strings during training, we define an autoencoding auxiliary task, which consists of encoding the input and decoding an output which is identical to the original string.

Then, our multi-task training objective is to maximize the joint log-likelihood of this auxiliary task and our segmentation main task:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{(w,c)\in\mathcal{T}} \log p_{\boldsymbol{\theta}}\left(c \mid e(w)\right) + \sum_{a\in\mathcal{A}} \log p_{\boldsymbol{\theta}}(a \mid e(a)) \quad (2)$$

$\mathcal{T}$ denotes the segmentation training data with examples consisting of a word w and its segmentation c. $\mathcal{A}$ denotes either a set of words in the language of the system or a set of random strings. The function e describes the encoder and depends on the model parameters $\boldsymbol{\theta}$, which are shared across the two tasks. For training, we use data from both sets at the same time and mark each example with an additional, task-specific input symbol.

We treat the size of $\mathcal{A}$ as a hyperparameter which we optimize on the development set separately for each language. Values we experiment with are m times the amount of instances in the original training set, with $m \in \{1, 2, 4, 8\}$.[3]

[3] An exception is Yorem Nokki, for which we do not have enough unlabeled data available, such that we experiment only with $m \in \{1, 2\}$.

There are multiple reasons why we expect multi-task training to improve the performance of the final model. First, multi-task training should act as a regularizer. Second, for our models, the segmentation task consists in large parts of learning to copy the input character sequence to the output. This, however, can be learned from any string and does not require annotated segmentation boundaries. Third, in the case of unlabeled data (i.e., not for random strings), we expect the character language model in the decoder to improve, since it is trained on additional data.

We denote models trained with multi-task training using unlabeled corpus data as **MTT-U** and models trained with multi-task training using random strings as **MTT-R**.

5.2 Data Augmentation

A second option to make use of unlabeled data or random strings is to extend the available training data with new examples made from those. The main question to answer here is how to include the new data into the existing datasets. We do this by building new training examples in a fashion similar to the multi-task setup. All newly created instances are of the form

$$w \mapsto w \tag{3}$$

where either $w \in V$ with V being the observed vocabulary of the language, e.g., words in a given unlabeled corpus, or $w \in R$ with R being a set of sequences of random characters from the alphabet Σ of the language.

Again, we treat the amount of additional training examples as a hyperparameter which we optimize on the development set separately for each language. We explore m times the amount of instances in the original training set, with $m \in \{1, 2, 4, 8\}$.

The reasons why we expect our data augmentation methods to lead to better segmentation models are similar to those for multi-task training.

We call models trained on datasets augmented with unlabeled corpus data or random strings **DA-U** or **DA-R**, respectively.

5.3 Differences Between Multi-task Training and Data Augmentation

The difference between MTT-U (resp. MTT-R) and DA-U (resp. MTT-U) is a single element in the input sequence (the one representing the task). However, this information enables the model to handle each given instance correctly at inference time. As a result, it gets more robust against noisy data, which seems crucial for our way of using unlabeled corpora. Consider, for example, the Nahuatl word $onemokokowaya$. Training on

$$onemokokowaya \mapsto onemokokowaya$$

will make the model learn *not* to segment words which consist of the morphemes $o, ne, mo, kokowa, ya$, which should ultimately hurt performance. The multi-task approach, in contrast, mitigates this problem.

As a conclusion, we expect the data augmentation approach with *unlabeled data* to not obtain outstanding performance, but rather consider it an important and informative baseline for the corresponding multi-task approach. Using *random strings*, the difference between the multi-task and the data augmentation approaches is less obvious: Real morphemes should appear rarely enough in the created random character sequences to avoid the negative effect which we expect for corpus words. We thus assume that the performances of MTT-R and DA-R should be similar.

6 Experiments

6.1 Data

We apply our models to the datasets described in §3. For the multi-task training and data augmentation using unlabeled data, we use (unsegmented) words from a parallel corpus collected by Gutierrez-Vasques et al. (2016) for Nahuatl and the closely related Mexicanero. For Wixarika we use data from Mager et al. (2018) and for Yorem Nokki we use text from Maldonado Martínez et al. (2010).

6.2 Baselines

Now, we will describe the baselines we use to evaluate the overall performance of our approaches.

Supervised seq2seq RNN (S2S). As a first baseline, we employ a fully supervised neural model without data augmentation or multi-task training, i.e., an attention-based encoder-decoder RNN (Bahdanau et al., 2015) which has been trained only on the available annotated data.

Semi-supervised MORFESSOR (MORF). We further compare to the semi-supervised version

of MORFESSOR (Kohonen et al., 2010), a well-known morphological segmentation system. During training, we tune the hyperparameters for each language on the respective development set. The best performing model is applied to the test set.

FlatCat (FC). Our next baseline is FlatCat (Grönroos et al., 2014), a variant of MORFESSOR. It consists of a hidden Markov model for segmentation. The states of the model correspond either to a word boundary and one of the four morph categories stem, prefix, suffix, and non-morpheme. It can work in an unsupervised way, but, similar to the previous baseline, can make effective use of small amounts of labeled data.

CRF. We further compare to a conditional random fields (CRF) (Lafferty et al., 2001) model, in particular a strong discriminative model for segmentation by Ruokolainen et al. (2014). It reduces the task to a classification problem with four classes: beginning of a morph, middle of a morph, end of a morph and single character morph. Training is again semi-supervised and the model was previously reported to obtain good results for small amounts of unlabeled data (Ruokolainen et al., 2014), which makes it very suitable for our minimal-resource setting.

6.3 Hyperparameters

Neural network parameters. All GRUs in both the encoder and the decoder have 100-dimensional hidden states. All embeddings are 300-dimensional.

For training, we use ADADELTA (Zeiler, 2012) with a minibatch size of 20. We initialize all weights to the identity matrix and biases to zero (Le et al., 2015). All models are trained for a maximum of 200 epochs, but we evaluate after every 5 epochs and apply the best performing model at test time. Our final reported results are averaged accuracies over 5 single training runs.

Optimizing the amount of auxiliary task data. The performance of our neural segmentation model in dependence of the amount of auxiliary task training data can be seen in Figure 1. As a general tendency across all languages, adding more data seems better, particularly for the autoencoding task with random strings. The only exception is Wixarika.

The final configurations we choose for m (cf. §5.1) in the case of multi-task training with the auxiliary task of autoencoding corpus data are $m = 4$ for Mexicanero, Nahuatl and Wixarika and $m = 1$ for Yorem Nokki. For multi-task training with autoencoding of random strings we select $m = 8$ for Mexicanero, Nahuatl and Yorem Nokki and $m = 4$ for Wixarika.

Optimizing the amount of artificial training data for data augmentation. Figure 2 shows the performance of the encoder-decoder depending on the amount of added artificial training data. In the case of random strings, again, adding more training data seems to help more. However, using corpus data seems to hurt performance and the more such examples we use, the worse accuracy we obtain. Thus, we conclude that (as expected) data augmentation with corpus data is not a good way to improve the model's performance. We will discuss this in more detail in §6.5.

Even though the final conclusion should be to not add much corpus data, we apply what gives best results on the development set. The final configurations we thus choose for DA-U are $m = 1$ for Mexicanero, Wixarika and Yorem Nokki and $m = 2$ for Nahuatl. For DA-R, we select $m = 4$ for Mexicanero, Wixarika and Yorem Nokki and $m = 8$ for Nahuatl.

6.4 Evaluation Metrics

Accuracy. First, we evaluate using accuracy on the token level. Thus, an example counts as correct if and only if the output of the system matches the reference solution exactly, i.e., if all output symbols are predicted correctly.

F1. Our second evaluation metric is border F1, which measures how many segment boundaries are predicted correctly by the model. While we use this metric because it is common for segmentation tasks, it is not ideal for our models since those are not guaranteed to preserve the input character sequence. We handle this problem as follows: In order to compare borders, we identify them by the position of their preceding letter, i.e., if in both the model's guess and the gold solution a segment border appears after the second character, it counts as correct. Wrong characters are ignored. Note that this comes with the disadvantage of erroneously inserted characters leading to all subsequent segment borders being counted as incorrect.

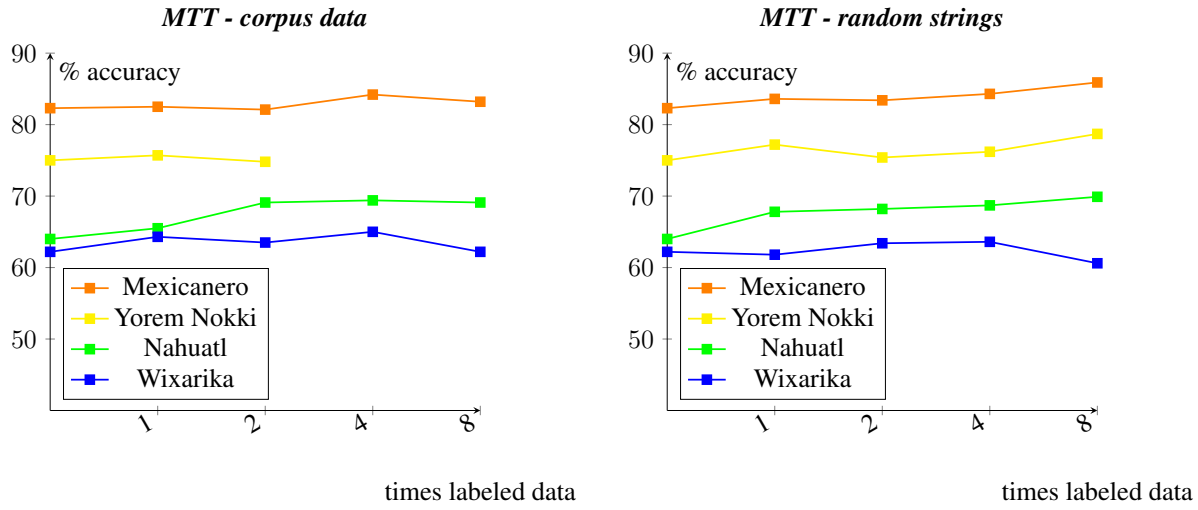

Figure 1: Accuracy on the development set in dependence of the amount of auxiliary task training data for multi-task learning.

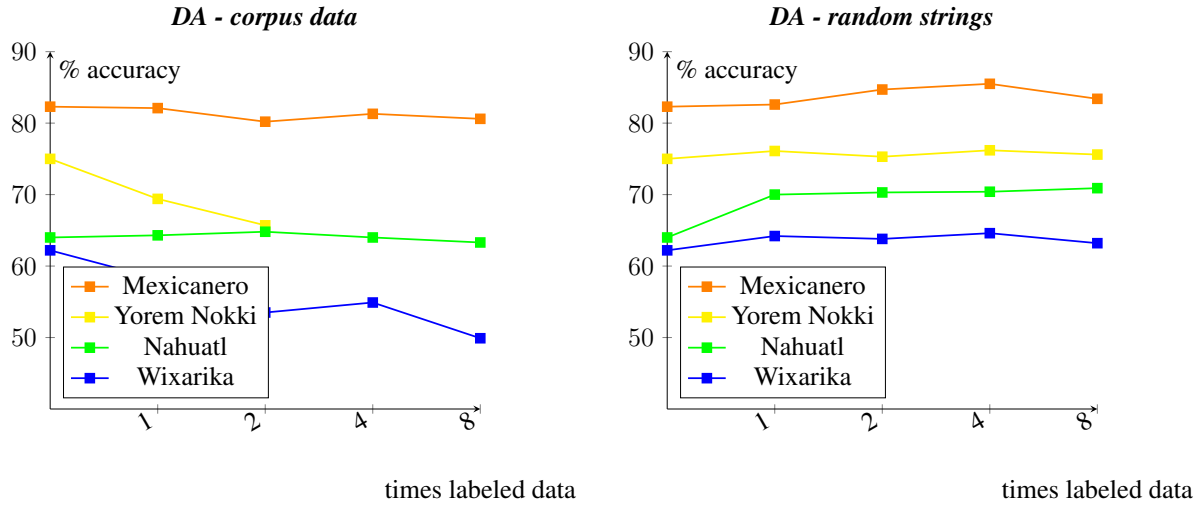

Figure 2: Accuracy on the development set in dependence of the amount of additional training data.

6.5 Test Results and Discussion

Table 4 shows that accuracy and F1 seem to be highly correlated for our task. The test results also give an answer to our first research question: The neural model S2S performs on par with CRF, the strongest baseline, for all languages but Nahuatl. Further, S2S and CRF both outperform MORF and FC by a wide margin. We may thus conclude that neural models are indeed applicable to segmentation of polysynthetic languages in a low-resource setting.

Second, we can see that all our proposed methods except for DA-U improve over S2S, the neural baseline: The accuracy of MTT-U is between 0.0141 (Wixarika) and 0.0547 (Mexicanero) higher than S2S's. MTT-R improves between 0.0380 (Wixarika) and 0.0532 (Yorem Nokki). Finally, DA-R outperforms S2S by 0.0367 to 0.0479 accuracy for Yorem Nokki and Mexicanero, respectively. The overall picture when considering F1 looks similar. Comparing our approaches to each other, there is no clear winner. This might be due to differences in the unlabeled data we use: the corpus we use for Mexicanero and Nahuatl is from dialects different from both respective test sets. Assuming that the effect of training a language model using unlabeled data and erroneously learning to not segment words are working against each other for MTT-U, this might explain why MTT-U is best for Mexicanero and the gap between MTT-U and MTT-R is smaller for Nahuatl than for Yorem Nokki and Wixarika.

As mentioned before (cf. §5.3), a simple data augmentation method using unlabeled data should

	Accuracy								F1

Table 4: Performances of our multi-task and data augmentation approaches compared to all baselines described in the text. The reported results for neural models are averages over 5 training runs. Best results per language and metric are in bold.

hurt performance. This is indeed the result of our experiments: DA-U performs worse than S2S for all languages except for Mexicanero, where the unlabeled corpus is from another language: the closely related Nahuatl. We thus conclude that multi-task training (instead of simple data augmentation) is crucial for the use of unlabeled data.

Finally, our methods compare favorably to all baselines, with the exception of CRF for Nahuatl. While CRF is overall the strongest baseline for our considered languages, our methods outperform it by up to 0.0214 accuracy or 0.0147 F1 for Mexicanero, 0.0322 accuracy or 0.0229 F1 for Wixarika and 0.0505 accuracy or 0.0340 F1 for Yorem Nokki. This shows the effectiveness of our fortified neural models for minimal-resource morphological segmentation.

7 Cross-Lingual Transfer Learning

We now want to investigate the performance of *one single model* trained on all languages at once. This is done in analogy to the multi-task training described in §5.1. We treat segmentation in each language as a separate task and train an attention-based encoder-decoder model on maximizing the joint log-likelihood:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{L_i \in L} \sum_{(w,c) \in \mathcal{T}_{L_i}} \log p_{\boldsymbol{\theta}}\left(c \mid e(w)\right) \tag{4}$$

$\mathcal{T}_{L_i}$ denotes the segmentation training data in language L_i and L is the set of our languages. As before, each training example consists of a word w and its segmentation c.

7.1 Experimental Setup

We keep all model parameters and the training regime as described in §6.3. However, our training data now consists of a combination of all available training data for all 4 languages. In order to enable the model to differentiate between the tasks, we prepend one language-specific input symbol to each instance. This corresponds to having one embedding in the input which marks the task. An example training instance for Yorem Nokki is

$$\textit{L=YN}\ ko'koreyene \mapsto ko'kore|ye|ne,$$

where *L=YN* indicates the language.

Due to the previous high correlation between accuracy and F1 we only use accuracy on the word level as the evaluation metric for this experiment.

	M-Lang	S-Lang	BestMTT	BestDA

Wixarika	.6021	.5754	.6134	**.6188**
Yorem N.	.6223	.6569	**.7101**	.6936

Table 5: Accuracies of our model trained on all languages (M-Lang) and the models trained on single languages (S-Lang). The highest multi-task and data augmentation accuracies are repeated for an easy comparison.

7.2 Results and Discussion

In Table 5, we show the results of the multi-lingual model, which was trained on all languages, compared to all individual models, as well as each respective best multi-task approach and data augmentation method. The results differ among languages: Most remarkably, for both Wixarika and Nahuatl, the accuracy of the multi-lingual model is higher than the one of the single-language model. This might be related to them being the languages with most training data available (cf. Table 3).

Note, however, that even for the remaining two languages—Mexicanero and Yorem Nokki—we hardly lose accuracy when comparing the multi-lingual to the individual models. Since we only use one model (instead of four), without increasing its size significantly, we thus reduce the amount of parameters by nearly 75%.

8 Related Work

Work on morphological segmentation was started more than 6 decades ago (Harris, 1951). Since then, many approaches have been developed: In the realm of unsupervised methods, two important systems are LINGUISTICS (Goldsmith, 2001) and MORFESSOR (Creutz and Lagus, 2002). The latter was later extended to a semi-supervised version (Kohonen et al., 2010) in order to make use of the abundance of unlabeled data which is available for many languages.

Ruokolainen et al. (2013) focused explicitly on low-resource scenarios and applied CRFs to morphological segmentation in several languages. They reported better results than earlier work, including semi-supervised approaches. In the following year, they extended their approach to be able to use unlabeled data as well, further improving performance (Ruokolainen et al., 2014).

Cotterell et al. (2015) trained a semi-Markov CRF (semi-CRF) (Sarawagi and Cohen, 2005) jointly on morphological segmentation, stemming and tagging. For the similar problem of Chinese word segmentation, Zhang and Clark (2008) trained a model jointly on part-of-speech tagging. However, we are not aware of any prior work on multi-task training or data augmentation for neural segmentation models.

In fact, the two only neural seq2seq approaches for morphological segmentation we know of focused on *canonical segmentation* (Cotterell et al., 2016) which differs from the *surface segmentation* task considered here in that it restores changes to the surface form of morphemes which occurred during word formation. Kann et al. (2016) also used an encoder-decoder RNN and combined it with a neural reranker. While our model architecture was inspired by them, their model was purely supervised. Additionally, they did not investigate the applicability of their neural seq2seq model in low-resource settings or for polysynthetic languages. Ruzsics and Samardzic (2017) extended the standard encoder-decoder architecture for canonical segmentation to contain a language model over segments and improved results. However, a big difference to our work is that they still used more than ten times as much training data as we have available for the indigenous Mexican languages we are working on here.

Another neural approach—this time for surface segmentation—was presented by Wang et al. (2016). The authors, instead of using seq2seq models, treat the task as a sequence labeling problem and use LSTMs to classify every character either as the beginning, middle or end of a morpheme, or as a single-character morpheme.

Cross-lingual knowledge transfer via language tags was proposed for neural seq2seq models before, both for tasks that handle sequences of words (Johnson et al., 2017) and tasks that work on sequences of characters (Kann et al., 2017). However, to the best of our knowledge, we are the first to try such an approach for a morphological segmentation task. In many other areas of NLP, cross-lingual transfer has been applied successfully, e.g., in entity recognition (Wang and Manning, 2014), language modeling (Tsvetkov et al., 2016), or parsing (Cohen et al., 2011; Søgaard, 2011; Ammar et al., 2016).

9 Conclusion and Future Work

We first investigated the applicability of neural seq2seq models to morphological surface segmentation for polysynthetic languages in minimal-resource settings, i.e., for considerably less than $1,000$ training instances. Although they are generally thought to require large amounts of training data, neural networks obtained an accuracy comparable to or higher than several strong baselines.

Subsequently, we proposed two novel multi-task training approaches and two novel data augmentation methods to further increase the performance of our neural models. Adding those, we improved over the neural baseline for all languages, and for Mexicanero, Wixarika and Yorem Nokki our final models outperformed all baselines by up to 5.05% absolute accuracy or 3.40% F1. Furthermore, we explored cross-lingual transfer between our languages and reduced the amount of necessary model parameters by about 75%, while improving performance for some of the languages.

We publically release our datasets for morphological surface segmentation of the polysynthetic minimal-resource languages Mexicanero, Nahuatl, Wixarika and Norem Yokki.

Improving Character-based Decoding Using Target-Side Morphological Information for Neural Machine Translation

Peyman Passban, Qun Liu, Andy Way

Dublin City University, Ireland
firstname.lastname@adaptcentre.ie

Abstract

Recently, neural machine translation (NMT) has emerged as a powerful alternative to conventional statistical approaches. However, its performance drops considerably in the presence of morphologically rich languages (MRLs). Neural engines usually fail to tackle the large vocabulary and high out-of-vocabulary (OOV) word rate of MRLs. Therefore, it is not suitable to exploit existing word-based models to translate this set of languages. In this paper, we propose an extension to the state-of-the-art model of Chung et al. (2016), which works at the character level and boosts the decoder with target-side morphological information. In our architecture, an additional morphology table is plugged into the model. Each time the decoder samples from a target vocabulary, the table sends auxiliary signals from the most relevant affixes in order to enrich the decoder's current state and constrain it to provide better predictions. We evaluated our model to translate English into German, Russian, and Turkish as three MRLs and observed significant improvements.

1 Introduction

Morphologically complex words (MCWs) are multi-layer structures which consist of different subunits, each of which carries semantic information and has a specific syntactic role. Table 1 gives a Turkish example to show this type of complexity. This example is a clear indication that word-based models are not suitable to process such complex languages. Accordingly, when translating MRLs, it might not be a good idea to treat words as atomic units as it demands a large vocabulary that imposes extra overhead. Since MCWs can appear in various forms we require a very large vocabulary to i) cover as many morphological forms and words as we can, and ii) reduce the number of OOVs. Neural models by their nature are complex, and we do not want to make them more complicated by working with large vocabularies. Furthermore, even if we have quite a large vocabulary set, clearly some words would remain uncovered by that. This means that a large vocabulary not only complicates the entire process, but also does not necessarily mitigate the OOV problem. For these reasons we propose an NMT engine which works at the character level.

Word	Translation
terbiye	good manners
terbiye.siz	rude
terbiye.siz.lik	rudeness
terbiye.siz.lik.leri	their rudeness
terbiye.siz.lik.leri.nden	from their rudeness

Table 1: Illustrating subword units in MCWs. The boldfaced part indicates the stem.

In this paper, we focus on translating into MRLs and issues associated with word formation on the target side. To provide a better translation we do not necessarily need a large target lexicon, as an MCW can be gradually formed during decoding by means of its subunits, similar to the solution proposed in character-based decoding models (Chung et al., 2016). Generating a complex word character-by-character is a better approach compared to word-level sampling, but it has other disadvantages.

One character can co-occur with another with almost no constraint, but a particular word or morpheme can only collocate with a very limited number of other constituents. Unlike words, characters are not meaning-bearing units and do not preserve syntactic information, so (in the extreme case) the

Proceedings of NAACL-HLT 2018, pages 58–68
New Orleans, Louisiana, June 1 - 6, 2018.

chance of sampling each character by the decoder is almost equal to the others, but this situation is less likely for words. The only constraint that prioritize which character should be sampled is information stored in the decoder, which we believe is insufficient to cope with all ambiguities. Furthermore, when everything is segmented into characters the target sentence with a limited number of words is changed to a very long sequence of characters, which clearly makes it harder for the decoder to remember such a long history. Accordingly, character-based information flows in the decoder may not be as informative as word- or morpheme-based information.

In the character-based NMT model everything is almost the same as its word-based counterpart except the target vocabulary whose size is considerably reduced from thousands of words to just hundreds of characters. If we consider the decoder as a classifier, it should in principle be able to perform much better over hundreds of classes (characters) rather than thousands (words), but the performance of character-based models is almost the same as or slightly better than their word-based versions. This underlines the fact that the character-based decoder is perhaps not fed with sufficient information to provide improved performance compared to word-based models.

Character-level decoding limits the search space by dramatically reducing the size of the target vocabulary, but at the same time widens the search space by working with characters whose sampling seems to be harder than words. The freedom in selection and sampling of characters can mislead the decoder, which prevents us from taking the maximum advantages of character-level decoding. If we can control the selection process with other constraints, we may obtain further benefit from restricting the vocabulary set, which is the main goal followed in this paper.

In order to address the aforementioned problems we redesign the neural decoder in three different scenarios. In the first scenario we equip the decoder with an additional morphology table including target-side affixes. We place an attention module on top of the table which is controlled by the decoder. At each step, as the decoder samples a character, it searches the table to find the most relevant information which can enrich its state. Signals sent from the table can be interpreted as additional constraints. In the second scenario we share the decoder between two output channels. The first one samples the target character and the other one predicts the morphological annotation of the character. This multi-tasking approach forces the decoder to send morphology-aware information to the final layer which results in better predictions. In the third scenario we combine these two models. Section 3 provides more details on our models.

Together with different findings that will be discussed in the next sections, there are two main contributions in this paper. We redesigned and tuned the NMT framework for translating into MRLs. It is quite challenging to show the impact of external knowledge such as morphological information in neural models especially in the presence of large parallel corpora. However, our models are able to incorporate morphological information into decoding and boost its quality. We inject the decoder with morphological properties of the target language. Furthermore, the novel architecture proposed here is not limited to morphological information alone and is flexible enough to provide other types of information for the decoder.

2 NMT for MRLs

There are several models for NMT of MRLs which are designed to deal with morphological complexities. García-Martínez et al. (2016) and Sennrich and Haddow (2016) adapted the factored machine translation approach to neural models. Morphological annotations can be treated as extra factors in such models. Jean et al. (2015) proposed a model to handle very large vocabularies. Luong et al. (2015) addressed the problem of rare words and OOVs with the help of a post-translation phase to exchange unknown tokens with their potential translations. Sennrich et al. (2016) used subword units for NMT. The model relies on frequent subword units instead of words. Costa-jussà and Fonollosa (2016) designed a model for translating from MRLs. The model encodes source words with a convolutional module proposed by Kim et al. (2016). Each word is represented by a convolutional combination of its characters.

Luong and Manning (2016) used a hybrid model for representing words. In their model, unseen and complex words are encoded with a character-based representation, with other words encoded via the usual surface-form embeddings. Vylomova et al. (2016) compared differ-

ent representation models (word-, morpheme, and character-level models) which try to capture complexities on the source side, for the task of translating from MRLs.

Chung et al. (2016) proposed an architecture which benefits from different segmentation schemes. On the encoder side, words are segmented into subunits with the byte-pair segmentation model (*bpe*) (Sennrich et al., 2016), and on the decoder side, one target character is produced at each time step. Accordingly, the target sequence is treated as a long chain of characters without explicit segmentation. Grönroos et al. (2017) focused on translating from English into Finnish and implicitly incorporated morphological information into NMT through multi-task learning. Passban (2018) comprehensively studied the problem of translating MRLs and addressed potential challenges in the field.

Among all the models reviewed in this section, the network proposed by Chung et al. (2016) could be seen as the best alternative for translating into MRLs as it works at the character level on the decoder side and it was evaluated in different settings on different languages. Consequently, we consider it as a baseline model in our experiments.

3 Proposed Architecture

We propose a compatible neural architecture for translating into MRLs. The model benefits from subword- and character-level information and improves upon the state-of-the-art model of Chung et al. (2016). We manipulated the model to incorporate morphological information and developed three new extensions, which are discussed in Sections 3.1, 3.2, and 3.3.

3.1 The Embedded Morphology Table

In the first extension an additional table containing the morphological information of the target language is plugged into the decoder to assist with word formation. Each time the decoder samples from the target vocabulary, it searches the morphology table to find the most relevant affixes given its current state. Items selected from the table act as guiding signals to help the decoder sample a better character.

Our base model is an encoder-decoder model with attention (Bahdanau et al., 2014), implemented using gated recurrent units (GRUs) (Cho et al., 2014). We use a four-layer model in our experiments. Similar to Chung et al. (2016) and Wu et al. (2016), we use bidirectional units to encode the source sequence. Bidirectional GRUs are placed only at the input layer. The forward GRU reads the input sequence in its original order and the backward GRU reads the input in the reverse order. Each hidden state of the encoder in one time step is a concatenation of the forward and backward states at the same time step. This type of bidirectional processing provides a richer representation of the input sequence.

On the decoder side, one target character is sampled from a target vocabulary at each time step. In the original encoder-decoder model, the probability of predicting the next token y_i is estimated based on i) the current hidden state of the decoder, ii) the last predicted token, and iii) the context vector. This process can be formulated as $p(y_i|y_1, ..., y_{i-1}, \mathbf{x}) = g(h_i, y_{i-1}, \mathbf{c}_i)$, where $g(.)$ is a softmax function, y_i is the target token (to be predicted), $\mathbf{x}$ is the representation of the input sequence, h_i is the decoder's hidden state at the i-th time step, and $\mathbf{c}_i$ indicates the context vector which is a weighted summary of the input sequence generated by the attention module. $\mathbf{c}_i$ is generated via the procedure shown in (1):

$$\mathbf{c}_i = \sum_{j=1}^{n} \alpha_{ij} s_j$$
$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{n} \exp(e_{ik})}; \quad e_{ij} = a(s_j, h_{i-1}) \tag{1}$$

where α_{ij} denotes the weight of the j-th hidden state of the encoder (s_j) when the decoder predicts the i-th target token, and $a()$ shows a combinatorial function which can be modeled through a simple feed-forward connection. n is the length of the input sequence.

In our first extension, the prediction probability is conditioned on one more constraint in addition to those three existing ones, as in $p(y_i|y_1, ..., y_{i-1}, \mathbf{x}) = g(h_i, y_{i-1}, \mathbf{c}_i, \mathbf{c}_i^m)$, where $\mathbf{c}_i^m$ is the morphological context vector and carries information from those useful affixes which can enrich the decoder's information. $\mathbf{c}_i^m$ is generated via an attention module over the morphology table which works in a similar manner to word-based attention model. The attention procedure for

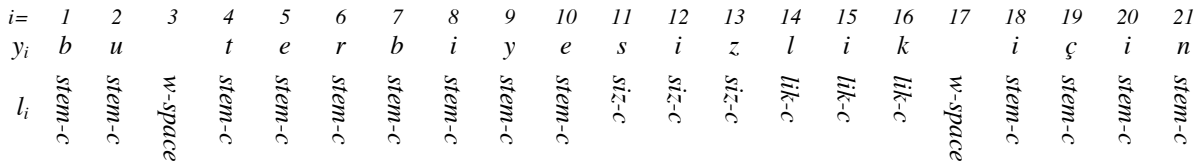

Figure 1: The target label that each output channel is supposed to predict when generating the Turkish sequence 'bu_1 $terbiyesizlik_2$ $için_3$' meaning '$because_3$ of_3 $this_1$ $rudeness_2$'.

generating $\mathbf{c}_i^m$ is formulated as in (2):

$$\mathbf{c}_i^m = \sum_{u=1}^{|\mathcal{A}|} \beta_{iu} f_u$$
$$\beta_{iu} = \frac{\exp\left(e_{iu}^m\right)}{\sum_{v=1}^{|\mathcal{A}|} \exp\left(e_{iv}\right)}; \quad e_{iu}^m = a^m(f_u, h_{i-1}) \tag{2}$$

where f_u represents the embedding of the u-th affix (u-th column) in the morphology/affix table $\mathcal{A}$, β_{iu} is the weight assigned to f_u when predicting the i-th target token, and a^m is a feed-forward connection between the morphology table and the decoder.

The attention module in general can be considered as a search mechanism, e.g. in the original encoder-decoder architecture the basic attention module finds the most relevant input words to make the prediction. In multi-modal NMT (Huang et al., 2016; Calixto et al., 2017) an extra attention module is added to the basic one in order to search the image input to find the most relevant image segments. In our case we have a similar additional attention module which searches the morphology table.

In this scenario, the morphology table including the target language's affixes can be considered as an external knowledge repository that sends auxiliary signals which accompany the main input sequence at all time steps. Such a table certainly includes useful information for the decoder. As we are not sure which affix preserves those pieces of useful information, we use an attention module to search for the best match. The attention module over the table works as a filter which excludes irrelevant affixes and amplifies the impact of relevant ones by assigning different weights (β values).

3.2 The Auxiliary Output Channel

In the first scenario, we embedded a morphology table into the decoder in the hope that it can enrich sampling information. Mathematically speaking, such an architecture establishes an extra constraint for sampling and can control the decoder's predictions. However, this is not the only way of constraining the decoder. In the second scenario, we define extra supervision to the network via another predictor (output channel). The first channel is responsible for generating translations and predicts one character at each time step, and the other one tries to understand the morphological status of the decoder by predicting the morphological annotation (l_i) of the target character.

The approach in the second scenario proposes a multi-task learning architecture, by which in one task we learn translations and in the other one morphological annotations. Therefore, all network modules –especially the last hidden layer just before the predictors– should provide information which is useful enough to make correct predictions in both channels, i.e. the decoder should preserve translation as well as morphological knowledge. Since we are translating into MRLs this type of mixed information (morphology+translation) can be quite useful.

In our setting, the morphological annotation l_i predicted via the second channel shows to which part of the word or morpheme the target character belongs, i.e. the label for the character is the morpheme that includes it. We clarify the prediction procedure via an example from our training set (see Section 4). When the Turkish word '*terbiyesizlik*' is generated, the first channel is supposed to predict *t*, *e*, *r*, up to *k*, one after another. For the same word, the second channel is supposed to predict *stem-C* for the fist 7 steps as the first 7 characters '*terbiye*' belong to the stem of the word. The *C* sign indicates that *stem-C* is a class label. The second channel should also predict *siz-C* when the first channel predicts *s* (eighth character), *i* (ninth character), and *z* (tenth character), and *lik-C* when the first channel samples the last three characters. Clearly, the second channel is a classifier which works over the {*stem-C*, *siz-C*, *lik-C*, ...} classes. Figure 1 illustrates a segment of a sentence including this Turkish word and explains which class

tags should be predicted by each channel.

To implement the second scenario we require a single-source double-target training corpus: [source sentence] → [sequence of target characters & sequence of morphological annotations] (see Section 4). The objective function should also be manipulated accordingly. Given a training set $\{\mathbf{x}_t, \mathbf{y}_t, \mathbf{m}_t\}_{t=1}^{T}$ the goal is to maximize the joint loss function shown in (3):

$$\lambda \sum_{t=1}^{T} \log P(\mathbf{y}_t|\mathbf{x}_t;\theta) + (1-\lambda) \sum_{t=1}^{T} \log P(\mathbf{m}_t|\mathbf{x}_t;\theta) \quad (3)$$

where $\mathbf{x}_t$ is the t-th input sentence whose translation is a sequence of target characters shown by $\mathbf{y}_t$. $\mathbf{m}_t$ is the sequence of morphological annotations and T is the size of the training set. θ is the set of network parameters and λ is a scalar to balance the contribution of each cost function. λ is adjusted on the development set during training.

3.3 Combining the Extended Output Layer and the Embedded Morphology Table

In the first scenario, we aim to provide the decoder with useful information about morphological properties of the target language, but we are not sure whether signals sent from the table are what we really need. They might be helpful or even harmful, so there should be a mechanism to control their quality. In the second scenario we also have a similar problem as the last layer requires some information to predict the correct morphological class through the second channel, but there is no guarantee to ensure that information in the decoder is sufficient for this sort of prediction. In order to address these problems, in the third extension we combine both scenarios as they are complementary and can potentially help each other.

The morphology table acts as an additional useful source of knowledge as it already consists of affixes, but its content should be adapted according to the decoder and its actual needs. Accordingly, we need a trainer to update the table properly. The extra prediction channel plays this role for us as it forces the network to predict the target language's affixes at the output layer. The error computed in the second channel is back-propagated to the network including the morphology table and updates its affix information into what the decoder actually needs for its prediction. Therefore, the second output channel helps us train better affix embeddings.

The morphology table also helps the second predictor. Without considering the table, the last layer only includes information about the input sequence and previously predicted outputs, which is not directly related to morphological information. The second attention module retrieves useful affixes from the morphology table and concatenates to the last layer, which means the decoder is explicitly fed with morphological information. Therefore, these two modules mutually help each other. The external channel helps update the morphology table with high-quality affixes (backward pass) and the table sends its high-quality signals to the prediction layer (forward pass). The relation between these modules and the NMT architecture is illustrated in Figure 2.

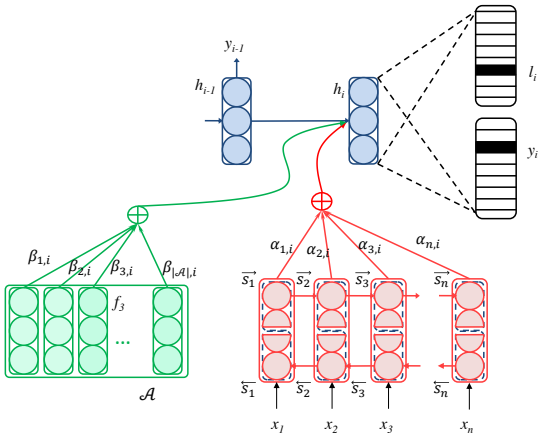

Figure 2: The architecture of the NMT model with an auxiliary prediction channel and an extra morphology table. This network includes only one decoder layer and one encoder layer. ⊕ shows the attention modules.

4 Experimental Study

As previously reviewed, different models try to capture complexities on the encoder side, but to the best of our knowledge the only model which proposes a technique to deal with complex constituents on the decoder side is that of Chung et al. (2016), which should be an appropriate baseline for our comparisons. Moreover, it outperforms other existing NMT models, so we prefer to compare our network to the best existing model. This model is referred to as CDNMT in our experiments. In the next sections first we explain our experimental setting, corpora, and how we build the morphology table (Section 4.1), and then report experimental results (Section 4.2).

4.1 Experimental Setting

In order to make our work comparable we try to follow the same experimental setting used in CDNMT, where the GRU size is 1024, the affix and word embedding size is 512, and the beam width is 20. Our models are trained using stochastic gradient descent with Adam (Kingma and Ba, 2015). Chung et al. (2016) and Sennrich et al. (2016) demonstrated that *bpe* boosts NMT, so similar to CDNMT we also preprocess the source side of our corpora using *bpe*. We use `WMT-15` corpora[1] to train the models, `newstest-2013` for tuning and `newstest-2015` as the test sets. For English–Turkish (En–Tr) we use the `OpenSubtitle2016` collection (Lison and Tiedemann, 2016). The training side of the English–German (En–De), English–Russian (En–Ru), and En–Tr corpora include 4.5, 2.1, and 4 million parallel sentences, respectively. We randomly select 3K sentences for each of the development and test sets for En–Tr. For all language pairs we keep the 400 most frequent characters as the target-side character set and replace the remainder (infrequent characters) with a specific character.

One of the key modules in our architecture is the morphology table. In order to implement it we use a look-up table whose columns include embeddings for the target language's affixes (each column represents one affix) which are updated during training. As previously mentioned, the table is intended to provide useful, morphological information so it should be initialized properly, for which we use a morphology-aware embedding-learning model. To this end, we use the neural language model of Botha and Blunsom (2014) in which each word is represented via a linear combination of the embeddings of its surface form and subunits, e.g. $\overrightarrow{terbiyesizlik} = \overrightarrow{terbiyesizlik} + \overrightarrow{terbiye} + \overrightarrow{siz} + \overrightarrow{lik}$. Given a sequence of words, the neural language model tries to predict the next word, so it learns sentence-level dependencies as well as intra-word relations. The model trains surface form and subword-level embeddings which provides us with high-quality affix embeddings.

Our neural language model is a recurrent network with a single 1000-dimensional GRU layer, which is trained on the target sides of our parallel corpora. The embedding size is 512 and we use a batch size of 100 to train the model. Before training the neural language model, we need to manipulate the training corpus to decompose words into morphemes for which we use Morfessor (Smit et al., 2014), an unsupervised morphological analyzer. Using Morfessor each word is segmented into different subunits where we consider the longest part as the stem of each word; what appears before the stem is taken as a member of the set of prefixes (there might be one or more prefixes) and what follows the stem is considered as a member of the set of suffixes.

Since Morfessor is an unsupervised analyzer, in order to minimize segmentation errors and avoid noisy results we filter its output and exclude subunits which occur fewer than 500 times.[2] After decomposing, filtering, and separating stems from affixes, we extracted several affixes which are reported in Table 2. We emphasize that there might be wrong segmentations in Morfessor's output, e.g. Turkish is a suffix-based language, so there are no prefixes in this language, but based on what Morfessor generated we extracted 11 different types of prefixes. We do not post-process Morfessor's outputs.

Language	Prefix	Suffix
German	75	160
Russian	110	260
Turkish	11	293

Table 2: The number of affixes extracted for each language.

Using the neural language model we train word, stem, and affix embeddings, and initialize the look-up table (but not other parts) of the decoder using those affixes. The look-up table includes high-quality affixes trained on the target side of the parallel corpus by which we train the translation model. Clearly, such an affix table is an additional knowledge source for the decoder. It preserves information which is very close to what the decoder actually needs. However, there might be some missing pieces of information or some incompatibility between the decoder and the table, so we do not freeze the morphology table during training, but let the decoder update it with respect to its needs in the forward and backward passes.

[1] `http://www.statmt.org/wmt15/`

[2] The number may seem a little high, but for a corpus with more than 115M words this is not a strict threshold in practice.

4.2 Experimental Results

Table 3 summarizes our experimental results. We report results for the *bpe→char* setting, which means the source token is a *bpe* unit and the decoder samples a character at each time step. CDNMT is the baseline model. Table 3 includes scores reported from the original CDNMT model (Chung et al., 2016) as well as the scores from our reimplementation. To make our work comparable and show the impact of the new architecture, we tried to replicate CDNMT's results in our experimental setting, we kept everything (parameters, iterations, epochs etc.) unchanged and evaluated the extended model in the same setting. Table 3 reports BLEU scores (Papineni et al., 2002) of our NMT models.

Model	En→De	En→Ru	En→Tr
CDNMT	21.33	26.00	-
CDNMT*	21.01	26.23	18.01
CDNMT*$_m$	**21.27**	**26.78**	**18.44**
CDNMT*$_o$	**21.39**	26.39	**18.59**
CDNMT*$_{mo}$	**21.48**	**26.84**	**18.70**

Table 3: CDNMT* is our implementation of CDNMT. m and o indicates that the base model is extended with the morphology table and the additional output channel, respectively. mo is the combination of both the extensions. The improvement provided by the boldfaced number compared to CDNMT* is statistically significant according to paired bootstrap re-sampling (Koehn, 2004) with $p = 0.05$.

Table 3 can be interpreted from different perspectives but the main findings are summarized as follows:

- The morphology table yields significant improvements for all languages and settings.
- The morphology table boosts the En–Tr engine more than others and we think this is because of the nature of the language. Turkish is an agglutinative language in which morphemes are clearly separable from each other, but in German and Russian morphological transformations rely more on fusional operations rather than agglutination.
- It seems that there is a direct relation between the size of the morphology table and the gain provided for the decoder, because Russian and Turkish have bigger tables and benefit from the table more than German which has fewer affixes.
- The auxiliary output channel is even more useful than the morphology table for all settings but En–Ru, and we think this is because of the morpheme-per-word ratio in Russian. The number of morphemes attached to a Russian word is usually more than those of German and Turkish words in our corpora, and it makes the prediction harder for the classifier (the more the number of suffixes attached to a word, the harder the classification task).
- The combination of the morphology table and the extra output channel provides the best result for all languages.

Figure 3 depicts the impact of the morphology table and the extra output channel for each language.

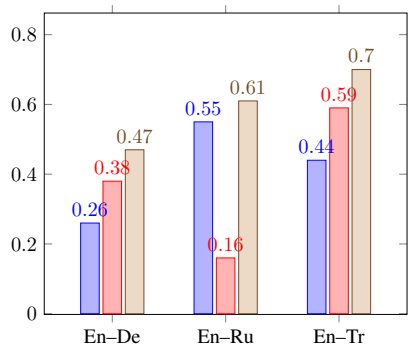

Figure 3: The y axis shows the difference between the BLEU score of CDNMT* and the extended model. The first, second, and third bars show the m, o, and mo extensions, respectively.

To further study our models' behaviour and ensure that our extensions do not generate random improvements we visualized some attention weights when generating '*terbiyesizlik*'. In Figure 4, the upper figure shows attention weights for all Turkish affixes, where the y axis shows different time steps and the x axis includes attention weights of all affixes (304 columns) for those time steps, e.g. the first row and the first column represents the attention weight assigned to the first Turkish affix when sampling ***t*** in '***t***erbiyesizlik'. While at the first glance the figure may appear to be somewhat confusing, but it provides some interesting insights which we elaborate next.

In addition to the whole attention matrix we also visualized a subset of weights to show how the morphology table provides useful information. In the second figure we study the behaviour of the morphology table for the first ($\boldsymbol{t}_1$), fifth ($\boldsymbol{i}_5$), ninth

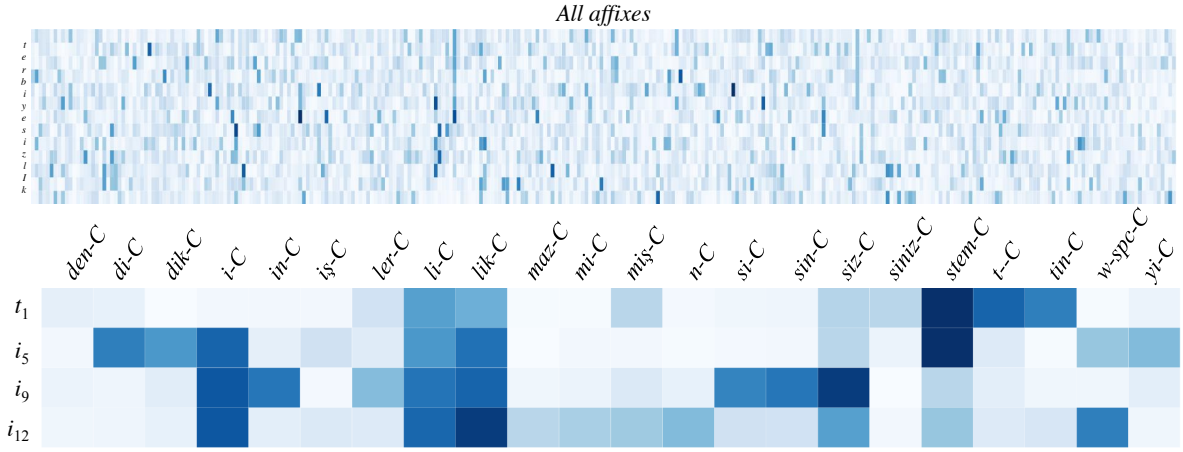

Figure 4: Visualizing the attention weights between the morphology table and the decoder when generating '*terbiyesizlik*.

($\boldsymbol{i}_9$), and twelfth ($\boldsymbol{i}_{12}$) time steps when generating the same Turkish word '$\boldsymbol{t}_1$*erbi*$\boldsymbol{i}_5$*yesi*$\boldsymbol{i}_9$*zli*$\boldsymbol{i}_{12}$*k*'. $\boldsymbol{t}_1$ is the first character of the word. We also have three $\boldsymbol{i}$ characters from different morphemes, where the first one is part of the stem, the second one belongs to the suffix '*siz*', and the third one to '*lik*'. It is interesting to see how the table reacts to the same character from different parts. For each time step we selected the top-10 affixes which have the highest attention weights. The set of top-10 affixes can be different for each step, so we made a union of those sets which gives us 22 affixes. The bottom part of Figure 4 shows the attention weights for those 22 affixes at each time step.

After analyzing the weights we observed interesting properties about the morphology table and the auxiliary attention module.[3] The main findings about the behaviour of the table are as follows:

- The model assigns high attention weights to *stem-C* for almost all time steps. However, the weights assigned to this class for $\boldsymbol{t}_1$ and $\boldsymbol{i}_5$ are much higher than those of affix characters (as they are part of the stem). The vertical lines in both figures approve this feature (bad behaviour).

- For some unknown reasons there are some affixes which have no direct relation to that particulate time step but they receive a high attention, such as *maz* in $\boldsymbol{t}_{12}$ (bad behaviour).

- For almost all time steps the highest attention weight belongs to the class which is expected to be selected, e.g. weights for ($\boldsymbol{i}_5$,*stem-C*) or ($\boldsymbol{i}_9$,*siz-C*) (good behaviour).

- The morphology table may send bad or good signals but it is consistent for similar or co-occurring characters, e.g. for the last three time steps $\boldsymbol{l}_{11}$, $\boldsymbol{i}_{12}$, and $\boldsymbol{k}_{13}$, almost the same set of affixes receives the highest attention weights. This consistency is exactly what we are looking for, as it can define a reliable external constraint for the decoder to guide it. Vertical lines on the figure also confirm this fact. They show that for a set of consecutive characters which belong to the same morpheme the attention module sends a signal from a particular affix (good behaviour).

- There are some affixes which might not be directly related to that time step but receive high attention weights. This is because those affixes either include the same character which the decoder tries to predict (e.g. *i-C* for $\boldsymbol{i}_4$ or *t-C* and *tin-C* for $\boldsymbol{t}_1$), or frequently appear with that part of the word which includes the target character (e.g. *mi-C* has a high weight when predicting $\boldsymbol{t}_1$ because $\boldsymbol{t}_1$ belongs to *terbiye* which frequently collocates with *mi-C*: *terbiye*+*mi*) (good behaviour).

Finally, in order to complete our evaluation study we feed the English-to-German NMT model with the sentence '*Terms and conditions for sending contributions to the BBC*', to show how the model behaves differently and generates a better target sentence. Translations generated by our models are illustrated in Table 4.

[3] Our observations are not based on this example alone as we studied other random examples, and the table shows consistent behaviour for all examples.

Reference:	*Geschäftsbedingungen für das Senden von Beiträgen an die BBC*
CDNMT*	*allgemeinen geschaftsbedingungen fur die versendung von Beiträgen an die BBC*
CDNMT$^*_{mo}$	*Geschäft s bedingungen für die versendung von Beiträgen zum BBC*

Table 4: Comparing translation results for the CDNMT* (baseline) and CDNMT$^*_{mo}$ (improved) models when the input sentence is '*Terms and conditions for sending contributions to the BBC*'.

The table demonstrates that our architecture is able to control the decoder and limit its selections, e.g. the word *'allgemeinen'* generated by the baseline model is redundant. There is no constraint to inform the baseline model that this word should not be generated, whereas our proposed architecture controls the decoder in such situations. After analyzing our model, we realized that there are strong attention weights assigned to the *w-space* (indicating white space characters) and *BOS* (beginning of the sequence) columns of the affix table while sampling the first character of the word *'Geschäft'*, which shows that the decoder is informed about the start point of the sequence. Similar to the baseline model's decoder, our decoder can sample any character including *'a'* of *'allgemeinen'* or *'G'* of *'Geschäft'*. Translation information stored in the baseline decoder is not sufficient for selecting the right character *'G'*, so the decoder wrongly starts with *'i'* and continues along a wrong path up to generating the whole word. However, our decoder's information is accompanied with signals from the affix table which force it to start with a better initial character, whose sampling leads to generating the correct target word.

Another interesting feature about the table is the new structure '*Geschäft s bedingungen'* generated by the improved model. As the reference translation shows, in the correct form these two structures should be glued together via *'s'*, which can be considered as an infix. As our model is supposed to detect this sort of intra-word relation, it treats the whole structure as two compounds which are connected to one another via an infix. Although this is not a correct translation and it would be trivial to post-edit into the correct output form, it is interesting to see how our mechanism forces the decoder to pay attention to intra-word relations.

Apart from these two interesting findings, the number of wrong character selections in the baseline model is considerably reduced in the improved model because of our enhanced architecture.

5 Conclusion and Future Work

In this paper we proposed a new architecture to incorporate morphological information into the NMT pipeline. We extended the state-of-the-art NMT model (Chung et al., 2016) with a morphology table. The table could be considered as an external knowledge source which is helpful as it increases the capacity of the model by increasing the number of network parameters. We tried to benefit from this advantage. Moreover, we managed to fill the table with morphological information to further boost the NMT model when translating into MRLs. Apart from the table we also designed an additional output channel which forces the decoder to predict morphological annotations. The error signals coming from the second channel during training inform the decoder with morphological properties of the target language. Experimental results show that our techniques were useful for NMT of MRLs.

As our future work we follow three main ideas. i) We try to find more efficient ways to supply morphological information for both the encoder and decoder. ii) We plan to benefit from other types of information such as syntactic and semantic annotations to boost the decoder, as the table is not limited to morphological information alone and can preserve other sorts of information. iii) Finally, we target sequence generation for fusional languages. Although our model showed significant improvements for both German and Russian, the proposed model is more suitable for generating sequences in agglutinative languages.

Abstract

In conversational speech, the acoustic signal provides cues that help listeners disambiguate difficult parses. For automatically parsing spoken utterances, we introduce a model that integrates transcribed text and acoustic-prosodic features using a convolutional neural network over energy and pitch trajectories coupled with an attention-based recurrent neural network that accepts text and prosodic features. We find that different types of acoustic-prosodic features are individually helpful, and together give statistically significant improvements in parse and disfluency detection F1 scores over a strong text-only baseline. For this study with known sentence boundaries, error analyses show that the main benefit of acoustic-prosodic features is in sentences with disfluencies, attachment decisions are most improved, and transcription errors obscure gains from prosody.

1 Introduction

While parsing has become a relatively mature technology for written text, parser performance on conversational speech lags behind. Speech poses challenges for parsing: transcripts may contain errors and lack punctuation; even perfect transcripts can be difficult to handle because of disfluencies (restarts, repetitions, and self-corrections), filled pauses ("um", "uh"), interjections ("like"), parentheticals ("you know", "I mean"), and sentence fragments. Some of these phenomena can be handled in standard grammars, but disfluencies typically require extensions of the model. Different approaches have been explored in both constituency parsing (Charniak and Johnson, 2001; Johnson and Charniak, 2004) and dependency parsing (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014).

Despite these challenges, speech carries helpful extra information – beyond the words – associated with the prosodic structure of an utterance and encoded via variation in timing and intonation. Speakers pause in locations that are correlated with syntactic structure (Grosjean et al., 1979), and listeners use prosodic structure in resolving syntactic ambiguities (Price et al., 1991). Prosodic cues also signal disfluencies by marking the interruption point (Shriberg, 1994). However, most speech parsing systems in practice take little advantage of these cues. Our study focuses on this last challenge, aiming to incorporate prosodic cues in a neural parser, handling disfluencies as constituents via a neural attention mechanism.

A challenge of incorporating prosody in parsing is that multiple acoustic cues interact to signal prosodic structure, including pauses, lengthening, fundamental frequency modulation, and spectral shape. These cues also vary with the phonetic segment, emphasis, emotion and speaker, so feature extraction typically involves multiple time windows and normalization techniques. The most successful constituent parsers have mapped these features to prosodic boundary posteriors by using labeled training data (Kahn et al., 2005; Hale et al., 2006; Dreyer and Shafran, 2007). The approach proposed here takes advantage of advances in neural networks to automatically learn a good feature representation without the need to explicitly represent prosodic constituents. To narrow the scope of this work and facilitate error analysis, our experiments use known transcripts and sentence segmentation.

Our work offers the following contributions. We introduce a framework for directly integrating acoustic-prosodic features with text in a neural encoder-decoder parser that does not require hand-annotated prosodic structure. We demonstrate improvements in constituent parsing of conversational

[*]Equal Contribution.

New Orleans, Louisiana, June 1 - 6, 2018.

speech over a high-quality text-only parser and provide analyses showing where prosodic features help and that assessment of their utility is affected by human transcription errors.

2 Task and Model Description

Our model maps a sequence of word-level input features to a linearized parse output sequence. The word-level input feature vector consists of the concatenation of (learnable) word embeddings $\boldsymbol{e_i}$ and several types of acoustic-prosodic features, described in Section 2.3.

2.1 Task Setup

We assume the availability of a training treebank of conversational speech (in our case, Switchboard-NXT (Calhoun et al., 2010)) and corresponding constituent parses. The transcriptions are preprocessed by removing punctuation and lower-casing all text to better mimic the speech recognition setting. Following Vinyals et al. (2015), the parse trees are linearized, and pre-terminals are normalized as "XX" (see Appendix A.1).

2.2 Encoder-Decoder Parser

Our attention-based encoder-decoder model is similar to the one used by Vinyals et al. (2015). The *encoder* is a deep long short-term memory recurrent neural network (LSTM-RNN) (Hochreiter and Schmidhuber, 1997) that reads in a word-level inputs,[1] represented as a sequence of vectors $\boldsymbol{x} = (\boldsymbol{x}_1, \cdots, \boldsymbol{x}_{T_s})$, and outputs high-level features $\boldsymbol{h} = (\boldsymbol{h}_1, \cdots, \boldsymbol{h}_{T_s})$ where $\boldsymbol{h}_i = \text{LSTM}(\boldsymbol{x}_i, \boldsymbol{h}_{i-1})$.[2]

The *parse decoder* is also a deep LSTM-RNN that predicts the linearized parse sequence $\boldsymbol{y} = (y_1, \cdots, y_{T_o})$ as follows:

$$P(\boldsymbol{y}|\boldsymbol{x}) = \prod_{t=1}^{T_o} P(y_t|\boldsymbol{h}, \boldsymbol{y_{<t}})$$

In attention-based models, the posterior distribution of the output y_t at time step t is given by:

$$P(y_t|\boldsymbol{h}, \boldsymbol{y_{<t}}) = \text{softmax}(\boldsymbol{W}_s[\boldsymbol{c}_t; \boldsymbol{d}_t] + \boldsymbol{b}_s),$$

where vector $\boldsymbol{b}_s$ and matrix $\boldsymbol{W}_s$ are learnable parameters; $\boldsymbol{c}_t$ is referred to as a *context vector* that summarizes the encoder's output $\boldsymbol{h}$; and $\boldsymbol{d}_t$ is the decoder hidden state at time step t, which captures the previous output sequence context $\boldsymbol{y_{<t}}$.

$$u_{it} = \boldsymbol{v}^\top \tanh(\boldsymbol{W}_1\boldsymbol{h}_i + \boldsymbol{W}_2\boldsymbol{d}_t + \boldsymbol{b}_a)$$

$$\boldsymbol{\alpha}_t = \text{softmax}(\boldsymbol{u}_t) \qquad \boldsymbol{c}_t = \sum_{i=1}^{T_s} \alpha_{ti}\boldsymbol{h}_i$$

where vectors $\boldsymbol{v}$, $\boldsymbol{b}_a$ and matrices $\boldsymbol{W}_1$, $\boldsymbol{W}_2$ are learnable parameters; $\boldsymbol{u}_t$ and $\boldsymbol{\alpha}_t$ are the attention score and attention weight vector, respectively, for decoder time step t.

The above attention mechanism is only *content*-based, i.e., it is only dependent on $\boldsymbol{h}_i$, $\boldsymbol{d}_t$. It is not *location*-aware, i.e., it does not consider the "location" of the previous attention vector. For parsing conversational text, location awareness is beneficial since disfluent structures can have duplicate words/phrases that may "confuse" the attention mechanism.

In order to make the model location-aware, the attention mechanism takes into account the previous attention weight vector $\boldsymbol{\alpha}_{t-1}$. In particular, we use the attention mechanism proposed by Chorowski et al. (2015), in which $\boldsymbol{\alpha}_{t-1}$ is represented via a feature vector $\boldsymbol{f}_t = \boldsymbol{F} * \boldsymbol{\alpha}_{t-1}$, where $\boldsymbol{F} \in \mathcal{R}^{k \times r}$ represents k learnable convolution filters of width r. The filters are used for performing 1-D convolution over $\boldsymbol{\alpha}_{t-1}$ to extract k features $\boldsymbol{f}_{ti}$ for each time step i of the input sequence. The extracted features are then incorporated in the alignment score calculation as:

$$u_{it} = \boldsymbol{v}^\top \tanh(\boldsymbol{W}_1\boldsymbol{h}_i + \boldsymbol{W}_2\boldsymbol{d}_t + \boldsymbol{W}_f\boldsymbol{f}_{ti} + \boldsymbol{b}_a)$$

where $\boldsymbol{W}_f$ is another learnable parameter matrix. Finally, the decoder state $\boldsymbol{d}_t$ is computed as $\boldsymbol{d}_t = \text{LSTM}([\tilde{\boldsymbol{y}}_{t-1}; \boldsymbol{c}_{t-1}], \boldsymbol{d}_{t-1})$, where $\tilde{\boldsymbol{y}}_{t-1}$ is the embedding vector corresponding to the previous output symbol y_{t-1}. As we will see in Sec. 4.1, the location-aware attention mechanism is especially useful for handling disfluencies.

2.3 Acoustic-Prosodic Features

In previous work using encoder-decoder models for parsing (Vinyals et al., 2015; Luong et al., 2016), vector $\boldsymbol{x}_i$ is simply the word embedding $\boldsymbol{e}_i$ of the word at position i of the input sentence. For parsing conversational speech, we can incorporate acoustic-prosodic features. Here we explore four types of features widely used in computational models of prosody: pauses, duration lengthening, fundamental frequency, and energy. Since prosodic cues are

[1] As in Vinyals et al. (2015) the input sequence is processed in reverse order, as shown in Figure 1.

[2] For brevity we omit the LSTM equations. The details can be found, e.g., in Zaremba et al. (2014).

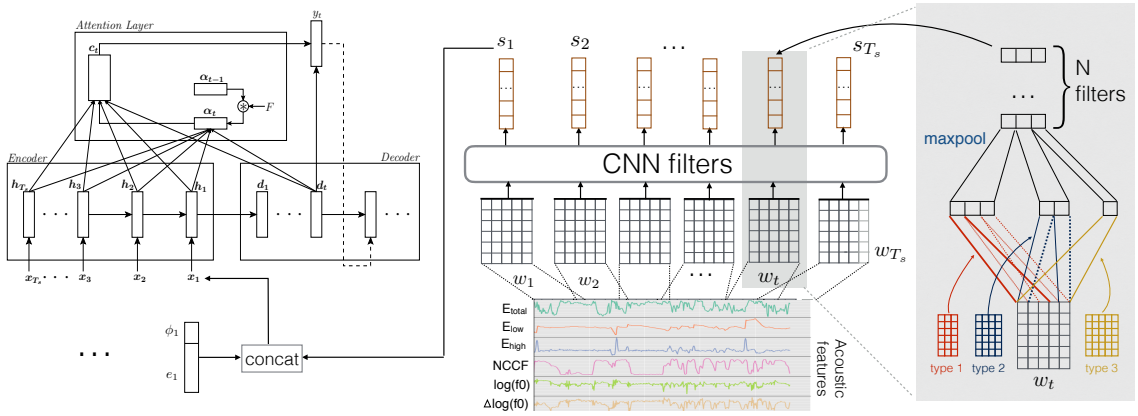

Figure 1: Left – An attention-based encoder-decoder reading the input $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_{T_s}$, where $\boldsymbol{x}_i = [\boldsymbol{e}_i \ \boldsymbol{\phi}_i \ \boldsymbol{s}_i]$ is composed of word embeddings $\boldsymbol{e}_i$, prosodic features $\boldsymbol{\phi}_i$, and learned (CNN-based) features $\boldsymbol{s}_i$. The encoder reads the input in *reverse* order and the decoder outputs the linearized parse $y_1, \cdots, y_t, \cdots$. Right – Detailed illustration of acoustic-prosodic feature learning module. CNN features are computed from input energy and pitch features; here the CNN filter parameters are $m = 3$ and $w = [3, 4, 5]$.

at sub- and multi-word time scales, they are integrated with the encoder-decoder using different mechanisms.

All features are extracted from transcriptions that are time-aligned at the word level.[3] We use time alignments associated with the corpus to be consistent with other studies. In a small number of cases, the time alignment for a particular word boundary is missing. Some cases are due to tokenization. For example, contractions, such as *don't* in the original transcript, are treated as separated words for the parser (*do* and *n't*), and the internal word boundary time is missing. In such cases, these internal times are estimated. In other cases, there are transcription mismatches that lead to missing time alignments, where we cannot estimate times. For the roughly 1% of sentences where time alignments are missing, we simply back off to the text-based parser.

Pause. The pause feature vector $\boldsymbol{p}_i$ for word i is the concatenation of pre-word pause feature $\boldsymbol{p}_{pre,i}$ and post-word pause feature $\boldsymbol{p}_{post,i}$, where each subvector is a learned embedding for 6 pause categories: no pause, missing, $0 < p \leq 0.05$ s, 0.05 s $< p \leq 0.2$ s, $0.2 < p \leq 1$ s, and $p > 1$ s (including turn boundaries). The bins are chosen based on the observed distribution (see Appendix A.1). We did not use (real-valued) pause duration directly, for two main reasons: (1) to handle missing time alignments; and (2) duration of pause does not matter beyond a threshold (e.g. $p > 1$ s).

Word duration. Both word duration and word-final duration lengthening are strong cues to prosodic phrase boundaries (Wightman et al., 1992; Pate and Goldwater, 2013). The word duration feature δ_i is computed as the actual word duration divided by the mean duration of the word, clipped to a maximum value of 5. The sample mean is used for frequent words (count ≥ 15). For infrequent words we estimate the mean as the sum over the sample means for the phonemes in the word's dictionary pronunciation. We refer to the manually defined prosodic feature pair of $\boldsymbol{p}_i$ and δ_i as ϕ_i.

Fundament frequency (f0) and Energy (E) contours (f0/E). We use a CNN to automatically learn the mapping from the time series of f0/E features to a word-level vector. The contour features are extracted from 25-ms frames with 10-ms hops using Kaldi (Povey et al., 2011). Three f0 features are used: warped Normalized Cross Correlation Function (NCCF), log-pitch with Probability of Voicing (POV)-weighted mean subtraction over a 1.5-second window, and the estimated derivative (delta) of the raw log pitch. Three energy features are extracted from the Kaldi 40-mel-frequency filter bank features: E_{total}, the log of total energy normalized by dividing by the speaker side's max total energy; E_{low}, the log of total energy in the lower 20 mel-frequency bands, normalized by total energy, and E_{high}, the log of total energy in the higher 20 mel-frequency bands, normalized by total energy. Multi-band energy features are used as a

[3] The assumption of known word alignments is standard for prosodic feature extraction in many spoken language processing studies. Time alignments can be obtained as a by-product of recognition or from forced alignment.

simple mechanism to capture articulatory strengthening at prosodic constituent onsets (Fourgeron and Keating, 1997).

Figure 1 summarizes the feature learning approach. The f0 and E features are processed at the word level: each sequence of frames corresponding to a time-aligned word (and potentially its surrounding context) is convolved with N filters of m sizes (a total of mN filters). The motivation for the multiple filter sizes is to enable the computation of features that capture information on different time scales. For each filter, we perform a 1-D convolution over the 6-dimensional f0/E features with a stride of 1. Each filter output is max-pooled, resulting in mN-dimensional speech features $\boldsymbol{s}_i$. Our overall acoustic-prosodic feature vector is the concatenation of $\boldsymbol{p}_i$, δ_i, and $\boldsymbol{s}_i$ in various combinations.

3 Experiments

3.1 Dataset

Our core corpus is Switchboard-NXT (Calhoun et al., 2010), a subset of the Switchboard corpus (Godfrey and Holliman, 1993): 2,400 telephone conversations between strangers; 642 of these were hand-annotated with syntactic parses and further augmented with richer layers of annotation facilitated by the NITE XML toolkit (Calhoun et al., 2010). Our sentence segmentations and syntactic trees are based on the annotations from the Treebank set, with a few manual corrections from the NXT release. This core dataset consists of 100K sentences, totaling 830K tokens forming a vocabulary of 13.5K words. We use the time alignments available from NXT, which is based on a corrected word transcript that occasionally differs from the Treebank, leading to some missing time alignments. We follow the sentence boundaries defined by the parsed data available,[4] and the data split (90% train; 5% dev; 5% test) defined by related work done on Switchboard (Charniak and Johnson, 2001; Kahn et al., 2005; Honnibal and Johnson, 2014).

3.2 Evaluation Metrics and Baselines

The standard evaluation metric for constituent parsing is the *parseval* metric which uses bracketing precision, recall, and F1, as in the canonical implementation of EVALB.[5] For written text, punctuation is sometimes represented as part of the sequence and impacts the final score, but for speech the punctuation is not explicitly available so it does not contribute to the score. Another challenge of transcribed speech is the presence of disfluencies. Speech repairs are indicated under "EDITED" nodes in Switchboard parse trees, which include structure under these nodes that is not of interest for simple text clean-up. Therefore, some studies report *flattened-edit parseval* F1 scores ("flat-F1"), which is *parseval* computed on trees where the structure under edit nodes has been eliminated so that all leaves are immediate children. We report both scores for the baseline text-only model showing that the differences are small, then use the standard *parseval* F1 score for most results.[6]

Disfluencies are particularly problematic for statistical parsers, as explained by Charniak and Johnson (2001), and some systems incorporate a separate disfluency detection stage. For this reason, and because it is useful for understanding system performance, most studies also report disfluency detection performance, which is measured in terms of the F1 score for detecting whether a word is in an edit region. Our approach does not involve a separate disfluency detection stage, but identifies disfluencies implicitly via the parse structure. Consequently, the disfluency detection results are not competitive with work that directly optimize for disfluency detection. We report disfluency detection scores primarily as a diagnostic.

Most previous work on integrating prosody and parsing has used the Switchboard corpus, but it is still difficult to compare results because of differences in constraints, objectives and the use of constituent vs. dependency structure, as discussed further in Section 6. The most relevant prior studies (on constituent parsing) that we compare to are a bit old. The text-only result from our neural parser represents a stronger baseline and is important for decoupling the impact of prosody vs. the parsing framework.

3.3 Model Training and Inference

Both the encoder and decoder are 3-layer deep LSTM-RNNs with 256 hidden units in each layer. For the location-aware attention, the convolution operation uses 5 filters of width 40 each. We use 512-dimensional embedding vectors to repre-

[4] Note that these sentence units can be inconsistent with other layers of Switchboard annotations, such as *slash units*.

[5] http://nlp.cs.nyu.edu/evalb/

[6] A variant of the "flat-F1" score is used in (Charniak and Johnson, 2001; Kahn et al., 2005), which uses a relaxed edited node precision and recall but also ignores filled pauses.

sent words and linearized parsing symbols, such as "(S".[7]

A number of configurations are explored for the acoustic-prosodic features, tuning based on dev set parsing performance. Pause embeddings are tuned over $\{4, 16, 32\}$ dimensions. For the CNN, we try different configurations of filter widths $w \in \{[10, 25, 50], [5, 10, 25, 50]\}$ and number of filters $N \in \{16, 32, 64, 128\}$ for each filter width.[8] These filter size combinations are chosen to capture f0 and energy phenomena on various levels: $w = 5, 10$ for sub-word, $w = 25$ for word, and $w = 50$ for word and extended context. Our best model uses 32-dimensional pause embeddings and $N = 32$ filters of widths $w = [5, 10, 25, 50]$, which corresponds to $m = 4$ and 128 filters.

For optimization we use Adam (Kingma and Ba, 2014) with a minibatch size of 64. The initial learning rate is 0.001 which is decayed by a factor of 0.9 whenever training loss, calculated after every 500 updates, degrades relative to the worst of its previous 3 values. All models are trained for up to 50 epochs with early stopping. For regularization, dropout with 0.3 probability is applied on the output of all LSTM layers (Pham et al., 2014).

For inference, we use a greedy decoder to generate the linearized parse. The output token with maximum posterior probability is chosen at every time step and fed as input in the next time step. The decoder stops upon producing the end-of-sentence symbol. We use TensorFlow (Abadi et al., 2015) to implement all models.[9]

4 Results

4.1 Text-only Results

Model	F1	flat-F1	fluent	disf
Berkeley	85.41	85.91	90.52	83.08
C-attn	83.33	83.20	90.86	79.94
CL-attn	**87.85**	**87.68**	**92.07**	**85.95**

Table 1: Scores of text-only models on the dev set: 2044 fluent and 3725 disfluent sentences. C-attn denotes *content*-only attention; CL-attn denotes *content+location* attention.

[7]The number of layers, dimension of hidden units, dimension of embedding, and convolutional attention filter parameters of the text-only parser were explored in earlier experiments on the development set and then fixed as described.

[8]Note that a filter of width 10 has size 6×10, since the features are of dimension 6.

[9]Our code resources can be found in Appendix A.1.

Model	Parse	Disf
Berkeley (text only)	85.41	62.45
CL-attn (text only)	87.85	79.50
CL-attn text and		
+ p	88.37	80.24
+ δ	88.04	77.41
+ p + δ	88.21	80.84
+ f0/E-CNN	88.52	80.81
+ p + f0/E-CNN	88.45	**81.19**
+ δ + f0/E-CNN	88.44	80.09
+ p + δ + f0/E-CNN	**88.59**	80.84

Table 2: Parse and disfluency detection F1 scores on the dev set. Flat-F1 scores were consistently 0.1%-0.3% lower for our models, but 0.2% higher for the Berkeley parser (85.64).

We first show our results on the model using only text (i.e. $\boldsymbol{x}_i = \boldsymbol{e}_i$) to establish a strong baseline, on top of which we can add acoustic-prosodic features. We experiment with the *content*-only attention model used by Vinyals et al. (2015) and the *content+location* attention of Chorowski et al. (2015). For comparison with previous non-neural models, we use a high-quality latent-variable parser, the Berkeley parser (Petrov et al., 2006), retrained on our Switchboard data. Table 1 compares the three text-only models. In terms of F1, the *content+location* attention beats the Berkeley parser by about 2.5% and *content*-only attention by about 4.5%. Flat-F1 scores for both encoder-decoder models is lower than their corresponding F1 scores, suggesting that the encoder-decoder models do well on predicting the internal structure of EDIT nodes while the reverse is true for the Berkeley parser.

To explain the gains of *content+location* attention over *content*-only attention, we compare their scores on fluent (without EDIT nodes) and disfluent sentences, shown in Table 1. It is clear that most of the gains for *content+location* attention are from disfluent sentences. A possible explanation is the presence of duplicate words or phrases in disfluent sentences, which can be problematic for a *content*-only attention model. Since our best model is the *content+location* attention model, we will henceforth refer to it as the "CL-attn" text-only model. All models using acoustic-prosodic features are extensions of this model, which provides a strong text-only baseline.

Model	Parse	Disf
CL-attn	87.79 (0.11)	78.65 (0.46)
best model	88.15 (0.41)	80.48 (0.70)

Table 3: Parse and disfluency detection F1 scores on the dev set: mean (and standard deviation) over 10 runs for the baseline text-only model (CL-attn) and the best model with prosody.

Model	Parse	Disfl
Berkeley	85.87	63.44
CL-attn	87.99	76.69
best model	**88.50**	**77.47**

Table 4: Parse and disfluency detection F1 scores on the test set. The best model has *statistically significant* gains over the text-only baseline with p-value < 0.02.

4.2 Adding Acoustic-Prosodic Features

We extend our CL-attn model with the three kinds of acoustic-prosodic features: pause (p), word duration (δ), and CNN mappings of fundamental frequency (f0) and energy (E) features (f0/E-CNN).

The results of several model configurations on our dev set are presented in Table 2. First, we note that adding any combination of acoustic-prosodic features (individually or in sets) improves performance over the text-only baseline. However, certain combinations of acoustic-prosodic features are not always better than their subsets. The *text* + p + δ + *f0/E-CNN* model that uses all three types of features has the best performance with a gain of 0.7% over the already-strong text-only baseline. We will henceforth refer to the *text* + p + δ + *f0/E-CNN* model as our "best model".

As a robustness check, we report results of averaging 10 runs on the CL-attn text-only and the best model in Table 3. We performed a bootstrap test (Efron and Tibshirani, 1993) that simulates 10^5 random test draws on the models giving median performance on the dev set. These *median* models gave a statistically significant difference between the text-only and best model (p-value < 0.02). Additionally, a simple t-test over the two sets of 10 results also shows statistical significance p-value < 0.03.

Table 4 presents the results on the test set. Again, adding the acoustic-prosodic features improves over the text-only baseline. The gains are statistically significant for the best model with p-value < 0.02, again using a bootstrap test with simulated 10^5 random test draws on the two models.

Model	Parse	Disfl
Text Only		
Kahn et al. (2005)	86.4	78.2
Hale et al. (2006)	71.16	41.7
CL-attn (text only)	87.99	76.7
Text + Prosody		
Kahn et al. (2005)	86.6	78.2
Hale et al. (2006)	71.05	36.2
best model	88.50	77.5

Table 5: Parse and disfluency detection F1 scores on the test set comparing to other reported results.

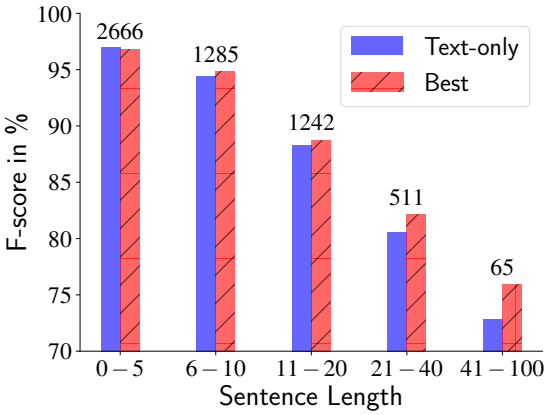

Figure 2: F1 scores of the text-only model and our best model as a function of sentence length.

Table 5 includes results from prior studies that compare systems using text alone with ones that incorporate prosody, given hand transcripts and sentence segmentation. It is difficult to compare systems directly, because of the many differences in the experimental set-up. For example, the original Charniak and Johnson (2001) result (reporting F=85.9 for parsing and F=78.2 for disfluencies) leverages punctuation in the text stream, which is not realistic for speech transcripts and not used in most other work. Our work benefits from more text training material than others, but others benefit from gold part-of-speech tags. Kahn et al. (2005) use a modified sentence segmentation. There are probably minor differences in handling of word fragments and scoring edit regions. Thus, this table primarily shows that our framework leads to more benefits from sentence-internal prosodic cues than others have obtained.

5 Analysis

Effect of sentence length. Figure 2 shows performance differences between our best model and the text-only model for varying sentence lengths.

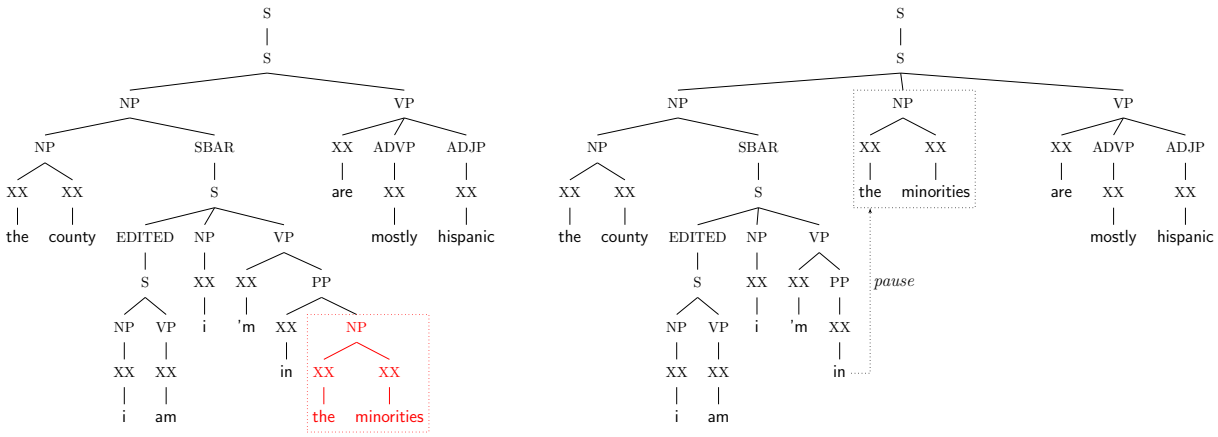

Figure 3: An example sentence from development data – *the county i am i 'm in [pause] the minorities are mostly hispanic*. The text-only parser (on the left) makes a PP Attachment error. The prosody-enhanced parser (on the right) uses the pause indicator to correctly predict a constituent change after the word *in*.

Model	fluent	disfluent
text-only	92.07	85.90
best model	92.03	**87.02**

Table 6: Dev set F1-score of text-only and best model on fluent (2029) vs. disfluent (3689) sentences.[10]

Both models do worse on longer sentences, as expected since the corresponding parse trees tend to be more complex. The performance difference between our best model and the text-only model increases with sentence length. This is likely because longer sentences more often have multiple prosodic phrases and disfluencies.

Effect of disfluencies. Table 6 presents parse scores on the subsets of fluent and disfluent sentences, showing that the performance gain is in the disfluent set (65% of the dev set sentences). Because sentence boundaries are given, and so many fluent sentences in spontaneous speech are short, there is less potential for benefit from prosody in the fluent set.

Types of errors. We use the Berkeley Parser Analyzer (Kummerfeld et al., 2012) to compare the types of errors made by the different parsers.[10] Table 7 presents the relative error reductions over the text-only baseline achieved by the text + p model and our best model for disfluent sentences. The two models differ in the types of error reductions they provide. Including pause information gives largest improvements on PP attachment and Modifier attachment errors. Adding the remaining acoustic-prosodic features helps to correct more types of attachment errors, especially VP and NP attachment. Figure 3 demonstrates one case where the pause feature helps in correcting a PP attachment error made by a text-only parser. Other interesting examples (see Appendix A.2) suggest that the learned f0/E features help reduce NP attachment errors where the audio reveals a prominent word at the constituent boundary, even though there is no pause at that word.

Error Type	Disfluent Sentences	
	text + p	best model
Clause Att.	5.7%	1.3%
Diff. Label	7.6%	4.2%
Modifier Att.	9.7%	19.1%
NP Att.	-2.7%	14.5%
NP Internal	7.8%	7.4%
PP Att.	10.1%	7.8%
1-Word Phrase	6.3%	6.8%
Unary	-1.1%	8.9%
VP Att.	0.0%	12.0%

Table 7: Relative error reduction over the text-only baseline in the disfluent subset (3689 sentences) of the development set. Shown here are the most frequent error types (with count $\geq$ 100 for the text-only model).

Effect of transcription errors. The results and analyses so far have assumed that we have reliable transcripts. In fact, the original transcripts contained errors, and the Treebank annotators used these without reference to audio files. Mississippi State University (MS-State) ran a clean-up project

[10] This analysis omits the 1% of the sentences that did not have timing information.

that produced more accurate word transcripts and time alignments (Deshmukh et al., 1998). The NXT corpus provides reconciliation between Treebank and MS-State transcripts in terms of annotating missed/extra/substituted words, but parses were not re-annotated. The transcript errors mean that the acoustic signal is inconsistent with the "gold" parse tree. Below are some examples of "fluent" sentences (according to the Treebank transcripts) with transcription errors, for which prosodic features "hurt" parsing. Words that transcribers missed are in brackets and those inserted are underlined.

S1: and because <uh> like if your spouse died <all of a sudden you be> all alone it 'd be nice to go someplace with people similar to you to have friends

S2: uh uh <i have had> my wife 's picked up a couple of things saying uh boy if we could refinish that 'd be a beautiful piece of furniture

Multi-syllable errors are especially problematic, leading to serious inconsistencies between the text and the acoustic signal. Further, the missed words lead to an incorrect attachment in the "gold" parse in S1 and a missing restart edit in S2. Indeed, for sentences with consecutive transcript errors, which we expect to impact the prosodic features, there is a statistically significant (p-value < 0.05) negative effect on parsing with prosody. Not included in this analysis are sentence boundary errors, which also change the "gold" parse. Thus, prosody may be more useful than results here indicate.

6 Related Work

Related work on parsing conversational speech has mainly addressed four problems: speech recognition errors, unknown sentence segmentation, disfluencies, and integrating prosodic cues. Our work addresses the last two problems, which involve studies based on hand-transcribed text and known sentence boundaries, as in much speech parsing work. The related studies are thus the focus of this discussion. We describe studies using the Switchboard corpus, since it has dominated work in this area, being the largest source of treebanked English spontaneous speech.

One major challenge of parsing conversational speech is the presence of disfluencies, which are grammatical and prosodic interruptions. Disfluencies include repetitions ('I am + I am'), repairs ('I am + we are'), and restarts ('What I + Today is the...'), where the '+' corresponds to an interruption point. Repairs often involve parallel grammatical constructions, but they can be more complex, involving hedging, clarifications, etc. Charniak and Johnson (Charniak and Johnson, 2001; Johnson and Charniak, 2004) demonstrated that disfluencies are different in character than other constituents and that parsing performance improves from combining a PCFG parser with a separate module for disfluency detection via parse rescoring. Our approach does not use a separate disfluency detection module; we hypothesized that the location-sensitive attention model helps handle these differences based on analysis of the text-only results (Table 1). However, more explicit modeling of disfluency pattern match characteristics in a dependency parser (Honnibal and Johnson, 2014) leads to better disfluency detection performance (F = 84.1 vs. 76.7 for our text only model). Pattern match features also benefit a neural model for disfluency detection alone (F = 87.0) (Zayats et al., 2016), and similar gains are observed by formulating disfluency detection in a transition-based framework (F = 87.5) (Wang et al., 2017). Experiments with oracle disfluencies as features improve the CL-attn text-only parsing performance from 87.85 to 89.38 on the test set, showing that more accurate disfluency modeling is a potential area of improvement.

It is well known that prosodic features play a role in human resolution of syntactic ambiguities, with more than two decades of studies seeking to incorporate prosodic features in parsing. A series of studies looked at constituent parsing informed by the presence (or likelihood) of prosodic breaks at word boundaries (Kahn et al., 2004, 2005; Hale et al., 2006; Dreyer and Shafran, 2007). Our approach improves over performance of these systems using raw acoustic features, without the need for hand-labeling prosodic breaks. The gain is in part due to the improved text-based parser, but the incremental benefit of prosody here is similar to that in these prior studies. (In prior work using acoustic feature directly (Gregory et al., 2004), prosody actually degraded performance.) Our analyses of the impact of prosody also extends prior work.

Prosody is also known to provide useful cues to sentence boundaries (Liu et al., 2006), and automatic sentence segmentation performance has been shown to have a significant impact on parsing performance (Kahn and Ostendorf, 2012). In our study, sentence boundaries are given so as to focus on the role of prosody in resolving sentence-internal parse ambiguity, for which prior work had

obtained smaller gains. Studies have also shown that parsing lattices or confusion networks can improve ASR performance (Kahn and Ostendorf, 2012; Yoshikawa et al., 2016). Our analysis of performance degradation for the system with prosody when the gold transcript and associated parse are in error suggests that prosody may have benefits for parsers operating on alternative ASR hypotheses.

The results we compare to in Section 4 are relatively old. More recent parsing results on spontaneous speech involve dependency parsers using only text (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Yoshikawa et al., 2016), with the exception of a study on unsupervised dependency parsing (Pate and Goldwater, 2013). With the recent success of transition-based neural approaches in dependency parsing, researchers have adapted transition-based ideas to constituent parsing (Zhu et al., 2013; Watanabe and Sumita, 2015; Dyer et al., 2016). These approaches have not yet been used with speech, to our knowledge, but we expect it to be straightforward to extend our prosody integration framework to these systems, both for dependency and constituency parsing.

7 Conclusion

We have presented a framework for directly integrating acoustic-prosodic features with text in a neural encoder-decoder parser that does not require hand-annotated prosodic structure. On conversational sentences, we obtained strong results when including word-level acoustic-prosodic features over using only transcriptions. The acoustic-prosodic features provide the largest gains when sentences are disfluent or long, and analysis of error types shows that these features are especially helpful in repairing attachment errors. In cases where prosodic features hurt performance, we observe a statistically significant negative effect caused by imperfect human transcriptions that make the "ground truth" parse tree and the acoustic signal inconsistent, which suggests that there is more to be gained from prosody than observed in prior studies. We thus plan to investigate aligning the Treebank and MS-State versions of Switchboard for future work.

Here, we assumed known sentence boundaries and hand transcripts, leaving open the question of whether increased benefits from prosody can be gained by incorporating sentence segmentation in parsing and/or in parsing ASR lattices. Most prior work using prosody in parsing has been on constituent parsing, since prosodic cues tend to align with constituent boundaries. However, it remains an open question as to whether dependency, constituency or other parsing frameworks are better suited to leveraging prosody. Our study builds on a parser that uses reverse order text processing, since it provides a stronger text-only baseline. However, the prosody modeling component relies only on a 1 second lookahead of the current word (for pause binning), so it could be easily incorporated in an incremental parser.

A Appendix

A.1 Miscellany

Our main model code is available at https://github.com/shtoshni92/speech_parsing. Most of the data preprocessing code is available at https://github.com/trangham283/seq2seq_parser/tree/master/src/data_preps. Part of our data preprocessing pipeline also uses https://github.com/syllog1sm/swbd_tools.

Table 8 shows statistics of our Switchboard dataset. As defined, for example, in (Charniak and Johnson, 2001; Honnibal and Johnson, 2014), the splits are: conversations sw2000 to sw3000 for training, sw4500 to sw4936 for validation (dev), and sw4000 to sw4153 for evaluation (test). In addition, previous work has reserved sw4154 to sw4500 for "future use" (dev2), but we added this set to our training set. That is, all of our models are trained on Switchboard conversations sw2000 to sw3000 as well as sw4154 to sw4500.

Section	# sentences	# words
Train	97,113	729,252
Dev	5,769	50,445
Test	5,901	48,625

Table 8: Data statistics.

Figure 4 illustrates the data preprocessing step. On the decoder end, we also use a post-processing step that merges the original sentence with the decoder output to obtain the standard constituent tree representation. During inference, in rare cases (and virtually none as our models converge), the decoder does not generate a valid parse sequence, due to the mismatch in brackets and/or the mismatch in the number of pre-terminals and terminals, i.e., num(XX) $\neq$ num(tokens). In such cases, we simply add/remove brackets from either end of the parse, or add/remove pre-terminal symbols XX in the middle of the parse to match the number of input tokens.

Figure 5 shows the distribution of pause durations in our training data. Our pause buckets of

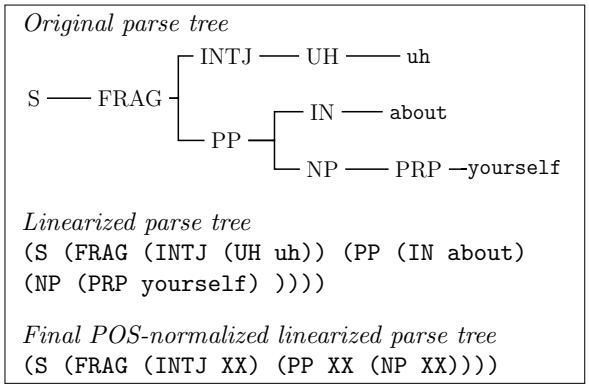

Figure 4: Data preprocessing. Trees are linearized; POS tags (pre-terminals) are normalized as "XX". Also note the annotation standard used for Switchboard data: The root node of the tree is an "S" node although it is not a complete sentence.

$0 < p \leq 0.05$ s, 0.05 s $< p \leq 0.2$ s, $0.2 < p \leq 1$ s, and $p > 1$ s described in the main paper were based on this distribution of pause lengths.

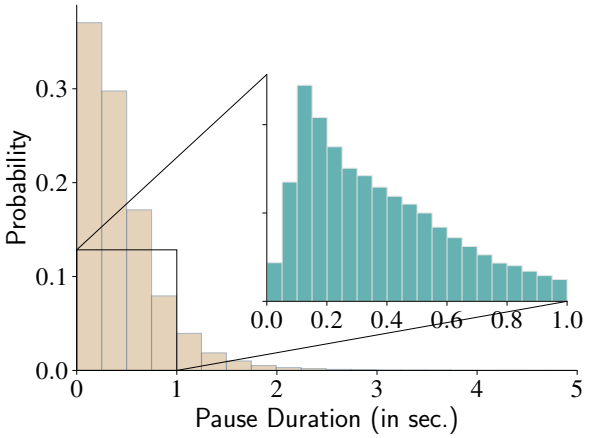

Figure 5: Histogram of inter-word pause durations in our training set. As expected, most of the pauses are less than 1 second. Further binning of pause durations ≤ 1 second reveals that the plot peaks around 0.2 seconds and continuously decays from there on. In some very rare cases, pauses of 5+ seconds occur within a sentence.

Table 9 shows the comprehensive error counts in all error categories defined in the Berkeley Parse Analyzer (Kummerfeld et al., 2012) in both the fluent and disfluent subsets.

A.2 Tree Examples

In figures 6, 7, and 8, we follow node correction notations as in (Kummerfeld et al., 2012). In particular, missing nodes are marked in blue on the gold tree, extra nodes are marked red in the predicted tree, and yellow nodes denote crossing.

Error Type	Fluent Subset			Disfluent Subset		
	text-only	text + p	best model	text-only	text + p	best model
Clause Attach.	126	132	123	631	595	600
Co-ordination	1	2	1	10	10	5

Table 9: Parse error counts comparison on the fluent (2029 sentences) and disfluent (3689 sentences) subsets of the development set across three parsers.

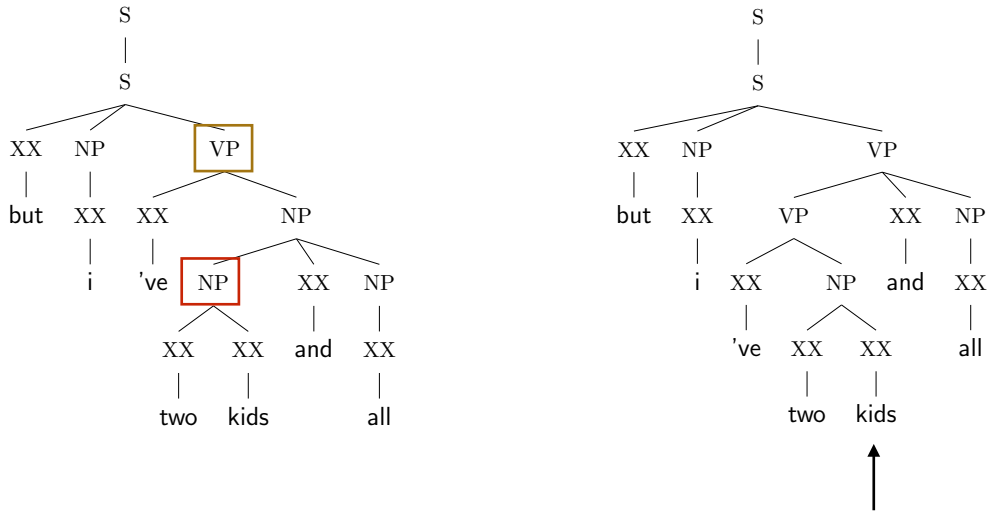

Figure 6: An example sentence from development data – *but i 've two kids and all*. Even though there are no pauses between all words, the word *kids* is lengthened in the audio sample, helping the prosody-enhanced parser (right) to recognize a major syntactic boundary, avoiding the NP Attachment error made by the text-only parser (left).

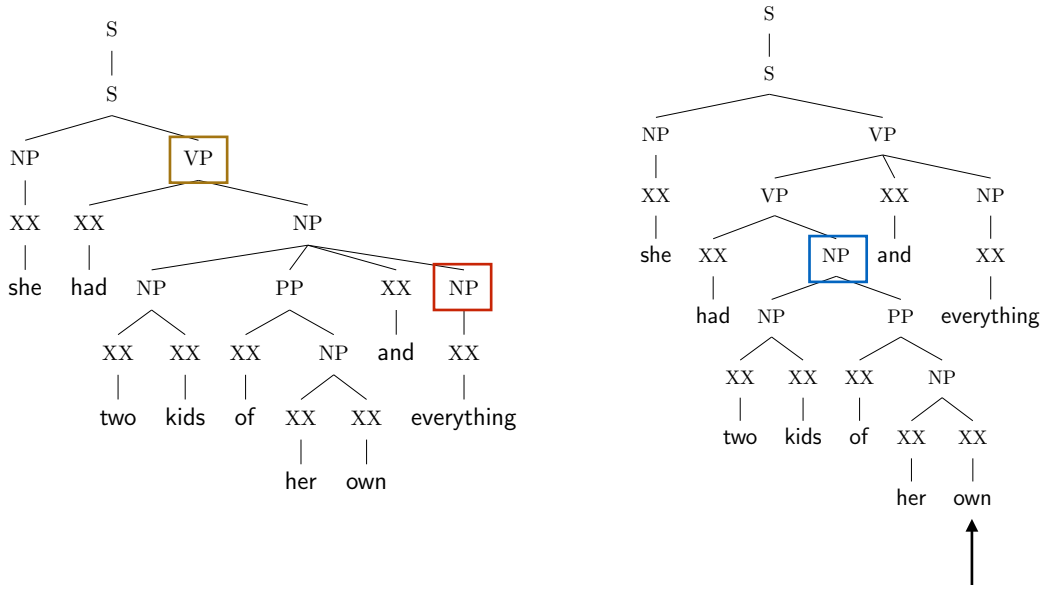

Figure 7: An example sentence from development data – *she had two kids of her own and everything*. There were no pauses between all words in this sentence, the audio sample showed that the word *own* was both lengthened and raised in intonation, giving the prosody-enhanced parser (right) a signal that *own* is on a syntactic boundary. On the other hand, the text-only parser (left) had no such information and made an NP-attachment error. This sentence also illustrates an interesting case where, in isolation, the text-only parse makes sense (i.e. *everything* being an object of *had*). However, in the context of this conversation (the speaker was talking about another person in an informal manner), *and everything* acts more like filler - e.g. "i play the violin *and stuff*"

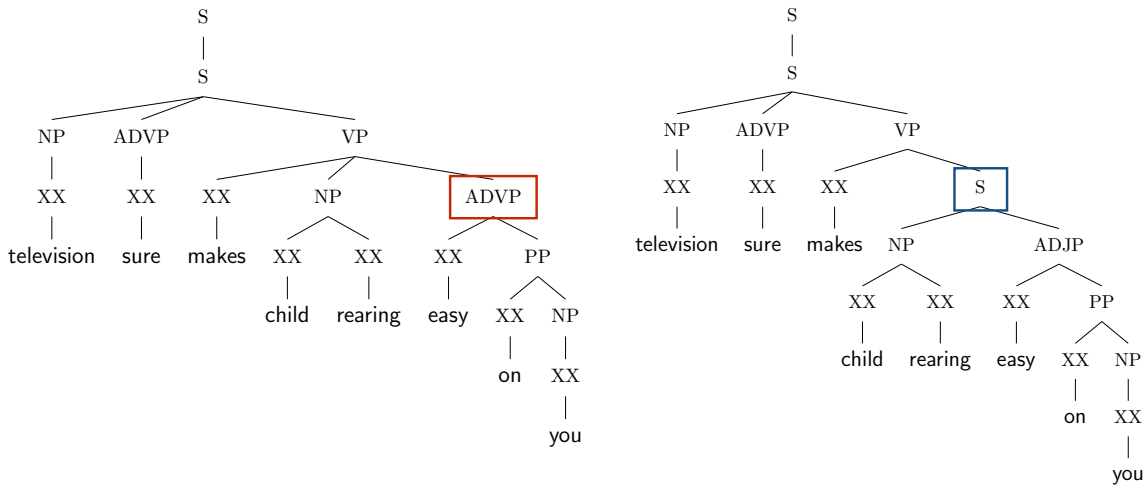

Figure 8: An example sentence from development data – *television sure makes child rearing easy on you*. This is an example where our prosody-enhanced parser (left) did worse than the text-only parser (right), which made no errors. The error type illustrated here is Different Label and Modifier Attachment. In the first iteration, the analyzer identifies a Different Label error (ADVP node), and in the second pass identifies the Modifier Attachment error.

Tied Multitask Learning for Neural Speech Translation

Antonios Anastasopoulos and **David Chiang**

Abstract

We explore multitask models for neural translation of speech, augmenting them in order to reflect two intuitive notions. First, we introduce a model where the second task decoder receives information from the decoder of the first task, since higher-level intermediate representations should provide useful information. Second, we apply regularization that encourages *transitivity* and *invertibility*. We show that the application of these notions on jointly trained models improves performance on the tasks of low-resource speech transcription and translation. It also leads to better performance when using attention information for word discovery over unsegmented input.

1 Introduction

Recent efforts in endangered language documentation focus on collecting spoken language resources, accompanied by spoken translations in a high resource language to make the resource interpretable (Bird et al., 2014a). For example, the BULB project (Adda et al., 2016) used the LIG-Aikuma mobile app (Bird et al., 2014b; Blachon et al., 2016) to collect parallel speech corpora between three Bantu languages and French. Since it's common for speakers of endangered languages to speak one or more additional languages, collection of such a resource is a realistic goal.

Speech can be interpreted either by transcription in the original language or translation to another language. Since the size of the data is extremely small, multitask models that jointly train a model for both tasks can take advantage of both signals. Our contribution lies in improving the sequence-to-sequence multitask learning paradigm, by drawing on two intuitive notions: that higher-level representations are more useful than lower-level representations, and that translation should be both transitive and invertible.

Higher-level intermediate representations, such as transcriptions, should in principle carry information useful for an end task like speech translation. A typical multitask setup (Weiss et al., 2017) shares information at the level of encoded frames, but intuitively, a human translating speech must work from a higher level of representation, at least at the level of phonemes if not syntax or semantics. Thus, we present a novel architecture for *tied* multitask learning with sequence-to-sequence models, in which the decoder of the second task receives information not only from the encoder, but also from the decoder of the first task.

In addition, *transitivity* and *invertibility* are two properties that should hold when mapping between levels of representation or across languages. We demonstrate how these two notions can be implemented through regularization of the attention matrices, and how they lead to further improved performance.

We evaluate our models in three experiment settings: low-resource speech transcription and translation, word discovery on unsegmented input, and high-resource text translation. Our high-resource experiments are performed on English, French, and German. Our low-resource speech experiments cover a wider range of linguistic diversity: Spanish-English, Mboshi-French, and Ainu-English.

In the speech transcription and translation tasks, our proposed model leads to improved performance against all baselines as well as previous multitask architectures. We observe improvements of up to 5% character error rate in the transcription task, and up to 2.8% character-level BLEU in the translation task. However, we didn't observe similar improvements in the text translation experiments. Finally, on the word discovery task, we improve upon previous work by about 3% F-score on both tokens and types.

Proceedings of NAACL-HLT 2018, pages 82–91
New Orleans, Louisiana, June 1 - 6, 2018.

2 Model

Our models are based on a sequence-to-sequence model with attention (Bahdanau et al., 2015). In general, this type of model is composed of three parts: a recurrent encoder, the attention, and a recurrent decoder (see Figure 1a).[1]

The encoder transforms an input sequence of words or feature frames $\mathbf{x}_1, \ldots, \mathbf{x}_N$ into a sequence of *input states* $\mathbf{h}_1, \ldots, \mathbf{h}_N$:

$$\mathbf{h}_n = \text{enc}(\mathbf{h}_{n-1}, \mathbf{x}_n).$$

The attention transforms the input states into a sequence of *context vectors* via a matrix of *attention weights*:

$$\mathbf{c}_m = \sum_n \alpha_{mn} \mathbf{h}_n.$$

Finally, the decoder computes a sequence of *output states* from which a probability distribution over output words can be computed.

$$\begin{aligned} \mathbf{s}_m &= \text{dec}(\mathbf{s}_{m-1}, \mathbf{c}_m, \mathbf{y}_{m-1}) \\ P(\mathbf{y}_m) &= \text{softmax}(\mathbf{s}_m). \end{aligned}$$

In a standard encoder-decoder *multitask* model (Figure 1b) (Dong et al., 2015; Weiss et al., 2017), we jointly model two output sequences using a shared encoder, but separate attentions and decoders:

$$\begin{aligned} \mathbf{c}^1_m &= \sum_n \alpha^1_{mn} \mathbf{h}_n \\ \mathbf{s}^1_m &= \text{dec}^1(\mathbf{s}^1_{m-1}, \mathbf{c}^1_m, \mathbf{y}^1_{m-1}) \\ P(\mathbf{y}^1_m) &= \text{softmax}(\mathbf{s}^1_m) \end{aligned}$$

and

$$\begin{aligned} \mathbf{c}^2_m &= \sum_n \alpha^2_{mn} \mathbf{h}_n \\ \mathbf{s}^2_m &= \text{dec}^2(\mathbf{s}^2_{m-1}, \mathbf{c}^2_m, \mathbf{y}^2_{m-1}) \\ P(\mathbf{y}^2_m) &= \text{softmax}(\mathbf{s}^2_m). \end{aligned}$$

We can also arrange the decoders in a *cascade* (Figure 1c), in which the second decoder attends only to the output states of the first decoder:

$$\begin{aligned} \mathbf{c}^2_m &= \sum_{m'} \alpha^{12}_{mm'} \mathbf{s}^1_{m'} \\ \mathbf{s}^2_m &= \text{dec}^2(\mathbf{s}^2_{m-1}, \mathbf{c}^2_m, \mathbf{y}^2_{m-1}) \\ P(\mathbf{y}^2_m) &= \text{softmax}(\mathbf{s}^2_m). \end{aligned}$$

[1]For simplicity, we have assumed only a single layer for both the encoder and decoder. It is possible to use multiple stacked RNNs; typically, the output of the encoder and decoder ($\mathbf{c}_m$ and $P(\mathbf{y}_m)$, respectively) would be computed from the top layer only.

Tu et al. (2017) use exactly this architecture to train on bitext by setting the second output sequence to be equal to the input sequence ($\mathbf{y}^2_i = \mathbf{x}_i$).

In our proposed *triangle* model (Figure 1d), the first decoder is as above, but the second decoder has two attentions, one for the input states of the encoder and one for the output states of the first decoder:

$$\begin{aligned} \mathbf{c}^2_m &= \left[\textstyle\sum_{m'} \alpha^{12}_{mm'} \mathbf{s}^1_{m'} \quad \sum_n \alpha^2_{mn} \mathbf{h}_n\right] \\ \mathbf{s}^2_m &= \text{dec}^2(\mathbf{s}^2_{m-1}, \mathbf{c}^2_m, \mathbf{y}^2_{m-1}) \\ P(\mathbf{y}^2_m) &= \text{softmax}(\mathbf{s}^2_m). \end{aligned}$$

Note that the context vectors resulting from the two attentions are concatenated, not added.

3 Learning and Inference

For compactness, we will write $\mathbf{X}$ for the matrix whose rows are the $\mathbf{x}_n$, and similarly $\mathbf{H}$, $\mathbf{C}$, and so on. We also write $\mathbf{A}$ for the matrix of attention weights: $[\mathbf{A}]_{ij} = \alpha_{ij}$.

Let θ be the parameters of our model, which we train on sentence triples $(\mathbf{X}, \mathbf{Y}^1, \mathbf{Y}^2)$.

3.1 Maximum likelihood estimation

Define the score of a sentence triple to be a log-linear interpolation of the two decoders' probabilities:

$$\begin{aligned} \text{score}(\mathbf{Y}^1, \mathbf{Y}^2 \mid \mathbf{X}; \theta) = \lambda \log P(\mathbf{Y}^1 \mid \mathbf{X}; \theta) + \\ (1 - \lambda) \log P(\mathbf{Y}^2 \mid \mathbf{X}, \mathbf{S}^1; \theta) \end{aligned}$$

where λ is a parameter that controls the importance of each sub-task. In all our experiments, we set λ to 0.5. We then train the model to maximize

$$\mathcal{L}(\theta) = \sum \text{score}(\mathbf{Y}^1, \mathbf{Y}^2 \mid \mathbf{X}; \theta),$$

where the summation is over all sentence triples in the training data.

3.2 Regularization

We can optionally add a regularization term to the objective function, in order to encourage our attention mechanisms to conform to two intuitive principles of machine translation: *transitivity* and *invertibility*.

***Transitivity* attention regularizer** To a first approximation, the translation relation should be transitive (Wang et al., 2006; Levinboim and Chiang, 2015): If source word $\mathbf{x}_i$ aligns to target word

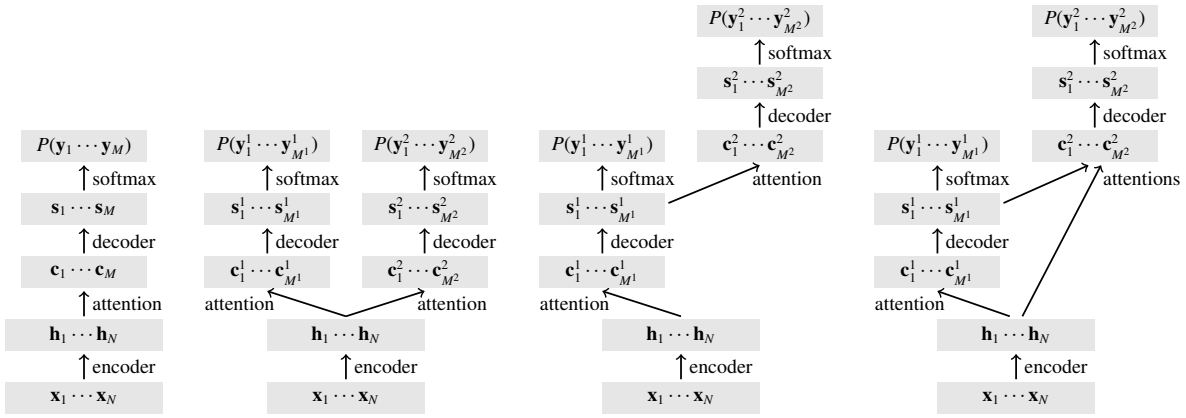

Figure 1: Variations on the standard attentional model. In the standard *single-task* model, the decoder attends to the encoder's states. In a typical *multitask* setup, two decoders attend to the encoder's states. In the *cascade* (Tu et al., 2017), the second decoder attends to the first decoder's states. In our proposed *triangle* model, the second decoder attends to both the encoder's states and the first decoder's states. Note that for clarity's sake there are dependencies not shown.

$\mathbf{y}^1_j$ and $\mathbf{y}^1_j$ aligns to target word $\mathbf{y}^2_k$, then $\mathbf{x}_i$ should also probably align to $\mathbf{y}^2_k$. To encourage the model to preserve this relationship, we add the following *transitivity* regularizer to the loss function of the *triangle* models with a small weight $\lambda_{\text{trans}} = 0.2$:

$$\mathcal{L}_{\text{trans}} = \text{score}(\mathbf{Y}^1, \mathbf{Y}^2) - \lambda_{\text{trans}} \left\|\mathbf{A}^{12}\mathbf{A}^1 - \mathbf{A}^2\right\|_2^2.$$

***Invertibility* attention regularizer** The translation relation also ought to be roughly invertible (Levinboim et al., 2015): if, in the *reconstruction* version of the *cascade* model, source word $\mathbf{x}_i$ aligns to target word $\mathbf{y}^1_j$, then it stands to reason that $\mathbf{y}_j$ is likely to align to $\mathbf{x}_i$. So, whereas Tu et al. (2017) let the attentions of the translator and the reconstructor be unrelated, we try adding the following *invertibility* regularizer to encourage the attentions to each be the inverse of the other, again with a weight $\lambda_{\text{inv}} = 0.2$:

$$\mathcal{L}_{\text{inv}} = \text{score}(\mathbf{Y}^1, \mathbf{Y}^2) - \lambda_{\text{inv}} \left\|\mathbf{A}^{1}\mathbf{A}^{12} - \mathbf{I}\right\|_2^2.$$

3.3 Decoding

Since we have two decoders, we now need to employ a two-phase beam search, following Tu et al. (2017):

1. The *first decoder* produces, through standard beam search, a set of triples each consisting of a candidate transcription $\hat{\mathbf{Y}}^1$, a score $P(\hat{\mathbf{Y}}^1)$, and a hidden state sequence $\hat{\mathbf{S}}$.

2. For each transcription candidate from the *first decoder*, the *second decoder* now produces through beam search a set of candidate translations $\hat{\mathbf{Y}}^2$, each with a score $P(\hat{\mathbf{Y}}^2)$.

3. We then output the combination that yields the highest total score$(\mathbf{Y}^1, \mathbf{Y}^2)$.

Corpus	Speakers	Segments	Hours
Ainu-English	1	2,668	2.5
Mboshi-French	3	5,131	4.4
Spanish-English	240	17,394	20

Table 1: Statistics on our speech datasets.

3.4 Implementation

All our models are implemented in DyNet (Neubig et al., 2017).[2] We use a dropout of 0.2, and train using Adam with initial learning rate of 0.0002 for a maximum of 500 epochs. For testing, we select the model with the best performance on dev. At inference time, we use a beam size of 4 for each decoder (due to GPU memory constraints), and the beam scores include length normalization (Wu et al., 2016) with a weight of 0.8, which Nguyen and Chiang (2017) found to work well for low-resource NMT.

4 Speech Transcription and Translation

We focus on speech transcription and translation of endangered languages, using three different cor-

Table 2: The multitask models outperform the baseline single-task model and the pivot approach (auto/text) on all language pairs tested. The *triangle* model also outperforms the simple multitask models on both tasks in almost all cases. The best results for each dataset and task are highlighted.

pora on three different language directions: Spanish (es) to English (en), Ainu (ai) to English, and Mboshi (mb) to French (fr).

4.1 Data

Spanish is, of course, not an endangered language, but the availability of the CALLHOME Spanish Speech dataset (LDC2014T23) with English translations (Post et al., 2013) makes it a convenient language to work with, as has been done in almost all previous work in this area. It consists of telephone conversations between relatives (about 20 total hours of audio) with more than 240 speakers. We use the original train-dev-test split, with the training set comprised of 80 conversations and dev and test of 20 conversations each.

Hokkaido Ainu is the sole surviving member of the Ainu language family and is generally considered a language isolate. As of 2007, only ten native speakers were alive. The Glossed Audio Corpus of Ainu Folklore provides 10 narratives with audio (about 2.5 hours of audio) and translations in Japanese and English.[3] Since there does not exist a standard train-dev-test split, we employ a cross validation scheme for evaluation purposes. In each fold, one of the 10 narratives becomes the test set, with the previous one (mod 10) becoming the dev set, and the remaining 8 narratives becoming the training set. The models for each of the 10 folds are trained and tested separately. On average, for each fold, we train on about 2000 utterances; the dev and test sets consist of about 270 utterances. We report results on the concatenation of all folds. The Ainu text is split into characters, except for the equals (=) and underscore (_) characters, which are used as phonological or structural markers and are thus merged with the following character.[4]

Mboshi (Bantu C25 in the Guthrie classification) is a language spoken in Congo-Brazzaville, without standard orthography. We use a corpus (Godard et al., 2017) of 5517 parallel utterances (about 4.4 hours of audio) collected from three native speakers. The corpus provides non-standard grapheme transcriptions (close to the language phonology) produced by linguists, as well as French translations. We sampled 100 segments from the training set to be our dev set, and used the original dev set (514 sentences) as our test set.

4.2 Implementation

We employ a 3-layer speech encoding scheme similar to that of Duong et al. (2016). The first bidirectional layer receives the audio sequence in the form of 39-dimensional Perceptual Linear Predictive (PLP) features (Hermansky, 1990) computed over overlapping 25ms-wide windows every 10ms. The second and third layers consist of LSTMs with hidden state sizes of 128 and 512 respectively. Each layer encodes every second output of the previous layer. Thus, the sequence is downsampled by a factor of 4, decreasing the computation load for the attention mechanism and the decoders. In the speech experiments, the decoders

[3] http://ainucorpus.ninjal.ac.jp/corpus/en/

[4] The data preprocessing scripts are released with the rest of our code.

output the sequences at the grapheme level, so the output embedding size is set to 64.

We found that this simpler speech encoder works well for our extremely small datasets. Applying our models to larger datasets with many more speakers would most likely require a more sophisticated speech encoder, such as the one used by Weiss et al. (2017).

4.3 Results

In Table 2, we present results on three small datasets that demonstrate the efficacy of our models. We compare our proposed models against three baselines and one "skyline." The first baseline is a traditional pivot approach (line 1), where the ASR output, a sequence of characters, is the input to a character-based NMT system (trained on gold transcriptions). The "skyline" model (line 2) is the same NMT system, but tested on gold transcriptions instead of ASR output. The second baseline is translation directly from source speech to target text (line 3). The last baseline is the standard *multitask* model (line 4), which is similar to the model of Weiss et al. (2017).

The *cascade* model (line 5) outperforms the baselines on the translation task, while only falling behind the *multitask* model in the transcription task. On all three datasets, the *triangle* model (lines 6, 7) outperforms all baselines, including the standard *multitask* model. On Ainu-English, we even obtain translations that are comparable to the "skyline" model, which is tested on gold Ainu transcriptions.

Comparing the performance of all models across the three datasets, there are two notable trends that verify common intuitions regarding the speech transcription and translation tasks. First, an increase in the number of speakers hurts the performance of the speech transcription tasks. The character error rates for Ainu are smaller than the CER in Mboshi, which in turn are smaller than the CER in CALLHOME. Second, the character-level BLEU scores increase as the amount of training data increases, with our smallest dataset (Ainu) having the lowest BLEU scores, and the largest dataset (CALLHOME) having the highest BLEU scores. This is expected, as more training data means that the translation decoder learns a more informed character-level language model for the target language.

Note that Weiss et al. (2017) report much higher BLEU scores on CALLHOME: our model underperforms theirs by almost 9 *word-level* BLEU points. However, their model has significantly more parameters and is trained on 10 times more data than ours. Such an amount of data would never be available in our endangered languages scenario. When calculated on the word-level, all our models' BLEU scores are between 3 and 7 points for the extremely low resource datasets (Mboshi-French and Ainu-English), and between 7 and 10 for CALLHOME. Clearly, the size of the training data in our experiments is not enough for producing high quality speech translations, but we plan to investigate the performance of our proposed models on larger datasets as part of our future work.

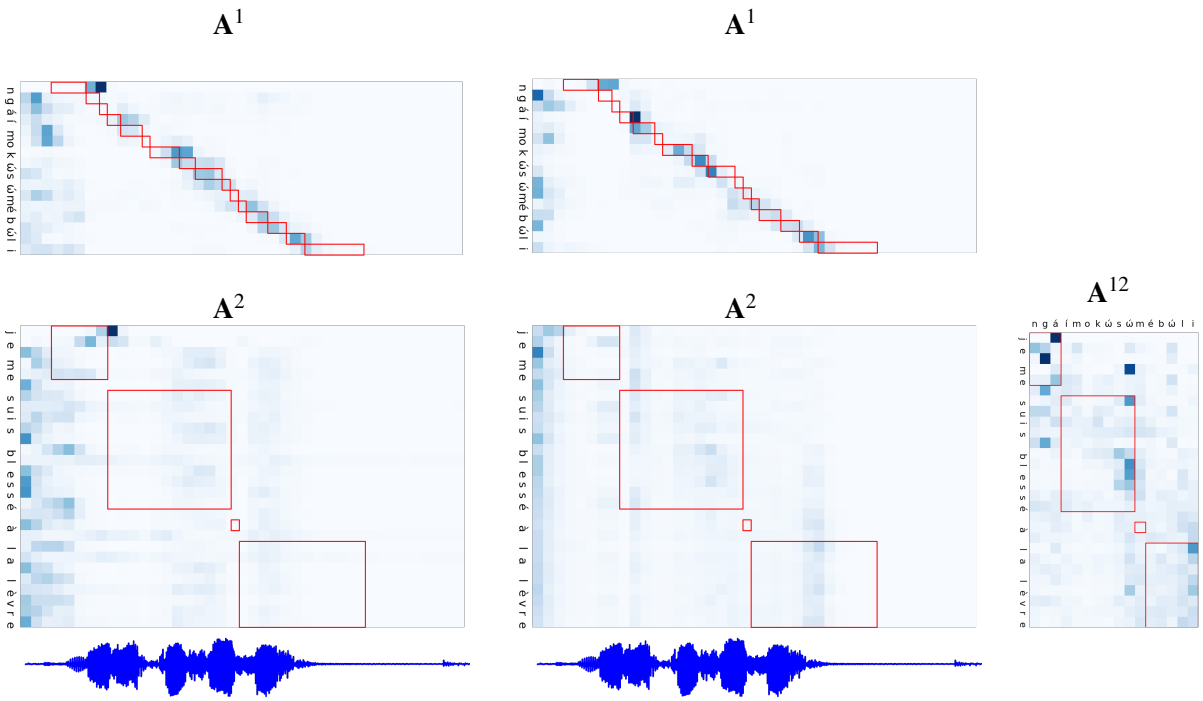
To evaluate the effect of using the combined score from both decoders at decoding time, we evaluated the *triangle* models using only the 1-best output from the speech model (lines 8, 9). One would expect that this would favor speech at the expense of translation. In transcription accuracy, we indeed observed improvements across the board. In translation accuracy, we observed a surprisingly large drop on Mboshi-French, but surprisingly little effect on the other language pairs – in fact, BLEU scores tended to go up slightly, but not significantly.

Finally, Figure 2 visualizes the attention matrices for one utterance from the baseline multitask model and our proposed *triangle* model. It is clear that our intuition was correct: the translation decoder receives most of its context from the transcription decoder, as indicated by the higher attention weights of $\mathbf{A}^{12}$. Ideally, the area under the red squares (gold alignments) would account for 100% of the attention mass of $\mathbf{A}^{12}$. In our triangle model, the total mass under the red squares is 34%, whereas the multitask model's correct attentions amount to only 21% of the attention mass.

5 Word Discovery

Although the above results show that our model gives large performance improvements, in absolute terms, its performance on such low-resource tasks leaves a lot of room for future improvement. A possible more realistic application of our methods is word discovery, that is, finding word boundaries in unsegmented phonetic transcriptions.

After training an attentional encoder-decoder model between Mboshi unsegmented phonetic se-



(a) multitask (b) triangle + transitivity

Figure 2: Attentions in an Mboshi-French sentence, extracted from two of our models. The red squares denote gold alignments. The second decoder of the *triangle* model receives most of its context from the first decoder through $\mathbf{A}^{12}$ instead of the source. The $\mathbf{A}^2$ matrix of the *triangle* model is more informed (34% correct attention mass) than the *multitask* one (21% correct), due to the *transitivity* regularizer.

quences and French word sequences, the attention weights can be thought of as soft alignments, which allow us to project the French word boundaries onto Mboshi. Although we could in principle perform word discovery directly on speech, we leave this for future work, and only explore single-task and reconstruction models.

5.1 Data

We use the same Mboshi-French corpus as in Section 4, but with the original training set of 4617 utterances and the dev set of 514 utterances. Our parallel data consist of the unsegmented phonetic Mboshi transcriptions, along with the word-level French translations.

5.2 Implementation

We first replicate the model of Boito et al. (2017), with a single-layer bidirectional encoder and single layer decoder, using an embedding and hidden size of 12 for the base model, and an embedding and hidden state size of 64 for the reverse model. In our own models, we set the embedding size to 32 for Mboshi characters, 64 for French words, and the hidden state size to 64. We smooth the attention weights $\mathbf{A}$ using the method of Duong et al. (2016) with a temperature $T = 10$ for the softmax computation of the attention mechanism.

Following Boito et al. (2017), we train models both on the *base* Mboshi-to-French direction, as well as the *reverse* (French-to-Mboshi) direction, with and without this smoothing operation. We further smooth the computed soft alignments of all models so that $a_{mn} = (a_{mn-1} + a_{mn} + a_{mn+1})/3$ as a post-processing step. From the *single-task* models we extract the $\mathbf{A}^1$ attention matrices. We also train *reconstruction* models on both directions, with and without the *invertibility* regularizer, extracting both $\mathbf{A}^1$ and $\mathbf{A}^{12}$ matrices. The two matrices are then combined so that $\mathbf{A} = \mathbf{A}^1 + (\mathbf{A}^{12})^T$.

5.3 Results

Evaluation is done both at the token and the type level, by computing precision, recall, and F-score over the discovered segmentation, with the best results shown in Table 3. We reimplemented the base (Mboshi-French) and reverse (French-Mboshi) models from Boito et al. (2017), and the performance of the base model was comparable to the one reported. However, we were unable to

Model (with smoothing)		Tokens			Types		
		Precision	Recall	F-score	Precision	Recall	F-score
Boito et al. 2017 (reported)	*base*	*5.85*	*6.82*	*6.30*	*6.76*	*15.00*	*9.32*
	reverse	*21.44*	*16.49*	*18.64*	*27.23*	*15.02*	*19.36*
Boito et al. 2017 (reimplementation)	base	6.87	6.33	6.59	6.17	13.02	8.37
	reverse	7.58	8.16	7.86	9.22	11.97	10.42

	reverse	**11.31**	**11.82**	**11.56**	9.29	14.75	11.40
reconstruction + $0.2\mathcal{L}_{\text{inv}}$		8.93	9.78	9.33	8.66	15.48	11.02
reconstruction + $0.5\mathcal{L}_{\text{inv}}$		7.42	10.00	8.52	**10.46**	16.36	**12.76**

Table 3: The reconstruction model with the *invertibility* regularizer produces more informed attentions that result in better word discovery for Mboshi with an Mboshi-French model. Scores reported by previous work are in *italics* and best scores from our experiments are in **bold**.

reproduce the significant gains that were reported when using the reverse model (*italicized* in Table 3). Also, our version of both the base and reverse singletask models performed better than our reimplementation of the baseline.

Furthermore, we found that we were able to obtain even better performance at the type level by combining the attention matrices of a reconstruction model trained with the *invertibility* regularizer. Boito et al. (2017) reported that combining the attention matrices of a base and a reverse model significantly reduced performance, but they trained the two models separately. In contrast, we obtain the base ($\mathbf{A}^1$) and the reverse attention matrices ($\mathbf{A}^{12}$) from a model that trains them jointly, while also tying them together through the *invertibility* regularizer. Using the regularizer is key to the improvements; in fact, we did not observe any improvements when we trained the reconstruction models without the regularizer.

6 Negative Results: High-Resource Text Translation

6.1 Data

For evaluating our models on text translation, we use the Europarl corpus which provides parallel sentences across several European languages. We extracted 1,450,890 three-way parallel sentences on English, French, and German. The concatenation of the newstest 2011–2013 sets (8,017 sentences) is our dev set, and our test set is the concatenation of the newstest 2014 and 2015 sets (6,003 sentences). We test all architectures on the six possible translation directions between English (en), French (fr) and German (de). All the sequences are represented by subword units with byte-pair encoding (BPE) (Sennrich et al., 2016) trained on each language with 32000 operations.

6.2 Experimental Setup

On all experiments, the encoder and the decoder(s) have 2 layers of LSTM units with hidden state size and attention size of 1024, and embedding size of 1024. For this high resource scenario, we only train for a maximum of 40 epochs.

6.3 Results

The accuracy of all the models on all six language pair directions is shown in Table 4. In all cases, the best models are the baseline single-task or simple multitask models. There are some instances, such as English-German, where the *reconstruction* or the *triangle* models are not statistically significantly different from the best model. The reason for this, we believe, is that in the case of text translation between so linguistically close languages, the lower level representations (the output of the encoder) provide as much information as the higher level ones, without the search errors that are introduced during inference.

A notable outcome of this experiment is that we do not observe the significant improvements with the *reconstruction* models that Tu et al. (2017) observed. A few possible differences between our experiment and theirs are: our models are BPE-based, theirs are word-based; we use Adam for optimization, they use Adadelta; our model has slightly fewer parameters than theirs; we test on less typologically different language pairs than

Model	$s \rightarrow t$					
	en→fr	en→de	fr→en	fr→de	de→en	de→fr
singletask	**20.92**	**12.69**	**20.96**	**11.24**	**16.10**	**15.29**

Table 4: BLEU scores for each model and translation direction $s \rightarrow t$. In the multitask, cascade, and triangle models, x stands for the third language, other than s and t. In each column, the best results are highlighted. The non-highlighted results are statistically significantly worse than the single-task baseline.

English-Chinese.

However, we also observe that in most cases our proposed regularizers lead to increased performance. The *invertibility* regularizer aids the *reconstruction* models in achiev slightly higher BLEU scores in 3 out of the 6 cases. The *transitivity* regularizer is even more effective: in 9 out the 12 source-target language combinations, the *triangle* models achieve higher performance when trained using the regularizer. Some of them are statistical significant improvements, as in the case of French to English where English is the intermediate target language and German is the final target.

7 Related Work

The speech translation problem has been traditionally approached by using the output of an ASR system as input to a MT system. For example, Ney (1999) and Matusov et al. (2005) use ASR output lattices as input to translation models, integrating speech recognition uncertainty into the translation model. Recent work has focused more on modelling speech translation without explicit access to transcriptions. Duong et al. (2016) introduced a sequence-to-sequence model for speech translation without transcriptions but only evaluated on alignment, while Anastasopoulos et al. (2016) presented an unsupervised alignment method for speech-to-translation alignment. Bansal et al. (2017) used an unsupervised term discovery system (Jansen et al., 2010) to cluster recurring audio segments into pseudowords and translate speech using a bag-of-words model. Bérard et al. (2016) translated synthesized speech data using a model similar to the Listen Attend and Spell model (Chan et al., 2016). A larger-scale study (Bérard et al., 2018) used an end-to-end neural system system for translating audio books between French and English. On a different line of work, Boito et al. (2017) used the attentions of a sequence-to-sequence model for word discovery.

Multitask learning (Caruana, 1998) has found extensive use across several machine learning and NLP fields. For example, Luong et al. (2016) and Eriguchi et al. (2017) jointly learn to parse and translate; Kim et al. (2017) combine CTC- and attention-based models using multitask models for speech transcription; Dong et al. (2015) use multitask learning for multiple language translation. Toshniwal et al. (2017) apply multitask learning to neural speech recognition in a less traditional fashion: the lower-level outputs of the speech encoder are used for fine-grained auxiliary tasks such as predicting HMM states or phonemes, while the final output of the encoder is passed to a character-level decoder.

Our work is most similar to the work of Weiss et al. (2017). They used sequence-to-sequence models to transcribe Spanish speech and translate it in English, by jointly training the two tasks in a multitask scenario where the decoders share the encoder. In contrast to our work, they use a large corpus for training the model on roughly 163 hours of data, using the Spanish Fisher and CALL-

HOME conversational speech corpora. The parameter number of their model is significantly larger than ours, as they use 8 encoder layers, and 4 layers for each decoder. This allows their model to adequately learn from such a large amount of data and deal well with speaker variation. However, training such a large model on endangered language datasets would be infeasible.

Our model also bears similarities to the architecture of the model proposed by Tu et al. (2017). They report significant gains in Chinese-English translation by adding an additional *reconstruction* decoder that attends on the last states of the *translation* decoder, mainly inspired by auto-encoders.

8 Conclusion

We presented a novel architecture for multitask learning that provides the second task with higher-level representations produced from the first task decoder. Our model outperforms both the single-task models as well as traditional multitask architectures. Evaluating on extremely low-resource settings, our model improves on both speech transcription and translation. By augmenting our models with regularizers that implement transitivity and invertibility, we obtain further improvements on all low-resource tasks.

These results will hopefully lead to new tools for endangered language documentation. Projects like BULB aim to collect about 100 hours of audio with translations, but it may be impractical to transcribe this much audio for many languages. For future work, we aim to extend these methods to settings where we don't necessarily have sentence triples, but where some audio is only transcribed and some audio is only translated.

Please Clap: Modeling Applause in Campaign Speeches

Abstract

This work examines the rhetorical techniques that speakers employ during political campaigns. We introduce a new corpus of speeches from campaign events in the months leading up to the 2016 U.S. presidential election and develop new models for predicting moments of audience applause. In contrast to existing datasets, we tackle the challenge of working with transcripts that derive from uncorrected closed captioning, using associated audio recordings to automatically extract and align labels for instances of audience applause. In prediction experiments, we find that lexical features carry the most information, but that a variety of features are predictive, including prosody, long-term contextual dependencies, and theoretically motivated features designed to capture rhetorical techniques.

1 Introduction

Every public speech involving a large audience can be seen as a game of coordination (Asch, 1951): at each moment, each individual member of the audience must decide in a split second whether to applaud at what has just been said. Applause is a potentially risky action: if an individual spontaneously claps but no one joins in, they suffer some negative social cost; the game is to judge from their own private information and content of the speech whether the rest of the audience will applaud at the same time they do.

Because of this cost, audiences respond to several interacting factors in a speaker's behavior: a.) the content of the message; b.) their delivery (so that changes in pitch, duration and gaze signal salient moments for which applause may be licensed); and c.) the verbal *design* of the message—those rhetorical strategies that speakers use to signal that applause is welcome (Atkinson, 1984; Heritage and Greatbatch, 1986).

In this work, we attempt to model all three of these dimensions in developing a computational model for applause. While past work has focused on these elements in isolation (Guerini et al., 2015; Liu et al., 2017) or for related problems such as laughter detection (Purandare and Litman, 2006; Chen and Lee, 2017; Bertero and Fung, 2016), we find that developing a holistic model encompassing all three aspects yields the most robust predictor of applause.

We focus on political speeches, and in particular those at campaign rallies, which lend themselves well to analysis of rhetorical strategies for several reasons. First, the speakers at these events prioritize maintaining the crowd's attention (Strangert, 2005). Motivated to drum up excitement and fervor among their supporters that they hope will carry beyond the event and into the voting booth, speakers pull out their strongest rhetorical tactics. Second, campaign speeches usually consist of a series of self-contained messages that can be fully expressed within a few utterances (Heritage and Greatbatch, 1986), yielding a well-defined observation of a complete rhetorical strategy. Lastly, these speeches are delivered by a single speaker to a partisan crowd, and clapping, cheering, and other responses are invited and expected.

We focus in particular in this work on operationalizating the verbal design of the speech; in so doing, one contribution we make is operationalizing the concepts of *tension* and *release*. Writers and performers often communicate with their audience on a fundamental level by building up tension, and then, at the proper time, delivering a satisfying release. These simple but pervasive concepts structure our experience of different modes of communication used throughout everyday life, including music (Madsen and Fredrickson, 1993), literature (Rabkin, 1973) and film (Carroll, 1996).

Tension in music can be built up by harmonic

Proceedings of NAACL-HLT 2018, pages 92–102
New Orleans, Louisiana, June 1 - 6, 2018.

movement away from a tonal center; release then comes with a return to that established tonic (Hindemith, 1937). One form of tension in literature is realized as suspense (Barthes and Duisit, 1975; Vorderer et al., 1996; Algee-Hewitt, 2016), in which a reader's knowledge of events is uncertain (either because those events take place in the narrative future or are withheld from narration), and released when that knowledge is revealed. In film, sudden changes in camera perspective create graphic tension, which is then released as the shot returns to a stable position (Bordwell, 2013). Often, it is the confluence of multiple sources of tension that mark the climax of a narrative (Hume, 2017). We draw on each of these strands of work in operationalizing tension and release as a rhetorical strategy.

In this work, we make the following contributions:

- We collect a new dataset of text and audio from 310 speeches from campaign events leading up to the 2016 U.S presidential election with associated tags for over 19,000 instances of audience applause.
- We introduce new textual and acoustic features inspired by tension and release, combine and compare them with features used in previous work, and deploy those features in a logistic regression model and in an LSTM to predict when applause is likely to occur. Code, data, and trained models are openly available to the public at `https://github.com/jrgillick/Applause/`.

2 Background and Previous Work

2.1 Rhetoric and Response

Heritage and Greatbatch (1986) conduct an extensive analysis of nearly 500 speeches from British political party conferences, manually associating each of over 2000 instances of applause with coded message types (e.g. External Attacks or Statements of Approval), rhetorical devices (e.g. Contrast/Antithesis or Headline-Punchline), and performance factors (e.g. speech stress or body language). They find most of these factors to be positively correlated with applause; one especially striking result is over two thirds of observed instances of applause can be explained through a set of seven rhetorical devices (including contrast, pursuit, position taking, and "the 3-part list"). Though each device is different, a common feature of most of these techniques is that they are not always carried out within a single sentence or utterance; they often depend on the relationship between a series of utterances or phrases. We argue in this work that some of these relationships can be characterized and subsequently operationalized within models as tension and release.

2.2 Predicting Applause

Recent work from Guerini et al. (2015) and Liu et al. (2017) approaches the task of applause prediction by looking at textual features of the individual sentences that immediately precede audience applause. Both follow the methodology proposed by Danescu-Niculescu-Mizil et al. (2012) in constructing a data set for binary classification, which is composed of sentences that generated applause, each paired with a single nearby sentence from the same document that did not lead to applause.

Guerini et al. (2015) examine a set of features designed to capture aspects of euphony, or "the inherent pleasantness of the sounds of words" that might make an utterance memorable or persuasive—such as rhyme, alliteration, homogeneity, and plosives. On the CORPS dataset (Guerini et al., 2013), which consists of the text of several thousand political speeches dating from 1917 to 2011, they define persuasive sentences as those that preceded annotations of either applause or laughter.

Liu et al. (2017), working with a corpus of TED talks, use logistic regression to predict applause from sentences using a combination of features: euphony (again from Guerini et al. (2015)), linguistic style markers derived from membership in LIWC categories, markers of emotional expression derived from membership in the NRC Emotion Lexicon, mentions of names, rhetorical questions (string matching for "?"), expressions of gratitude (matching a handcrafted list of word stems including "thank*" and "grateful*"), and expressions seeking applause (matching the pattern "applau*"). Liu et al. (2017) also report that adding the same features for earlier sentences beyond the final sentence that preceded the applause caused the prediction accuracy to go down. Chen and Lee (2017) and Bertero and Fung (2016) run similar binary classification experiments but pre-

dict laughter as opposed to applause. Bertero and Fung (2016) analyze punchlines from the TV sitcom "The Big Bang Theory" and report 70% accuracy using an LSTM. They touch briefly on the notion of tension and release in humor, as punchlines typically depend on a previous line as a setup in order to be funny.

3 Data

3.1 Corpus Acquisition

In this work, we focus on a new data set of campaign speeches from the 2016 U.S. presidential race, which we obtain from the public domain broadcasts of C-SPAN. We downloaded about 500 speeches from presidential candidates, vice presidential candidates, or former presidents, collecting audio files and transcripts that were tagged in the categories "Campaign 2016" and "Speech" and which took place between 12/01/2015 and 12/01/2016. We then excluded events that took place outside of a traditional campaign speech setting (e.g. town hall events) or events that contained multiple speakers without a speaker identification tied to the transcript, which yielded a final set of 310 speeches from 16 speakers. Because different types of events have different social norms around when and whether applause is appropriate (Atkinson, 1984; Heritage and Greatbatch, 1986), we control for these factors to some degree by restricting our dataset to events in similar settings and within a single year. As a point of comparison, the C-SPAN dataset contains 62 instances of applause per speech on average, whereas the CORPS data (Guerini et al., 2013) contains 13.

3.2 Applause Detection in Audio

Since our C-SPAN data originates in video, we have access to the audio information of a speech event, which we employ both for feature extraction and for automatically identifying when applause occurs. Following Clement and McLaughlin (2016), we train an acoustic model using a set of poetry readings from the PennSound archive to distinguish applause from speech. We used logistic regression on the standard set of MFCC features and found similar results on the PennSound data to the reported classification accuracy of 99.4%. In a manual inspection of 100 applause segments from 5 different speeches in the C-SPAN corpus, our applause detector achieved 92% precision, 90% recall, and 91% F1 score. Due to variation in the nature of applause in a crowd (sometimes we observe examples of isolated clapping and cheering, mixed laughter and applause, or applause interrupting the speaker), some ambiguity is inherent among the labels.

We also measure the applause by first running the speeches through the audio source separation algorithm from Chandna et al. (2017), which was trained to separate voice from music, and then measuring the RMSE loudness of the separated non-vocal track. We found that the separation worked well, qualitatively matching with the results from the applause detection classifier.

3.3 Forced Alignment

To match the identified segments of applause in the audio files with the relevant text from the transcriptions, we ran forced alignment using the Kaldi Toolkit (Povey et al., 2011). Since the C-SPAN transcripts are sourced from uncorrected closed captioning, the text contains a number of misspellings and paraphrases, which we handled by discarding the 12% of words for which forced alignment failed. Though these transcriptions are not as accurate as what we would find in professionally transcribed datasets, previous work has shown that it is possible to achieve good accuracy in downstream tasks even with high error rates in transcription (Peskin et al., 1993; Novotney and Callison-Burch, 2010). Moreover, the caliber of transcripts derived from closed captioning is representative of the data that would be available in real time for practical use at future speech events.

To estimate the accuracy of the closed captions, we manually transcribed selections from 5 speeches in the C-SPAN data totaling about 25 minutes and 2250 words, finding 30.9% WER relative to the reference transcriptions in our sample. Many of the errors are due to omitted words and phrases in the closed captions, which may occur as a result of transcribers' inability to keep up with the pace of fast speeches; in this sample, the closed caption texts contained 17% fewer words than our gold standard transcriptions.

After finding the alignments, we segmented out a list of utterances by defining a minimum period of silence between words. Since many of the transcripts do not have punctuation, we find that dividing the text into utterances yielded qualitatively more coherent units than sentence boundary detec-

Speaker	Number of Speeches	Number of Utterances	Number Applauded	Percentage
Donald Trump	86	27493	7357	0.27
Hilary Clinton	72	12825	3933	0.31
Bernie Sanders	40	10994	3529	0.32
Ted Cruz	23	5873	1041	0.18

Carly Fiorina	5	1222	129	0.11
Jeb Bush	5	1482	191	0.13
Rand Paul	4	939	134	0.14
Gary Johnson	3	354	56	0.16
Chris Christie	3	1868	42	0.022
Rick Santorum	1	245	17	0.07
Total	**310**	**80849**	**19273**	**0.24**

Table 1: Speakers and applause in C-SPAN corpus

tion. Dividing into utterances is also conducive to building a dataset for binary classification, since every pause by the speaker yields an opportunity for applause. We chose a pause length of 0.7 seconds, but in future work we might be able to improve our models by adapting this threshold to the rate of speech in order to maintain consistent phrase sizes across different speakers. Given this set of utterances, we paired each utterance with a "positive" or "negative" label, determined by whether applause occurred within 1.5 seconds of the end of the utterance. All of these preprocessing choices were made during the corpus preparation phase, prior to any experimental evaluation.

Table 1 provides summary statistics for the number of speakers, speeches, utterances, and acts of applause in our data.

4 Models

In our models, we draw features from previous work on applause or humor prediction and then supplement them with a new set of features inspired by the ideas of tension and release and by the rhetorical strategies of Heritage and Greatbatch (1986).

4.1 Features adapted from existing work

LIWC. Features for membership in 73 LIWC categories proved to be the most effective for applause prediction in TED talks (Liu et al., 2017).

Euphony. We adopt the 4 features for "euphony" defined by Guerini et al. (2015): Rhyme, Alliteration, Homogeneity, and Plosives.

Lexical. Guerini et al. (2015) find n-grams to be highly predictive of both applause and laughter. We operationalize these features with bigrams, including in our model all bigrams that appear at least 5 times in the corpus.

Embeddings. Bertero and Fung (2016) use sentence embeddings learned from a CNN encoder as input to an LSTM. We adopt this feature for use in our neural models, encoding phrases using the Skip-Thought model of Kiros et al. (2015).

Acoustic. Purandare and Litman (2006) use a set of features intended to capture elements of prosody in a model for humor prediction in television dialogue. These features include the mean, max, min, range, and standard deviation values in an utterance's pitch (F0) and energy (RMS), along with features for internal silence and for tempo. We compute the F0 statistics with Reaper (Talkin, 2015) and the energy statistics with Librosa (McFee et al., 2015).

4.2 New Features

4.2.1 Repetition

Repeated Words. Rhetorical strategies such as "The 3-part List" and "Contrast" rely on repetition to drive home important points. We capture this phenomenon by computing the proportion of words in each utterance that also appear in the immediately preceding phrase.

Longest Common Subsequence. Repeating an entire phrase, especially one with a politically charged topic, serves to build tension through the notion of "theme and variation" as is often realized

in music (Cope, 2005); an example of this phenomenon in our data can be found in the following passage:

> *We will not allow the* party of Lincoln and Reagan to fall into the hands of a con artist. *We will not allow the* next president of the United States to be a socialist like Bernie Sanders. And *we will not allow the* next president of the United States to be someone under FBI investigation like Hillary Clinton.
>
> [Marco Rubio, Mar. 1, 2016]

We calculate this theme and variation by measuring the longest common subsequence between adjacent phrases.

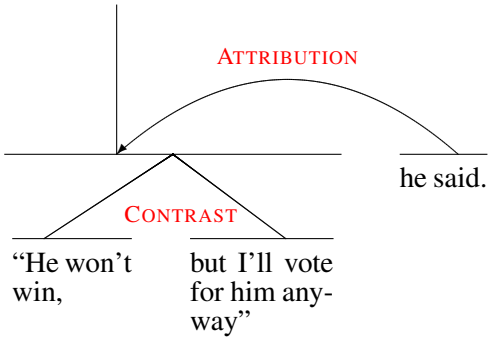
4.2.2 Deltas

Delta features (local approximations to derivatives) are commonly used in speech recognition and audio classification systems (Povey et al., 2011). In a discourse, either highly similar or drastically different neighboring pairs of utterances may indicate dramatic moments. We operationalize these features by explicitly adding a delta measurement for every feature in our model, which captures the difference between every feature at time t and the same feature at time $t-1$. For K-dimensional vector embeddings, we calculate deltas as their cosine distance.

4.2.3 RST

Rhetorical Structure Theory (RST) provides a foundation for describing the ways in which functional components of a text combine to form a coherent whole (Thompson and Mann, 1987). At the core of RST is a categorization system consisting of relations between elementary discourse units (EDUs). Relations between units are typically hierarchical (a nucleus and a satellite), but can also be defined between equally significant units (two nuclei).

A typical RST tree can be seen below, where the sentence *"He won't win, but I'll vote for him anyway", he said* is decomposed into three elementary discourse units (EDUs); those discourse units form the leaves of a tree with intermediate structure between subphrases and labeled edges along each branch.



Some of the rhetorical strategies defined by Heritage and Greatbatch (1986), such as "Contrast," map directly to RST relations, while others do not have a clear one-to-one mapping but are qualitatively similar in their descriptions. While RST has been used with success for classification problems in the past (Ji and Smith, 2017; Bhatia et al., 2015), it has not yet been employed in existing models for applause prediction. In our work, we parse the rhetorical structure of the extracted sequence of phrases using the RST parser of Ji and Eisenstein (2014). From the structure of this RST tree, we extract two classes of features.

RST label. First, we operationalize the rhetorical category for an individual elementary discourse unit. While the span of text within a single EDU is implicated in several rhetorical relations throughout the tree (as *He won't win* bears a CONTRAST relationship with *but I'll vote for him anyway* and is part of the ATTRIBUTION relationship with *he said*), each EDU bears exactly one leaf relationship with the rest of the tree—here, *He won't win* is a nucleus of a CONTRAST relationship, *but I'll vote for him anyway* is also a nucleus of a CONTRAST relationship, and *he said* is the satellite of an ATTRIBUTION relationship.

We featurize a sentence as the set of all such typed relationships that EDUs within it hold; each typed relationship is the conjunction of the label (e.g., CONTRAST, ATTRIBUTION) and directionality (Nucleus, Satellite).

Rhetorical phrase closures. In order to further operationalize the notion of predictability of applause, we measure the number of rhetorical phrases that a given discourse segment brings to *closure*. We can illustrate this with figure 1, which presents a sample RST tree with only the spans annotated (i.e., without RST labels or nucleus/satellite directed edges). This tree spans 10 elementary discourse units; each non-terminal node is annotated with the span of the subtree

rooted at that node (so the root spans all ten EDUs, while its left child spans only the first five). The final discourse unit (EDU 10) is the final EDU in three rhetorical phrases (those spanning EDUs 9-10, 6-10 and the entire discourse 1-10). We might hypothesize that the greater number of discourse phrases that a given discourse unit closes, the stronger the signal it provides that applause is licensed (and hence the greater likelihood to be followed by applause empirically). For a sentence with multiple discourse units, we featurize this value as the maximum number of rhetorical phrases closed by any unit it contains.

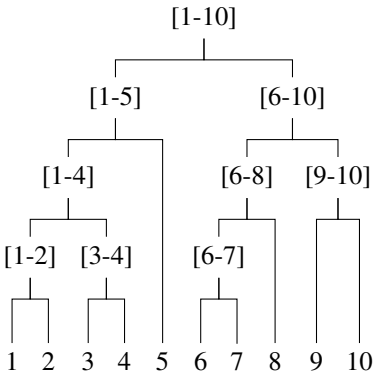


Figure 1: Unlabeled RST phrase tree; non-terminal nodes list the ranges of the elementary discourse units they span.

5 Experiments

We present two experiments to uncover the degree to which we are able to predict applause from different operationalizations of a politician's campaign speech: one in which have access to a politician's previous speeches, and can learn their specific nuances and stock phrases used to solicit applause; and another in which we seek to uncover the broader rhetorical strategies common to multiple speakers.

We refer to the following sets of features when we summarize results:

- **Guerini.** Euphony features from Guerini et al. (2015).
- **Liu.** LIWC features and additional matchers for handcrafted regular expressions from Liu et al. (2017)
- **Audio.** All acoustic features described in §4.1 above.
- **Combined.** Combination of features from Guerini, Liu, and Audio.
- **Tension.** Combination of RST (§4.2.3), repetition (§4.2.1), and delta features (§4.2.2).
- **N-gram.** Bigram features.
- **Skip-Thought.** 4800 dimensional Skip-Thought embeddings.

5.1 Intra-speaker validation

Access to a politician's previous speeches provides a great deal of evidence for understanding their rhetorical strategies for soliciting applause; speakers often give variations of the same speech at different campaign events, and rely on a fixed set of stock phrases (e.g., "Yes, We Can," "Make America Great Again") and general strategies to solicit reactions (Lu, 1999; Miller, 1939; Petrow and Sullivan, 2007). To model this, we attempt to predict a speaker's likelihood of applause using only information from their own speeches.

We use logistic regression with ℓ_2 regularization for this experiment, with hyperparameters chosen through cross-validation on the training data. We run 10-fold cross validation for each speaker, and leave-one-out cross validation for those speakers with fewer than 10 speeches (we exclude Rick Santorum from this experiment because we have only one speech from him), with whole speeches divided across folds so that no utterances from the same speech ever appear in both training and test sets. Reported results aggregate the predictions across all speakers to calculate the final accuracies. We choose utterances (or sequences of utterances) that directly precede applause as positive examples, pairing each one with a negative example randomly chosen from the same speech. Since we use different amounts of data for each speaker, we are not able to compare accuracies across all speakers, but we can see that some speakers are significantly easier to model: for example, our best model reaches 0.719 accuracy on Bernie Sanders but only 0.660 on Donald Trump.

Table 2 summarizes the results, comparing across different combinations of features as well as across a scope of a single phrase or multiple phrases. All feature combinations are scoped over a single utterance unless otherwise noted.

5.2 Inter-speaker validation

At the same time, many of the strategies identified by Heritage and Greatbatch (1986) are gener-

Model	Mean Accuracy	Mean F1	Max F1	Min F1
Guerini	0.566	0.533	0.659 (Bernie Sanders)	0.422 (Donald Trump)
Liu	0.601	0.594	0.649 (Bernie Sanders)	0.499 (Jeb Bush)
Audio	0.598	0.574	0.634 (Hilary Clinton)	0.516 (Donald Trump)
Combined	0.646	0.640	0.685 (Bernie Sanders)	0.598 (Marco Rubio)
N-gram	0.637	0.578	0.672 (Bernie Sanders)	0.478 (Barack Obama)
Combined+Tension	0.639	0.635	0.682 (Bernie Sanders)	0.585 (Jeb Bush)
Combined (3-Phrase)	0.645	0.640	0.671 (Bernie Sanders)	0.587 (Bill Clinton)
Combined+Tension (3-Phrase)	0.626	0.624	0.665 (Bernie Sanders)	0.602 (Marco Rubio)
Combined+N-gram	0.673	0.661	0.711 (Bernie Sanders)	0.600 (Marco Rubio)
Combined+Tension+N-gram	0.671	0.658	0.711 (Bernie Sanders)	0.599 (Marco Rubio)

Table 2: Intra-speaker predictive accuracy (logistic regression). The 95% confidence interval for Mean Accuracy and Mean F1 is within $\pm$ 0.005, and the 95% confidence interval for Max F1 and Min F1 (1 speaker at a time) is within $\pm$ 0.05.

alized rhetorical devices used to solicit applause; we should expect then that a model trained on a fixed set of speakers should be able to generalize to speakers not in the training data. To test this more realistic scenario, we performed K-fold cross-validation on all of the speakers in our dataset, holding out one speaker in turn for each fold (so that the same speaker did not appear in the training and test partitions).

In this experiment, we use both logistic regression and neural models (sharing training data between speakers has the added benefit of allowing us enough data to reasonably train a neural model). All logistic regression models were trained in the same way is in the intra-speaker case. Our feed-forward and LSTM models use a hidden state size of 100 for models including phrase embeddings (4800 dimensions) and a hidden state of size 25 for models without phrase embeddings. All LSTM models use a standard formulation of attention (Bahdanau et al., 2014), and all neural models are trained with dropout (Srivastava et al., 2014) and the ADAM optimizer (Kingma and Ba, 2014). We implemented the models using Keras (Chollet et al., 2015) and Tensorflow (Abadi et al., 2016).

Table 3 summarizes these results, and table 4 shows the coefficients for the most significant features.

Logistic Regression Models	Acc.	F1
Guerini	0.557	0.534
Liu	0.577	0.541
Audio	0.573	0.548
Combined	0.615	0.601
N-gram	0.594	0.578
Combined+Tension	0.617	0.605
Combined (3-Phrase)	0.614	0.601
Combined+Tension (3-Phrase)	0.615	0.600
Combined+N-gram	0.633	0.598
Combined+Tension+N-gram	0.630	0.594
Neural Models	**Acc.**	**F1**
Feed-Forward:Skip-Thought	0.577	0.562
Feed-Forward:Combined+Tension	0.620	0.620
LSTM:Skip-Thought(3-Phrase)	0.585	0.583
LSTM:Combined+Tension(3-Phrase)	0.626	0.616
LSTM:Combined+Tension(5-Phrase)	0.628	0.625
LSTM:Combined+Tension(8-Phrase)	0.629	0.621

6 Analysis

Each of the feature classes we operationalize offers some ability to recognize what Heritage and Greatbatch (1986) term the "projectability" of applause—the ability of an audience to see an applaudable moment on the horizon.

Audio. Perhaps not surprising in retrospect is the ability of acoustic features (only summary statistics of the pitch and energy) to solicit applause: higher pitch and energy, and a broader pitch range are all predictive of applause; while past work has focused on textual indicators of applause, these results suggest that *how* a message is delivered is equally important.

Lexical. The use of explicit n-grams improves performance significantly in the intra-speaker setting, where they are able to capture stock phrases employed by the same speaker at different events. N-grams are also predictive across different speakers, though the performance gains are not as high in the inter-speaker setting.

The strongest bigrams predictive of applause include moral declaratives like *should not* (e.g., "and billionaires **should not** be able to buy elections" [Bernie Sanders]), *right to* ("you have a **right to** be angry" [Marco Rubio]), and *should be* ("They should be ashamed of that kind of behavior" [Hillary Clinton]); call-outs to the audience such as *this room* ("Love the people in **this room**"

Significant Features	Coefficient
Expression of Gratitude	0.472
LIWC FOCUSFUTURE	0.340
Homogeneity (Guerini)	0.301
Mean Energy (Audio)	0.293
LIWC BODY	0.203
Min Energy (Audio)	0.165
Max Pitch (Audio)	0.157
LIWC TENTATIVE	-0.161
LIWC THEY	-0.172
LIWC VERB	-0.216
LIWC FUNCTION	-0.228
Pitch Standard Deviation (Audio)	-0.249
LIWC SHEHE	-0.275
LIWC FOCUSPAST	-0.342

Table 4: Most significant positive and negative features for the Combined+Tension regression model in the inter-speaker setting.

[Donald Trump]) and *listening to* ("our campaign is **listening to** our Latino brothers and sisters" [Bernie Sanders]); and politically charged topics such as *political revolution*, *equal pay*, *immigration reform*, *planned parenthood*, *campaign contributors* and *police officers*.

LIWC. Among broader lexical category features, we see the LIWC FOCUSFUTURE category strongly indicative of applause; this category includes auxilaries like *will, going, gonna* (including conjunctions *I'll*) and future-oriented verbs like *anticipate*; also important are categories of BODY (including *heart, hands, brain*) and REWARD (including *succeed, optimism, great*).

Rhetorical. While RST features were not as predictive for applause as other (likely correlated) features, we still see a strong alignment between the RST features most associated with applause and those rhetorical devices outlined by Heritage and Greatbatch (1986): in particular, a clear relationship between applause and the RST category of ANTITHESIS (a contrastive relation between two discourse units with a clear nucleus and satellite, rather than two equal nuclei) and PURPOSE (a relation between a discourse unit that must take place in order for another to be realized). As expected, phrases that close more discourse units tend to be more predictive of applause.

Contextual. Though lexical features from the final utterance significantly outweigh the effects of previous context in the intra-speaker setting, in the inter-speaker case we leveraged gains from long-term context in the LSTM to reach a similar level of performance attained from the lexical features, but without access to lexical cues provided by the n-grams at all. This result suggests that the improved performance in the intra-speaker setting may be largely due to the presence of specific words and catch-phrases; the other stylistic features are more easily generalized to new speakers.

7 "Please clap"

As a further measure of out-of-sample validity, we can analyze the predictions we make for the single example where a speaker wears his communicative intent on his sleeve. On February 2, 2016, presidential candidate Jeb Bush spoke to a crowd in New Hampshire a week before their state primary. His speech ended with the following:

> So here's my pledge to you. [I] will be a commander-in-chief who will have the back of the military, I won't trash talk, I won't be a divider-in-chief or an agitator-in-chief, I won't be out there blowharding talking a big game without backing it up; I think the next President needs to be a lot quieter but send a signal that we're prepared to act in the national security interests of this country to get back in the business of creating a more peaceful world . . . . . Please clap.
>
> [Jeb Bush, Feb 2, 2016][1]

Bush's admonition to the audience ("please clap") earned criticism in news coverage at the time (Benen, 2016), but also presents us with a rare insight into a speaker's true rhetorical intention; in this case, Bush was soliciting applause and was vocal about not being able to do so.

Does our model recover this true intention? Indeed it does; while the opening *So here's my pledge to you* is predicted to not solicit applause (with applause probability of 24.8%), the segment that ends with *peaceful world* is strongly predicted to have been followed by applause (with an applause probability of 94.5%). The strongest features are again lexical (*this country*, *commander in chief*), a LIWC focus on the future (elicited by *will*), and an RST PURPOSE relation (evoked by *to get back in the business of creating a more peaceful world*).

8 Conclusion

We present in this work a new dataset for the analysis of political rhetoric derived from the public campaign speeches of politicians during the 2016 United States presidential election, along with empirical results assessing the performance of different operationalizations of rhetoric derived from the theoretical work of Heritage and Greatbatch (1986) and others in order to measure and predict the occurrence of applause. We introduce several new features designed to capture elements of tension and release in public performance, including rhetorical contrast, closure, repetition and movement across speech segments; while each of these features in isolation is able to predict applause to varying degree and comport with our prior understanding of their utility, we find that lexicalized features are among the strongest source of information in determining applause; while audiences react to many dimensions of a speaker's style, the words they use—as slogan, stock phrases, and indicators of more complex rhetorical functions like moral valuations and imperatives—matter most.

As detailed in previous work (Liu et al., 2017; Haider et al., 2017; Clement and McLaughlin, 2016), understanding and identifying climactic moments in speeches can be useful for a variety of reasons, including learning to give better talks, automatically summarizing videos and transcripts, and analyzing social dynamics within crowds. One additional interesting application of this work is to bring to the surface occasions where a speaker uses typical applause-seeking devices but does not receive applause (the "Please Clap" moments); we leave to future work identifying the reverse, when speakers receive applause without invoking common techniques (for example, to identify instances of *claques* paid to clap).

9 Acknowledgments

Abstract

We present a neural architecture for modeling argumentative dialogue that explicitly models the interplay between an Opinion Holder's (OH's) reasoning and a challenger's argument, with the goal of predicting if the argument successfully changes the OH's view. The model has two components: (1) *vulnerable region detection*, an attention model that identifies parts of the OH's reasoning that are amenable to change, and (2) *interaction encoding*, which identifies the relationship between the content of the OH's reasoning and that of the challenger's argument. Based on evaluation on discussions from the Change My View forum on Reddit, the two components work together to predict an OH's change in view, outperforming several baselines. A posthoc analysis suggests that sentences picked out by the attention model are addressed more frequently by successful arguments than by unsuccessful ones.[1]

1 Introduction

Through engagement in argumentative dialogue, interlocutors present arguments with the goals of winning the debate or contributing to the joint construction of knowledge. Especially modeling the knowledge co-construction process requires understanding of both the substance of viewpoints and how the substance of an argument connects with what it is arguing against. Prior work on argumentation in the NLP community, however, has focused mainly on the first goal and has often reduced the concept of a viewpoint as a discrete side (e.g., pro vs against, or liberal vs conservative), missing more nuanced and complex details of viewpoints. In addition, while the strength of the argument and the side it represents have been addressed relatively often, the dialogical aspects of argumentation have received less attention.

To bridge the gap, we present a model that jointly considers an Opinion Holder's (OH's) expressed viewpoint with a challenger's argument in order to predict if the argument succeeded in altering the OH's view. The first component of the architecture, **vulnerable region detection**, aims to identify important parts in the OH's reasoning that are key to impacting their viewpoint. The intuition behind our model is that addressing certain parts of the OH's reasoning often has little impact in changing the OH's view, even if the OH realizes the reasoning is flawed. On the other hand, some parts of the OH's reasoning are more open to debate, and thus, it is reasonable for the model to learn and attend to parts that have a better chance to change an OH's view when addressed.

The second component of the architecture, **interaction encoding**, aims to identify the connection between the OH's sentences and the challenger's sentences. Meaningful interaction in argumentation may include agreement/disagreement, topic relevance, or logical implication. Our model encodes the interaction between every pair of the OH's and the challenger's sentences as interaction embeddings, which are then aggregated and used for prediction. Intuitively, the interactions with the most vulnerable regions of the OH's reasoning are most critical. Thus, in our complete model, the interaction embeddings are weighted by the vulnerability scores computed in the first component.

We evaluate our model on discussions from the Change My View forum on Reddit, where users (OHs) post their views on various issues, partic-

New Orleans, Louisiana, June 1 - 6, 2018.

ipate in discussion with challengers who try to change the OH's view, and acknowledge when their views have been impacted. Particularly, we aim to answer the following questions:

- RQ1. Does the architecture of vulnerable region detection and interaction encoding help to predict changes in view?
- RQ2. Can the model identify vulnerable sentences, which are more likely to change the OH's view when addressed? If so, what properties constitute vulnerability?
- RQ3. What kinds of interactions between arguments are captured by the model?

We use our model to predict whether a challenger's argument has impacted the OH's view and compare the result with several baseline models. We also present a posthoc analysis that illuminates the model's behavior in terms of vulnerable region detection and meaningful interaction.

For the remainder of the paper, we position our work in the literature (Section 2) and examine the data (Section 3). Then we explain our model design (Section 4). Next, we describe the experiment settings (Section 5), discuss the results (Section 6), and conclude the paper (Section 7).

2 Background

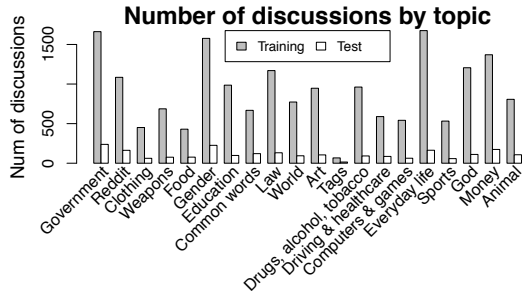
Argumentation theories have identified important dialogical aspects of (non-)persuasive argumentation, which motivate our attempt to model the interaction of OH's and challenger's arguments. Persuasive arguments build on the hearer's accepted premises (Walton, 2008) and appeal to emotion effectively (Aristotle and Kennedy, 2007). From a challenger's perspective, effective strategies for these factors could be derived from the OH's background and reasoning. On the other hand, non-persuasive arguments may commit fallacies, such as contradicting the OH's accepted premises, diverting the discussion from the relevant and salient points suggested by the OH, failing to address the issues in question, misrepresenting the OH's reasoning, and shifting the burden of proof to the OH by asking a question (Walton, 2008). These fallacies can be identified only when we can effectively model how the challenger argues in relation to the OH's reasoning.

While prior work in the NLP community has studied argumentation, such as predicting debate winners (Potash and Rumshisky, 2017; Zhang et al., 2016; Wang et al., 2017; Prabhakaran et al., 2013) and winning negotiation games (Keizer et al., 2017), this paper addresses a different angle: predicting whether an argument against an OH's reasoning will successfully impact the OH's view. Some prior work investigates factors that underlie viewpoint changes (Tan et al., 2016; Lukin et al., 2017; Hidey et al., 2017; Wei et al., 2016), but none target our task of identifying the specific arguments that impact an OH's view.

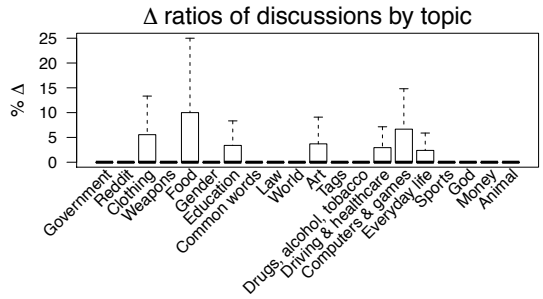
Changing an OH's view depends highly on argumentation quality, which has been the focus of much prior work. Wachsmuth et al. (2017) reviewed theories of argumentation quality assessment and suggested a unified framework. Prior research has focused mainly on the presentation of an argument and some aspects in this framework without considering the OH's reasoning. Specific examples include politeness, sentiment (Tan et al., 2016; Wei et al., 2016), grammaticality, factuality, topic-relatedness (Habernal and Gurevych, 2016b), argument structure (Niculae et al., 2017), topics (Wang et al., 2017), and argumentative strategies (e.g., anecdote, testimony, statistics) (Al Khatib et al., 2017). Some of these aspects have been used as features to predict debate winners (Wang et al., 2017) and view changes (Tan et al., 2016). Habernal and Gurevych (2016a) used crowdsourcing to develop an ontology of reasons for strong/weak arguments.

The persuasiveness of an argument, however, is highly related to the OH's reasoning and how the argument connects with it. Nonetheless, research on this relationship is quite limited in the NLP community. Existing work uses word overlap between the OH's reasoning and an argument as a feature in predicting the OH's viewpoint (Tan et al., 2016). Some studies examined the relationship between the OH's personality traits and receptivity to arguments with different topics (Ding and Pan, 2016) or degrees of sentiment (Lukin et al., 2017).

The most relevant to our work is the related task by Tan et al. (2016). Their task used the same discussions from the Change My View forum as in our work and examined various stylistic features (sentiment, hedging, question marks, etc.) and word overlap features to identify discussions that impacted the OH's view. However, our task is different from theirs in that they made predictions on



(a) Number of discussions by topic.



(b) Delta ratios in discussions by topic. (e.g., a discussion has a 10% ratio if 10% of the OH's replies have a Δ.)

Figure 1: Discussion characteristics by topic.

Opinion Holder (OH)

CMV: DNA tests (especially for dogs) are bullshit. For my line of work (which is not the DNA testing), … I have NEVER seen a DNA test return that a dog is purebred, or even anywhere close to purebred. … these tests are consistently way off on their results. … **My mother recently had a DNA test done showing she is 1/4 black.** I believe this is also incorrect since she knows who her parents and grandparents are, and none of them are black. …

Challenger 1

I'm not sure what exactly these particular DNA tests are looking at, but they are probably analyzing either SNPs or VNTRs. There's nothing stopping a SNP from mutating at any given generation, or a VNTR from shrinking or expanding due to errors during DNA replication. … **The take-home message is that DNA testing isn't complete bullshit, but it does have limitations.**

Challenger 2

Knowing your grandparents "aren't black" doesn't really rule out being 25% African American, genetically, because genes combine during fertilization almost completely randomly. … Basically, the biggest conclusion from this information is that **race is only barely genetic. It's mostly a social construct.**

Figure 2: A discussion from Change My View.

initial comments only, while we did so for all comments replied to by the OH in each discussion. Our task is more challenging because comments that come later in a discussion have a less direct connection to the original post. Another challenge is the extreme skew in class distribution in our data, whereas Tan et al. (2016) ensured a balance between the positive and negative classes.

The Change My View forum has received attention from recent studies. For example, *ad hominem* (attacking an arguer) arguments have been studied, along with their types and causes (Habernal et al., 2018). Another study annotated semantic types of arguments and analyzed the relationship between semantic types and a change in view (Hidey et al., 2017). Although this work did not look at the interaction between OHs and specific challengers, it provides valuable insight into persuasive arguments. Additionally, the semantic types may potentially allow our model to better model complex interaction in argumentation.

3 Data

Our study is based on discussions from the Change My View (CMV) forum[2] on Reddit. In this forum, users (opinion holders, OHs) post their views on a wide range of issues and invite other users (challengers) to change their expressed viewpoint. If an OH gains a new insight after reading a comment, he/she replies to that comment with a Δ symbol and specifies the reasons behind his/her view change. DeltaBot monitors the forum and marks comments that received a Δ, which we will use as labels indicating whether the comment successfully changed the OH's view.

CMV discussions provide interesting insights into how people accept new information through argumentation, as OHs participate in the discussions with the explicit goal of exposing themselves to new perspectives. In addition, the rules and moderators of this forum assure high quality discussions by requiring that OHs provide enough reasoning in the initial post and replies.

We use the CMV dataset compiled by Tan et al. (2016)[3]. The dataset is composed of 18,363 discussions from January 1, 2013–May 7, 2015 for training data and 2,263 discussions from May 8–September 1, 2015 for test data.

[2] https://www.reddit.com/r/changemyview

[3] https://chenhaot.com/pages/changemyview.html

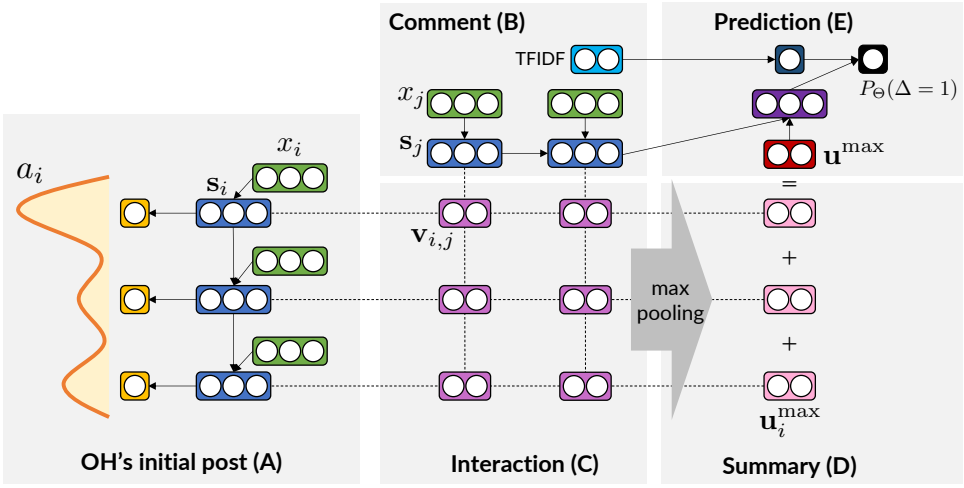


Figure 3: Architecture of Attentive Interaction Model.

Qualitative analysis We conducted qualitative analysis to better understand the data. First, to see if there are topical effects on changes in view, we examined the frequency of view changes across different topics. We ran Latent Dirichlet Allocation (Blei et al., 2003) with 20 topics, taking each discussion as one document. We assigned each discussion the topic that has the highest standardized probability. The most discussed topics are government, gender, and everyday life (Figure 1a). As expected, the frequency of changes in view differs across topics (Figure 1b). The most malleable topics are food, computers & games, clothing, art, education, and everyday life. But even in the food domain, OHs give out a Δ in less than 10% of their replies in most discussions.

In order to inform the design of our model, we sampled discussions not in the test set and compared comments that did and did not receive a Δ. A common but often unsuccessful argumentation strategy is to correct detailed reasons and minor points of the OH's reasoning—addressing those points often has little effect, regardless of the validity of the points. On the contrary, successful arguments usually catch incomplete parts in the OH's reasoning and offer another way of looking at an issue without threatening the OH. For instance, in the discussion in Figure 2, the OH presents a negative view on DNA tests, along with his/her reasoning and experiences that justify the view. Challenger 1 addresses the OH's general statement and provides a new fact, which received a Δ. On the other hand, Challenger 2 addresses the OH's issue about race but failed to change the OH's view.

When a comment addresses the OH's points, its success relies on various interactions, including the newness of information, topical relatedness, and politeness. For example, Challenger 1 provides new information that is topically dissimilar to the OH's original reasoning. In contrast, Challenger 2's argument is relatively similar to the OH's reasoning, as it attempts to directly correct the OH's reasoning. These observations motivate the design of our Attentive Interaction Model, described in the next section.

4 Model Specification

Our **Attentive Interaction Model** predicts the probability of a comment changing the OH's original view, $P(\Delta = 1)$, given the OH's initial post and the comment. The architecture of the model (Figure 3) consists of detecting vulnerable regions in the OH's post (sentences important to address to change the OH's view), embedding the interactions between every sentence in the OH's post and the comment, summarizing the interactions weighted by the vulnerability of OH sentences, and predicting $P(\Delta = 1)$.

The main idea of our model is the architecture for capturing interactions in vulnerable regions, rather than methods for measuring specific argumentation-related features (e.g., agreement/disagreement, contraction, vulnerability, etc.). To better measure these features, we need much richer information than the dataset provides (discussion text and Δs). Therefore, our proposed architecture is not to replace prior work on argumentation features, but rather to complement it at a higher, architectural level that can poten-

tially integrate various features. Moreover, our architecture serves as a lens for analyzing the vulnerability of OH posts and interactions with arguments.

Formal definition of the model (Figure 3 (A) and (B)) Denote the OH's initial post by $d^O = (x_1^O, ..., x_{M^O}^O)$, where x_i is the ith sentence, and M^O is the number of sentences. The sentences are encoded via an RNN, yielding a hidden state for the ith sentence $\mathbf{s}_i^O \in \mathbb{R}^{D^S}$, where D^S is the dimensionality of the hidden states. Similarly, for a comment $d^C = (x_1^C, ..., x_{M^C}^C)$, hidden states of the sentences $\mathbf{s}_j^C, j = 1, \cdots, M^C$, are computed.

Vulnerable region detection (Figure 3 (A)) Given the OH's sentences, the model computes the vulnerability of the ith sentence $g(\mathbf{s}_i^O) \in \mathbb{R}^1$ (e.g., using a feedforward neural network). From this vulnerability, the attention weight of the sentence is calculated as

$$a_i = \frac{\exp g(\mathbf{s}_i^O)}{\sum_{i'=1}^{M^O} \exp g(\mathbf{s}_{i'}^O)}.$$

Interaction encoding (Figure 3 (C)) The model computes the interaction embedding of every pair of the OH's ith sentence and the comment's jth sentence,

$$\mathbf{v}_{i,j} = \mathbf{h}(\mathbf{s}_i^O, \mathbf{s}_j^C) \in \mathbb{R}^{D^I},$$

where D^I is the dimensionality of interaction embeddings, and $\mathbf{h}$ is an interaction function between two sentence embeddings. $\mathbf{h}$ can be a simple inner product (in which case $D^I = 1$), a feedforward neural network, or a more complex network. Ideally, each dimension of $\mathbf{v}_{i,j}$ indicates a particular type of interaction between the pair of sentences.

Interaction summary (Figure 3 (D)) Next, for each of the OH's sentences, the model summarizes what types of meaningful interaction occur with the comment's sentences. That is, given all interaction embeddings for the OH's ith sentence, $\mathbf{v}_{i,1}, \cdots, \mathbf{v}_{i,M^C}$, the model conducts max pooling for each dimension,

$$\mathbf{u}_i^{\max} = \left(\max_j(\mathbf{v}_{i,j,1}), \cdots, \max_j(\mathbf{v}_{i,j,D^I}) \right),$$

where $\mathbf{v}_{i,j,k}$ is the kth dimension of $\mathbf{v}_{i,j}$ and $\mathbf{u}_i^{\max} \in \mathbb{R}^{D^I}$. Intuitively, max pooling is to capture the existence of an interaction and its highest intensity for each of the OH's sentences—the interaction does not have to occur in all sentences of the comment. Since we have different degrees of interest in the interactions in different parts of the OH's post, we take the attention-weighted sum of $\mathbf{u}_i^{\max}$ to obtain the final summary vector

$$\mathbf{u}^{\max} = \sum_{i=1}^{M^O} a_i \mathbf{u}_i^{\max}.$$

Prediction (Figure 3 (E)) The prediction component consists of at least one feedforward neural network, which takes as input the summary vector $\mathbf{u}^{\max}$ and optionally the hidden state of the last sentence in the comment $\mathbf{s}_{M^C}$. More networks may be used to integrate other features as input, such as TFIDF-weighted n-grams of the comment. The outputs of the networks are concatenated and fed to the final prediction layer to compute $P(\Delta = 1)$. Using a single network that takes different kinds of features as input does not perform well, because the features are in different spaces, and linear operations between them are probably not meaningful.

Loss The loss function is composed of binary cross-entropy loss and margin ranking loss. Assume there are total N^D initial posts written by OHs, and the lth post has N_l comments. The binary cross-entropy of the lth post and its tth comment measures the similarity between the predicted $P(\Delta = 1)$ and the true Δ as:

$$\begin{aligned} BCE_{l,t} = &- \Delta_{l,t} \log P_\Theta(\Delta_{l,t} = 1) \\ &- (1 - \Delta_{l,t}) \log(1 - P_\Theta(\Delta_{l,t} = 1)), \end{aligned}$$

where $\Delta_{l,t}$ is the true $\Delta \in \{0, 1\}$ of the comment and P_Θ is the probability predicted by our model with parameters Θ. Since our data is skewed to negatives, the model may overpredict $\Delta = 0$. To adjust this bias, we use margin ranking loss to drive the predicted probability of positives to be greater than the predicted probability of negatives to a certain margin. The margin ranking loss is defined on a pair of comments C_1 and C_2 with $\Delta_{C_1} > \Delta_{C_2}$ as:

$$\begin{aligned} &MRL_{C_1,C_2} = \\ &\quad \max\{0, P_\Theta(\Delta_{C_2} = 1) - P_\Theta(\Delta_{C_1} = 1) + \epsilon\}, \end{aligned}$$

where ϵ is a margin. Combining the two losses, our final loss is

$$\frac{1}{N^D} \sum_{l=1}^{N^D} \frac{1}{N_l} \sum_{t=1}^{N_l} BCE_{l,t} + \mathbb{E}_{C_1,C_2}\left[MRL_{C_1,C_2}\right].$$

	Train	Val	Test	CD
# discussions	4,357	474	638	1,548
# pairs	42,710	5,153	7,356	18,909
# positives	1,890	232	509	1,097

Table 1: Data statistics. (CD: cross-domain test)

For the expectation in the ranking loss, we consider all pairs of comments in each minibatch and take the mean of their ranking losses.

5 Experiment

Our task is to predict whether a comment would receive a Δ, given the OH's initial post and the comment. We formulate this task as binary prediction of $\Delta \in \{0, 1\}$. Since our data is highly skewed, we use as our evaluation metric the AUC score (Area Under the Receiver Operating Characteristic Curve), which measures the probability of a positive instance receiving a higher probability of $\Delta = 1$ than a negative instance.

5.1 Data Preprocessing

We exclude (1) DeltaBot's comments with no content, (2) comments replaced with *[deleted]*, (3) system messages that are included in OH posts and DeltaBot's comments, (4) OH posts that are shorter than 100 characters, and (5) discussions where the OH post is excluded. We treat the title of an OH post as its first sentence. After this, every comment to which the OH replies is paired up with the OH's initial post. A comment is labeled as $\Delta = 1$ if it received a Δ and $\Delta = 0$ otherwise. Details are described in Appendix B.

The original dataset comes with training and test splits (Figure 1a). After tokenization and POS tagging with Stanford CoreNLP (Manning et al., 2014), our vocabulary is restricted to the most frequent 40,000 words from the training data. For a validation split, we randomly choose 10% of training discussions for each topic.

We train our model on the seven topics that have the highest Δ ratios (Figure 1b). We test on the same set of topics for in-domain evaluation and on the other 13 topics for cross-domain evaluation. The main reason for choosing the most malleable topics is that these topics provide more information about people learning new perspectives, which is the focus of our paper. Some statistics of the resulting data are in Table 1.

5.2 Inputs

We use two basic types of inputs: sentence embeddings and TFIDF vectors. These basic inputs are by no means enough for our complex task, and most prior work utilizes higher-level features (politeness, sentiment, etc.) and task-specific information. Nevertheless, our experiment is limited to the basic inputs to minimize feature engineering and increase replicability, but our model is general enough to incorporate other features as well.

Sentence embeddings Our input sentences x are sentence embeddings obtained by a pretrained sentence encoder (Conneau et al., 2017) (this is different from the sentence encoder in our model). The pretrained sentence encoder is a BiLSTM with max pooling trained on the Stanford Natural Language Inference corpus (Bowman et al., 2015) for textual entailment. Sentence embeddings from this encoder, combined with logistic regression on top, showed good performance in various transfer tasks, such as entailment and caption-image retrieval (Conneau et al., 2017).

TFIDF A whole post or comment is represented as a TFIDF-weighted bag-of-words, where IDF is based on the training data. We consider the top 40,000 n-grams ($n = 1, 2, 3$) by term frequency.

Word Overlap Although integration of handcrafted features is behind the scope of this paper, we test the word overlap features between a comment and the OH's post, introduced by Tan et al. (2016), as simple proxy for the interaction. For each comment, given the set of its words C and that of the OH's post O, these features are defined as $\left[|C \cap O|, \frac{|C \cap O|}{|C|}, \frac{|C \cap O|}{|O|}, \frac{|C \cap O|}{|C \cup O|}\right]$.

5.3 Model Setting

Network configurations For sentence encoding, Gated Recurrent Units (Cho et al., 2014) with hidden state sizes 128 or 192 are explored. For attention, a single-layer feedforward neural network (FF) with one output node is used. For interaction encoding, we explore two interaction functions: (1) the inner product of the sentence embeddings and (2) a two-layer FF with 60 hidden nodes and three output nodes with a concatenation of the sentence embeddings as input. For prediction, we explore (1) a single-layer FF with either one output node if the summary vector $\mathbf{u}^{\max}$ is the only input or 32 or 64 output nodes with ReLU activation

if the hidden state of the comment's last sentence is used as input, and optionally (2) a single-layer FF with 1 or 3 output nodes with ReLU activation for the TFIDF-weighted n-grams of the comment. The final prediction layer is a single-layer FF with one output node with sigmoid activation that takes the outputs of the two networks above and optionally the word overlap vector. The margin ϵ for the ranking margin loss is 0.5. Optimization is performed using AdaMax with the initial learning rate 0.002, decayed by 5% every epoch. Training stops after 10 epochs if the average validation AUC score of the last 5 epochs is lower than that of the first 5 epochs; otherwise, training runs 5 more epochs. The minibatch size is 10.

Input configurations The prediction component of the model takes combinations of the inputs: MAX ($\mathbf{u}^{\max}$), HSENT (the last hidden state of the sentence encoder $\mathbf{s}^C_{MC}$), TFIDF (TFIDF-weighted n-grams of the comment), and WDO (word overlap).

5.4 Baseline

The most similar prior work to ours (Tan et al., 2016) predicted whether an OH would ever give a Δ in a discussion. The work used logistic regression with bag-of-words features. Hence, we also use logistic regression as our baseline to predict $P(\Delta = 1)$. Simple logistic regression using TFIDF is a relatively strong baseline, as it beat more complex features in the aforementioned task.

Model configurations Different regularization methods (L1, L2), regularization strengths ($2^\wedge\{-1, 0, 1, 2\}$), and class weights for positives (1, 2, 5) are explored. Class weights penalize false-negatives differently from false-positives, which is appropriate for the skewed data.

Input configurations The model takes combinations of the inputs: TFIDF (TFIDF-weighted n-grams of the comment), TFIDF (+OH) (concatenation of the TFIDF-weighted n-grams of the comment and the OH's post), WDO (word overlap), and SENT (the sum of the input sentence embeddings of the comment).

6 Results

Table 2 shows the test AUC scores for the baseline and our model in different input configurations. For each configuration, we chose the optimal parameters based on validation AUC scores.

Model	Inputs	ID	CD
LR	SENT	62.8	62.5
LR	TFIDF (+OH)	69.5	69.1
LR	TFIDF	70.9	**69.6**
LR	SENT+TFIDF	64.0	63.1
LR	TFIDF+WDO	71.1	69.5
AIM	MAX	70.5	67.5
AIM	MAX+TFIDF	**72.0***	69.4
AIM	MAX+TFIDF+WDO	70.9	68.4
(A)IM	HSENT	69.6	67.6
(A)IM	HSENT+TFIDF	69.0	67.6
(A)IM	MAX+TFIDF	69.5	68.1

Table 2: AUC scores. (ID: in-domain AUC (%), CD: cross-domain AUC (%), LR: logistic regression, AIM: Attention Interaction Model, (A)IM: AIM without attention.) *: $p < 0.05$ using the DeLong test compared to LR with TFIDF.

RQ1. Does the architecture of vulnerable region detection and interaction encoding help to predict changes in view? Both interaction information learned by our model and surface-level n-grams in TFIDF have strong predictive power, and attending to vulnerable regions helps. The highest score is achieved by our model (AIM) with both MAX and TFIDF as input (72.0%). The performance drops if the model does not use interaction information—(A)IM with HSENT (69.6%)—or vulnerability information—(A)IM with MAX+TFIDF (69.5%).

TFIDF by itself is also a strong predictor, as logistic regression with TFIDF performs well (70.9%). There is a performance drop if TFIDF is not used in most settings. This is unsurprising because TFIDF captures some topical or stylistic information that was shown to play important roles in argumentation in prior work (Tan et al., 2016; Wei et al., 2016). Simply concatenating both comment's and OH's TFIDF features does not help (69.5%), most likely due to the fact that a simple logistic regression does not capture interactions between features.

When the hand-crafted word overlap features are integrated to LR, the accuracy is increased slightly, but the difference is not statistically significant compared to LR without these features nor to the best AIM configuration. These features do not help AIM (70.9%), possibly because the information is redundant, or AIM requires a more de-

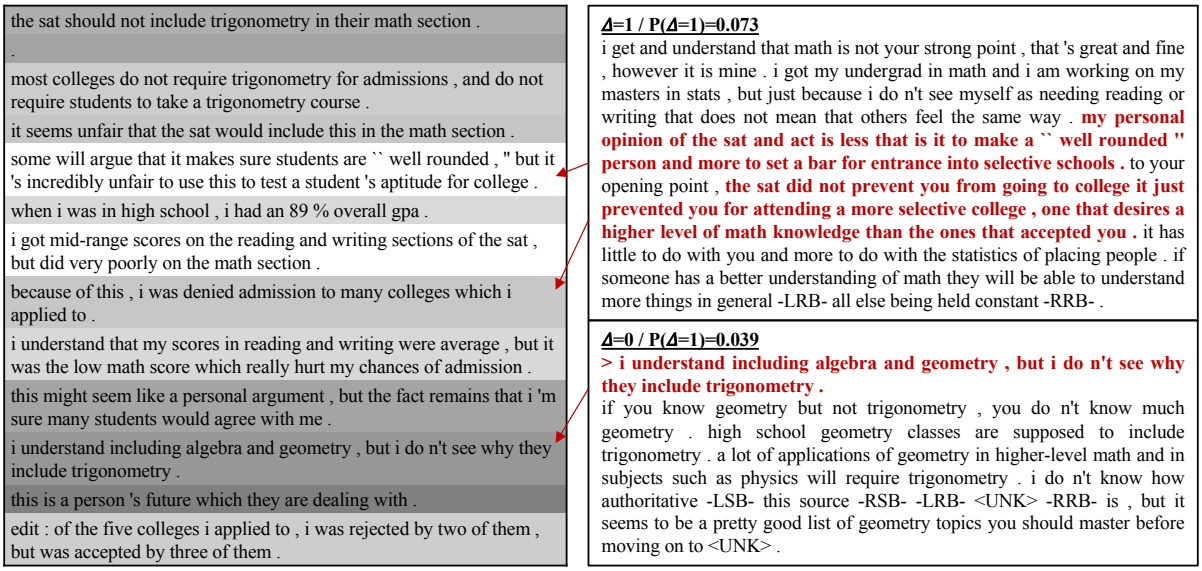

Figure 4: Example discussion with the OH's initial post (left), a successful comment (top right), and an unsuccessful comment (bottom right). The OH's post is colored based on attention weights (the higher attention the brighter). Sentences with college and SAT sections (*reading*, *writing*, *math*) get more attention than sentences with other subjects (*algebra*, *geometry*). The successful comment addresses parts with high attention, whereas the unsuccessful comment addresses parts with low attention.

liberate way of integrating hand-crafted features.

For cross-domain performance, logistic regression with TFIDF performs best (69.6%). Our interaction information does not transfer to unseen topics as well as TFIDF. This weakness is alleviated when our model uses TFIDF in addition to MAX, increasing the cross-domain score (from 67.5% to 69.4%). We expect that information about vulnerability would have more impact within domain than across domains because it may learn domain-specific information about which kinds of reasoning are vulnerable.

The rest of the section reports our qualitative analysis based on the best model configuration.

RQ2. Can the model identify vulnerable sentences, which are more likely to change the OH's view when addressed? If so, what properties constitute vulnerability? Our rationale behind vulnerable region detection is that the model is able to learn to pay more attention to sentences that are more likely to change the OH's view when addressed. If the model successfully does this, then we expect more alignment between the attention mechanism and sentences that are actually addressed by successful comments that changed the OH's view.

To verify if our model works as designed, we randomly sampled 30 OH posts from the test set, and for each post, the first successful and unsuccessful comments. We asked a native English speaker to annotate each comment with the two most relevant sentences that it addresses in the OH post, without knowledge of how the model computes vulnerability and whether the comment is successful or not.

After this annotation, we computed the average attention weight of the two selected sentences for each comment. We ran a paired sample t-test and confirmed that the average attention weight of sentences addressed by successful comments was significantly greater than that of sentences addressed by unsuccessful comments ($p < 0.05$). Thus, as expected in the case where the attention works as designed, the model more often picks out the sentences that successful challengers address.

As to what the model learns as vulnerability, in most cases, the model attends to sentences that are not punctuation marks, bullet points, or irrelevant to the topic (e.g., *can you cmv?*). A successful example is illustrated in Figure 4. More successful and unsuccessful examples are included in Appendix C.

RQ3. What kinds of interactions between arguments are captured by the model? We first use existing argumentation theories as a lens for interpreting interaction embeddings (refer to Sec-

tion 2). For this, we sampled 100 OH posts with all their comments and examined the 150 sentence pairs that have the highest value for each dimension of the interaction embedding (the dimensionality of interaction embeddings is 3 for the best performing configuration). 22% of the pairs in a dimension capture the comment asking the OH a question, which could be related to shifting the burden of proof. In addition, 23% of the top pairs in one dimension capture the comment pointing out that the OH may have missed something (e.g., *you don't know the struggles ...*). This might represent the challengers' attempt to provide premises that are missing in the OH's reasoning.

As providing missing information plays an important role in our data, we further examine if this attempt by challengers is captured in interaction embeddings even when it is not overtly signaled (e.g., *You don't know ...*). We first approximate the novelty of a challenger's information with the topic similarity between the challenger's sentence and the OH's sentence, and then see if there is a correlation between topic similarity and each dimension of interaction embeddings (details are in Appendix D). As a result, we found only a small but significant correlation (Pearson's $r = -0.04$) between topic similarity with one of the three dimensions.

Admittedly, it is not trival to interpret interaction embeddings and find alignment between embedding dimensions and argumentation theories. The neural network apparently learns complex interactions that are difficult to interpret in a human sense. It is also worth noting that the top pairs contain many duplicate sentences, possibly because the interaction embeddings may capture sentence-specific information, or because some types of interaction are determined mainly by one side of a pair (e.g., disagreement is manifested mostly on the challenger's side).

TFIDF We examine successful and unsuccessful styles reflected in TFIDF-weighted n-grams, based on their weights learned by logistic regression (top n-grams with the highest and lowest weights are in Appendix E). First, challengers are more likely to change the OH's view when talking about themselves than mentioning the OH in their arguments. For instance, first-person pronouns (e.g., *i* and *me*) get high weights, whereas second-person pronouns (e.g., *you_are* and *then_you*) get low weights. Second, different kinds of politeness seem to play roles. For example, markers of negative politeness (*can* and *can_be*, as opposed to *should* and *no*) and negative face-threatening markers (*thanks*), are associated with receiving a Δ. Third, asking a question to the OH (e.g., *why*, *do_you*, and *are_you*) is negatively associated with changing the OH's view.

7 Conclusion

We presented the Attentive Interaction Model, which predicts an opinion holder (OH)'s change in view through argumentation by detecting vulnerable regions in the OH's reasoning and modeling the interaction between the reasoning and a challenger's argument. According to the evaluation on discussions from the Change My View forum, sentences identified by our model to be vulnerable were addressed more by successful challengers than by unsuccessful ones. The model also effectively captured interaction information so that both vulnerability and interaction information increased accuracy in predicting an OH's change in view.

One key limitation of our model is that making a prediction based only on one comment is not ideal because we miss context information that connects successive comments. As a discussion between a challenger and the OH proceeds, the topic may digress from the initial post. In this case, detecting vulnerable regions and encoding interactions for the initial post may become irrelevant. We leave the question of how to transfer contextual information from the overall discussion as future work.

Our work is a step toward understanding how to model argumentative interactions that are aimed to enrich an interlocutor's perspective. Understanding the process of productive argumentation would benefit both the field of computational argumentation and social applications, including cooperative work and collaborative learning.

A Implementation Details

A.1 Topics in the Data

Topics are extracted using LatentDirichletAllocation in scikit-learn v0.19.1, with the following setting:

- `n_components`: 20
- `max_iter`: 200
- `learning_method`: online
- `learning_offset`: 50

A.2 AIM

We implemented our model in PyTorch 0.3.0.

A.3 Baseline

We use LogisticRegression in scikit-learn v0.19.1, with the default settings.

A.4 TFIDF Features

TFIDF is extracted using TfidfVectorizer in scikit-learn v0.19.1, with the default setting.

B Data Preprocessing

In the CMV forum, DeltaBot replies to an OH's comment with the confirmation of a Δ, along with the user name to which the OH replied. For most OH replies, the (non-)existence of a Δ indicates whether a comment to which the OH replied changed the OH's view. However, an OH's view is continually influenced as they participate in argumentation, and thus a Δ given to a comment may not necessarily be attributed to the comment itself. One example is when a comment does not receive a Δ when the OH reads it for the first time, but the OH comes back and gives it a Δ after they interact with other comments. In such cases, we may want to give a credit to the comment that actually led the OH to reconsider a previous comment and change the view.

Hence, we use the following labeling that considers the order in which OHs read comments. We treat the (non-)existence of a Δ in an OH comment as a label for the last comment that the OH read. We reconstruct the order in which the OH reads comments as follows. We assume that when the OH writes a comment, he/she has read all prior comments in the path to that comment.

Based on this assumption, we linearize (i.e., flatten) the original tree structure of the initial post and all subsequent comments into a linear sequence S. Starting with empty S, for each of the OH's comments in chronological order, its ancestor comments that are yet to be in S and the comment itself are appended to S. And for each of the OH's comments, its preceding comment in S is labeled with $\Delta = 1$ if the OH's comment has a Δ and 0 otherwise.

This ensures that the label of a comment to which the OH replied is the (non-)existence of a Δ in the OH's first reply. If an OH reply is not the first reply to a certain comment (as in the scenario mentioned above), or a comment to which the OH replied is missing, the (non-)existence of a Δ in that reply is assigned to the comment that we assume the OH read last, which is located right before the OH's comment in the restructured sequence.

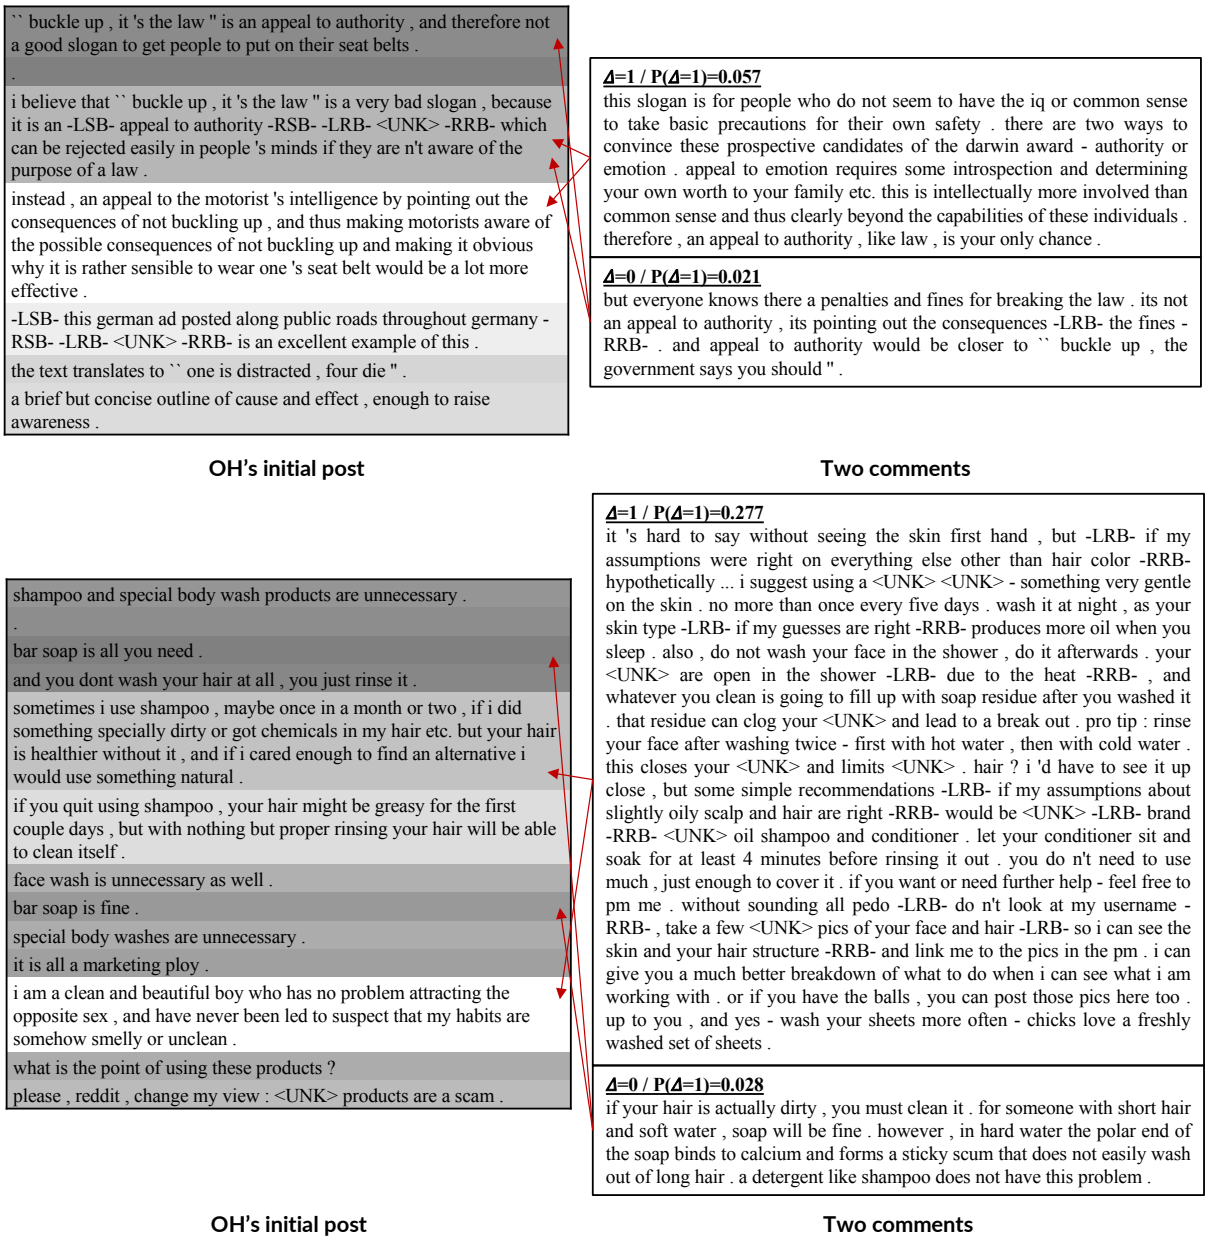

Figure 5: Successful examples of vulnerable region detection.

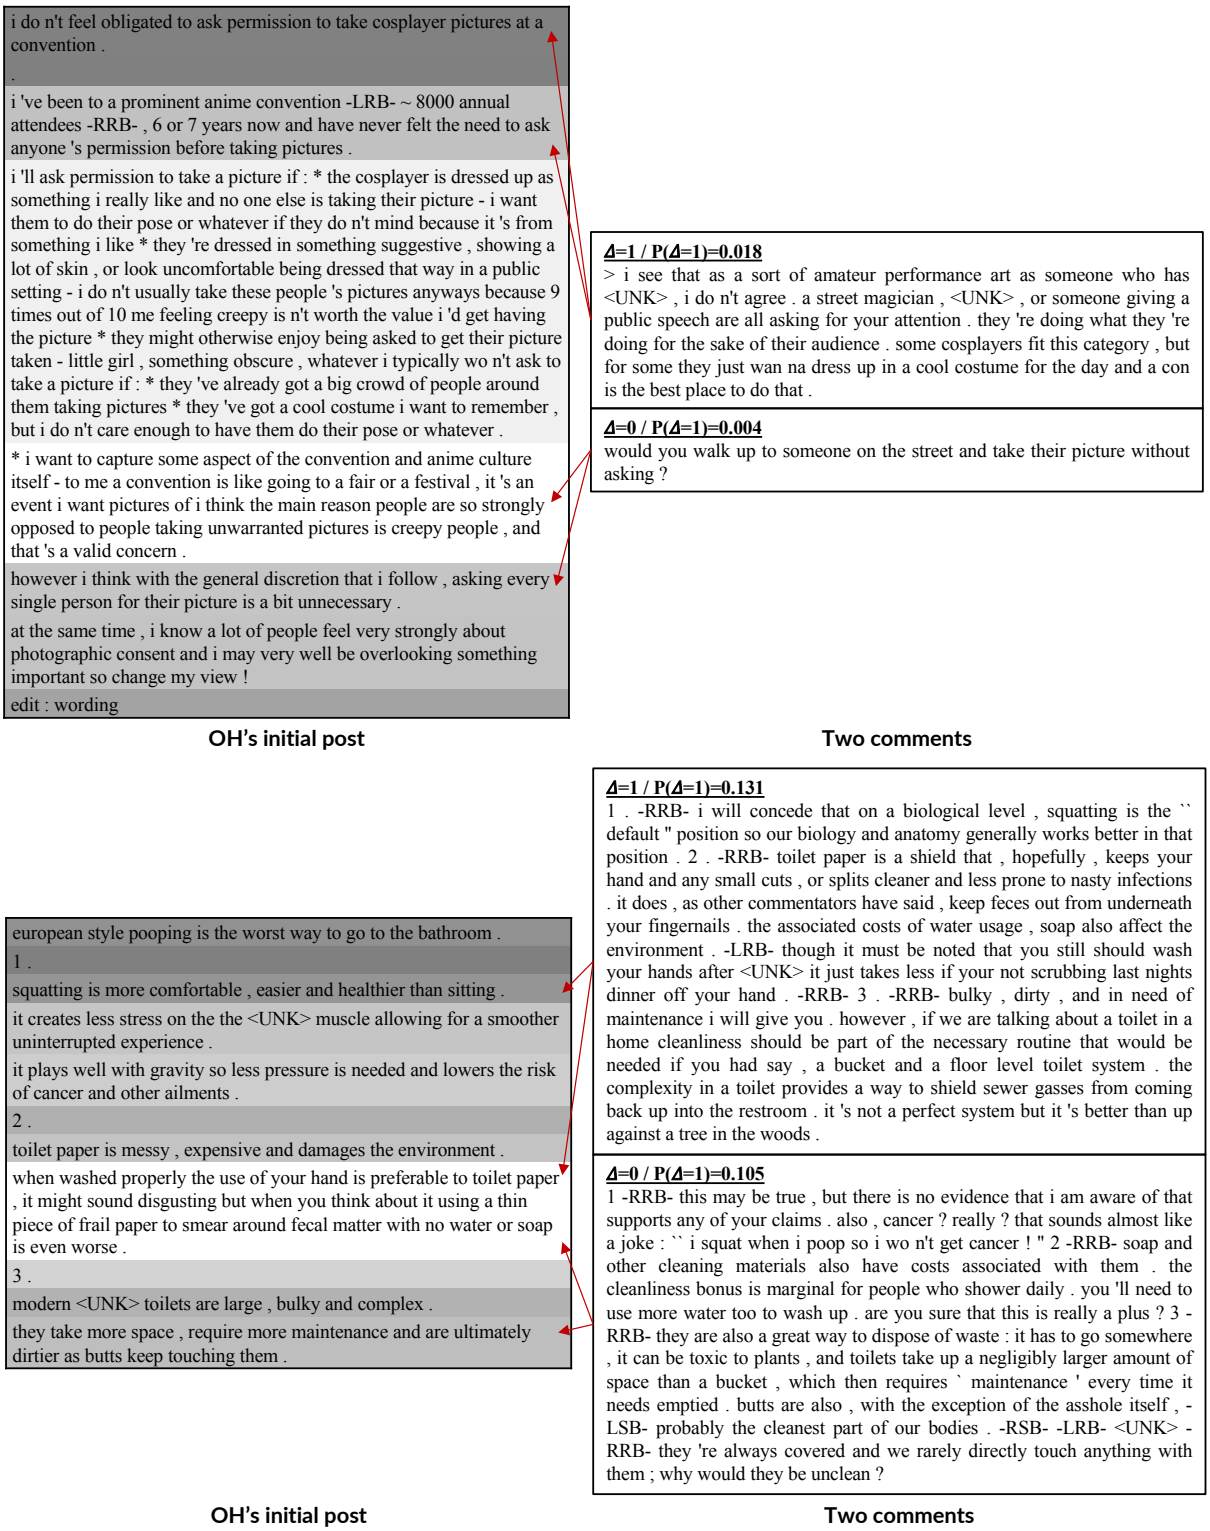

Figure 6: Unsuccessful examples of vulnerable region detection.

n-grams for $\Delta = 1$	n-grams for $\Delta = 0$
and, in, for, use, it, on, thanks, often, delta, time, depression, -RRB-, lot, -LRB-, or, i, can, &, with, more, as, band, *, #, me, -LRB-_-RRB-, can_be, has, deltas, when	?, >, sex, why, do_you, wear, relationship, child, are_you, op, mother, should, wearing, teacher, then, it_is, same, no, circumcision, you_are, then_you, baby, story

Table 3: Top n-grams with the most positive/negative weights for logistic regression.

C Vulnerability Examples

Figure 5 and Figure 6 show successful and unsuccessful examples of vulnerable region detection. All examples are from the test set.

D Topic Similarity between Sentences

The topic similarity between a pair of sentences is computed as the consine similarity between the topic distributions of the sentences.

The first step is to extract topics. Using LatentDirichletAllocation in scikit-learn v0.19.1, we ran LDA on the entire data with 100 topics, taking each post/comment as a document. We treat the top 100 words for each topic as topic words.

The second step is to compute the topic distribution of each sentence. We simply counted the frequency of occurrences of topic words for each topic, and normalized the frequencies across topics.

Lastly, we computed the cosine similarity between the topic distributions of a pair of sentences.

E Top TFIDF n-grams

The n-grams that contribute most to Δ prediction for logistic regression are shown in table 3.

Automatic Focus Annotation: Bringing Formal Pragmatics Alive in Analyzing the Information Structure of Authentic Data

Ramon Ziai **Detmar Meurers**
Collaborative Research Center 833
University of Tübingen
{rziai,dm}@sfs.uni-tuebingen.de

Abstract

Analyzing language in context, both from a theoretical and from a computational perspective, is receiving increased interest. Complementing the research in linguistics on discourse and information structure, in computational linguistics identifying discourse concepts was also shown to improve the performance of certain applications, for example, Short Answer Assessment systems (Ziai and Meurers, 2014).

Building on the research that established detailed annotation guidelines for manual annotation of information structural concepts for written (Dipper et al., 2007; Ziai and Meurers, 2014) and spoken language data (Calhoun et al., 2010), this paper presents the first approach automating the analysis of focus in authentic written data. Our classification approach combines a range of lexical, syntactic, and semantic features to achieve an accuracy of 78.1% for identifying focus.

1 Introduction

The interpretation of language is well known to depend on context. Both in theoretical and computational linguistics, discourse and information structure of sentences are thus receiving increased interest: attention has shifted from the analysis of isolated sentences to the question how sentences are structured in discourse and how information is packaged in sentences analyzed in context.

As a consequence, a rich landscape of approaches to discourse and information structure has been developed (Kruijff-Korbayová and Steedman, 2003). Among these perspectives, the Focus-Background dichotomy provides a particularly valuable structuring of the information in a sentence in relation to the discourse. (1) is an example question-answer pair from Krifka and Musan (2012, p. 4) where the focus in the answer is marked by brackets.

(1) Q: *What did John show Mary?*
A: *John showed Mary* $[\![$*the PICtures*$]\!]_F$.

In the answer in (1), the NP *the pictures* is focussed and hence indicates that there are alternative things that John could show Mary. It is commonly assumed that focus here typically indicates the presence of alternative *denotations* (denotation focus, Krifka and Musan 2012, p.8), making it a semantic notion. Depending on the language, different devices are used to mark focus, such as prosodic focus marking or different syntactic constructions (e.g. clefts). In this paper, we adopt a notion of focus based on alternatives, as advanced by Rooth (1992) and more recently, Krifka and Musan (2012), who define focus as indicating "the presence of alternatives that are relevant for the interpretation of linguistic expressions" (Krifka and Musan, 2012, p. 7). Formal semantics has tied the notion of alternatives to an explicit relationship between questions and answers called Question-Answer Congruence (Stechow, 1991), where the idea is that an answer is congruent to a question if both evoke the same set of alternatives. Questions can thus be seen as a way of making alternatives explicit in the discourse, an idea also taken up by the Question-Under-Discussion (QUD) approach (Roberts, 2012) to discourse organization.

Complementing the theoretical linguistic approaches, in the last decade corpus-based approaches started exploring which information structural notions can reliably be annotated in what kind of language data. While the information status (Given-New) dimension can be annotated successfully (Riester et al., 2010; Nissim et al., 2004) and even automated (Hempelmann et al., 2005; Nissim, 2006; Cahill and Riester, 2012), the inter-annotator agreement results for Focus-Background (Ritz et al., 2008; Calhoun et al., 2010) show that it is difficult to obtain high levels of agreement, especially due to disagreement

Proceedings of NAACL-HLT 2018, pages 117–128
New Orleans, Louisiana, June 1 - 6, 2018.

about the extent or size of the focused unit.

More recently, Ziai and Meurers (2014) showed that for data collected in task contexts including explicit questions, such as answers to reading comprehension questions, reliable focus annotation is possible. In addition, an option for externally validating focus annotation was established by showing that such focus annotation improves the performance of Short Answer Assessment (SAA) systems. Focus enables the system to zoom in on the part of the answer addressing the question instead of considering all parts of the answer as equal.

In this paper, we want to build on this strand of research and develop an approach for automatically identifying focus in authentic data including explicit question contexts. In contrast to Calhoun (2007) and Sridhar et al. (2008), who make use of prosodic properties to tackle the identification of focus for content words in spoken language data, we target the analysis of written texts.

We start in section 2 by discussing relevant related work before introducing the gold standard focus annotation we are using as foundation of our work in section 3. Section 4 then presents the different types of features used for predicting which tokens form a part of the focus. In section 5 we employ a supervised machine learning setup to evaluate the perspective and specific features in terms of the ability to predict the gold standard focus labeling. Building on these intermediate results and the analysis thereof in section 6, in section 7 we then present two additional feature groups which lead to our final focus detection model. Finally, section 8 explores options for extrinsically showing the value of the automatic focus annotation for the automatic meaning assessment of short answers. It confirms that focus analysis pays off when aiming to generalize assessment to previously unseen data and contexts.

2 Previous Approaches

There is only a very small number of approaches dealing with automatically labeling information structural concepts.[1] Most approaches related to detecting focus automatically almost exclusively center on detecting the 'kontrast' notion in the English Switchboard corpus (Calhoun et al., 2010). We therefore focus on the Switchboard-based approaches here.

The availability of the annotated Switchboard corpus (Calhoun et al., 2005, 2010) sparked interest in information-structural categories and enabled several researchers to publish studies on detecting focus. This is especially true for the Speech Processing community, and indeed many approaches described below are intended to improve computational speech applications in some way, by detecting prominence through a combination of various linguistic factors. Moreover, with the exception of Badino and Clark (2008), all approaches use prosodic or acoustic features.

All approaches listed below tackle the task of detecting 'kontrast' (as focus is called in the Switchboard annotation) automatically on various subsets of the corpus using different features and classification approaches. For each approach, we therefore report the features and classifier used, the data set size as reported by the authors, the (often very high) majority baseline for a binary distinction between 'kontrast' and background, and the best accuracy obtained. If available in the original description of the approach, we also report the accuracy obtained without acoustic and prosodic features.

Calhoun (2007) investigated how focus can be predicted through what she calls "prominence structure". The essential claim is that a "focus is more likely if a word is more prominent than expected given its syntactic, semantic and discourse properties". The classification experiment is based on 9,289 words with a 60% majority baseline for the 'background' class. Calhoun (2007) reports 77.7% for a combination of prosodic, syntactic and semantic features in a logistic regression model. Without the prosodic and acoustic features, the accuracy obtained is at 74.8%. There is no information on a separation between training and test set, likely due to the setup of the study being geared towards determining relevant factors in predicting focus, not building a focus prediction model for a real application case. Relatedly, the approach uses only gold-standard annotation already available in the corpus as the basis for features, not automatic annotation.

Sridhar et al. (2008) use lexical, acoustic and part-of-speech features in trying to detect pitch accent, givenness and focus. Concerning focus, the work attempts to extend Calhoun (2007)'s analysis to "understand what prosodic and acoustic dif-

[1] For a broader perspective of computational approaches in connection with information structure, see Stede (2012).

ferences exist between the focus classes and background items in conversational speech". 14,555 words of the Switchboard corpus are used in total, but filtered for evaluation later to balance the skewed distribution between 'kontrast' and 'background'. With the thus obtained random baseline of 50%, Sridhar et al. (2008) obtain 73% accuracy when using all features, which again drops only slightly to 72.95% when using only parts of speech. They use a decision tree classifier to combine the features in 10-fold cross-validation for training and testing.

Badino and Clark (2008) aim to model contrast both for its role in analyzing discourse and information structure, and for its potential in speech applications. They use a combination of lexical, syntactic and semantic features in an SVM classifier. No acoustic or prosodic features are employed in the model. In selecting the training and testing data, they filter out many 'kontrast' instances, such as those triggered across sentence boundaries, those above the word level, and those not sharing the same broad part of speech with the trigger word. The resulting data set has 8,602 instances, of which 96.8% are 'background'. Badino and Clark (2008) experiment with different kernel settings for the SVM and obtain the best result of 97.19% using a second-order polynomial kernel, and leave-one-out testing.

In contrast to all approaches above, we target the analysis of written texts, for which prosodic and acoustic information is not available, so we must rely on lexis, syntax and semantics exclusively. Also, the vast majority of the approaches discussed make direct use of the manually annotated information in the corpus they use in order to derive their features. While this is a viable approach when the aim is to determine the relevant factors for focus detection, it does not represent a real-life case where annotated data often unavailable. In our focus detection model, we only use automatically determined annotation as the basis for our features for predicting focus.

Since our approach also makes use of question properties, it is also worth mentioning that there are a number of approaches on Answer Typing as a step in Question Answering (QA) approaches in order to constrain the search space of possible candidate answers and improve accuracy. While earlier approaches such as Li and Roth (2002) used a fixed set of answer types for classifying factoid questions, other approaches such as Pinchak and Lin (2006) avoid assigning pre-determined classes to questions and instead favor a more data-driven label set. In more recent work, Lally et al. (2012) use a sophisticated combination of deep parsing, lexical clues and broader question labels to analyze questions.

3 Data

The present work is based on the German CREG corpus (Ott et al., 2012). CREG contains responses by American learners of German to comprehension questions on reading texts. Each response is rated by two teaching assistants with regard to whether it answers the question or not. While many responses contain ungrammatical language, the explicit questions in CREG generally make it possible to interpret responses. More importantly for our work, they can be seen as Questions Under Discussion and thus form an ideal foundation for focus annotation in authentic data.

As a reference point for the automatic detection of focus, we used the CREG-ExpertFocus data set (De Kuthy et al., 2016) containing 3,187 student answers and 990 target answers (26,980 words in total). It was created using the incremental annotation scheme described in Ziai and Meurers (2014), where annotators first look at the surface question form, then determine the set of alternatives, and finally mark instances of the alternative set in answers. De Kuthy et al. (2016) report substantial agreement in CREG-ExpertFocus ($\kappa \geq .7$) and provide an adjudicated gold standard, which thus presents a high-quality basis for training our focus detection classifier.

4 Focus Detection Model

As described in section 3 above, focus was marked in a span-based way in the data set used: each instance of focus starts at a specific word and ends at another word. Since in principle any part of speech can be focused, we cannot constrain ourselves to a pre-defined set of markables for automatic classification. We therefore conceptualized the task of automatic focus detection on a per-word level: for each word in an answer, as identified by the OpenNLP tokenizer and sentence segmenter[2], the classifier needs to decide whether it is an instance of *focus* or *background*. Besides the choice of

[2] `http://opennlp.apache.org`

classification algorithm, the crucial question naturally is the choice of linguistic features, which we turn to next.

4.1 Features

Various types of linguistic information on different linguistic levels can in principle be relevant for focus identification, from morphology to semantics. We start by exploring five groups of features, which are outlined below. In section 7, we discuss two more groups designed to address specific problems observed with the initial model.

Syntactic answer properties (SynAns) A word's part-of-speech and syntactic function are relevant general indicators with respect to focus: since we are dealing with meaning alternatives, the meaning of e.g. a noun is more likely to denote an alternative than a grammatical function word such as a complementizer or article.

Similarly, a word in an argument dependency relation is potentially a stronger indicator for a focused alternative in a sentence than a word in an adjunct relation. We therefore included two features: the word's **part-of-speech** tag in the STTS tag set (Schiller et al., 1995) determined using TreeTagger (Schmid, 1994), and the **dependency relation to the word's head** in the Hamburg dependency scheme (Foth et al., 2014, p. 2327) determined using MaltParser (Nivre et al., 2007) as features in our model.

Question properties The question constitutes the direct context for the answer and dictates its information structure and information requirements to fulfill. In particular, the type of *wh*-phrase (if present) of a question is a useful indicator of the type of required information: a *who*-question, such as 'Who rang the doorbell?', will typically be answered with a noun phrase, such as 'the milkman'. We identified **surface question forms** such as *who*, *what*, *how* etc. using a regular expression approach developed by Rudzewitz (2015) and included them as features. Related to question forms, we also extracted the question word's **dependency relation to its head**, analogous to the answer feature described above.

Surface givenness As a rough and robust approximation to information status, we add a boolean feature indicating the **presence of the current word in the question**. We use the lemmatized form of the word as determined by TreeTagger (Schmid, 1994).

Positional properties Where a word occurs in the answer or the question can be relevant for its information structural status. It has been observed since Halliday (1967) that given material tends to occur earlier in sentences (here: answers), while new or focused content tends to occur later. We encode this observation in three different features: the **position of the word in the answer** (normalized by sentence length), the **distance from the finite verb** (in words), and the **position of the word in the question** (if it is given).

Conjunction features To explicitly tie answer properties to question properties, we explored different combinations of the features described above. Specifically, we encoded the **current word's POS depending on the question form**, and the **current word's POS depending on the *wh*-word's POS**. To constrain the feature space and get rid of unnecessary distinctions, we converted the answer word's POS to a coarse-grained version before computing these features, which collapses all variants of determiners, pronouns, adjectives/adverbs, prepositions, nouns and verbs into one label, respectively.[3]

5 Intrinsic Evaluation

5.1 Setup

To employ the features described above in an actual classifier, we trained a logistic regression model using the WEKA toolkit (Hall et al., 2009). We also experimented with other classification algorithms such as SVMs, but found that they did not offer superior performance for this task. The data set used consists of all expert focus annotation available (3,187 student answers, see section 3), with the exception of the answers occurring in the extrinsic evaluation test set we use in section 8, which leaves a total of 2,240 student answers with corresponding target answers and questions. We used 10-fold cross-validation on this data set to experiment and select the optimal model for focus detection.

[3]For a list (in German) of the full tag set, see `http://www.ims.uni-stuttgart.de/forschung/ressourcen/lexika/TagSets/stts-table.html`

5.2 Results

Table 1 lists the accuracies[4] obtained for our different feature groups, as well as three baselines: a POS baseline, following Sridhar et al. (2008), a baseline that only includes the simple givenness feature, and the majority baseline. The majority class is *focus*, occurring in 58.1% of the 26,980 cases (individual words).

	Accuracy for		
Feature set	*focus*	*backgr.*	both
Majority baseline	100%	0%	58.1%
Givenness baseline	81.5%	42.5%	65.1%
POS baseline	89.2%	39.6%	68.4%
SynAns	82.8%	50.3%	69.2%
+ Question	83.8%	53.1%	70.9%
+ Given	84.8%	62.0%	74.8%
+ Position	84.9%	66.5%	77.2%
+ Conjunction	85.2%	66.7%	**77.4%**

Table 1: Initial focus detection model

We can see that each feature group incrementally adds to the final model's performance, with particularly noticeable boosts coming from the givenness and positional features. Another clear observation is that the classifier is much better at detecting *focus* than *background*, possibly also due to the skewedness of the data set. Note that performance on *background* increases also with the addition of the 'Question' feature set, indicating the close relation between the set of alternatives introduced by the question and the focus selecting from that set, even though our approximation to computationally determining alternatives in questions is basic. It is also clear that the information intrinsic in the answers, as encoded in the 'SynAns' and 'Position' feature sets, already provides significant performance benefits, suggesting that a classifier trained only on these features could be trained and applied to settings where no explicit questions are available.

6 Qualitative Analysis

In order to help explain the gap between automatic and manual focus annotation, let us take a step back from quantitative evaluation and examine a few characteristic examples in more detail.

Figure 1 shows a case where a *why*-question is answered with an embedded 'weil' (because) clause. The classifier successfully marked 'weil' and the end of the clause as *focus*, but left out the pronoun 'es' (it) in the middle, presumably because pronouns are given and often not focused in other answers. We did experiment with using a sequence classification approach in order to remedy such problems, but it performed worse overall than the logistic regression model we presented in section 4. We therefore suggest that in such cases, a global constraint stating that *why*-questions are typically answered with a full clause would be a more promising approach, combining knowledge learned bottom-up from data with top-down linguistic insight.

In Figure 2, we can see two different problems. One is again a faulty gap, namely the omission of the conjunction 'und' (and). The other is the focus marking of the word 'AG' (corporation) in the beginning of the sentence: since the question asks for an enumeration of the institutions that form a corporation, marking 'AG' as focused is erroneous. This problem likely occurs often with nouns because the classifier has learned that content words are often focused. Moreover, the surface givenness feature does not encode that 'AG' is in fact an abbreviation of 'Aktiengesellschaft' and therefore given. It would thus be beneficial to extend our analysis of givenness beyond surface identity, a direction we explore in the next section.

Finally, Figure 3 presents a case where an enumeration is marked correctly, including the conjunctive punctuation in between, showing that cases of longer foci are indeed within reach for a word-by-word focus classifier.

7 Extending the Model

Based on our analysis of problematic cases outlined in the previous section, we explored two different avenues for improving our focus detection model, which we describe below.

7.1 Distributional Givenness

We have seen in section 5.2 that surface-based givenness is helpful in predicting focus. However, it clearly has limitations, as for example synonymy cannot be captured on the surface. We also exemplified one such limitation in Figure 2. In order to overcome these limitations, we implemented an approach based on distributional semantics. This avenue is motivated by the fact that Ziai et al. (2016) have shown Givenness modeled

[4]We show per-class and overall accuracies, the former is also known as recall or true positive rate.

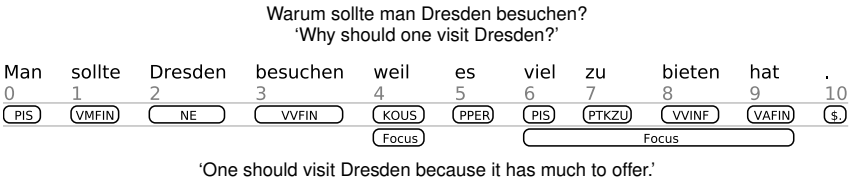

Figure 1: Focus with a faulty gap in between

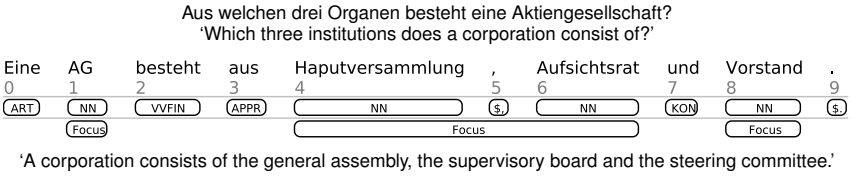

Figure 2: Focus with a faulty outlier (and a faulty gap)

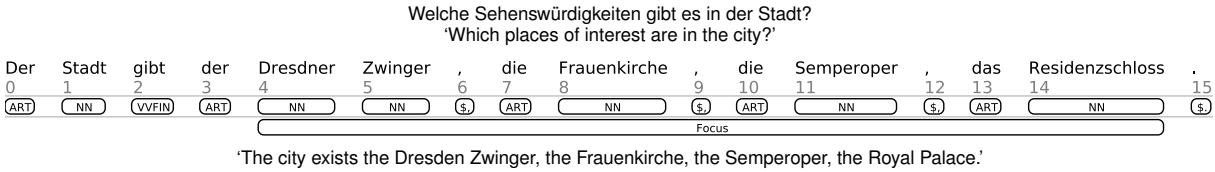

Figure 3: Enumeration with correct focus

as distributional similarity to be helpful for SAA at least in some cases. We used the word vector model they derived from the DeWAC corpus (Baroni et al., 2009) using word2vec's continuous bag-of-words training algorithm with hierarchical softmax (Mikolov et al., 2013). The model has a vocabulary of 1,825,306 words and uses 400 dimensions for each.

Having equipped ourselves with a word vector model, the question arises how to use it in focus detection in such a way that it complements the positive impact that surface-based givenness already demonstrates. Rather than using an empirically determined (and hence data-dependent) empirical threshold for determining givenness as done by Ziai et al. (2016), we here use raw cosine similarities[5] as features and let the classifier assign appropriate weights to them during training. Concretely, we calculate **maximum, minimum and average cosine between the answer word and the question words**. As a fourth feature, we calculate the **cosine between the answer word and the additive question word vector**, which is the sum of the individual question word vectors.

7.2 Constituency-based Features

Another source of evidence we wanted to exploit is constituency-based syntactic annotation. So far, we have worked with part-of-speech tags and dependency relations as far as syntactic representation is concerned. However, while discontinuous focus is possible, focus as operationalized in the scheme by Ziai and Meurers (2014) most often marks an adjacent group of words, a tendency that our word-based classifier did not always follow, as exemplified by the cases in Figures 1 and 2. Such groups very often correspond to a syntactic phrase, so constituent membership is likely indicative in predicting the focus status of an individual word. Similarly, the topological field (Höhle, 1986) identifying the major section of a sentence in relation to the clausal main verb is potentially relevant for a word's focus status.

Cheung and Penn (2009) present a parsing model that demonstrates good performance in determining both topological fields and phrase structure for German. The model is trained on the TüBa-D/Z treebank (Telljohann et al., 2004), whose rich syntactic model encodes topological fields as nodes in the syntax tree itself. Following Cheung and Penn (2009), we trained an updated version of their model using the current version of the Berkeley Parser (Petrov and Klein, 2007) and release 10 of the TüBa-D/Z.[6]

Based on the new parsing model, we integrated two new features into our focus detection model:

[5] We normalize cosine similarity as cosine distance to obtain positive values between 0 and 2: $dist = 1 - sim$

[6] `http://www.sfs.uni-tuebingen.de/en/ascl/resources/corpora/tueba-dz.html`

the **direct parent constituent node of a word** and **the nearest topological field node of a word**.

7.3 Final Results

Table 2 shows the impact of the new feature groups discussed above.

Feature set	Accuracy for *focus*	*backgr.*	both
Majority baseline	100%	0%	58.1%
Givenness baseline	81.5%	42.5%	65.1%
POS baseline	89.2%	39.6%	68.4%
Initial model (sec. 5.2)	85.2%	66.7%	77.4%
+ dist. Givenness	84.7%	68.0%	77.7%
+ constituency	84.8%	68.7%	**78.1%**

Table 2: Final focus detection performance

While the improvements may seem modest quantitatively, they show that the added features are well-motivated and do make an impact. Overall, it is especially apparent that the key to better performance is reducing the number of false positives in this data set: while the accuracy for focus stays roughly the same, the one for background improves steadily with each feature set addition.

8 Extrinsic Evaluation

Complementing the intrinsic evaluation above, in this section we demonstrate how focus can be successfully used to improve performance in an authentic CL task, namely Short Answer Assessment (SAA).

8.1 Setup

It has been pointed out that evaluating the annotation of a theoretical linguistic notion only intrinsically is problematic because there is no non-theoretical grounding involved (Riezler, 2014). Therefore, besides a comparison to the gold standard, we also evaluated the resulting annotation in a larger computational task, the automatic meaning assessment of short answers to reading comprehension questions. Here the goal is to decide, given a question (Q) and a correct target answer (TA), whether the student answer (SA) actually answers the question or not. An example from Meurers et al. (2011) is shown in Figure 4.

We used the freely available CoMiC system (Comparing Meaning in Context, Meurers et al. 2011) as a testbed for our experiment. CoMiC is an alignment-based system operating in three stages:

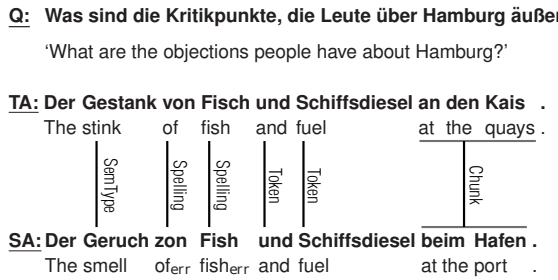

Figure 4: Short Answer Assessment example

1. Annotating linguistic units (words, chunks and dependencies) in student and target answer on various levels of abstraction

2. Finding alignments of linguistic units between student and target answer based on annotation (see Figure 4)

3. Classifying the student answer based on number and type of alignments (see Table 3), using a supervised machine learning setup

Feature	Description
1. Keyword Overlap	Percent of dependency heads aligned (relative to target)
2./3. Token Overlap	Percent of aligned target/student tokens
4./5. Chunk Overlap	Percent of aligned target/student chunks (as identified by OpenNLP[3])
6./7. Triple Overlap	Percent of aligned target/student dependency triples
8. Token Match	Percent of token alignments that were token-identical
9. Similarity Match	Percent of token alignments resolved using PMI-IR (Turney, 2001)
10. Type Match	Percent of token alignments resolved using GermaNet hierarchy (Hamp and Feldweg, 1997)
11. Lemma Match	Percent of token alignments that were lemma-resolved
12. Synonym Match	Percent of token alignments sharing same GermaNet synset
13. Variety of Match (0-5)	Number of kinds of token-level alignments (features 8–12)

Table 3: Standard features in the CoMiC system

In stage 2, CoMiC integrates a simplistic approach to givenness, excluding all words from alignment that are mentioned in the question. We transferred the underlying method to the notion of focus and implemented a component that excludes all non-focused words from alignment, resulting

[3] http://opennlp.apache.org/

in alignments between focused parts of answers only. The hypothesis is that the alignment of focused elements in answers adds information about the quality of the answer with respect to the question, leading to a higher answer classification accuracy.

We experimented with two different settings involving the standard CoMiC system and a focus-augmented variant: i) using standard CoMiC with the givenness filter by itself as a baseline, and ii) augmenting standard CoMiC by additionally producing a focus version of each classification feature in Table 3. In each case, we used WEKA's *k*-nearest-neighbor implementation for CoMiC, following positive results by Rudzewitz (2016).

We use two test sets randomly selected from the CREG-5K data set (Ziai et al., 2016), one based on an 'unseen answers' and one based on an 'unseen questions' test scenario, based on the methodology of (Dzikovska et al., 2013): in 'unseen answers', the test set can contain answers to the same questions already part of the training set (but not the answers themselves), whereas in 'unseen questions' both questions and answers are new in the test set. In order to arrive at a fair and generalizable testing setup, we removed all answers from the CREG-5K training set that also occur in the CREG-ExpertFocus set used to train our focus detection classifier. This ensures that neither the focus classifier nor CoMiC have seen any of the test set answers before.

The resulting smaller training set contains 1606 student answers, while the test sets contain 1002 (unseen answers) and 1121 (unseen questions), respectively.

8.2 Results

Table 4 summarizes the results for the different CoMiC variants and test sets in terms of accuracy in classifying answers as *correct* vs. *incorrect*. 'Standard CoMiC' refers to the standard CoMiC system and '+Focus' refers to the augmented system using both feature versions. For reference on what is possible with Focus information, we provide the results of the oracle experiment by De Kuthy et al. (2016), even though the test setup and data setup are slightly different. In addition to our two test sets introduced above, we tested the systems on the training set using 10-fold cross validation. We also provide the majority baseline of the respective data set along with the majority class.

One can see that in general, the focus classifier seems to introduce too much noise to positively impact classification results. The standard CoMiC system outperforms the focus-augmented version for the cross validation case and the 'unseen answers' set. This is in contrast to the experiments reported by De Kuthy et al. (2016) using manual focus information, where the augmented system clearly outperforms all other variants. This shows that while focus information is clearly useful in Short Answer Assessment, it needs to be reliable enough to be of actual benefit. Recall also that the way we use focus information in CoMiC implies a strong commitment: only focused words are aligned and included in feature extraction, which does not produce the desired result if the focus information is not accurate. A possible way of remedying this situation would be to use focus as an extra feature or less strict modifier of existing features. There is thus room for improvement both in the automatic detection of focus and its use in extrinsic tasks.

However, one result stands out encouragingly: in the 'unseen questions' case, the focus-augmented version beats standard CoMiC, if only by a relatively small margin. This shows that even automatically determined information structural properties provide benefits when more concrete information, in the form of previously seen answers to the same questions, is not available. Our classifier thus successfully transfers general knowledge about focus to new question material.

9 Conclusion

We presented the first automatic focus detection approach for written data, and the first such approach for German. The approach uses a rich feature set including abstractions to grammatical notions (parts of speech, dependencies), word order aspects captured by a topological field model of German, an approximation of Givenness and the relation between material in the answer and that of the question word.

Using a word-by-word classification approach that takes into account both syntactic and semantic properties of answer and question words, we achieve an accuracy of 78.1% on a data set of 26,980 words in 10-fold cross validation. The focus detection pipeline developed for the experiment is freely available to other researchers.

Complementing the intrinsic evaluation, we

Test set	Instances	Majority baseline	CoMiC	+Focus
Oracle experiment reported by De Kuthy et al. (2016) on CREG-ExpertFocus				
leave-one-out	3187	51.0% *(correct)*	83.2%	85.6%
10-fold CV	1606	54.4% *(correct)*	**83.2%**	82.3%
Unseen answers	1002	51.3% *(correct)*	**80.6%**	80.5%
Unseen questions	1121	51.1% *(incorrect)*	77.4%	**78.4%**

Table 4: CoMiC results on different test sets using standard and focus-augmented features

provide an extrinsic evaluation of the approach as part of a larger CL task, the automatic content assessment of answers to reading comprehension questions. We show that while automatic focus detection does not yet improve content assessment for answers similar to the ones previously seen, it does provide a benefit in test cases where the questions and answers are completely new, i.e., where the system needs to generalize beyond the specific cases and contexts previously seen.

Contextualizing our work, one can see two different strands of research in the automatic analysis of focus. In comparison to Calhoun (2007) and follow-up approaches, who mainly concentrate on linking prosodic prominence to focus in dialogues, we do not limit our analysis to content words, but analyze every word of an utterance. This is made feasible due to the explicit task context we have in the form of answers to reading comprehension questions. We believe this nicely illustrates two avenues for obtaining relevant evidence on information structure: On the one hand, there is evidence obtained bottom-up through the data such as the rich information on prominence in spoken language data such as the corpus used by Calhoun (2007). On the other hand, there is top-down evidence from the task context, which sets up expectations about what is to be addressed for the current question under discussion. Following the QUD research strand, the approach presented in this paper could be scaled up beyond explicit question-answer pairs: De Kuthy et al. (2018) spell out an explicit analysis of text in terms of QUDs and show that it is possible to annotate explicit QUDs with high inter-annotator agreement. Combined with an automated approach to question generation, it could thus be possible to recover implicit QUDs from text and subsequently apply our current approach to any text, based on an independently established, general formal pragmatic analysis.

Finally, the qualitative analysis we exemplified is promising in terms of obtaining valuable insights to be addressed in future work. For example, the analysis identified faulty gaps in focus marking. In future work, integrating insights from theoretical linguistic approaches to focus and the notion of focus projection established there (cf., e.g., De Kuthy and Meurers 2012) could provide more guidance for ensuring contiguity of focus domains.

Abstract

Style transfer is the task of automatically transforming a piece of text in one particular style into another. A major barrier to progress in this field has been a lack of training and evaluation datasets, as well as benchmarks and automatic metrics. In this work, we create the largest corpus for a particular stylistic transfer (formality) and show that techniques from the machine translation community can serve as strong baselines for future work. We also discuss challenges of using automatic metrics.

1 Introduction

One key aspect of *effective communication* is the accurate expression of the style or tone of some content. For example, writing a more *persuasive email* in a marketing position could lead to increased sales; writing a more *formal email* when applying for a job could lead to an offer; and writing a more *polite note* to your future spouse's parents, may put you in a good light. Hovy (1987) argues that by varying the style of a text, people convey more information than is present in the literal meaning of the words. One particularly important dimension of style is formality (Heylighen and Dewaele, 1999). Automatically changing the style of a given content to make it more formal can be a useful addition to any writing assistance tool.

In the field of style transfer, to date, the only available dataset has been for the transformation of modern English to Shakespeare, and it led to the application of phrase-based machine translation (PBMT) (Xu et al., 2012) and neural machine translation (NMT) (Jhamtani et al., 2017) models to the task. The lack of an equivalent or larger dataset for any other form of style transfer has blocked progress in this field. Moreover, prior work has mainly borrowed metrics from machine translation (MT) and paraphrase communities for evaluating style transfer. However, it is not clear if those metrics are the best ones to use for this task. In this work, we address these issues through the following three contributions:

- **Corpus:** We present Grammarly's Yahoo Answers Formality Corpus (GYAFC), the largest dataset for any style containing a total of 110K informal / formal sentence pairs. Table 1 shows sample sentence pairs.
- **Benchmarks:** We introduce a set of learning models for the task of formality style transfer. Inspired by work in low resource MT, we adapt existing PBMT and NMT approaches for our task and show that they can serve as strong benchmarks for future work.
- **Metrics:** In addition to MT and paraphrase metrics, we evaluate our models along three axes: *formality*, *fluency* and *meaning preservation* using existing automatic metrics. We compare these metrics with their human judgments and show there is much room for further improvement.

Informal:	*I'd say it is punk though.*
Formal:	*However, I do believe it to be punk.*
Informal:	*Gotta see both sides of the story.*
Formal:	*You have to consider both sides of the story.*

Table 1: Informal sentences with formal rewrites.

In this paper, we primarily focus on the *informal* to *formal* direction since we collect our dataset for this direction. However, we evaluate our models on the *formal* to *informal* direction as well.[1] All data, model outputs, and evaluation results have been made public[2] in the hope that they will encourage more research into style transfer.

*This research was performed when the first author was at Grammarly.

[1] Results are in the supplementary material.

[2] https://github.com/raosudha89/GYAFC-corpus

Proceedings of NAACL-HLT 2018, pages 129–140
New Orleans, Louisiana, June 1 - 6, 2018.

In the following two sections we discuss related work and the GYAFC dataset. In §4, we detail our rule-based and MT-based approaches. In §5, we describe our human and automatic metric based evaluation. In §6, we describe the results of our models using both human and automatic evaluation and discuss how well the automatic metrics correlate with human judgments.

2 Related Work

Style Transfer with Parallel Data: Sheikha and Inkpen (2011) collect pairs of formal and informal words and phrases from different sources and use a natural language generation system to generate informal and formal texts by replacing lexical items based on user preferences. Xu et al. (2012) (henceforth XU12) was one of the first works to treat style transfer as a sequence to sequence task. They generate a parallel corpus of 30K sentence pairs by scraping the modern translations of Shakespeare plays and train a PBMT system to translate from modern English to Shakespearean English.[3] More recently, Jhamtani et al. (2017) show that a copy-mechanism enriched sequence-to-sequence neural model outperforms XU12 on the same set. In text simplification, the availability of parallel data extracted from English Wikipedia and Simple Wikipedia (Zhu et al., 2010) led to the application of PBMT (Wubben et al., 2012a) and more recently NMT (Wang et al., 2016) models. We take inspiration from both the PBMT and NMT models and apply several modifications to these approaches for our task of transforming the formality style of the text.

Style Transfer without Parallel Data: Another direction of research directly controls certain attributes of the generated text *without* using parallel data. Hu et al. (2017) control the sentiment and the tense of the generated text by learning a disentangled latent representation in a neural generative model. Ficler and Goldberg (2017) control several linguistic style aspects simultaneously by conditioning a recurrent neural network language model on specific style (professional, personal, length) and content (theme, sentiment) parameters. Under NMT models, Sennrich et al. (2016a) control the politeness of the translated text via side constraints, Niu et al. (2017) control the level of formality of MT output by selecting phrases of a requisite formality level from the k-best list during decoding. In the field of text simplification, more recently, Xu et al. (2016) learn large-scale paraphrase rules using bilingual texts whereas Kajiwara and Komachi (2016) build a monolingual parallel corpus using sentence similarity based on alignment between word embeddings. Our work differs from these methods in that we mainly address the question of how much leverage we can derive by collecting a large amount of informal-formal sentence pairs and build models that learn to transfer style directly using this parallel corpus.

Identifying Formality: There has been previous work on detecting formality of a given text at the lexical level (Brooke et al., 2010; Lahiri et al., 2011; Brooke and Hirst, 2014; Pavlick and Nenkova, 2015), at the sentence level (Pavlick and Tetreault, 2016) and at the document level (Sheikha and Inkpen, 2010; Peterson et al., 2011; Mosquera and Moreda, 2012). In our work, we reproduce the sentence-level formality classifier introduced in Pavlick and Tetreault (2016) (PT16) to extract informal sentences for GYAFC creation and to automatically evaluate system outputs.

Evaluating Style Transfer: The problem of style transfer falls under the category of natural language generation tasks such as machine translation, paraphrasing, etc. Previous work on style transfer (Xu et al., 2012; Jhamtani et al., 2017; Niu et al., 2017; Sennrich et al., 2016a) has re-purposed the MT metric BLEU (Papineni et al., 2002) and the paraphrase metric PINC (Chen and Dolan, 2011) for evaluation. Additionally, XU12 introduce three new automatic style metrics based on cosine similarity, language model and logistic regression that measure the degree to which the output matches the target style. Under human based evaluation, on the other hand, there has been work on a more fine grained evaluation where human judgments were separately collected for adequacy, fluency and style (Xu et al., 2012; Niu et al., 2017). In our work, we conduct a more thorough evaluation where we evaluate model outputs on the three criteria of *formality*, *fluency* and *meaning* using both automatic metrics and human judgments.

E&M	52,595	2,877	1,416	2,356	1,082
F&R	51,967	2,788	1,332	2,247	1,019

Table 3: GYAFC dataset statistics

3 GYAFC **Dataset**

3.1 Creation Process

Yahoo Answers,[4] a question answering forum, contains a large number of informal sentences and allows redistribution of data. Hence, we use the Yahoo Answers L6 corpus[5] to create our GYAFC dataset of informal and formal sentence pairs. In order to ensure a uniform distribution of data, we remove sentences that are questions, contain URLs, and are shorter than 5 words or longer than 25. After these preprocessing steps, 40 million sentences remain. The Yahoo Answers corpus consists of several different domains like *Business, Entertainment & Music, Travel, Food,* etc. PT16 show that the formality level varies significantly across different genres. In order to control for this variation, we work with two specific domains that contain the most informal sentences and show results on training and testing within those categories. We use the formality classifier from PT16 to identify informal sentences. We train this classifier on the *Answers* genre of the PT16 corpus which consists of nearly 5,000 randomly selected sentences from Yahoo Answers manually annotated on a scale of -3 (very informal) to 3 (very formal).[6] We find that the domains of *Entertainment & Music* and *Family & Relationships* contain the most informal sentences and create our GYAFC dataset using these domains. Table 2 shows the number of formal and informal sentences in all of Yahoo Answers corpus and within the two selected domains. Sentences with a score less than 0 are considered as informal and sentences with a score greater than 0 are considered as formal.

Next, we randomly sample a subset of 53,000 informal sentences each from the *Entertainment & Music* (E&M) and *Family & Relationships* (F&R) categories and collect one formal rewrite per sentence using Amazon Mechanical Turk. The workers are presented with detailed instructions, as well as examples. To ensure quality control, four experts, two of which are the authors of this paper, reviewed the rewrites of the workers and rejected those that they felt did not meet the required standards. They also provided the workers with reasons for rejection so that they would not repeat the same mistakes. Any worker who repeatedly performed poorly was eventually blocked from doing the task. We use this train set to train our models for the style transfer tasks in both directions.

Since we want our tune and test sets to be of higher quality compared to the train set, we recruit a set of 85 expert workers for this annotation who had a 100% acceptance rate for our task and who had previously done more than 100 rewrites. Further, we collect multiple references for the tune/test set to adapt PBMT tuning and evaluation techniques to our task. We collect four different rewrites per sentence using our expert workers by randomly assigning sentences to the experts until four rewrites for each sentence are obtained.[7] To create our tune and test sets for the *informal* to *formal* direction, we sample an additional 3,000 informal sentences for our tune set and 1,500 sentences for our test set from each of the two domains.

To create our tune and test sets for the *formal* to *informal* direction, we start with the same tune and test split as the first direction. For each formal rewrite[8] from the first direction, we collect three different informal rewrites using our expert workers as before. These three informal rewrites along with the original informal sentence become our set of four references for this direction of the task. Table 3 shows the exact number of sentences in our train, tune and test sets.

3.2 Analysis

The following quantitative and qualitative analyses are aimed at characterizing the changes between the original informal sentence and its formal

[4] https://answers.yahoo.com/answer

[5] https://webscope.sandbox.yahoo.com/catalog.php?datatype=l

[6] http://www.seas.upenn.edu/~nlp/resources/formality-corpus.tgz

[7] Thus, note that the four rewrites are not from the same four workers for each sentence

[8] Out of four, we pick the one with the most edit distance with the original informal. Rationale explained in Section 3.2

rewrite in the GYAFC train split.[9] We present our analysis here on only the E&M domain data since we observe similar patterns in F&R.

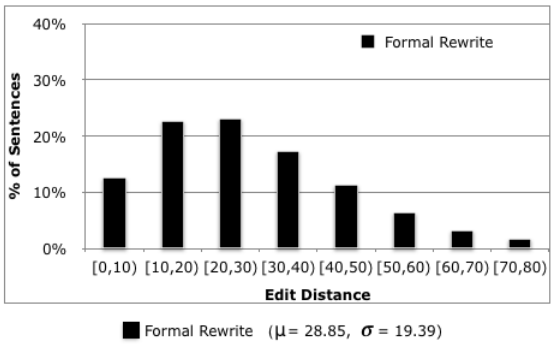

Figure 1: Percentage of sentences binned according to formality score in train set of E&M.

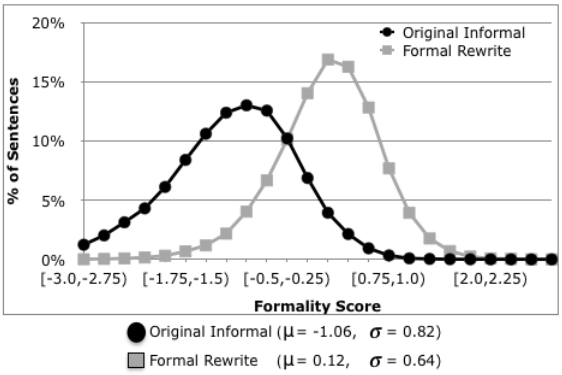

Figure 2: Percentage of sentences binned according to formality score in train set of E&M

Quantitative Analysis: While rewriting sentences more formally, humans tend to make a wide range of lexical/character-level edits. In Figure 1, we plot the distribution of the character-level Levenshtein edit distance between the original informal and the formal rewrites in the train set and observe a standard deviation of $\sigma = 19.39$ with a mean $\mu = 28.85$. Next, we look at the difference in the formality level of the original informal and the formal rewrites in GYAFC. We find that the classifier trained on the *Answers* genre of PT16 dataset correlates poorly (Spearman $\rho = 0.38$) with human judgments when tested on our domain specific datasets. Hence, we collect formality judgments on a scale of -3 to +1, similar to PT16, for an additional 5000 sentences each from both domains and obtain a formality classifier with higher correlation (Spearman $\rho = 0.56$). We use this retrained classifier for our evaluation in §5 as well.

In Figure 2, we plot the distribution of the formality scores on the original informal sentence and their formal rewrites in the train set and observe an increase in the mean formality score as we go from informal (-1.06) to formal rewrites (0.12). As compared to edit distance and formality, we observe a much lower variation in sentence lengths with the mean slightly increasing from informal (11.93) to their formal rewrites (12.56) in the train set.

Qualitative Analysis: To understand what stylistic choices differentiate formal from informal text, we perform an analysis similar to PT16 and look at 50 rewrites from both domains and record the frequency of the types of edits that workers made when creating a more formal sentence.[10] In contrast to PT16, we observe a higher percentage of phrasal paraphrases (47%), edits to punctuations (40%) and expansion of contractions (12%). This is reflective of our sentences coming from very informal domains of Yahoo Answers. Similar to PT16, we also observe capitalization (46%) and normalization (10%).

4 Models

We experiment with three main classes of approaches: a rule-based approach, PBMT and NMT. Inspired by work in low resource machine translation, we apply several modifications to the standard PBMT and NMT models and create a set of strong benchmarks for the style transfer community. We apply these models to both directions of style transfer: *informal* to *formal* and *formal* to *informal*. In our description, we refer to the two styles as *source* and *target*. We summarize the models below and direct the reader to supplementary material for further detail.

4.1 Rule-based Approach

Corresponding to the category of edits described in §3.2, we develop a set of rules to automatically make an informal sentence more formal where we capitalize first word and proper nouns, remove repeated punctuations, handcraft a list of expansion for contractions etc. For the *formal* to *informal* direction, we design a similar set of rules in the opposite direction.

[9] We observe similar patterns on the tune and test set.

[10] Examples of edits in supplementary material.

4.2 Phrase-based Machine Translation

Phrased-based machine translation models have had success in the fields of machine translation, style transfer (XU12) and text simplification (Wubben et al., 2012b; Xu et al., 2016). Inspired by work in low resource machine translation, we use a combination of training regimes to develop our model. We train on the output of the rule-based approach when applied to GYAFC. This is meant to force the PBMT model to learn generalizations *outside* the rules. To increase the data size, we use self-training (Ueffing, 2006), where we use the PBMT model to translate the large number of in-domain sentences from GYAFC belonging to the the source style and use the resultant output to retrain the PBMT model. Using subselection, we only select rewrites that have an Levenshtein edit distance of over 10 characters when compared to the source to encourage the model to be less conservative. Finally, we upweight the rule-based GYAFC data via duplication (Sennrich et al., 2016b). For our experiments, we use Moses (Koehn et al., 2007). We train a 5-gram language model using KenLM (Heafield et al., 2013), and use target style sentences from GYAFC and the sub-sampled target style sentences from out-of-domain Yahoo Answers, as in Moore and Lewis (2010), to create a large language model.

4.3 Neural Machine Translation

While encoder-decoder based neural network models have become quite successful for MT(Sutskever et al., 2014; Bahdanau et al., 2014; Cho et al., 2014), the field of style transfer, has not yet been able to fully take advantage of these advances owing to the lack of availability of large parallel data. With GYAFC we can now show how well NMT techniques fare for style transfer. We experiment with three NMT models:

NMT baseline: Our baseline model is a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) encoder-decoder model with attention (Bahdanau et al., 2014).[11] We pretrain the input word embeddings on Yahoo Answers using GloVE (Pennington et al., 2014). As in our PBMT based approach, we train our NMT baseline model on the output of the rule-based approach when applied to GYAFC.

NMT Copy: Jhamtani et al., (2017) introduce a copy-enriched NMT model for style transfer to better handle stretches of text which should not be changed. We incorporate this mechanism into our NMT Baseline.

NMT Combined: The size of our parallel data is smaller than the size typically used to train NMT models. Motivated by this fact, we propose several variants to the baseline models that we find helps minimize this issue. We augment the data used to train NMT Copy via two techniques: 1) we run the PBMT model on additional source data, and 2) we use back-translation (Sennrich et al., 2016c) of the PBMT model to translate the large number of in-domain target style sentences from GYAFC. To balance the over one million artificially generated pairs from the respective techniques, we upweight the rule-based GYAFC data via duplication.[12]

5 Evaluation

As discussed earlier, there has been very little research into best practices for style transfer evaluation. Only a few works have included a human evaluation (Xu et al., 2012; Jhamtani et al., 2017), and automatic evaluations have employed BLEU or PINC (Xu et al., 2012; Chen and Dolan, 2011), which have been borrowed from other fields and not vetted for this task. In our work, we conduct a more thorough and detailed evaluation using both humans and automatic metrics to assess transformations. Inspired by work in the paraphrase community (Callison-Burch, 2008), we solicit ratings on how formal, how fluent and how meaning-preserving a rewrite is. Additionally, we look at the correlation between the human judgments and the automatic metrics.

5.1 Human-based Evaluation

We perform human-based evaluation to assess model outputs on the four criteria: *formality*, *fluency*, *meaning* and *overall*. For a subset of 500 sentences from the test sets of both *Entertainment & Music* and *Family & Relationship* domains, we collect five human judgments per sentence per criteria using Amazon Mechanical Turk as follows:

[11] Details are in the supplementary material.

[12] Training data sizes for different methods are summarized in the supplementary material.

Formality: Following PT16, workers rate the formality of the source style sentence, the target style reference rewrite and the target style model outputs on a discrete scale of -3 to +3 described as: *-3: Very Informal, -2: Informal, -1: Somewhat Informal, 0: Neutral, 1: Somewhat Formal, 2: Formal and 3: Very Formal*.

Fluency: Following Heilman et al. (2014), workers rate the fluency of the source style sentence, the target style reference rewrite and the target style model outputs on a discrete scale of 1 to 5 described as: *5: Perfect, 4: Comprehensible, 3: Somewhat Comprehensible, 2: Incomprehensible*. We additionally provide an option of *1: Other* for sentences that are incomplete or just a fragment.

Meaning Preservation: Following the annotation scheme developed for the Semantic Textual Similarity (STS) dataset (Agirre et al., 2016), given two sentences i.e. the source style sentence and the target style reference rewrite or the target style model output, workers rate the meaning similarity of the two sentences on a scale of 1 to 6 described as: *6: Completely equivalent, 5: Mostly equivalent, 4: Roughly equivalent, 3: Not equivalent but share some details, 2: Not equivalent but on same topic, 1: Completely dissimilar*.

Overall Ranking: In addition to the fine-grained human judgments, we collect judgments to assess the overall ranking of the systems. Given the original source style sentence, the target style reference rewrite and the target style model outputs, we ask workers to rank the rewrites in the order of their overall formality, taking into account both fluency and meaning preservation. We then rank the model using the equation below:

$$rank(model) = \frac{1}{|S|} \sum_{s \in S} \frac{1}{|J|} \sum_{j \in J} rank(s_{model}, j) \quad (1)$$

where, $model$ is the one of our models, S is a subset of 500 test set sentences, J is the set of five judgments, s_{model} is the model rewrite for sentence s, and $rank(s_{model}, j)$ is the rank of s_{model} in judgment j.

The two authors of the paper reviewed these human judgments and found that in majority of the cases the annotations looked correct. But as is common in any such crowdsourced data collection process, there were some errors, especially in the overall ranking of the systems.

5.2 Automatic Metrics

We cover each of the human evaluations with a corresponding automatic metric:

Formality: We use the formality classifier described in PT16. We find that the classifier trained on the *answers* genre of PT16 dataset does not perform well when tested on our datasets. Hence, we collect formality judgments for an additional 5000 sentences and use the formality classifier re-trained on this in-domain data.

Fluency: We use the reimplementation[13] of Heilman et al. (2014) (H14 in Table 4) which is a statistical model for predicting the grammaticality of a sentence on a scale of 0 to 4 previously shown to be effective for other generation tasks like grammatical error correction (Napoles et al., 2016).

Meaning Preservation: Modeling semantic similarity at a sentence level is a fundamental language processing task, and one that is a wide open field of research. Recently, He et al., (2015) (HE15 in Table 4) developed a convolutional neural network based sentence similarity measure. We use their off-the-shelf implementation[14] to train a model on the STS and use it to measure the meaning similarity between the original source style sentence and its target style rewrite (both reference and model outputs).

Overall Ranking: We experiment with BLEU (Papineni et al., 2002) and PINC (Chen and Dolan, 2011) as both were used in prior style evaluations, as well as TERp (Snover et al., 2009).

6 Results

In this section, we discuss how well the five models perform in the *informal* to *formal* style transfer task using human judgments (§6.1) and automatic metrics (§6.2), the correlation of the automatic metrics and human judgments to determine the ef-

Table 4: Results of models on 500 test sentences from E&M for *informal* to *formal* task evaluated using human judgments and automatic metrics for three criteria of evaluation: formality, fluency and meaning preservation. Scores marked with * are significantly different from the rule-based scores with $p < 0.001$.

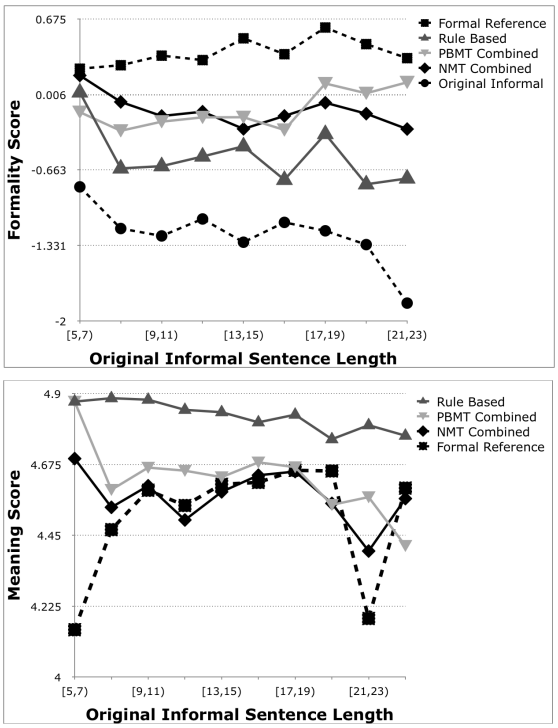

Figure 3: For varying sentence lengths of the original informal sentence the *formality* and the *meaning* scores from human judgments on different model outputs and on the original informal and the formal reference sentences.

ficacy of the metrics (§6.3) and present a manual analysis (§6.4). We randomly select 500 sentences from each test set and run all five models. We use the entire train and tune split for training and tuning. We discuss results only on the E&M domain and list results on the F&R domain in the supplementary material.

Table 4 shows the results for human §6.1 and automatic §6.2 evaluation of model rewrites. For all metrics except *TERp*, a higher score is better. For each of the automatic metrics, we evaluate against four human references. The row *'Original Informal'* contains the scores when the original informal sentence is compared with the four formal reference rewrites. Comparing the model scores to this score helps us understand how closer are the model outputs to the formal reference rewrites compared to initial distance between the informal and the formal reference rewrite.

6.1 Results using Human Judgments

The columns marked *'Human'* in Table 4 show the human judgments for the models on the three separate criteria of *formality*, *fluency* and *meaning* collected using the process described in Section 5.1.[15] The NMT Baseline and Copy models beat others on the formality axis by a significant margin. Only the NMT Combined model achieves a statistically higher fluency score when compared to the rule-based baseline model. As expected, the rule-based model is the most meaning preserving since it is the most conservative. Figure 3 shows the trend in the four leading models along *formality* and *meaning* for varying lengths of the source sentence. NMT Combined beats PBMT on *formality* for shorter lengths whereas the trend reverses as the length increases. PBMT generally preserves meaning more than the NMT Combined. We find that the fluency scores for all models decreases as the sentence length increases which is similar to the trend generally observed with machine translation based approaches.

Since a good style transfer model is the one that attains a balanced score across all the three axes, we evaluate the models on a combination of these metrics[16] shown under the column *'Combined'* in Table 4. NMT Combined is the only model having a combined score statistically greater than the rule-based approach.

[15] Out of the four reference rewrites, we pick one at random to show to Turkers.

[16] We recalibrate the scores to normalize for different ranges.

Finally, Table 5 shows the overall rankings of the models from best to worst in both domains. PBMT and NMT Combined models beat the rule-based model although not significantly in the E&M domain but significantly in the F&R domain. Interestingly, the rule-based approach attains third place with a score significantly higher than NMT Copy and NMT Baseline models. It is important to note here that while such a rule-based approach is relatively easy to craft for the formality style transfer task, the same may not be true for other styles like politeness or persuasiveness.

E&M	F&R
(2.03*) Reference	(2.13*) Reference
(2.47) PBMT	(2.38*) PBMT
(2.48) NMT Combined	(2.38*) NMT Combined
(2.54) Rule-based	(2.56) Rule-based
(3.03*) NMT Copy	(2.72*) NMT Copy
(3.03*) NMT Baseline	(2.79*) NMT Baseline

Table 5: Ranking of different models on the *informal* to *formal* style transfer task. Rankings marked with * are significantly different from the rule-based ranking with $p < 0.001$.

Automatic	**Human**	**E&M**	**F&R**
Formality	*Formality*	0.47	0.45
Fluency	*Fluency*	0.48	0.46
Meaning	*Meaning*	0.33	0.30
BLEU	*Overall*	-0.48	-0.43
TERp	*Overall*	0.31	0.30
PINC	*Overall*	0.11	0.08

Table 6: Spearman rank correlation between automatic metrics and human judgments. The first three metrics are correlated with their respective human judgments and the last three metrics are correlated with the *overall ranking* human judgments. All correlations are statistically significant with $p < 0.001$.

6.2 Results with Automatic Metrics

Under automatic metrics, the formality and meaning scores align with the human judgments with the NMT Baseline and NMT Copy winning on formality and rule-based winning on meaning. The fluency score of the NMT Baseline is the highest in contrast to human judgments where the NMT Combined wins. This discrepancy could be due to H14 being trained on *essays* which contains sentences of a more formal genre compared to Yahoo Answers. In fact, the fluency classifier scores the formal reference quite low as well. Under overall metrics, PBMT and NMT Combined models beat other models as per BLEU (significantly) and TERp (not significantly). NMT Baseline and NMT copy win over other models as per PINC which can be explained by the fact that PINC measures lexical dissimilarity with the source and NMT models tend towards making more changes. Although such an analysis is useful, for a more thorough understanding of these metrics, we next look at their correlation with human judgments.

6.3 Metric Correlation

We report the spearman rank correlation coefficient between automatic metrics and human judgments in Table 6. For *formality*, *fluency* and *meaning*, the correlation is with their respective human judgments whereas for BLEU, TERp and PINC, the correlation is with the overall ranking.

We see that the formality and the fluency metrics correlate moderately well while the meaning metric correlates comparatively poorly. To be fair, the HE15 classifier was trained on the STS dataset which contains more formal writing than informal. BLEU correlates moderately well (better than what XU12 observed for the Shakespeare task) whereas the correlation drops for TERp. PINC, on the other hand, correlates very poorly with a positive correlation with rank when it should have a negative correlation with rank, just like BLEU. This sheds light on the fact that PINC, on its own, is not a good metric for style transfer since it prefers lexical edits at the cost of meaning changes. In the Shakespeare task, XU12 did observe a higher correlation with PINC (0.41) although the correlation was not with overall system ranking but rather only on the style metric. Moreover, in the Shakespeare task, changing the text is more favorable than in formality.

6.4 Manual Analysis

The prior evaluations reveal the relative performance differences between approaches. Here, we identify trends per and between approaches. We sample 50 informal sentences total from both domains and then analyze the outputs from each model. We present sample sentences in Table 7.

The NMT Baseline and NMT Copy tend to have the most variance in their performance. This is likely due to the fact that they are trained on only 50K sentence pairs, whereas the other models are trained on much more data. For shorter sentences, these models make some nice formal transformations like from '*very dumb*' to '*very foolish*'. However, for longer sentences, these models make drastic meaning changes and drop some content altogether (see examples in Table 7). On the

Entertainment & Music	
Original Informal	Wow , I am very dumb in my observation skills .....
Reference Formal	I do not have good observation skills .
Rule-based	Wow , I am very dumb in my observation skills .
PBMT	Wow , I am very dumb in my observation skills .
NMT Baseline	I am very foolish in my observation skills .
NMT Copy	Wow , I am very foolish in my observation skills .
NMT Combined	I am very unintelligent in my observation skills .
Family & Relationship	
Original Informal	i hardly everrr see him in school either usually i see hima t my brothers basketball games .
Reference Formal	I hardly ever see him in school . I usually see him with my brothers playing basketball .
Rule-based	I hardly everrr see him in school either usually I see hima t my brothers basketball games .
PBMT	I hardly see him in school as well, but my brothers basketball games .
NMT	I rarely see him in school , either I see him at my brother 's basketball games .
NMT Copy	I hardly see him in school either , usually I see him at my brother 's basketball games .
NMT Combined	I rarely see him in school either usually I see him at my brothers basketball games .

Table 7: Sample model outputs with references from both E&M and F&R domains on the *informal* to *formal* task

other hand, the PBMT and NMT Combined models have lower variance in their performance. They make changes more conservatively but when they do, they are usually correct. Thus, most of the outputs from these two models are usually meaning preserving but at the expense of a lower formality score improvement.

In most examples, all models are good at removing very informal words like '*stupid*', '*idiot*' and '*hell*', with PBMT and NMT Combined models doing slightly better. All models struggle when the original sentence is very informal or disfluent. They all also struggle with sentence completions that humans seem to be very good at. This might be because humans assume a context when absent, whereas the models do not. Unknown tokens, either real words or misspelled words, tend to wreak havoc on all approaches. In most cases, the models simply did not transform that section of the sentence, or remove the unknown tokens. Most models are effective at low-level changes such as writing out numbers, inserting commas, and removing common informal phrases.

7 Conclusions and Future Work

The goal of this paper was to move the field of style transfer forward by creating a large training and evaluation corpus to be made public, showing that adapting MT techniques to this task can serve as strong baselines for future work, and analyzing the usefulness of existing metrics for overall style transfer as well as three specific criteria of automatic style transfer evaluation. We view this work as rigorously expanding on the foundation set by XU12 five years earlier. It is our hope that with a common test set, the field can finally benchmark approaches which do not require parallel data.

We found that while the NMT systems perform well given automatic metrics, humans had a slight preference for the PBMT approach. That being said, two of the neural approaches (NMT Baseline and Copy) often made successful changes and larger rewrites that the other models could not. However, this often came at the expense of a meaning change.

We also introduced new metrics and vetted all metrics using comparison with human judgments. We found that previously-used metrics did not correlate well with human judgments, and thus should be avoided in system development or final evaluation. The formality and fluency metrics correlated best and we believe that some combination of these metrics with others would be the best next step in the development of style transfer metrics. Such a metric could then in turn be used to optimize MT models. Finally, in this work we focused on one particular style, formality. The long term goal is to generalize the methods and metrics to any style.

Acknowledgments

The authors would like to thank Yahoo Research for making their data available. The authors would also like to thank Junchao Zheng and Claudia Leacock for their help in the data creation process, Courtney Napoles for providing the fluency scores, Marcin Junczys-Dowmunt, Rico Sennrich, Ellie Pavlick, Maksym Bezva, Dimitrios Alikaniotis and Kyunghyun Cho for helpful discussion and the three anonymous reviewers for their useful comments and suggestions.

Improving Implicit Discourse Relation Classification by Modeling Inter-dependencies of Discourse Units in a Paragraph

Zeyu Dai, Ruihong Huang
Department of Computer Science and Engineering
Texas A&M University
{jzdaizeyu, huangrh}@tamu.edu

Abstract

We argue that semantic meanings of a sentence or clause can not be interpreted independently from the rest of a paragraph, or independently from all discourse relations and the overall paragraph-level discourse structure. With the goal of improving implicit discourse relation classification, we introduce a paragraph-level neural networks that model inter-dependencies between discourse units as well as discourse relation continuity and patterns, and predict a sequence of discourse relations in a paragraph. Experimental results show that our model outperforms the previous state-of-the-art systems on the benchmark corpus of PDTB.

1 Introduction

PDTB-style discourse relations, mostly defined between two adjacent text spans (i.e., discourse units, either clauses or sentences), specify how two discourse units are logically connected (e.g., causal, contrast). Recognizing discourse relations is one crucial step in discourse analysis and can be beneficial for many downstream NLP applications such as information extraction, machine translation and natural language generation.

Commonly, explicit discourse relations were distinguished from implicit ones, depending on whether a discourse connective (e.g., "because" and "after") appears between two discourse units (Prasad et al., 2008a). While explicit discourse relation detection can be framed as a discourse connective disambiguation problem (Pitler and Nenkova, 2009; Lin et al., 2014) and has achieved reasonable performance (F1 score $>$ 90%), implicit discourse relations have no discourse connective and are especially difficult to identify (Lin et al., 2009, 2014; Xue et al., 2015). To fill the gap, implicit discourse relation prediction has drawn significant research interest recently and progress has been made (Chen et al., 2016; Liu and Li, 2016) by modeling compositional meanings of two discourse units and exploiting word interactions between discourse units using neural tensor networks or attention mechanisms in neural nets. However, most of existing approaches ignore wider paragraph-level contexts beyond the two discourse units that are examined for predicting a discourse relation in between.

To further improve implicit discourse relation prediction, we aim to improve discourse unit representations by positioning a discourse unit (DU) in its wider context of a paragraph. The key observation is that semantic meaning of a DU can not be interpreted independently from the rest of the paragraph that contains it, or independently from the overall paragraph-level discourse structure that involve the DU. Considering the following paragraph with four discourse relations, one relation between each two adjacent DUs:

(1): *[The Butler, Wis., manufacturer went public at $15.75 a share in August 1987,]*$_{DU1}$ *and* ***(Explicit-Expansion)*** *[Mr. Sim's goal then was a $29 per-share price by 1992.]*$_{DU2}$ ***(Implicit-Expansion)*** *[Strong earnings growth helped achieve that price far ahead of schedule, in August 1988.]*$_{DU3}$ ***(Implicit-Comparison)*** *[The stock has since softened, trading around $25 a share last week and closing yesterday at $23 in national over-the-counter trading.]*$_{DU4}$ *But* ***(Explicit-Comparison)*** *[Mr. Sim has set a fresh target of $50 a share by the end of reaching that goal.]*$_{DU5}$

Clearly, each DU is an integral part of the paragraph and not independent from other units. *First*, predicting a discourse relation may require understanding wider paragraph-level contexts beyond two relevant DUs and the overall discourse structure of a paragraph. For example, the implicit "Comparison" discourse relation between DU3 and DU4 is difficult to identify without the back-

Proceedings of NAACL-HLT 2018, pages 141–151
New Orleans, Louisiana, June 1 - 6, 2018.

ground information (the history of per-share price) introduced in DU1 and DU2. *Second*, a DU may be involved in multiple discourse relations (e.g., DU4 is connected with both DU3 and DU5 with a "Comparison" relation), therefore the pragmatic meaning representation of a DU should reflect all the discourse relations the unit was involved in. *Third*, implicit discourse relation prediction should benefit from modeling discourse relation continuity and patterns in a paragraph that involve easy-to-identify explicit discourse relations (e.g., "Implicit-Comparison" relation is followed by "Explicit-Comparison" in the above example).

Following these observations, we construct a neural net model to process a paragraph each time and jointly build meaning representations for all DUs in the paragraph. The learned DU representations are used to predict a sequence of discourse relations in the paragraph, including both implicit and explicit relations. Although explicit relations are not our focus, predicting an explicit relation will help to reveal the pragmatic roles of its two DUs and reconstruct their representations, which will facilitate predicting neighboring implicit discourse relations that involve one of the DUs.

In addition, we introduce two novel designs to further improve discourse relation classification performance of our paragraph-level neural net model. First, previous work has indicated that recognizing explicit and implicit discourse relations requires different strategies, we therefore untie parameters in the discourse relation prediction layer of the neural networks and train two separate classifiers for predicting explicit and implicit discourse relations respectively. This unique design has improved both implicit and explicit discourse relation identification performance. Second, we add a CRF layer on top of the discourse relation prediction layer to fine-tune a sequence of predicted discourse relations by modeling discourse relation continuity and patterns in a paragraph.

Experimental results show that the intuitive paragraph-level discourse relation prediction model achieves improved performance on PDTB for both implicit discourse relation classification and explicit discourse relation classification.

2 Related Work

2.1 Implicit Discourse Relation Recognition

Since the PDTB (Prasad et al., 2008b) corpus was created, a surge of studies (Pitler et al., 2009; Lin et al., 2009; Liu et al., 2016; Rutherford and Xue, 2016) have been conducted for predicting discourse relations, primarily focusing on the challenging task of implicit discourse relation classification when no explicit discourse connective phrase was presented. Early studies (Pitler et al., 2008; Lin et al., 2009, 2014; Rutherford and Xue, 2015) focused on extracting linguistic and semantic features from two discourse units. Recent research (Zhang et al., 2015; Rutherford et al., 2016; Ji and Eisenstein, 2015; Ji et al., 2016) tried to model compositional meanings of two discourse units by exploiting interactions between words in two units with more and more complicated neural network models, including the ones using neural tensor (Chen et al., 2016; Qin et al., 2016; Lei et al., 2017) and attention mechanisms (Liu and Li, 2016; Lan et al., 2017; Zhou et al., 2016). Another trend is to alleviate the shortage of annotated data by leveraging related external data, such as explicit discourse relations in PDTB (Liu et al., 2016; Lan et al., 2017; Qin et al., 2017) and unlabeled data obtained elsewhere (Rutherford and Xue, 2015; Lan et al., 2017), often in a multi-task joint learning framework.

However, nearly all the previous works assume that a pair of discourse units is independent from its wider paragraph-level contexts and build their discourse relation prediction models based on *only* two relevant discourse units. In contrast, we model inter-dependencies of discourse units in a paragraph when building discourse unit representations; in addition, we model global continuity and patterns in a sequence of discourse relations, including both implicit and explicit relations.

Hierarchical neural network models (Liu and Lapata, 2017; Li et al., 2016) have been applied to RST-style discourse parsing (Carlson et al., 2003) mainly for the purpose of generating text-level hierarchical discourse structures. In contrast, we use hierarchical neural network models to build context-aware sentence representations in order to improve implicit discourse relation prediction.

2.2 Paragraph Encoding

Abstracting latent representations from a long sequence of words, such as a paragraph, is a challenging task. While several novel neural network models (Zhang et al., 2017b,a) have been introduced in recent years for encoding a paragraph, Recurrent Neural Network (RNN)-based

methods remain the most effective approaches. RNNs, especially the long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) models, have been widely used to encode a paragraph for machine translation (Sutskever et al., 2014), dialogue systems (Serban et al., 2016) and text summarization (Nallapati et al., 2016) because of its ability in modeling long-distance dependencies between words. In addition, among four typical pooling methods (sum, mean, last and max) for calculating sentence representations from RNN-encoded hidden states for individual words, max-pooling along with bidirectional LSTM (Bi-LSTM) (Schuster and Paliwal, 1997) yields the current best universal sentence representation method (Conneau et al., 2017). We adopted a similar neural network architecture for paragraph encoding.

3 The Neural Network Model for Paragraph-level Discourse Relation Recognition

3.1 The Basic Model Architecture

Figure 1 illustrates the overall architecture of the discourse-level neural network model that consists of two Bi-LSTM layers, one max-pooling layer in between and one softmax prediction layer. The input of the neural network model is a paragraph containing a sequence of discourse units, while the output is a sequence of discourse relations with one relation between each pair of adjacent discourse units[1].

Given the words sequence of one paragraph as input, the lower Bi-LSTM layer will read the whole paragraph and calculate hidden states as word representations, and a max-pooling layer will be applied to abstract the representation of each discourse unit based on individual word representations. Then another Bi-LSTM layer will run over the sequence of discourse unit representations and compute new representations by further modeling semantic dependencies between discourse units within paragraph. The final softmax prediction layer will concatenate representations of two adjacent discourse units and predict the discourse relation between them.

Word Vectors as Input: The input of the paragraph-level discourse relation prediction model is a sequence of word vectors, one vector per word in the paragraph. In this work, we used the pre-trained 300-dimension Google English word2vec embeddings[2]. For each word that is not in the vocabulary of Google word2vec, we will randomly initialize a vector with each dimension sampled from the range $[-0.25, 0.25]$. In addition, recognizing key entities and discourse connective phrases is important for discourse relation recognition, therefore, we concatenate the raw word embeddings with extra linguistic features, specifically one-hot Part-Of-Speech tag embeddings and one-hot named entity tag embeddings[3].

Building Discourse Unit Representations: We aim to build discourse unit (DU) representations that sufficiently leverage cues for discourse relation prediction from paragraph-wide contexts, including the preceding and following discourse units in a paragraph. To process long paragraph-wide contexts, we take a bottom-up two-level abstraction approach and progressively generate a compositional representation of each word first (low level) and then generate a compositional representation of each discourse unit (high level), with a max-pooling operation in between. At both word-level and DU-level, we choose Bi-LSTM as our basic component for generating compositional representations, mainly considering its capability to capture long-distance dependencies between words (discourse units) and to incorporate influences of context words (discourse units) in each side.

Given a variable-length words sequence $X = (x_1, x_2, ..., x_L)$ in a paragraph, the word-level Bi-LSTM will process the input sequence by using two separate LSTMs, one process the word sequence from the left to right while the other follows the reversed direction. Therefore, at each word position t, we obtain two hidden states $\overrightarrow{h_t}, \overleftarrow{h_t}$. We concatenate them to get the word representation $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$. Then we apply max-pooling over the sequence of word representations for words in a discourse unit in order to get the discourse unit embedding:

[1] In PDTB, most of discourse relations were annotated between two adjacent sentences or two adjacent clauses. For exceptional cases, we applied heuristics to convert them.

[2] Downloaded from https://docs.google.com/uc?id=0B7XkCwpI5KDYNlNUTTlSS21pQmM

[3] Our feature-rich word embeddings are of dimension 343, including 300 dimensions for word2vec embeddings + 36 dimensions for Part-Of-Speech (POS) tags + 7 dimensions for named entity tags. We used the Stanford CoreNLP to generate POS tags and named entity tags.

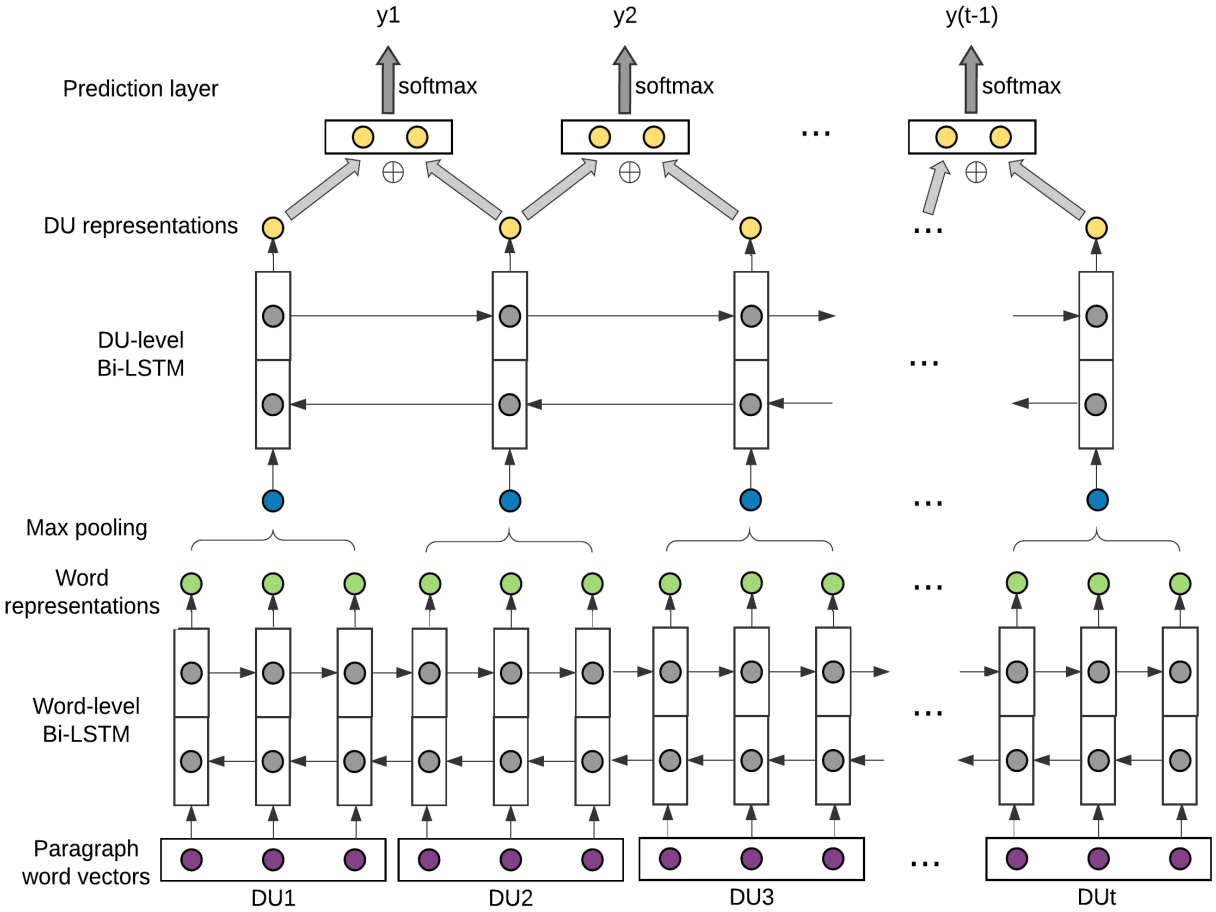

Figure 1: The Basic Model Architecture for Paragraph-level Discourse Relations Sequence Prediction.

$$MP_{DU}[j] = \max_{i=DU\_start}^{DU\_end} h_i[j] \quad (1)$$

$$where, 1 \leq j \leq hidden\_node\_size \quad (2)$$

Next, the DU-level Bi-LSTM will process the sequence of discourse unit embeddings in a paragraph and generate two hidden states $\overrightarrow{hDU_t}$ and $\overleftarrow{hDU_t}$ at each discourse unit position. We concatenate them to get the discourse unit representation $hDU_t = [\overrightarrow{hDU_t}, \overleftarrow{hDU_t}]$.

The Softmax Prediction Layer: Finally, we concatenate two adjacent discourse unit representations hDU_{t-1} and hDU_t and predict the discourse relation between them using a softmax function:

$$y_{t-1} = softmax(W_y * [hDU_{t-1}, hDU_t] + b_y) \quad (3)$$

3.2 Untie Parameters in the Softmax Prediction Layer (Implicit vs. Explicit)

Previous work (Pitler and Nenkova, 2009; Lin et al., 2014; Rutherford and Xue, 2016) has revealed that recognizing explicit vs. implicit discourse relations requires different strategies. Note that in the PDTB dataset, explicit discourse relations were distinguished from implicit ones, depending on whether a discourse connective exists between two discourse units. Therefore, explicit discourse relation detection can be simplified as a discourse connective phrase disambiguation problem (Pitler and Nenkova, 2009; Lin et al., 2014). On the contrary, predicting an implicit discourse relation should rely on understanding the overall

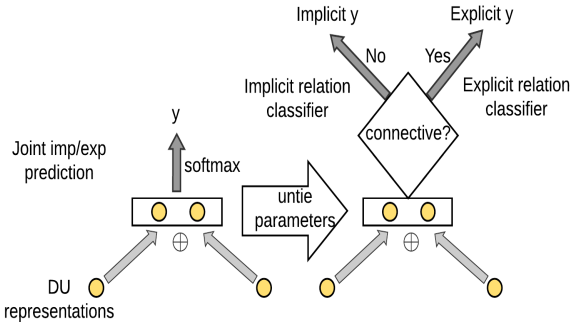

Figure 2: Untie Parameters in the Prediction Layer

contents of its two discourse units (Lin et al., 2014; Rutherford and Xue, 2016).

Considering the different natures of explicit vs. implicit discourse relation prediction, we decide to untie parameters at the final discourse relation prediction layer and train two softmax classifiers, as illustrated in Figure 2. The two classifiers have different sets of parameters, with one classifier for *only* implicit discourse relations and the other for *only* explicit discourse relations.

$$y_{t-1} = \begin{cases} softmax(W_{exp}[hDU_{t-1}, hDU_t] + b_{exp}), & exp \\ softmax(W_{imp}[hDU_{t-1}, hDU_t] + b_{imp}), & imp \end{cases} \quad (4)$$

The loss function used for the neural network training considers loss induced by both implicit relation prediction and explicit relation prediction:

$$Loss = Loss_{imp} + \alpha * Loss_{exp} \quad (5)$$

The α, in the full system, is set to be 1, which means that minimizing the loss in predicting either type of discourse relations is equally important. In the evaluation, we will also evaluate a system variant, where we will set $\alpha = 0$, which means that the neural network will not attempt to predict explicit discourse relations and implicit discourse relation prediction will not be influenced by predicting neighboring explicit discourse relations.

3.3 Fine-tune Discourse Relation Predictions Using a CRF Layer

Data analysis and many linguistic studies (Pitler et al., 2008; Asr and Demberg, 2012; Lascarides and Asher, 1993; Hobbs, 1985) have repeatedly shown that discourse relations feature continuity and patterns (e.g., a temporal relation is likely to be followed by another temporal relation). Especially, Pitler et al. (2008) firstly reported that patterns exist between implicit discourse relations and their neighboring explicit discourse relations.

Motivated by these observations, we aim to improve implicit discourse relation detection by making use of easily identifiable explicit discourse relations and taking into account global patterns of discourse relation distributions. Specifically, we add an extra CRF layer at the top of the softmax prediction layer (shown in figure 3) to fine-tune predicted discourse relations by considering their inter-dependencies.

The Conditional Random Fields (Lafferty et al., 2001) (CRF) layer updates a state transition matrix, which can effectively adjust the current label depending on proceeding and following labels. Both training and decoding of the CRF layer can be solved efficiently by using the Viterbi algorithm. With the CRF layer, the model jointly assigns a sequence of discourse relations between each two adjacent discourse units in a paragraph, including both implicit and explicit relations, by considering relevant discourse unit representations as well as global discourse relation patterns.

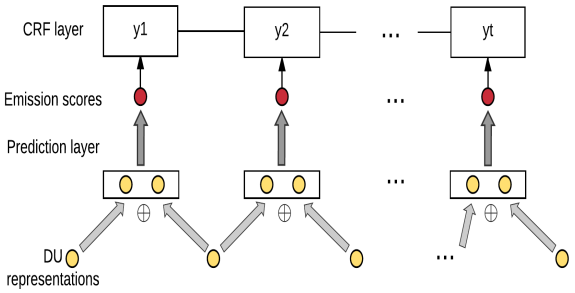

Figure 3: Fine-tune Discourse Relations with a CRF layer.

4 Evaluation

4.1 Dataset and Preprocessing

The Penn Discourse Treebank (PDTB): We experimented with PDTB v2.0 (Prasad et al., 2008b) which is the largest annotated corpus containing 36k discourse relations in 2,159 Wall Street Journal (WSJ) articles. In this work, we focus on the top-level[4] discourse relation senses which are consist of four major semantic classes: Comparison (Comp), Contingency (Cont), Expansion (Exp) and Temporal (Temp). We followed the same PDTB section partition (Rutherford and Xue, 2015) as previous work and used sections 2-20 as training set, sections 21-22 as test set, and sections 0-1 as development set. Table 1 presents the data distributions we collected from PDTB.

Preprocessing: The PDTB dataset documents its annotations as a list of discourse relations, with each relation associated with its two discourse units. To recover the paragraph context for a discourse relation, we match contents of its two annotated discourse units with all paragraphs in corresponding raw WSJ article. When all the matching was completed, each paragraph was split into a sequence of discourse units, with one discourse relation (implicit or explicit) between each two ad-

[4]In PDTB, the sense label of discourse relation was annotated hierarchically with three levels.

Type	Class	Train	Dev	Test	Total
Implicit	Comp	1942	197	152	2291

jacent discourse units[5]. Following this method, we obtained 14,309 paragraphs in total, each contains 3.2 discourse units on average. Table 2 shows the distribution of paragraphs based on the number of discourse units in a paragraph.

4.2 Parameter Settings and Model Training

We tuned the parameters based on the best performance on the development set. We fixed the weights of word embeddings during training. All the LSTMs in our neural network use the hidden state size of 300. To avoid overfitting, we applied dropout (Hinton et al., 2012) with dropout ratio of 0.5 to both input and output of LSTM layers. To prevent the exploding gradient problem in training LSTMs, we adopt gradient clipping with gradient L2-norm threshold of 5.0. These parameters remain the same for all our proposed models as well as our own baseline models.

We chose the standard cross-entropy loss function for training our neural network model and adopted Adam (Kingma and Ba, 2014) optimizer with the initial learning rate of 5e-4 and a mini-batch size of 128[6]. If one instance is annotated with two labels (4% of all instances), we use both of them in loss calculation and regard the prediction as correct if model predicts one of the annotated labels. All the proposed models were implemented with Pytorch[7] and converged to the best performance within 20-40 epochs.

To alleviate the influence of randomness in neural network model training and obtain stable experimental results, we ran each of the proposed models and our own baseline models ten times and report the average performance of each model instead of the best performance as reported in many previous works.

4.3 Baseline Models and Systems

We compare the performance of our neural network model with several recent discourse relation recognition systems that only consider two relevant discourse units.

- (Rutherford and Xue, 2015): improves implicit discourse relation prediction by creating more training instances from the Gigaword corpus utilizing explicitly mentioned discourse connective phrases.
- (Chen et al., 2016): a gated relevance network (GRN) model with tensors to capture semantic interactions between words from two discourse units.
- (Liu et al., 2016): a convolutional neural network model that leverages relations between different styles of discourse relations annotations (PDTB and RST (Carlson et al., 2003)) in a multi-task joint learning framework.
- (Liu and Li, 2016): a multi-level attention-over-attention model to dynamically exploit features from two discourse units for recognizing an implicit discourse relation.
- (Qin et al., 2017): a novel pipelined adversarial framework to enable an adaptive imitation competition between the implicit network and a rival feature discriminator with access to connectives.
- (Lei et al., 2017): a Simple Word Interaction Model (SWIM) with tensors that captures both linear and quadratic relations between words from two discourse units.
- (Lan et al., 2017): an attention-based LSTM neural network that leverages explicit discourse relations in PDTB and unannotated external data in a multi-task joint learning framework.

[5] In several hundred discourse relations, one discourse unit is complex and can be further separated into two elementary discourse units, which can be illustrated as [DU1-DU2]-DU3. We simplify such cases to be a relation between DU2 and DU3.

[6] Counted as the number of discourse relations rather than paragraph instances.

Table 3: Multi-class Classification Results on PDTB. We report accuracy (Acc) and macro-average F1-scores for both explicit and implicit discourse relation predictions. We also report class-wise F1 scores.

4.4 Evaluation Settings

On the PDTB corpus, both binary classification and multi-way classification settings are commonly used to evaluate the implicit discourse relation recognition performance. We noticed that all the recent works report class-wise implicit relation prediction performance in the binary classification setting, while none of them report detailed performance in the multi-way classification setting. In the binary classification setting, separate "one-versus-all" binary classifiers were trained, and each classifier is to identify one class of discourse relations. Although separate classifiers are generally more flexible in combating with imbalanced distributions of discourse relation classes and obtain higher class-wise prediction performance, one pair of discourse units may be tagged with all four discourse relations without proper conflict resolution. Therefore, the multi-way classification setting is more appropriate and natural in evaluating a practical end-to-end discourse parser, and we mainly evaluate our proposed models using the four-way multi-class classification setting.

Since none of the recent previous work reported class-wise implicit relation classification performance in the multi-way classification setting, for better comparisons, we re-implemented the neural tensor network architecture (so-called SWIM in (Lei et al., 2017)) which is essentially a Bi-LSTM model with tensors and report its detailed evaluation result in the multi-way classification setting. As another baseline, we report the performance of a Bi-LSTM model without tensors as well. Both baseline models take two relevant discourse units as the only input.

For additional comparisons, We also report the performance of our proposed models in the binary classification setting.

4.5 Experimental Results

Multi-way Classification: The first section of table 3 shows macro average F1-scores and accuracies of previous works. The second section of table 3 shows the multi-class classification results of our implemented baseline systems. Consistent with results of previous works, neural tensors, when applied to Bi-LSTMs, improved implicit discourse relation prediction performance. However, the performance on the three small classes (Comp, Cont and Temp) remains low.

The third section of table 3 shows the multi-class classification results of our proposed paragraph-level neural network models that capture inter-dependencies among discourse units. The first row shows the performance of a variant of our basic model, where we only identify implicit relations and ignore identifying explicit relations by setting the α in equation (5) to be 0. Compared with the baseline Bi-LSTM model, the only difference is that this model considers paragraph-wide contexts and model inter-dependencies among discourse units when building representation for individual DU. We can see that this model has greatly improved implicit relation classification perfor-

Model	Comp	Cont	Exp	Temp
(Chen et al., 2016)	40.17	54.76	-	31.32
(Liu et al., 2016)	37.91	55.88	69.97	37.17

	Implicit		Explicit	
Model	Macro	Acc	Macro	Acc
Basic System ($\alpha = 1$)	49.92	59.08	93.05	93.83
+ Untie Parameters	50.47	**59.85**	93.95	94.74
+ the CRF Layer	**51.84**	59.75	**94.17**	**94.82**

Table 5: Multi-class Classification Results of Ensemble Models on PDTB.

mance across all the four relations and improved the macro-average F1-score by over 7 percents. In addition, compared with the baseline Bi-LSTM model with tensor, this model improved implicit relation classification performance across the three small classes, with clear performance gains of around 2 and 8 percents on contingency and temporal relations respectively, and overall improved the macro-average F1-score by 2.2 percents.

The second row shows the performance of our basic paragraph-level model which predicts both implicit and explicit discourse relations in a paragraph. Compared to the variant system (the first row), the basic model further improved the classification performance on the first three implicit relations. Especially on the contingency relation, the classification performance was improved by another 1.42 percents. Moreover, the basic model yields good performance for recognizing explicit discourse relations as well, which is comparable with previous best result (92.05% macro F1-score and 93.09% accuracy as reported in (Pitler et al., 2008)).

After untying parameters in the softmax prediction layer, implicit discourse relation classification performance was improved across all four relations, meanwhile, the explicit discourse relation classification performance was also improved. The CRF layer further improved implicit discourse relation recognition performance on the three small classes. In summary, our full paragraph-level neural network model achieves the best macro-average F1-score of 48.82% in predicting implicit discourse relations, which outperforms previous neural tensor network models (e.g., (Lei et al., 2017)) by more than 2 percents and outperforms the best previous system (Lan et al., 2017) by 1 percent.

Binary Classification: From table 4, we can see that compared against the best previous systems, our paragraph-level model with untied parameters in the prediction layer achieves F1-score improvements of 6 points on Comparison and 7 points on Temporal, which demonstrates that paragraph-wide contexts are important in detecting minority discourse relations. Note that the CRF layer of the model is not suitable for binary classification.

4.6 Ensemble Model

As we explained in section 4.2, we ran our models for 10 times to obtain stable average performance. Then we also created ensemble models by applying majority voting to combine results of ten runs. From table 5, each ensemble model obtains performance improvements compared with single model. The full model achieves performance boosting of (51.84 - 48.82 = 3.02) and (94.17 - 93.21 = 0.96) in macro F1-scores for predicting implicit and explicit discourse relations respectively. Furthermore, the ensemble model achieves the best performance for predicting both implicit

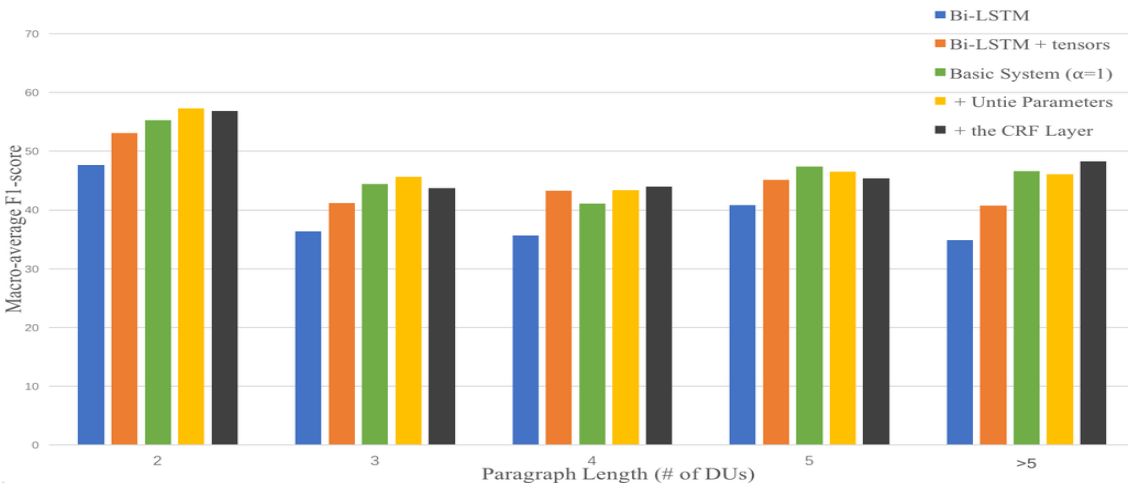

Figure 4: Impact of Paragraph Length. We plot the macro-average F1-score of implicit discourse relation classification on instances with different paragraph length.

and explicit discourse relations simultaneously.

4.7 Impact of Paragraph Length

To understand the influence of paragraph lengths to our paragraph-level models, we divide paragraphs in the PDTB test set into several subsets based on the number of DUs in a paragraph, and then evaluate our proposed models on each subset separately. From Figure 4, we can see that our paragraph-level models (the latter three) overall outperform DU-pair baselines across all the subsets. As expected, the paragraph-level models achieve clear performance gains on long paragraphs (with more than 5 DUs) by extensively modeling mutual influences of DUs in a paragraph. But somewhat surprisingly, the paragraph-level models achieve noticeable performance gains on short paragraphs (with 2 or 3 DUs) as well. We hypothesize that by learning more appropriate discourse-aware DU representations in long paragraphs, our paragraph-level models reduce bias of using DU representations in predicting discourse relations, which benefits discourse relation prediction in short paragraphs as well.

4.8 Example Analysis

For the example (1), the baseline neural tensor model predicted both implicit relations wrongly ("Implicit-Contingency" between DU2 and DU3; "Implicit-Expansion" between DU3 and DU4), while our paragraph-level model predicted all the four discourse relations correctly, which indicates that paragraph-wide contexts play a key role in implicit discourse relation prediction.

For another example:

(2): *[Marshall came clanking in like Marley's ghost dragging those chains of brigades and air wings and links with Arab despots.]*$_{DU1}$ ***(Implicit-Temporal)*** *[He wouldn't leave]*$_{DU2}$ *until* ***(Explicit-Temporal)*** *[Mr. Cheney promised to do whatever the Pentagon systems analysts told him.]*$_{DU3}$

Our basic paragraph-level model wrongly predicted the implicit discourse relation between DU1 and DU2 to be "Implicit-Comparison", without being able to effectively use the succeeding "Explicit-Temporal" relation. On the contrary, the full model corrected this mistake by modeling discourse relation patterns with the CRF layer.

5 Conclusion

We have presented a paragraph-level neural network model that takes a sequence of discourse units as input, models inter-dependencies between discourse units as well as discourse relation continuity and patterns, and predicts a sequence of discourse relations in a paragraph. By building wider-context informed discourse unit representations and capturing the overall discourse structure, the paragraph-level neural network model outperforms the best previous models for implicit discourse relation recognition on the PDTB dataset.

A Deep Ensemble Model with Slot Alignment for Sequence-to-Sequence Natural Language Generation

Juraj Juraska, Panagiotis Karagiannis, Kevin K. Bowden and **Marilyn A. Walker**
Natural Language and Dialogue Systems Lab
University of California, Santa Cruz
{jjuraska,pkaragia,kkbowden,mawalker}@ucsc.edu

Abstract

Natural language generation lies at the core of generative dialogue systems and conversational agents. We describe an ensemble neural language generator, and present several novel methods for data representation and augmentation that yield improved results in our model. We test the model on three datasets in the restaurant, TV and laptop domains, and report both objective and subjective evaluations of our best model. Using a range of automatic metrics, as well as human evaluators, we show that our approach achieves better results than state-of-the-art models on the same datasets.

1 Introduction

There has recently been a substantial amount of research in natural language processing (NLP) in the context of personal assistants, such as Cortana or Alexa. The capabilities of these conversational agents are still fairly limited and lacking in various aspects, one of the most challenging of which is the ability to produce utterances with human-like coherence and naturalness for many different kinds of content. This is the responsibility of the natural language generation (NLG) component.

Our work focuses on language generators whose inputs are structured *meaning representations* (MRs). An MR describes a single dialogue act with a list of key concepts which need to be conveyed to the human user during the dialogue. Each piece of information is represented by a slot-value pair, where the *slot* identifies the type of information and the *value* is the corresponding content. *Dialogue act* (DA) types vary depending on the dialogue manager, ranging from simple ones, such as a *goodbye* DA with no slots at all, to complex ones, such as an *inform* DA containing multiple slots with various types of values (see example in Table 1).

MR	*inform* (name [**The Golden Curry**], food [**Japanese**], priceRange [**moderate**], familyFriendly [**yes**], near [**The Bakers**])
Utt.	Located near **The Bakers**, **kid-friendly** restaurant, **The Golden Curry**, offers **Japanese** cuisine with a **moderate** price range.

Table 1: An example of an MR and a corresponding reference utterance.

A natural language generator must produce a syntactically and semantically correct utterance from a given MR. The utterance should express all the information contained in the MR, in a natural and conversational way. In traditional language generator architectures, the assembling of an utterance from an MR is performed in two stages: *sentence planning*, which enforces semantic correctness and determines the structure of the utterance, and *surface realization*, which enforces syntactic correctness and produces the final utterance form.

Earlier work on statistical NLG approaches were typically hybrids of a handcrafted component and a statistical training method (Langkilde and Knight, 1998; Stent et al., 2004; Rieser and Lemon, 2010). The handcrafted aspects, however, lead to decreased portability and potentially limit the variability of the outputs. New corpus-based approaches emerged that used semantically aligned data to train language models that output utterances directly from their MRs (Mairesse et al., 2010; Mairesse and Young, 2014). The alignment provides valuable information during training, but the semantic annotation is costly.

The most recent methods do not require aligned data and use an *end-to-end* approach to training, performing sentence planning and surface realization simultaneously (Konstas and Lapata, 2013). The most successful systems trained on unaligned data use recurrent neural networks (RNNs) paired with an encoder-decoder system design (Mei et al.,

Proceedings of NAACL-HLT 2018, pages 152–162
New Orleans, Louisiana, June 1 - 6, 2018.

2016; Dušek and Jurčíček, 2016), but also other concepts, such as imitation learning (Lampouras and Vlachos, 2016). These NLG models, however, typically require greater amount of data for training due to the lack of semantic alignment, and they still have problems producing syntactically and semantically correct output, as well as being limited in naturalness (Nayak et al., 2017).

Here we present a neural ensemble natural language generator, which we train and test on three large unaligned datasets in the restaurant, television, and laptop domains. We explore novel ways to represent the MR inputs, including novel methods for delexicalizing slots and their values, automatic slot alignment, as well as the use of a semantic reranker. We use automatic evaluation metrics to show that these methods appreciably improve the performance of our model. On the largest of the datasets, the E2E dataset (Novikova et al., 2017b) with nearly 50K samples, we also demonstrate that our model significantly outperforms the baseline *E2E NLG Challenge*[1] system in human evaluation. Finally, after augmenting our model with stylistic data selection, subjective evaluations reveal that it can still produce overall better results despite a significantly reduced training set.

2 Related Work

NLG is closely related to machine translation and has similarly benefited from recent rapid development of deep learning methods. State-of-the-art NLG systems build thus on deep neural *sequence-to-sequence* models (Sutskever et al., 2014) with an *encoder-decoder* architecture (Cho et al., 2014) equipped with an *attention* mechanism (Bahdanau et al., 2015). They typically also rely on slot *delexicalization* (Mairesse et al., 2010; Henderson et al., 2014), which allows the model to better generalize to unseen inputs, as exemplified by TGen (Dušek and Jurčíček, 2016). However, Nayak et al. (2017) point out that there are frequent scenarios where delexicalization behaves inadequately (see Section 5.1 for more details), and Agarwal and Dymetman (2017) show that a *character-level* approach to NLG may avoid the need for delexicalization, at the potential cost of making more semantic omission errors.

The end-to-end approach to NLG typically requires a mechanism for aligning slots on the output utterances: this allows the model to generate utterances with fewer missing or redundant slots. Cuayáhuitl et al. (2014) perform automatic slot labeling using a Bayesian network trained on a labeled dataset, and show that a method using spectral clustering can be extended to unlabeled data with high accuracy. In one of the first successful neural approaches to language generation, Wen et al. (2015a) augment the generator's inputs with a control vector indicating which slots still need to be realized at each step. Wen et al. (2015b) take the idea further by embedding a new sigmoid gate into their LSTM cells, which directly conditions the generator on the DA. More recently, Dušek and Jurčíček (2016) supplement their encoder-decoder model with a trainable classifier which they use to rerank the beam search candidates based on missing and redundant slot mentions.

Our work builds upon the successful attentional encoder-decoder framework for sequence-to-sequence learning and expands it through ensembling. We explore the feasibility of a domain-independent slot aligner that could be applied to any dataset, regardless of its size, and beyond the reranking task. We also tackle some challenges caused by delexicalization in order to improve the quality of surface realizations, while retaining the ability of the neural model to generalize.

	E2E	TV	Laptop

|validation set|	4672	1407	2649
|test set|	630	1407	2649
total	47363	7035	13242
DA types	1	14	14
slot types	8	16	20

Table 2: Overview of the number of samples, as well as different DA and slot types, in each dataset .

3 Datasets

We evaluated the models on three datasets from different domains. The primary one is the recently released E2E restaurant dataset (Novikova et al., 2017b) with 48K samples. For benchmarking we use the TV dataset and the Laptop dataset (Wen et al., 2016) with 7K and 13K samples, respectively. Table 2 summarizes the proportions of the training, validation, and test sets for each dataset.

3.1 E2E Dataset

The E2E dataset is by far the largest one available for task-oriented language generation in the restaurant domain. The human references were

[1] http://www.macs.hw.ac.uk/InteractionLab/E2E/

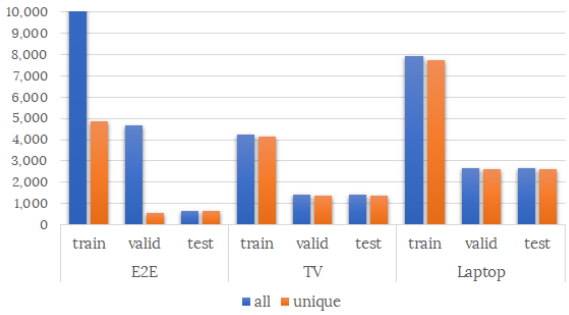

Figure 1: Proportion of unique MRs in the datasets. Note that the number of MRs in the E2E dataset was cut off at 10K for the sake of visibility of the small differences between other column pairs.

collected using pictures as the source of information, which was shown to inspire more informative and natural utterances (Novikova et al., 2016). With nearly 50K samples, it offers almost 10 times more data than the San Francisco restaurant dataset introduced in Wen et al. (2015b), which has frequently been used for benchmarks. The reference utterances in the E2E dataset exhibit superior lexical richness and syntactic variation, including more complex discourse phenomena. It aims to provide higher-quality training data for end-to-end NLG systems to learn to produce more naturally sounding utterances. The dataset was released as a part of the E2E NLG Challenge.

Although the E2E dataset contains a large number of samples, each MR is associated on average with 8.65 different reference utterances, effectively offering less than 5K unique MRs in the training set (Fig. 1). Explicitly providing the model with multiple ground truths, it offers multiple alternative utterance structures the model can learn to apply for the same type of MR. The delexicalization, as detailed later in Section 5.1, improves the ability of the model to share the concepts across different MRs.

The dataset contains only 8 different slot types, which are fairly equally distributed. The number of slots in each MR ranges between 3 and 8, but the majority of MRs consist of 5 or 6 slots. Even though most of the MRs contain many slots, the majority of the corresponding human utterances, however, consist of one or two sentences only (Table 3), suggesting a reasonably high level of sentence complexity in the references.

3.2 TV and Laptop Datasets

The reference utterances in the TV and the Laptop datasets were collected using Amazon Mechanical Turk (AMT), one utterance per MR. These two datasets are similar in structure, both using the same 14 DA types.[2] The Laptop dataset, however, is almost twice as large and contains 25% more slot types.

slots	3	4	5	6	7	8
sent.	1.09	1.23	1.41	1.65	1.84	1.92
prop.	5%	18%	32%	28%	14%	3%

Table 3: Average number of sentences in the reference utterance for a given number of slots in the corresponding MR, along with the proportion of MRs with specific slot counts.

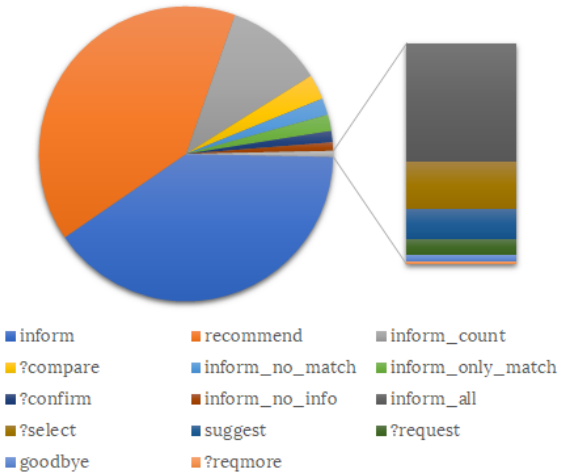

Figure 2: Proportion of DAs in the Laptop dataset.

Although both of these datasets contain more than a dozen different DA types, the vast majority (68% and 80% respectively) of the MRs describe a DA of either type `inform` or `recommend` (Fig. 2), which in most cases have very similarly structured realizations, comparable to those in the E2E dataset. DAs such as `suggest`, `?request`, or `goodbye` are represented by less than a dozen samples, but are significantly easier to learn to generate an utterance from because the corresponding MRs contain three slots at the most.

4 Ensemble Neural Language Generator

4.1 Encoder-Decoder with Attention

Our model uses the standard encoder-decoder architecture with attention, as defined in Bahdanau et al. (2015). Encoding the input into a sequence of context vectors instead of a single vector enables the decoder to learn what specific parts of the

[2] We noticed the MRs with the `?request` DA type in the TV dataset have no slots provided, as opposed to the Laptop dataset, so we imputed these in order to obtain valid MRs.

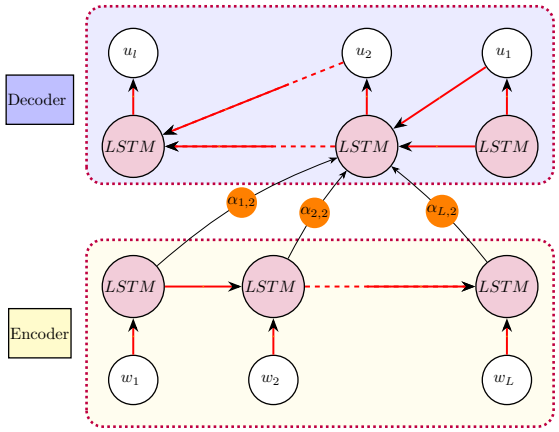

Figure 3: Standard architecture of a single-layer encoder-decoder LSTM model with attention. For each time step t in the output sequence, the attention scores $\alpha_{t,1}, \ldots, \alpha_{t,L}$ are calculated. This diagram shows the attention scores only for $t = 2$.

input sequence to pay attention to, given the output generated so far. In this attentional encoder-decoder architecture, the probability of the output at each time step t of the decoder depends on a distinct context vector q_t in the following way:

$$P(u_t|u_1, \ldots, u_{t-1}, \mathbf{w}) = g(u_{t-1}, s_t, q_t) \ ,$$

where in the place of function g we use the softmax function over the size of the vocabulary, and s_t is a hidden state of the decoder RNN at time step t, calculated as:

$$s_t = f(s_{t-1}, u_{t-1}, q_t) \ .$$

The context vector q_t is obtained as a weighted sum of all the hidden states $h_1, \ldots, h_L$ of the encoder:

$$q_t = \sum_{i=1}^{L} \alpha_{t,i} h_i \ ,$$

where $\alpha_{t,i}$ corresponds to the attention score the t-th word in the target sentence assigns to the i-th item in the input MR.

We compute the attention score $\alpha_{t,i}$ using a multi-layer perceptron (MLP) jointly trained with the entire system (Bahdanau et al., 2015). The encoder's and decoder's hidden states at time i and t, respectively, are concatenated and used as the input to the MLP, namely:

$$\alpha_{t,i} = softmax\left(\mathbf{w}^T tanh\left(W[h_i; s_t]\right)\right) \ ,$$

where W and $\mathbf{w}$ are the weight matrix and the vector of the first and the second layer of the MLP, respectively. The learned weights indicate the level of influence of the individual words in the input sequence on the prediction of the word at time step t of the decoder. The model thus learns a soft alignment between the source and the target sequence.

4.2 Ensembling

In order to enhance the quality of the predicted utterances, we create three neural models with different encoders. Two of the models use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) encoder, whereas the third model has a CNN (LeCun et al., 1998) encoder. We train these models individually for a different number of epochs and then combine their predictions.

Initially, we attempted to combine the predictions of the models by averaging the log-probability at each time step and then selecting the word with the maximum log-probability. We noticed that the quality, as well as the BLEU score of our utterances, decreased significantly. We believe that this is due to the fact that different models learn different sentence structures and, hence, combining predictions at the probability level results in incoherent utterances.

Therefore, instead of combining the models at the log-probability level, we accumulate the top 10 predicted utterances from each model type using beam search and allow the reranker (see Section 4.4) to rank all candidate utterances taking the proportion of slots they successfully realized into consideration. Finally, our system predicts the utterance that received the highest score.

4.3 Slot Alignment

Our training data is inherently unaligned, meaning our model is not certain which sentence in a multi-sentence utterance contains a given slot, which limits the model's robustness. To accommodate this, we create a heuristic-based slot aligner which automatically preprocesses the data. Its primary goal is to align chunks of text from the reference utterances with an expected value from the MR. Applications of our slot aligner are described in subsequent sections and in Table 4.

In our task, we have a finite set of slot mentions which must be detected in the corresponding utterance. Moreover, from our training data we can see that most slots are realized by inserting a specific set of phrases into an utterance. Using this insight, we construct a gazetteer, which primarily searches for overlapping content between the MR and each

sentence in an utterance, by associating all possible slot realizations with their appropriate slot type. We additionally augment the gazetteer using a small set of handcrafted rules which capture cases not easily encapsulated by the above process, for example, associating the `priceRange` slot with a chunk of text using currency symbols or relevant lexemes, such as "cheap" or "high-end". While handcrafted, these rules are transferable across domains, as they target the slots, not the domains, and mostly serve to counteract the noise in the E2E dataset. Finally, we use WordNet (Fellbaum, 1998) to further augment the size of our gazetteer by accounting for synonyms and other semantic relationships, such as associating "pasta" with the `food[Italian]` slot.

4.4 Reranker

As discussed in Section 4.2, our model uses beam search to produce a pool of the most likely utterances for a given MR. While these results have a probability score provided by the model, we found that relying entirely on this score often results in the system picking a candidate which is objectively worse than a lower scoring utterance (i.e. one missing more slots and/or realizing slots incorrectly). We therefore augment that score by multiplying it by the following score which takes the slot alignment into consideration:

$$s_{\text{align}} = \frac{N}{(N_u + 1) \cdot (N_o + 1)},$$

where N is the number of all slots in the given MR, and N_u and N_o represent the number of unaligned slots (those not observed by our slot aligner) and over-generated slots (those which have been realized but were not present in the original MR), respectively.

5 Data Preprocessing

5.1 Delexicalization

We enhance the ability of our model to generalize the learned concepts to unseen MRs by delexicalizing the training data. Moreover, it reduces the amount of data required to train the model. We identify the categorical slots whose values always propagate verbatim to the utterance, and replace the corresponding values in the utterance with placeholder tokens. The placeholders are eventually replaced in the output utterance in post-processing by copying the values from the input MR. Examples of such slots would be `name` or `near` in the E2E dataset, and `screensize` or `processor` in the TV and the Laptop dataset.

Previous work identifies categorical slots as good delexicalization candidates that improve the performance of the model (Wen et al., 2015b; Nayak et al., 2017). However, we chose not to delexicalize those categorical slots whose values can be expressed in alternative ways, such as "less than $20" and "cheap", or "on the riverside" and "by the river". Excluding these from delexicalization may lead to an increased number of incorrect realizations, but it encourages diversity of the model's outputs by giving it a freedom to choose among alternative ways of expressing a slot-value in different contexts. This, however, assumes that the training set contains a sufficient number of samples displaying this type of alternation so that the model can learn that certain phrases are synonymous. With its multiple human references for each MR, the E2E dataset has this property.

As Nayak et al. (2017) point out, delexicalization affects the sentence planning and the lexical choice around the delexicalized slot value. For example, the realization of the slot `food[`*`Italian`*`]` in the phrase "serves *Italian* food" is valid, while the realization of `food[`*`fast food`*`]` in "serves *fast food* food" is clearly undesired. Similarly, a naive delexicalization can result in "a Italian restaurant", whereas the article should be "an". Another problem with articles is singular versus plural nouns in the slot value. For example, the slot `accessories` in the TV dataset, can take on values such as "remote control", as well as "3D glasses", where only the former requires an article before the value.

We tackle this issue by defining different placeholder tokens for values requiring different treatment in the realization. For instance, the value "Italian" of the `food` slot is replaced by `slot_vow_cuisine_food`, indicating that the value starts with a vowel and represents a cuisine, while "fast food" is replaced by `slot_con_food`, indicating that the value starts with a consonant and cannot be used as a term for cuisine. The model thus learns to generate "a" before `slot_con_food` and "an" before `slot_vow_cuisine_food` when appropriate, as well as to avoid generating the word "food" after `food`-slot placeholders that do not contain the word "cuisine". All these rules are general and

can automatically be applied across different slots and domains.

5.2 Data Expansion

Slot Permutation

In our initial experiments, we tried expanding the training set by permuting the slot ordering in the MRs as suggested in Nayak et al. (2017). From different slot orderings of every MR we sampled five random permutations (in addition to the original MR), and created new pseudo-samples with the same reference utterance. The training set thus increased six times in size.

Using such an augmented training set might add to the model's robustness, nevertheless it did not prove to be helpful with the E2E dataset. In this dataset, we observed the slot order to be fixed across all the MRs, both in the training and the test set. As a result, for the majority of the time, the model was training on MRs with slot orders it would never encounter in the test set, which ultimately led to a decreased performance in prediction on the test set.

Utterance/MR Splitting

Taking a more utterance-oriented approach, we augment the training set with single-sentence utterances paired with their corresponding MRs. These new pseudo-samples are generated by splitting the existing reference utterances into single sentences and using the slot aligner introduced in Section 4.3 to identify the slots that correspond to each sentence. The MRs of the new samples are created as the corresponding subsets of slots and, whenever the sentence contains the name (of the restaurant/TV/etc.) or a pronoun referring to it (such as "it" or "its"), the `name` slot is included too. Finally, a new `position` slot is appended to every new MR, indicating whether it represents the first sentence or a subsequent sentence in the original utterance. An example of this splitting technique can be seen in Table 4. The training set almost doubled in size through this process.

Since the slot aligner works heuristically, not all utterances are successfully aligned with the MR. The vast majority of such cases, however, is caused by reference utterances in the datasets having incorrect or entirely missing slot mentions. There is a noticeable proportion of those, so we leave them in the training set with the unaligned slots removed from the MR so as to avoid confusing the model when learning from such samples.

MR	name [The Waterman], food [English], priceRange [cheap], customer rating [average], area [city centre], familyFriendly [yes]
Utt.	There is a family-friendly, cheap restaurant in the city centre, called The Waterman. It serves English food and has an average rating by customers.
New MR #1	name [The Waterman], priceRange [cheap], area [city centre], familyFriendly [yes], *position [outer]*
New MR #2	name [The Waterman], food [English], customer rating [average], *position [inner]*

Table 4: An example of the utterance/MR splitting.

MR	name [Wildwood], eatType [coffee shop], food [English], priceRange [moderate], customer rating [1 out of 5], near [Ranch]
Simple utt.	Wildwood provides English food for a moderate price. It has a low customer rating and is located near Ranch. It is a coffee shop.
Elegant utt.	A low-rated English style coffee shop around Ranch, called Wildwood, has moderately priced food.

Table 5: Contrastive example of a simple and a more elegant reference utterance style for the same MR in the E2E dataset.

5.3 Sentence Planning via Data Selection

The quality of the training data inherently imposes an upper bound on the quality of the predictions of our model. Therefore, in order to bring our model to produce more sophisticated utterances, we experimented with filtering the training data to contain only the most natural sounding and structurally complex utterances for each MR. For instance, we prefer having an elegant, single-sentence utterance with an apposition as the reference for an MR, rather than an utterance composed of three simple sentences, two of which begin with "it" (see the examples in Table 5).

We assess the complexity and naturalness of each utterance by the use of discourse phenomena, such as contrastive cues, subordinate clauses, or aggregation. We identify these in the utterance's parse-tree produced by the Stanford CoreNLP toolkit (Manning et al., 2014) by defining a set of rules for extracting the discourse phenomena. Furthermore, we consider the number of sentences used to convey all the information in the corresponding MR, as longer sentences tend to exhibit more advanced discourse phenomena. Penalizing utterances for too many sentences contributes to reducing the proportion of generic reference utter-

ances, such as the "simple" example in the above table, in the filtered training set.

6 Evaluation

Researchers in NLG have generally used both automatic and human evaluation. Our results report the standard automatic evaluation metrics: BLEU (Papineni et al., 2002), NIST (Przybocki et al., 2009), METEOR (Lavie and Agarwal, 2007), and ROUGE-L (Lin, 2004). For the E2E dataset experiments, we additionally report the results of the human evaluation carried out on the CrowdFlower platform as a part of the E2E NLG Challenge.

6.1 Experimental Setup

We built our ensemble model using the seq2seq framework (Britz et al., 2017) for TensorFlow. Our individual LSTM models use a bidirectional LSTM encoder with 512 cells per layer, and the CNN models use a pooling encoder as in Gehring et al. (2017). The decoder in all models was a 4-layer RNN decoder with 512 LSTM cells per layer and with attention. The hyperparameters were determined empirically. After experimenting with different beam search parameters, we settled on the beam width of 10. Moreover, we employed the length normalization of the beams as defined in Wu et al. (2016), in order to encourage the decoder to favor longer sequences. The length penalty providing the best results on the E2E dataset was 0.6, whereas for the TV and Laptop datasets it was 0.9 and 1.0, respectively.

6.2 Experiments on the E2E Dataset

We start by evaluating our system on the E2E dataset. Since the reference utterances in the test set were kept secret for the E2E NLG Challenge, we carried out the metric evaluation using the validation set. This was necessary to narrow down the models that perform well compared to the baseline. The final model selection was done based on a human evaluation of the models' outputs on the test set.

6.2.1 Automatic Metric Evaluation

In the first experiment, we assess what effect the augmenting of the training set via utterance splitting has on the performance of different models. The results in Table 6 show that both the LSTM and the CNN models clearly benefit from additional pseudo-samples in the training set. This can likely be attributed to the model having access to more granular information about which parts of the utterance correspond to which slots in the MR. This may assist the model in sentence planning and building a stronger association between parts of the utterance and certain slots, such as that "it" is a substitute for the name.

		BLEU	NIST	METEOR	ROUGE
LSTM	$\bar{\mathbf{s}}$	0.6664	8.0150	0.4420	0.7062
	$\mathbf{s}$	0.6930‡	8.4198	0.4379	0.7099
CNN	$\bar{\mathbf{s}}$	0.6599	7.8520	0.4333	0.7018
	$\mathbf{s}$	0.6760†	8.0440	0.4448	0.7055

Table 6: Automatic metric scores of different models tested on the E2E dataset, both unmodified ($\bar{\mathbf{s}}$) and augmented ($\mathbf{s}$) through the utterance splitting. The symbols † and ‡ indicate statistically significant improvement over the $\bar{\mathbf{s}}$ counterpart with $p < 0.05$ and $p < 0.01$, respectively, based on the paired t-test.

Testing our ensembling approach reveals that reranking predictions pooled from different models produces an ensemble model that is overall more robust than the individual submodels. The submodels fail to perform well in all four metrics at once, whereas the ensembling creates a new model that is more consistent across the different metric types (Table 7).[3] While the ensemble model decreases the proportion of incorrectly realized slots compared to its individual submodels on the validation set, on the test set it only outperforms two of the submodels in this aspect (Table 8). Analyzing the outputs, we also observed that the CNN model surpassed the two LSTM models in the ability to realize the "fast food" and "pub" values reliably, both of which were hardly present in the validation set but very frequent in the test set. On the official E2E test set, our ensemble model performs comparably to the baseline model, TGen (Dušek and Jurčíček, 2016), in terms of automatic metrics (Table 9).

6.2.2 Human Evaluation

It is known that automatic metrics function only as a general and vague indication of the quality of an utterance in a dialogue (Liu et al., 2016; Novikova et al., 2017a). Systems which score similarly according to these metrics could produce utterances that are significantly different because automatic

[3] The scores here correspond to the model submitted to the E2E NLG Challenge. Subsequently, we found better performing models according to some metrics: see Table 6.

	BLEU	NIST	METEOR	ROUGE
LSTM1	0.6661	8.1626	0.4644	0.7018
LSTM2	0.6493	7.9996	0.4649	0.6995
CNN	0.6636	7.9617	0.4700	0.7107
Ensem.	0.6576	8.0761	0.4675	0.7029

Table 7: Automatic metric scores of three different models and their ensemble, tested on the *validation set* of the E2E dataset. LSTM2 differs from LSTM1 in that it was trained longer.

	Validation set	Test set
LSTM1	0.116%	0.988%
LSTM2	0.145%	1.241%
CNN	0.232%	0.253%
Ensem.	0.087%	0.965%

Table 8: Error rate of the ensemble model compared to its individual submodels.

metrics fail to capture many of the characteristics of natural sounding utterances. Therefore, to better assess the structural complexity of the predictions of our model, we present the results of a human evaluation of the models' outputs in terms of both naturalness and quality, carried out by the E2E NLG Challenge organizers.

Quality examines the grammatical correctness and adequacy of an utterance given an MR, whereas *naturalness* assesses whether a predicted utterance could have been produced by a native speaker, irrespective of the MR. To obtain these scores, crowd workers ranked the outputs of 5 randomly selected systems from worst to best. The final scores were produced using the TrueSkill algorithm (Sakaguchi et al., 2014) through pairwise comparisons of the human evaluation scores among the 20 competing systems.

Our system, trained on the E2E dataset without stylistic selection (Section 5.3), achieved the highest quality score in the E2E NLG Challenge, and was ranked second in naturalness.[4] The system's performance in quality (the primary metric) was significantly better than the competition according to the TrueSkill evaluation, which used bootstrap resampling with a p-level of $p \leq 0.05$. Comparing these results with the scores achieved by the baseline model in quality and naturalness (5th and 6th place, respectively) reinforces our belief that models that perform similarly on the automatic metrics (Table 9) can exhibit vast differences in the structural complexity of their generated utterances.

[4]The system that surpassed ours in naturalness was ranked the last according to the quality metric.

	BLEU	NIST	METEOR	ROUGE
TGen	0.6593	8.6094	*0.4483*	*0.6850*
Ensem.	*0.6619*	*8.6130*	0.4454	0.6772

Ex. #1	The Cricketers is a cheap Chinese restaurant near All Bar One in the riverside area, **but it has an average customer rating and is not family friendly**.
Ex. #2	**If you are looking for** a coffee shop near The Rice Boat, **try** Giraffe.

Table 10: Examples of generated utterances that contain more advanced discourse phenomena.

6.2.3 Experiments with Data Selection

After filtering the E2E training set as described in Section 5.3, the new training set consisted of approximately 20K pairs of MRs and utterances. Interestingly, despite this drastic reduction in training samples, the model was able to learn more complex utterances that contained the natural variations of the human language. The generated utterances exhibited discourse phenomena such as contrastive cues (see Example #1 in Table 10), as well as a more conversational style (Example #2). Nevertheless, the model also failed to realize slots more frequently.

In order to observe the effect of stylistic data selection, we conducted a human evaluation where we assessed the utterances based on *error rate* and *naturalness*. The error rate is calculated as the percentage of slots the model failed to realize divided by the total number of slots present among all samples. The annotators ranked samples of utterance triples – corresponding to three different ensemble models – by naturalness from 1 to 3 (3 being the most natural, with possible ties). The *conservative* model combines three submodels all trained on the full training set, the *progressive* one combines submodels solely trained on the filtered dataset, and finally, the *hybrid* is an ensemble of three models only one of which is trained on the full training set, so as to serve as a fallback.

The impact of the reduction of the number of

Ensemble model	Error rate	Naturalness
Conservative	*0.40%*	2.196
Progressive	1.60%	2.118
Hybrid	*0.40%*	*2.435*

Table 11: Average error rate and naturalness metrics obtained from six annotators for different ensemble models.

training samples becomes evident by looking at the score of the progressive model (Table 11), where this model trained solely on the reduced dataset had the highest error rate. We observe, however, that a hybrid ensemble model manages to perform the best in terms of the error rate, as well as the naturalness.

These results suggest that filtering the dataset through careful data selection can help to achieve better and more natural sounding utterances. It significantly improves the model's ability to produce more elegant utterances beyond the "[name] is... It is/has..." format, which is only too common in neural language generators in this domain.

6.3 Experiments on TV and Laptop Datasets

In order to provide a better frame of reference for the performance of our proposed model, we utilize the RNNLG benchmark toolkit[5] to evaluate our system on two additional, widely used datasets in NLG, and compare our results with those of a state-of-the-art model, SCLSTM (Wen et al., 2015b). As Table 12 shows, our ensemble model performs competitively with the baseline on the TV dataset, and it outperforms it on the Laptop dataset by a wide margin. We believe the higher error rate of our model can be explained by the significantly less aggressive slot delexicalization than the one used in SCLSTM. That, however, gives our model a greater lexical freedom and, with it, the ability to produce more natural utterances.

The model trained on the Laptop dataset is also a prime example of how an ensemble model is capable of extracting the best learned concepts from each individual submodel. By combining their knowledge and compensating thus for each other's weaknesses, the ensemble model can achieve a lower error rate, as well as a better overall quality, than any of the submodels individually.

7 Conclusion and Future Work

In this paper we presented our ensemble attentional encoder-decoder model for generating natural utterances from MRs. Moreover, we presented novel methods of representing the MRs to improve performance. Our results indicate that the proposed utterance splitting applied to the training set greatly improves the neural model's accuracy and ability to generalize. The ensembling method paired with the reranking based on slot alignment also contributed to the increase in quality of the generated utterances, while minimizing the number of slots that are not realized during the generation. This also enables the use of a less aggressive delexicalization, which in turn stimulates diversity in the produced utterances.

We showed that automatic slot alignment can be utilized for expanding the training data, as well as for utterance reranking. Our alignment currently relies in part on empirically observed heuristics, and a more robust aligner would allow for more flexible expansion into new domains. Since the stylistic data selection noticeably improved the diversity of our system's outputs, we believe this is a method with future potential, which we intend to further explore. Finally, it is clear that current automatic evaluation metrics in NLG are only sufficient for providing a vague idea as to the system's performance; we postulate that leveraging the reference data to train a classifier will result in a more conclusive automatic evaluation metric.

Abstract

This paper presents a novel, data-driven language model that produces entire lyrics for a given input melody. Previously proposed models for lyrics generation suffer from the inability of capturing the relationship between lyrics and melody partly due to the unavailability of lyrics-melody aligned data. In this study, we first propose a new practical method for creating a large collection of lyrics-melody aligned data and then create a collection of 1,000 lyrics-melody pairs augmented with precise syllable-note alignments and word/sentence/paragraph boundaries. We then provide a quantitative analysis of the correlation between word/sentence/paragraph boundaries in lyrics and melodies. We then propose an RNN-based lyrics language model conditioned on a featurized melody. Experimental results show that the proposed model generates fluent lyrics while maintaining the compatibility between boundaries of lyrics and melody structures.

1 Introduction

Writing lyrics for a given melody is a challenging task. Unlike prose text, writing lyrics requires both knowledge and consideration of music-specific properties such as the structure of melody, rhythms, etc. (Austin et al., 2010; Ueda, 2010). A simple example is the correlation between word boundaries in lyrics and the rests in a melody. As shown in Figure 1, a single word spanning beyond a long melody rest can sound unnatural. When writing lyrics, a lyricist must consider such constraints in content and lexical selection, which can impose extra cognitive loads.

This consideration when writing lyrics has motivated a wide-range of studies for the task of computer-assisted lyrics writing (Barbieri et al., 2012; Abe and Ito, 2012; Potash et al., 2015; Watanabe et al., 2017). Such studies aim to model the

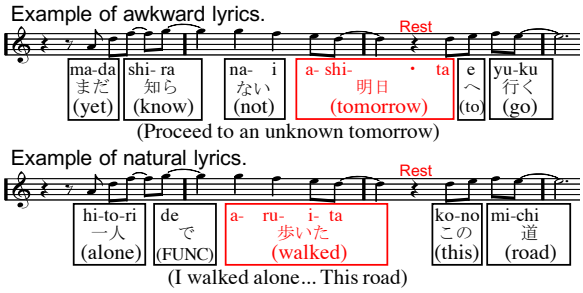

Figure 1: Examples of awkward and natural lyrics. FUNC indicates a function word. The song is from the RWC Music Database (RWC-MDB-P-2001 No.20) (Goto et al., 2002).

language in lyrics and to design a computer system for assisting lyricists in writing. They propose to constrain their models to generate only lyrics that satisfy given conditions on syllable counts, rhyme positions, etc. However, such constraints are assumed to be manually provided by a human user, which requires the user to interpret a source melody and transform their interpretation to a set of constraints. To assist users with transforming a melody to constraints, a language model that automatically captures the relationship between lyrics and melody is required.

Some studies (Oliveira et al., 2007; Oliveira, 2015; Nichols et al., 2009) have quantitatively analyzed the correlations between melody and phonological aspects of lyrics (e.g., the relationship between a beat and a syllable stress). However, these studies do not address the relationship between melody and the *discourse structure* of lyrics. Lyrics are not just a sequence of syllables but a meaningful sequence of words. Therefore, it is desirable that the sentence/paragraph boundaries are determined based on both melody rests and context words.

Considering such line/paragraph structure of lyrics, we present a novel language model that gen-

Proceedings of NAACL-HLT 2018, pages 163–172
New Orleans, Louisiana, June 1 - 6, 2018.

erates lyrics whose word, sentence, and paragraph boundaries are appropriate for a given melody, without manually transforming the melody to syllable constraints. This direction of research has received less attention because it requires a large dataset consisting of aligned pairs of melody and segment boundaries of lyrics which has yet to exist.

To address this issue, we leverage a publicly-available collection of digital music scores and create a dataset of digital music scores each of which specifics a melody score augmented with syllable information for each melody note. We collected 1,000 Japanese songs from an online forum where many amateur music composers upload their music scores. We then automatically aligned each music score with the raw text data of the corresponding lyrics in order to augment it with the word, sentence, and paragraph boundaries.

The availability of such aligned, parallel data opens a new area of research where one can conduct a broad range of data-oriented research for investigating and modeling correlations between melodies and discourse structure of lyrics. In this paper, with our melody-lyrics aligned songs, we investigate the phenomena that (i) words, sentences, and paragraphs rarely span beyond a long melody rest and (ii) the boundaries of larger components (i.e., paragraphs) tend to coincide more with longer rests. To the best of our knowledge, there is no previous work that provides any quantitative analysis of this phenomenon with this size of data (see Section 7).

Following this analysis, we build a novel, data-driven language model that generates fluent lyrics whose sentence and paragraph boundaries fit an input melody. We extend a Recurrent Neural Network Language Model (RNNLM) (Mikolov et al., 2010) so that its output can be conditioned on a featurized melody. Both our quantitative and qualitative evaluations show that our model captures the consistency between melody and boundaries of lyrics while maintaining word fluency.

2 Melody-lyric alignment data

Our goal is to create a melody-conditioned language model that captures the correlations between melody patterns and discourse segments of lyrics. The data we need for this purpose is a collection of melody-lyrics pairs where the melody and lyrics are aligned at the level of not only note-syllable alignment but also discourse components

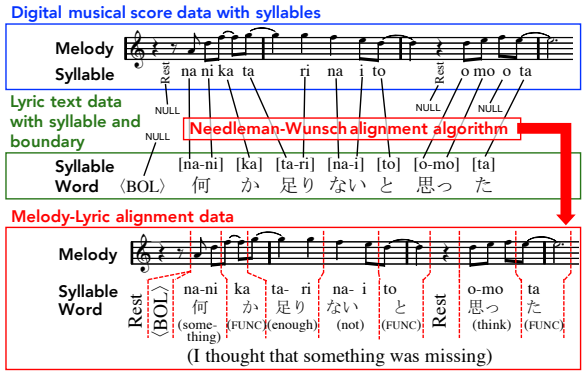

Figure 2: Melody-lyrics alignment using the Needleman Wunsch algorithm. BOL denotes a line boundary.

(i.e., word/sentence/paragraph boundaries) of a lyric, as illustrated in the bottom of Figure 2. We create such a dataset by automatically combining two types of data available from online forum sites: digital music score data (the top of Figure 2) and raw lyrics data (the middle).

A digital music score specifies a melody score augmented with syllable information for each melody note (see the top of Figure 2). Score data augmented in this way is sufficient for analyzing the relationship between the phonological aspects of lyrics and melody, but it is insufficient for our goal since the structural information of the lyrics is not included. We thus augment score data further with boundaries of sentences, and paragraphs, where we assume that sentences and paragraphs of lyrics are approximately captured by *lines* and *blocks*,[1] respectively, of the lyrics in the raw text.

The integration of music scores and raw lyrics is achieved by (1) applying a morphological analyzer[2] to raw lyrics for word segmentation and Chinese character pronunciation prediction and (2) aligning music score with raw lyrics at the syllable level as illustrated in Figure 2. For this alignment, we employ the Needleman-Wunsch algorithm (Needleman and Wunsch, 1970). This alignment process is reasonably accurate because it fails in principle only when the morphological analysis fails in Chinese character pronunciation prediction, which occurs for only less than 1% of the words in the data set.

With this procedure, we obtained 54,181 Japanese raw lyrics and 1,000 digital musical

[1] Blocks are assumed to be segmented by empty lines.

[2] To extract word boundaries and syllable information for Japanese lyrics, we apply MeCab parser (Kudo et al., 2004).

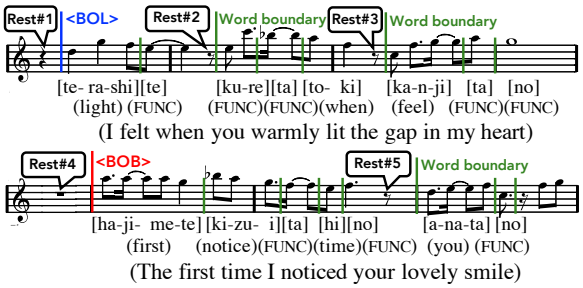

Figure 3: Example boundaries appearing immediately after a rest. BOB indicates a block boundary.

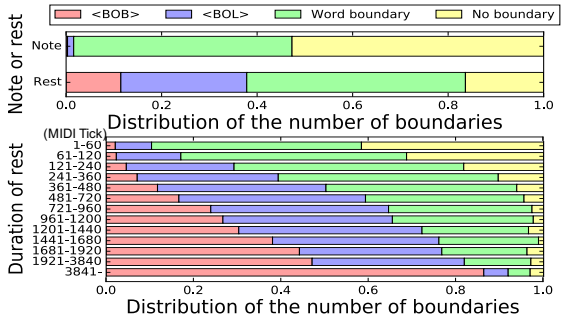

Figure 4: Distribution of the number of boundaries in the melody-lyrics alignment data.

scores from online forum sites[3]; we thus created 1,000 melody-lyrics pairs. We refer to these 1,000 melody-lyrics pairs as a *melody-lyrics alignment* data[4] and refer to the remaining 53,181 lyrics without melody as a *raw lyrics* data.

We randomly split the 1,000 melody-lyrics alignments into two sets: 90% for analyzing/training and the remaining 10% for testing. From those, we use 20,000 of the most frequent words whose syllable counts are equal to or less than 10, and converted others to a special symbol ⟨unknown⟩. All of the digital music score data we collected were distributed in the UST format, a common file format designed specifically for recently emerging computer vocal synthesizers. While we focus on Japanese music in this study, our method for data creation is general enough to be applied to other language formats such as MusicXML and ABC, because transferring such data formats to UST is straightforward.

[3]For selecting the 1,000 songs, we chose only frequently downloaded or highly popular songs to ensure the quality of the resulting dataset.

[4]We publicly release all source URLs of the 1,000 songs (https://github.com/KentoW/melody-lyrics).

3 Correlations between melody and lyric

In this section, we examine two phenomena related to boundaries of lyrics: (1) the positions of lyrics segment boundaries are biased to melody rest positions, and (2) the probability of boundary occurrence depends on the duration of a rest, i.e., a shorter rest tends to be a word boundary and a longer rest tends to be a block boundary, as shown in Figure 3. All analyses were performed on the training split of the melody-lyrics alignment data, which is described in Section 2.

For the first phenomenon, we first calculated the distribution of boundary appearances at the positions of melody notes and rests. Here, by the *boundary of a line* (or block), we refer to the position of the beginning of the line (or block).[5] In Figure 3, we say, for example, that the boundary of the first block beginning "*te-ra-shi te*" coincides with Rest#1. The result, shown at the top of Figure 4, indicates that line and block boundaries are strongly biased to rest positions and are far less likely to appear at note positions. Words, lines, and blocks rarely span beyond a long melody rest.

The bottom of Figure 4 shows the detailed distributions of boundary occurrences for different durations of melody rests, where durations of 480 and 1920 correspond to a quarter rest and a whole rest, respectively. The results exhibit a clear, strong tendency that the boundaries of larger segments tend to coincide more with longer rests. To the best of our knowledge, this is the first study that has ever provided such strong empirical evidence for the phenomena related to the correlations between lyrics segments and melody rests. It is also important to note that the choice of segment boundaries looks like a probabilistic process (i.e., there is a long rest without a block boundary). This observation suggests the difficulty of describing the correlations of lyrics and melody in a rule-based fashion and motivates our probabilistic approach as we present in the next section.

4 Melody-conditioned language model

Our goal is to build a language model that generates fluent lyrics whose discourse segment fit a given melody in the sense that generated segment boundaries follow the distribution observed in Section 3. We propose to pursue this goal by conditioning a

[5]The beginning of a line/block and the end of a line/block are equivalent since there is no melody between the end and beginning of a line/block.

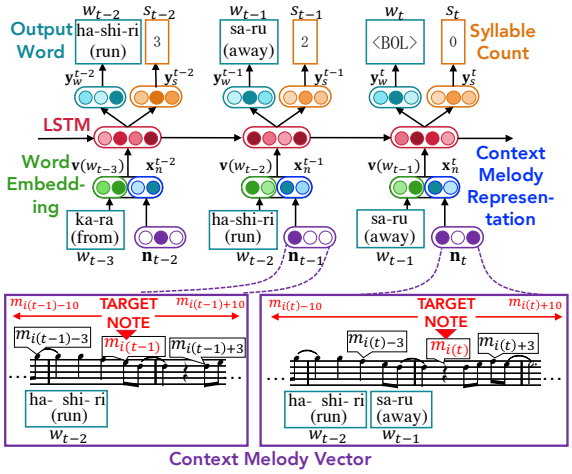

Figure 5: Melody-conditioned RNNLM.

standard RNNLM with a featurized input melody. We call this model a *Melody-conditioned RNNLM*.

The network structure of the model is illustrated in Figure 5. Formally, we are given a melody $\mathbf{m} = m_1,...,m_i,...,m_I$ that is a sequence of notes and rests, where m includes a pitch and a duration information. Our model generates lyrics $\mathbf{w} = w_1,...,w_t,...,w_T$ that is a sequence of words and segment boundary symbols: ⟨BOL⟩ and ⟨BOB⟩, special symbols denoting a line and a block boundary, respectively. For each time step t, the model outputs a single word or boundary symbol taking a pair of the previously generated word w_{t-1} and the musical feature vector $\mathbf{n}_t$ for the current word position which includes context window-based features that we describe in the following section. In this model, we assume that the syllables of the generated words and the notes in the input melody have a one-to-one correspondence. Therefore, the position of the incoming note/rest for a word position t (referred to as a target note for t) is uniquely determined by the syllable counts of the previously generated words.[6] The target note for t is denoted as $m_{i(t)}$ by defining a function $i(\cdot)$ which maps time step t to the index of the next note in t.

Here, the challenging issue with this model is training. Generally, language models require a large amount of text data to learn well. Moreover, this is also the case for learning correlation between rest positions and *syllable counts*. As shown in Figure 4, most words are supposed to not overlap a long rest. This means, for example, that when the incoming melody sequence for a next word position is *note, note, (long) rest, note, note*, as the sequence following to $m_{i(t-1)}$ in Figure 5, it is desirable to select a word whose syllable count is two or less so that the generated word does not overlap the long rest. If there is sufficient data available, this tendency may be learned directly from the correlation between rests and words without explicitly considering the syllable count of a word. However, our melody-lyrics alignments for 1,000 songs are insufficient for this purpose.

We take two approaches to address this data sparsity problem. First, we propose two training strategies that increase the number of training examples using raw lyrics that can be obtained in greater quantities. Second, we construct a model that predicts the number of syllables in each word, as well as words themselves, to explicitly supervise the correspondence between rest positions and syllable counts.

In the following sections, we first describe the details of the proposed model and then present the training strategies used to obtain better models with our melody-lyrics alignment data.

4.1 Model construction

The proposed model is based on a standard RNNLM (Mikolov et al., 2010):

$$P(\mathbf{w}) = \prod_{t=1}^{T} P(w_t|w_0, ..., w_{t-1}), \quad (1)$$

where context words are encoded using LSTM (Hochreiter and Schmidhuber, 1997) and the probabilities over words are calculated by a softmax function. $w_0 = \langle \mathrm{B} \rangle$ is a symbol denoting the beginning of lyrics. We extend this model such that each output is conditioned by the context melody vectors $\mathbf{n}_1, ..., \mathbf{n}_t$, as well as previous words:

$$P(\mathbf{w}|\mathbf{m}) = \prod_{t=1}^{T} P(w_t|w_0, ..., w_{t-1}, \mathbf{n}_1, ..., \mathbf{n}_t). \quad (2)$$

The model simultaneously predicts the syllable counts of words by sharing the parameters of LSTM with the above word prediction model in order to learn the correspondence between the melody segments and syllable counts:

$$P(\mathbf{s}|\mathbf{m}) = \prod_{t=1}^{T} P(s_t|w_0, ..., w_{t-1}, \mathbf{n}_1, ..., \mathbf{n}_t), \quad (3)$$

where $\mathbf{s} = s_1, ..., s_T$ is a sequence of syllable counts, which corresponds to $\mathbf{w}$.

[6] Note that our melody-lyrics alignment data used in training does not make this assumption, but we can still uniquely identify the positions of target notes based on the obtained melody-word alignment.

For each time step t, the model outputs a word distribution $\mathbf{y}_w^t \in \mathbb{R}^V$ and a distribution of syllable count $\mathbf{y}_s^t \in \mathbb{R}^S$ using a softmax function:

$$\mathbf{y}_w^t = \text{softmax}(\text{BN}(\mathbf{W}_w \mathbf{z}_t)), \quad (4)$$

$$\mathbf{y}_s^t = \text{softmax}(\text{BN}(\mathbf{W}_s \mathbf{z}_t)), \quad (5)$$

where $\mathbf{z}_t$ is the output of the LSTM for each time step. V is the vocabulary size and S is the syllable count threshold.[7] $\mathbf{W}_w$ and $\mathbf{W}_s$ are weight matrices. BN denotes batch normalization (Ioffe and Szegedy, 2015).

The input to the LSTM in each time step t is a concatenation of the embedding vector of the previous word $\mathbf{v}(w_{t-1})$ and the context melody representation $\mathbf{x}_n^t$, which is a nonlinear transformation of the context melody vector $\mathbf{n}_t$:

$$\mathbf{x}^t = [\mathbf{v}(w_{t-1}), \mathbf{x}_n^t], \quad (6)$$

$$\mathbf{x}_n^t = \text{ReLU}(\mathbf{W}_n \mathbf{n}_t + \mathbf{b}_n), \quad (7)$$

where $\mathbf{W}_n$ is a weight matrix and $\mathbf{b}_n$ is a bias.

To generate lyrics, the model searches for the word sequence with the greatest probability (Eq. 2) using beam search. The model stops generating lyrics when the syllable count of the lyrics reaches the number of notes in the input melody.

Note that our model is not specific to the language of lyrics. The model only requires the sequences of melody, words, and syllable counts and does not use any language-specific features.

4.2 Context melody vector

In Section 3, we indicated that the positions of rests and their durations are important factors for modeling boundaries of lyrics. Thus, we collect a sequence of notes and rests around the current word position (i.e., time step t) and encode their information into context melody vector $\mathbf{n}_t$ (see the bottom of Figure 5).

The context melody vector $\mathbf{n}_t$ is a binary feature vector that includes a musical notation type (i.e., note or rest), a duration[8], and a pitch for each note/rest in the context window. We collect notes and rests around the target note $m_{i(t)}$ for the current word position t with a window size of 10 (i.e., $m_{i(t)-10}, ..., m_{i(t)}, ..., m_{i(t)+10}$).

For pitch information, we use a gap (pitch interval) between a target note $m_{i(t)}$ and its previous note $m_{i(t-1)}$. Here, the pitch is represented by a MIDI note number in the range 0 to 127. For example, the target and its previous notes are 68 and 65, respectively, and the gap is $+3$.

[7] The syllable counts of the ⟨BOL⟩ and ⟨BOB⟩ are zero.

[8] We rounded each duration to one of the values 60, 120, 240, 360, 480, 720, 960, 1200, 1440, 1680, 1920, and 3840 and use one-hot encoding for each rounded duration.

Algorithm 1 Pseudo melody generation

```
for each syllable in the input-lyrics do
    b ← get boundary type next to the syllable
    sample note pitch p ~ P(p_i | p_{i-2}, p_{i-1})
    sample note duration d_note ~ P(d_note | b)
    assign note with (p, d_note) to the syllable
    sample binary variable r ~ P(r | b)
    if r = 1 then
        insert rest with duration d_rest ~ P(d_rest | b)
    end if
end for
```

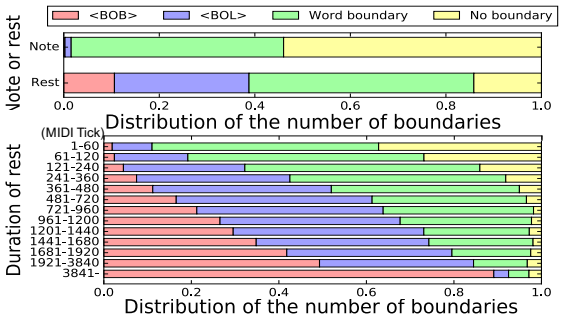

Figure 6: Distribution of the number of boundaries in pseudo-data.

4.3 Training strategies

Pretraining The size of our melody-lyrics alignment data is limited. However, we can obtain a large amount of raw lyrics. We, therefore, pretrain the model with 53,181 raw lyrics and then fine-tune it with the melody-lyrics alignment data. In pretraining, all context melody vectors $\mathbf{n}_t$ are zero vectors. We refer to these pretrained and fine-tuned models as *Lyrics-only* and *Fine-tuned* models, respectively.

Learning with pseudo-melody We propose a method to increase the melody-lyrics alignment data by attaching *pseudo melodies* to the obtained 53,181 raw lyrics. We refer to the model that uses this data as the *Pseudo-melody* model.

Algorithm 1 shows the details of pseudo-melody generation. For each syllable in the lyrics, we first assign a note to the syllable by sampling the probability distributions. The pitch of each note is generated based on the trigram probability. Then, we determine whether to generate a rest next to it. Since we established the correlations between rests and boundaries of lyrics in Section 3, the probability for a rest and its duration is conditioned by a boundary

type next to the target syllable. All probabilities are calculated using the training split of the melody-lyrics alignment data.

Figure 6 shows the distributions of the number of boundaries in the pseudo data. The distributions closely resemble those of gold data in Figure 4.

5 Quantitative evaluation

We evaluate the proposed Melody-conditioned RNNLMs quantitatively based on two evaluation metrics: (1) a test set perplexity for measuring the fluency; (2) a line/block boundary replication task for measuring the consistency between the melody and boundaries in the generated lyrics.

5.1 Experimental setup

In our model, we chose the dimensions of the word embedding vectors and context melody representation vectors to 512 and 256, respectively, and the dimension of the LSTM hidden state was 768. We used a categorical cross-entropy loss for outputs $\mathbf{y}_w^t$ and $\mathbf{y}_s^t$, Adam (Kingma and Ba, 2014) with an initial learning rate of 0.001 for parameter optimization, and a mini-batch size of 32. We applied an early-stopping strategy with a maximum epoch number of 100, and training was terminated after five epochs of unimproved loss on the validation set. For lyrics generation, we used a beam search with a width of 10. An example of the generated lyrics is shown in the supplemental material.

5.2 Evaluation metrics

Perplexity Test-set perplexity (PPL) is a standard evaluation measure for language models. PPL measures the predictability of wording in original lyrics, where a lower PPL value indicates that the model can generate fluent lyrics. We used PPL and its variant PPL-W, which excludes line/block boundaries, to investigate the predictability of words.

Accuracy of boundary replication Under the assumption that the line and block boundaries of the original lyrics are placed at appropriate positions in the melody, we evaluated consistency between the melody and boundaries in the generated lyrics by measuring the reproducibility of the boundaries in the original lyrics. Here the metric we used was F_1-measure of the boundary positions. We also asked a person to place line and block boundaries at plausible positions for randomly selected 10 input melodies that the evaluator has never heard. This person is not a professional musician but an experienced performer educated on musicology. The bottom part of Table 1 represents the human performance.

Model	Perplexity PPL	Perplexity PPL-W	F_1-measure BOB	F_1-measure BOL	F_1-measure UB
Lyrics-only	138.0	225.0	0.121	0.061	0.106
Full-data	135.9	222.1	0.122	0.063	0.108
Alignment-only	173.3	314.8	0.298	0.287	0.477
Heuristic	175.8	284.7	**0.373**	0.239	0.402
Fine-tuned	152.2	275.5	0.260	**0.302**	**0.479**
Pseudo-melody	**115.7**	**197.5**	0.318	0.241	0.406
(w/o $\mathbf{y}_s$)					
Fine-tuned	155.1	278.1	0.318	0.241	0.366
Pseudo-melody	118.0	201.5	0.312	0.250	0.406
Human	-	-	0.717	0.671	0.751

Table 1: Results of the quantitative evaluation. "UB" denotes the score for unlabeled matching of line/block boundaries. "w/o $\mathbf{y}_s$" denotes the exclusion of the syllable-count output layer.

5.3 Effect of Melody-conditioned RNNLM

To investigate the effect of our language models, we compared the following six models. The first one is (1) a *Lyrics-only* model, a standard RNNLM trained with 54,081 song lyrics without melody information. The second and third ones are baseline Melody-conditioned RNNLMs where the proposed training strategies are not applied: (2) a *Full-data* model trained with mixed data (54,081 song lyrics and 900 melody-lyrics alignments of those), and (3) an *Alignment-only* model trained with only 900 melody-lyrics alignment data. The fourth one is a strong baseline to evaluate the performance of the proposed approaches: (4) a *Heuristic* model that (i) assigns a line/block boundary to a rest based on its duration with the same probability, as reported in Figure 4, and (ii) fills the space between any two boundaries with lyrics of the appropriate syllable counts. This *Heuristic* model computes the following word probability:

$$P(w_t|w_0,...,w_{t-1},\mathbf{m}) = \quad (8)$$

$$\begin{cases} Q(\langle \mathrm{BOB}\rangle|m_{i(t+1)}) & (\text{if } w_t = \langle \mathrm{BOB}\rangle) \\ Q(\langle \mathrm{BOL}\rangle|m_{i(t+1)}) & (\text{if } w_t = \langle \mathrm{BOL}\rangle) \\ (1 - Q(\langle \mathrm{BOB}\rangle|m_{i(t+1)}) - Q(\langle \mathrm{BOL}\rangle|m_{i(t+1)}))\times & \\ \frac{P_{\mathrm{LSTM}}(w_t|w_0,...,w_{t-1})}{1-P_{\mathrm{LSTM}}(\langle \mathrm{BOL}\rangle|w_0,...,w_{t-1})-P_{\mathrm{LSTM}}(\langle \mathrm{BOB}\rangle|w_0,...,w_{t-1})} & \\ \qquad (\text{otherwise}) \end{cases}$$

where Q is the same probability as reported in Figure 4. P_{LSTM} is the word probability calculated by a standard LSTM language model. The remaining two are Melody-conditioned RNNLMs with the proposed learning strategies: (5) *Fine-tuned* and (6) *Pseudo-melody* models.

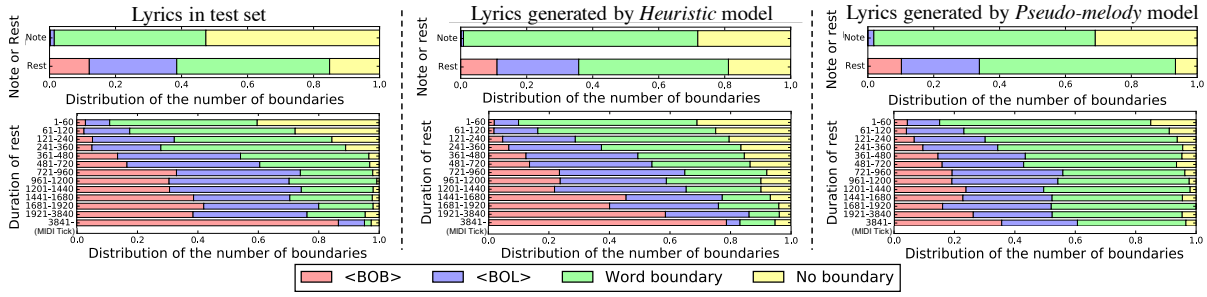

Figure 7: Distribution of the number of boundaries in the test set and lyrics generated by the *Heuristic* and *Pseudo-melody* models.

The top part of Table 1 summarizes the performance of these models. Regarding the boundary replication, the *Heuristic*, *Alignment-only*, *Fine-tuned*, and *Pseudo-melody* models achieved higher performance than the *Lyrics-only* model for unlabeled matching of line/block boundaries (i.e., UB). This result indicates that our Melody-conditioned RNNLMs successfully capture the consistency between melody and boundaries of lyrics. The results of the *Full-data* model is low (as expected) because the size of the melody-lyrics alignment data is far smaller than that of the raw lyrics data and this harms the learning process of the dependency between melody and lyrics. For the block boundary, the *Heuristic* model achieved the best performances. For the line boundary, the *Fine-tuned* model achieved the best performances.

Regarding PPL and PPL-W, the *Lyrics-only*, *Full-data*, and *Pseudo-melody* models show better results than the other models. The *Fine-tuned* model shows reduced performance compared with the *Lyrics-only* model because fine-tuning with a small amount of data causes overfitting in the language model. Also, the training size of the *Alignment-only* model is insufficient for learning a language model of lyrics. Interestingly, the *Pseudo-melody* model achieved better performance than the *Full-data* model and overall achieved the best score. This result indicates that the *Pseudo-melody* model uses the information of a given melody to make a better prediction of its lyrics word sequence. On the other hand, the *Heuristic* model had the worst performance, despite training with a large amount of raw lyrics. We analyze the reason for such performance and describe our results in Section 5.5. It is not necessarily clear which to choose, either the *Fine-tuned* or *Pseudo-melody* model, which may depend also on the size and diversity of the training and test data. However, one can conclude at least that combining a limited-scale collection of melody-lyrics alignment data with a far larger collection of lyrics-alone data boosts the model's capability of generating a fluent lyrics which structurally fits well the input melody.

5.4 Effect of predicting syllable-counts

To investigate the effect of predicting syllable-counts, we compared the performance of the proposed models to models that exclude the syllable-count output layer $\mathbf{y}_s$. The middle part of Table 1 summarizes the results. For the pretraining strategy, the use of $\mathbf{y}_s$ successfully alleviates data sparsity when learning the correlation between syllable counts and melodies from only words themselves. As can be seen, the model without $\mathbf{y}_s$ shows reduced performance relative to both PPLs and the boundary replication. On the other hand, for the pseudo-melody strategy, the two models are competitive in both measures. This means that the *Pseudo-melody* model obtained a sufficient amount of word-melody input pairs to learn the correlation.

5.5 Analysis of melody and generated lyrics

To examine whether the models can capture correlations between rests and boundaries of lyrics, we calculate the proportion of the word, line, and block boundaries in the original lyrics and in the lyrics generated by the *Heuristic* and *Pseudo-melody* model for the test set (Figure 7). The proportion of ⟨BOL⟩ and ⟨BOB⟩ generated by the *Heuristic* model are almost equivalent to those of the original lyrics. On the other hand, for the *Pseudo-melody* model, the proportion of line/block boundary types for the longer rests are smaller than that of the original lyrics.

Although the *Heuristic* model reproduces the proportion of the original line/block boundaries, the model had a low performance in terms of PPL,

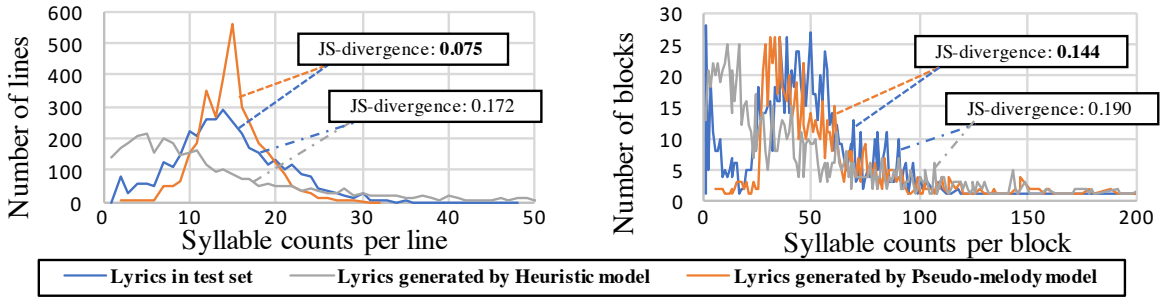

Figure 8: Distribution of the syllable count of the generated lines/blocks

	Heuristic		*Lyrics-only*		*Fine-tuned*		*Pseudo-melody*		*Human* (Upper-bound)	
Measure	Means ± SD	Median	Means ± SD	Median	Means ± SD	Median	Means ± SD	Median	Means ± SD	Median
L	2.06±1.08	2	2.33±1.23	2	**2.85**±1.20	3	**2.93**±1.14	3	3.56±1.33	4
G	2.28±1.07	2	**2.81**±1.16	3	2.79±1.06	3	**2.97**±1.08	3	3.50±1.25	4
LM	2.34±1.07	2	**2.91**±1.15	3	2.70±1.13	3	**2.96**±1.09	3	3.49±1.35	4
DM	2.33±1.10	2	**2.80**±1.06	3	2.59±1.11	3	**2.89**±1.07	3	3.49±1.30	4
OQ	2.01±1.01	2	2.59±1.15	3	2.42±1.08	2	**2.65**±1.01	3	3.32±1.19	4

Table 2: Results of the qualitative evaluation.

as shown in Section 5.3. By investigating the lyrics generated by the *Heuristic* model, we found that the model tends to generate line/block boundaries after the melody rest, even if the two rests are quite close. Figure 8 shows the distributions of the syllable per line / block frequency and the distributions of the Jensen-Shannon divergence. While the Heuristic model tends to generate short lines/blocks, our model generates the lyrics so that lines/blocks do not become too short. This result supports that (i) our model is trained using melody and lyric contexts and (ii) the heuristic approach, which simply generates line/block boundaries based on the distribution in Figure 4, cannot generate fluent lyrics with well-formed line/block lengths.

6 Qualitative evaluation

To asses the quality of the generated lyrics, inspired by (Oliveira, 2015), we asked 50 Yahoo crowdsourcing workers to answer the following five questions using a five-point Likert scale:

Listenability (L) When listening to melody and lyrics, are the positions of words, lines, and segments natural? (1=*Poor* to 5=*Perfect*)

Grammaticality (G) Are the lyrics grammatically correct? (1=*Poor* to 5=*Perfect*)

Line-level meaning (LM) Is each line in the lyrics meaningful? (1=*Unclear* to 5=*Clear*)

Document-level meaning (DM) Are the entire lyrics meaningful? (1=*Unclear* to 5=*Clear*)

Overall quality (OQ) What is the overall quality of the lyrics? (1=*Terrible* to 5=*Great*)

For the evaluation sets, we randomly selected four melodies from the RWC Music Database (Goto et al., 2002). For each melody, we prepared four lyrics generated by the *Heuristic*, *Lyrics-only*, *Fine-tuned*, and *Pseudo-melody* models. Moreover, to obtain an upper bound for this evaluation, we used the lyrics created by amateur writers: we asked four native Japanese speakers to write lyrics on the evaluation melody. One writer was a junior high school teacher of music who had experience in music composition and writing lyrics. Three writers were graduate students with different levels of musical expertise. Two of the three writers had experience with music composition, but none of them had experience with writing lyrics.[9] As a result, we obtained 50 (workers) × 4 (melodies) × 5 (lyrics) samples in total. We note that workers did not know whether lyrics were created by a human or generated by a computer.

Table 2 shows the average scores, standard deviations, and medians for each measure. Regarding the "Listenability" evaluation, workers gave high scores to the *Fine-tuned* and *Pseudo-melody* models that are trained using both the melody and lyrics. This result is consistent with the perplexity evaluation result. On the other hand, regarding the "Grammaticality" and "Meaning" evaluation, workers gave high scores to the *Lyrics-only* and *Pseudo-melody* models that are well-trained on a large amount of text data. This result is consistent with the result of

[9]We release lyrics and audio files used in the qualitative evaluation on the Web (https://github.com/KentoW/deep-lyrics-examples).

the boundary replication task. Regarding the "Overall quality" evaluation, the *Pseudo-melody* model outperformed all other models. These results indicate our pseudo data learning strategy contributes to generating high-quality lyrics. However, the quality of lyrics automatically generated is still worse than the quality of lyrics that humans produce, and it still remains an open challenge for future research to develop computational models that generate high-quality lyrics.

7 Related work

In the literature, a broad range of research efforts has been reported for computationally modeling lyrics-specific properties such as meter, rhythm, rhyme, stress, and accent Greene et al. (2010); Reddy and Knight (2011); Watanabe et al. (2014, 2016). While these studies provide insightful findings on the properties of lyrics, none of those takes the approach of using melody-lyrics parallel data for modeling correlations of lyrics and melody structures. One exception is the work of Nichols et al. (2009), who used melody-lyrics parallel data to investigate, for example, the correlation between syllable stress and pitch; however, their exploration covers only correlations at the prosody level but not structural correlations.

The same trend can be seen also in the literature of automatic lyrics generation, where most studies utilize only lyrics data. Barbieri et al. (2012) and Abe and Ito (2012) propose a model for generating lyrics under a range of constraints provided in terms of rhyme, rhythm, part-of-speech, etc. Potash et al. (2015) proposes an RNNLM that generates rhymed lyrics under the assumption that rhymes tend to coincide with the end of lines. In those studies, the melody is considered only indirectly; namely, input prosodic/linguistic constraints/preferences on lyrics are assumed to be manually provided by a human user because the proposed models are not capable of interpreting and transforming a given melody to constraints/preferences.

For generating lyrics for a given melody, we have so far found in the literature two studies which propose a method. Oliveira et al. (2007) and Oliveira (2015) manually analyze correlations among melodies, beats, and syllables using 42 Portuguese songs and propose a set of heuristic rules for lyrics generation. Ramakrishnan A et al. (2009) attempt to induce a statistical model for generating melodic Tamil lyrics from melody-lyrics parallel data using only ten songs. However, the former captures only phonological aspects of melody-lyrics correlations and can generate a small fragment of lyrics (not an entire lyrics) for a given piece of melody. The latter suffers from the severe shortage of data and fails to conduct empirical experiments.

8 Conclusion and future work

This paper has presented a novel data-driven approach for building a melody-conditioned lyrics language model. We created a 1,000-song melody-lyrics alignment dataset and conducted a quantitative investigation into the correlations between melodies and segment boundaries of lyrics. No prior work has ever conducted such a quantitative analysis of melody-lyrics correlations with this size of data. We have also proposed a RNN-based, melody-conditioned language model that generates fluent lyrics whose word/line/block boundaries fit a given input melody. Our experimental results have shown that: (1) our Melody-conditioned RNNLMs capture the consistency between melody and boundaries of lyrics while maintaining word fluency; (2) combining a limited-scale collection of melody-lyrics alignment data with a far larger collection of lyrics-alone data for training the model boosts the model's competence; (3) we have also produced positive empirical evidence for the effect of applying a multi-task learning schema where the model is trained for syllable count prediction as well as for word prediction; and (4) the human judgments collected via crowdsourcing showed that our model improves the quality of generated lyrics.

For future directions, we plan to further extend the proposed model for capturing other aspects of lyrics/melody discourse structure such as repetitions, verse-bridge-chorus structure, and topical coherence of discourse segment. The proposed method for creating melody-lyrics alignment data enables us to explore such a broad range of aspects of melody-lyrics correlations.

Abstract

In this paper, we investigate the use of discourse-aware rewards with reinforcement learning to guide a model to generate long, coherent text. In particular, we propose to learn neural rewards to model cross-sentence ordering as a means to approximate desired discourse structure. Empirical results demonstrate that a generator trained with the learned reward produces more coherent and less repetitive text than models trained with cross-entropy or with reinforcement learning with commonly used scores as rewards.

1 Introduction

Defining an ideal loss for training text generation models remains an open research question. Many existing approaches based on variants of recurrent neural networks (Hochreiter and Schmidhuber, 1997; Cho et al., 2014) are trained using cross-entropy loss (Bahdanau et al., 2015; Vinyals et al., 2015; Xu et al., 2015; Rush et al., 2015), often augmented with additional terms for topic coverage or task-specific supervision (Kiddon et al., 2016; Yang et al., 2017).

Training with cross-entropy, however, does not always correlate well with achieving high scores on commonly used evaluation measures such as ROUGE (Lin, 2004), BLEU (Papineni et al., 2002), or CIDEr (Vedantam et al., 2015). Another current line of research therefore explores training generation models that directly optimize the target evaluation measure (Wu et al., 2016; Ranzato et al., 2015; Paulus et al., 2018; Rennie et al., 2017) using reinforcement learning methods such as the REINFORCE algorithm (Williams, 1992).

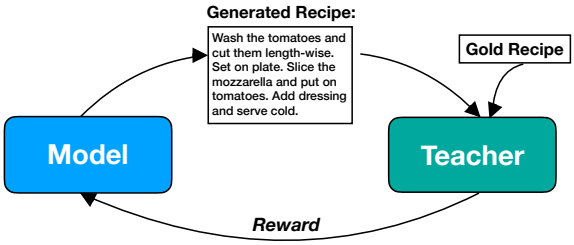

Figure 1: The generator is rewarded for imitating the discourse structure of the gold sequence.

Importantly, most automatic measures are based on local n-gram patterns, providing only a limited and myopic perspective of overall text quality. As a result, while models trained to directly optimize these measures can yield improvements on the same measures, they may not lead to better quality in terms of overall coherence or discourse structure. Indeed, recent studies have reported cases where commonly used measures do not align well with desired aspects of generation quality (Rennie et al., 2017; Li et al., 2016).

The challenge, however, is to define a global score that can measure the complex aspects of text quality beyond local n-gram patterns. In this paper, we investigate *learning* neural rewards and their use in a reinforcement learning regime with a specific focus on learning more discourse-aware and coherent text generation. Our approach shares the spirit of the work of Lowe et al. (2017), where neural scores were learned to approximate human judgments of dialogue quality. The key difference is that our rewards can be fully automatically constructed without requiring human judgments and can be trained in an unsupervised manner.

More specifically, we propose a neural reward learning scheme that is trained to capture cross-sentence ordering structure as a means to approximate the desired discourse structure in documents. The learned *teacher* computes rewards for the

* Work done while author was at Microsoft Research

Proceedings of NAACL-HLT 2018, pages 173–184
New Orleans, Louisiana, June 1 - 6, 2018.

underlying text generator (see Figure 1), which is trained using self-critical reinforcement learning (Rennie et al., 2017). We also present a new method for distributing sentence-level rewards for more accurate credit assignment.

We test our approach on the task of generating cooking recipes, and evaluate using automatic overlap metrics that measure discourse structure. We also provide human judgments that yield comprehensive insights into the model behavior induced by the learned neural rewards. Empirical results demonstrate that a generator trained with the discourse-aware rewards produces text that is more coherent and less repetitive than models trained with cross-entropy or reinforcement learning with other commonly used scores.

2 Neural Teachers

Recent work in image captioning (Rennie et al., 2017), machine translation (Wu et al., 2016), and summarization (Paulus et al., 2018) has investigated using policy gradient methods to fine-tune neural generation models using automatic measures such as CIDEr as the reward. However, because most existing automatic measures focus on local n-gram patterns, fine-tuning on those measures may yield deteriorated text despite increased automatic scores, especially for tasks that require long coherent generation (§6.1).

Since writing out a scoring term that quantifies the quality of discourse coherence is an open research question, we take inspiration from previous research that *learns* the overall ordering structure of a document as an approximation of the discourse structure (Barzilay and Lapata, 2005, 2008; Barzilay and Lee, 2004; Li and Hovy, 2014), and propose two neural teachers that can learn to score an ordered sequence of sentences. The scores from these neural teachers are then used to formulate rewards (§4.2) that guide coherent long text generation systems in a policy gradient reinforcement learning setup. Notably, the neural teachers are trained offline on gold sequences in an unsupervised manner prior to training the generator. They are not trained jointly with the generator and their parameters are fixed during policy learning.

2.1 Notation

We define a document of n sentences as $S = \{s_0, ..., s_n\}$ where each sentence s_j has L_j words.

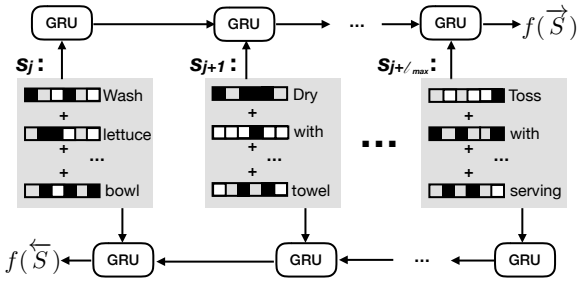

Figure 2: The teacher encodes the sentences of the document in the forward and reverse order.

2.2 Absolute Order Teacher

The first teacher explored is motivated by work on deep semantic similarity models (Huang et al., 2013), which approximated the similarity between queries and documents in information retrieval tasks. We extend this approach to modeling temporal patterns by training a sentence encoder to minimize the similarity between a sequence encoded in its forward order, and the same sequence encoded in the reverse order (see Figure 2).

To focus the teacher on discourse structure, we design the encoder to capture *sentence order*, instead of *word order*. Words in each sentence s_j are encoded using a bag of words:

$$\mathbf{s}_j = \sum_{i=1}^{L_j} x_{ij} \tag{1}$$

where x_{ij} is a word embedding and $\mathbf{s}_j$ is a sentence embedding. Each $\mathbf{s}_j$ is passed to a gated recurrent unit (GRU) and the final output of the hidden unit is used as the representation for the full document:

$$h_j = \text{GRU}(\mathbf{s}_j, h_{j-1}) \tag{2}$$

$$f(S) = h_n \tag{3}$$

where $f(S)$ is the representation of the sentences of the document and h_n is the final output vector of the GRU. To capture properties of temporal coherence among document sentences, the teacher is trained to minimize $\mathcal{L}_{abs}$, the cosine similarity between the sentence embedding from reading the sentences in the forward order, $\overrightarrow{S}$ and from reading the sentences in the reverse order, $\overleftarrow{S}$:

$$\mathcal{L}_{abs} = \frac{\langle f(\overrightarrow{S}), f(\overleftarrow{S}) \rangle}{\|f(\overrightarrow{S})\| \|f(\overleftarrow{S})\|} \tag{4}$$

Intuitively, by parametrizing only relations between *sentences* (with the GRU layer) and not those between *words*, the teacher only captures sentence ordering properties. When training the neural generator (§4), we use this learned teacher to generate a reward that judges the generated sequence's ordering similarity to the gold sequence.

2.3 Relative Order Teacher

While the absolute ordering teacher evaluates the temporal coherence of the entire generation, we may want our teacher to be able to judge finer-grained patterns between sentences. In recipes, for example, where sentences correspond to process steps, the teacher should capture implicit script knowledge (Schank and Abelson, 1975) among groups of sentences. Consequently, the teacher should reward sentences individually for how they fit with surrounding sentences.

In many current approaches for using policy gradient methods to optimize a model with respect to a global score, each sentence receives the same reward. This framework assumes each sentence is equally responsible for the reward gathered by the full sequence, allowing potentially appropriate subsequences to be incorrectly penalized. We design the relative order teacher to address this issue.

The relative order teacher is trained in the same way as the absolute order model. A bag of words embedding is computed for each sentence in the gold sequence. Subsequences of the gold document that have ℓ sentences are selected where $\ell \in (\ell_{min}, \ell_{max})$. For a subsequence beginning at sentence j, the model computes:

$$f(S_{j:j+\ell}) = \text{GRU}(\mathbf{s}_{j+\ell}, h_{j+\ell-1}) \tag{5}$$

where $f(S_{j:j+\ell})$ is the encoded representation of sentences $\{s_j, ...s_{j+\ell}\}$ and h_{j-1} would be initialized as a vector of zeros. The relative ordering teacher is trained to minimize $\mathcal{L}_{rel}$, the cosine similarity between gold orders of subsequences:

$$\mathcal{L}_{rel} = \frac{\langle f(\overrightarrow{S}_{j:j+\ell}), f(\overleftarrow{S}_{j:j+\ell})\rangle}{\|f(\overrightarrow{S}_{j:j+\ell})\|\|f(\overleftarrow{S}_{j:j+\ell})\|} \tag{6}$$

where the arrow above S signifies the order in which the sentences are processed. The relative ordering teacher learns to identify local sentence patterns among ordered sentences, thereby learning how to reward sequences that are temporally coherent.

3 Generator Architecture

In the task of recipe generation, the model is given a title of a recipe such as *"Cheese Sandwich"* and a list of ingredients (e.g., cheese, bread, etc.) and must generate the full multi-sentence recipe text. Similar to data to document generation tasks, the model must generate a full long-form text from sparse input signal, filling in missing information on its own (Wiseman et al., 2017).

3.1 Notation

Using the same notation as Kiddon et al. (2016), we are given a set of recipe title words $\{g_1, ..., g_n\}$ (e.g., { "cheese", "sandwich" }) and a list of ingredients $E = \{\mathbf{i}_1, ..., \mathbf{i}_{|E|}\}$ where each $\mathbf{i}$ can be a single- or multi-word ingredient phrase (e.g., "onions" or "onions, chopped"). In the following paragraphs, all W variables are projections matrices and all b variables are bias vectors.

3.2 Encoder

We use a modification of the baseline encoder of Kiddon et al. (2016). First, the title words are encoded as a bag of embeddings, $\mathbf{g}$. Second, each ingredient phrase $\mathbf{i}$ is encoded as a bag of embeddings vector, $\mathbf{e_i}$. The ingredient embeddings are inputs to a bidirectional gated recurrent unit, which yields an output vector $\mathbf{e}$. The final encoder output is the concatenation of these two representations, $\mathbf{h}^e = [\mathbf{g}, \mathbf{e}]$.

3.3 Decoder

The decoder is a separate gated recurrent unit that receives $\mathbf{h}^e$ from the encoder to initialize its hidden state $\mathbf{h}^d_0$ and must generate a full recipe word by word. At each time step, the model receives an input token embedding, x_t, as well as the output from the encoder $\mathbf{h}^e$:

$$a_t = \sigma(W_1 h^d_{t-1} + W_2 x_t + b_1) \tag{7}$$

$$\mathbf{z}_t = a_t \mathbf{h}^e \tag{8}$$

$$\tilde{x}_t = [x_t, \mathbf{z}_t] \tag{9}$$

where $\tilde{x}_t$ is the input to the recurrent unit at every time step. The recipe generator is pretrained to minimize the negative loglikelihood of predicting the next token in the recipe:

$$L_{mle} = -\sum_{t=1}^{T} \log P(x_t | x_0, ..., x_{t-1}, \mathbf{h}^e) \tag{10}$$

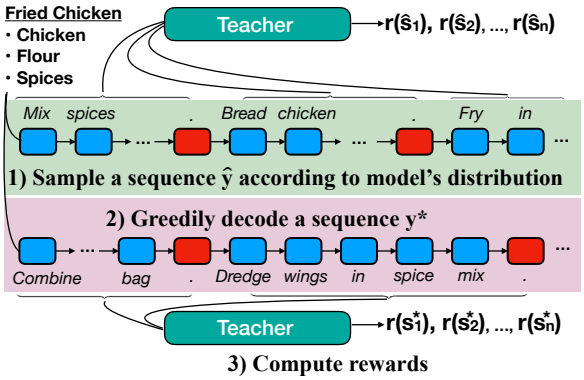

Figure 3: The model generates a recipe by sampling from its output vocabulary distribution and greedily decodes a baseline recipe. The generated sentences are passed to the teacher, which yields a reward for each sentence in each recipe.

where $\mathbf{h}^e$ is the encoded representation of the title and ingredients from Section 3.2 and T is the number of words in the gold recipe.

4 Policy Learning

Training a recipe generation model using maximum likelihood estimation produces generations that are locally coherent, but lack understanding of domain knowledge. By using a teacher that rewards the model for capturing cooking recipe discourse semantics, the model learns a policy that produces generations that better model the underlying recipe process. We learn a policy using the self-critical approach of Rennie et al. (2017).

4.1 Self-critical sequence training

In self-critical sequence training, outlined in Figure 3, the model learns by being rewarded for sampling sequences that receive more reward than a greedily decoded sequence. For each training example, a sequence $\hat{y}$ is generated by sampling from the model's distribution $P(\hat{y}_t|\hat{y}_0, ..., \hat{y}_{t-1}, \mathbf{h}^e)$ at each time step t. Once the sequence is generated, the teacher produces a reward $r(\hat{y}_t)$ for each token in the sequence. A second sequence y^* is generated by argmax decoding from $P(y^*_t|y^*_0, ..., y^*_{t-1}, \mathbf{h}^e)$ at each time step t. The model is trained to minimize:

$$\mathcal{L}_{rl} = -\sum_{t=1}^{T}(r(\hat{y}_t) - r(y^*_t)) \log P(\hat{y}_t|\hat{y}_0, ..., \hat{y}_{t-1}, \mathbf{h}^e) \tag{11}$$

where $r(y^*_t)$ is the reward produced by the teacher for tokens of the greedily decoded sequence. Because $r(y^*)$ can be viewed as a *baseline* reward that sampled sequences should receive more than, the model learns to generate sequences that receive more reward from the teacher than the best sequence that can be greedily decoded from the current policy. This approach allows the model to *explore* sequences that yield higher reward than the current best policy.

4.2 Rewards

As we decode a sequence $y = \{y_0..., y_t\}$, we track a sentence index that is the number of sentence delimiter tokens (e.g., ".") generated by the model. The model then implicitly decodes a set of generated sentences, $S' = \{s_0, ..., s_n\}$. These sentences are provided to the teachers defined in Section 2, which compute a score for the generated sequence. We explain the procedure for producing a token reward $r(y_t)$ from these scores below.

Absolute Order Once a sequence has been generated, the absolute order teacher computes a reward for y in the following way:

$$r_{abs}(y) = \frac{\langle f(S'), f(\overrightarrow{S})\rangle}{\|f(S')\|\|f(\overrightarrow{S})\|} - \frac{\langle f(S'), f(\overleftarrow{S})\rangle}{\|f(S')\|\|f(\overleftarrow{S})\|} \tag{12}$$

where $\overrightarrow{S}$ is the forward-ordered corresponding gold sequence and $\overleftarrow{S}$ is the reverse-ordered gold sequence. Both terms in the reward computation are variations of the loss function on which the absolute order teacher was trained (Equation (4)). This reward compares the generated sequence to both sentence orders of the gold sequence, and rewards generations that are more similar to the forward order of the gold sequence. Because the cosine similarity terms in Equation (12) are bounded in $[-1, 1]$, the model receives additional reward for generating sequences that are different from the reverse-ordered gold sequence.

Relative Order Similarly, the relative order reward is generated by the relative order teacher (§2.3), which evaluates subsequences of sentences, rather than the whole sequence. For a sentence s_j, the reward is computed as:

$$r_{rel}(s_j) = \frac{1}{L}\sum_{\ell=\ell_{min}}^{\ell_{max}}\left(\frac{\langle f(S'_{j-\ell:j}), f(\overrightarrow{S}_{j-\ell:j})\rangle}{\|f(S'_{j-\ell:j})\|\|f(\overrightarrow{S}_{j-\ell:j})\|} - \frac{\langle f(S'_{j-\ell:j}), f(\overleftarrow{S}_{j-\ell:j})\rangle}{\|f(S'_{j-\ell:j})\|\|f(\overleftarrow{S}_{j-\ell:j})\|}\right) \tag{13}$$

where ℓ_{min} and ℓ_{max} define the window of sentences to include in the computation of the reward. Similar to the absolute order teacher, the relative order teacher produces scores bounded in $[-1, 1]$, giving the model additional reward for generating sequences that are different from the reverse-ordered gold subsequences.

Credit Assignment When rewarding tokens with the absolute ordering teacher, each generated token receives the same sequence-level reward from the absolute order teacher:

$$r(y_t) = r_{abs}(y) \tag{14}$$

The relative order teacher, meanwhile, computes rewards for sentences based on their imitation of nearby sentences in the gold recipe. Rather than combining all rewards from the teacher to compute a full sequence reward, sentences should only be rewarded for their own quality. Each token in a sentence corresponds to a position in the full sequence. When relative order rewards are computed by the teacher, the correct sentence reward is indexed for each token. Consequently, when training with a relative order teacher, words only receive rewards for the sentences they belong to:

$$r(y_t) = \sum_{j=1}^{|S|} \mathbb{1}(y_t \in \hat{s}_j) r_{rel}(\hat{s}_j) \tag{15}$$

where $|S|$ is the number of sentences in the generated recipe, and $\mathbb{1}$ is an indicator variable identifying word y_t belonging to sentence s_j.

4.3 Mixed Training

As the model learns parameters to optimize the amount of reward it receives from the teacher, it is not explicity encouraged to produce fluent generations. The model quickly learns to generate simple sequences that *exploit* the teacher for high rewards despite being incoherent recipes (e.g., Figure 4). Consequently, it is possible that generated sequences are no longer readable (Pasunuru and Bansal, 2017; Paulus et al., 2018).

Title: Chili Grits
Ingredients: boiling water, butter, shredded cheddar cheese, jalapenos, eggs, chicken cream of soup, salt
Generated Recipe: Here .

Figure 4: Recipe generated from a self-critical model with no mixed training

To remedy this effect, the model optimizes a mixed objective that balances learning the discourse-focused policy while maintaining the generator's language model:

$$\mathcal{L}_{mix} = \gamma \mathcal{L}_{rl} + (1 - \gamma)\mathcal{L}_{mle} \tag{16}$$

where L_{mle} is the objective from Equation (10), L_{rl} is the objective from either Equation (11), and γ is a hyperparameter in [0, 1].

5 Experimental Setup

5.1 Datasets

We use the Now You're Cooking dataset with the same training/test/development splits from Kiddon et al. (2016). For training, we use 109567 recipes with 1000 recipes set aside for both development and test.

5.2 Training

Teacher Models The teachers are trained before the recipe generator and their parameters are fixed during generation. We tune hyperparameters on the development set. To train the relative order teacher, we sample 20 subsequences from each recipe of $\ell_{min} = 3$ to $\ell_{max} = 6$ sentences. Additional details are provided in Appendix A.2.

Recipe Generator We pretrain a recipe generator using a variant of the encoder-decoder baseline from Kiddon et al. (2016). Comprehensive hyperparameter details can be found in Appendix A.3.

Policy Learning We train a different model for three different teacher-provided rewards: absolute ordering (AO), relative ordering (RO) and a joint reward of relative ordering and BLEU-4 (RO + B4), where the full-sequence BLEU-4 reward and the sentence-level relative ordering reward are summed at each time step. The best model for the absolute and relative ordering rewards are the ones that receive the highest average reward on the development set. The best model for the mixed reward was chosen as the one that achieved the highest average geometric mean of BLEU-4 reward and average relative ordering reward for each generated sequence y in the development set:

$$\bar{r} = \frac{r_{b4}(y)}{T} \sum_{t=1}^{T} r_{RO}(y_t) \tag{17}$$

where r_{b4} is the BLEU-4 score of the whole generated sequence, and r_{RO} is computed using Equa-

tion (15). Our best models use $\gamma = 0.97$ when training with the mixed objective from Equation (16).

5.3 Baselines

As baselines, we report results for a model trained only with cross-entropy loss (MLE) and for re-implemented versions of models from Rennie et al. (2017) and Paulus et al. (2018). These baselines achieved state of the art results in image captioning and document summarization tasks. We found, however, that their high γ (1 and 0.9984, respectively) led to low fluency, resulting in reduced performance on word-level scores. To control for this effect, we trained additional versions of each baseline with different values for γ and report the best performing configurations (see Table 1).

6 Results

6.1 Overlap Metrics

Scores We compute the example-level BLEU-1, BLEU-4, and ROUGE-L (R-L) scores for all recipes in the test set. A generated recipe, however, must be coherent at both the *word-level*, linking words and phrases sensibly, and the *world-level*, describing events that are grounded in real-world actions. Because n-gram scores do not evaluate if a generated recipe models this latent process, we also report these scores on the *action* and *state change* sequence described in the recipe. These words depict a *simulated* world where actions are taken and state changes are induced. A generated recipe should follow the sequence of actions taken in the gold recipe, and induce the same state changes as those in the gold recipe.

We use the state change lexicon from Bosselut et al. (2018) to map recipe words to ordered sequences of actions and state changes. Each entry in the lexicon contains an action in the cooking domain as well as the state changes that result from that action in the set of {LOCATION, COMPOSITION, COOKEDNESS, TEMPERATURE, SHAPE, CLEANLINESS}.

Action sequences are formed by mapping lemmas of words in generated sequences to entries in the lexicon. We compare these event sequences to the gold event sequences using the same scores as for words – BLEU-1, BLEU-4, and ROUGE-L. Intuitively, these scores can be seen as evaluating the following: whether the generated recipe depicts the same actions (AB1), subsequences of consecutive actions (AB4), and full action sequence (AR-L) as the gold recipe.

State change sequences are more coarse-grained than action sequences, and are formed by mapping actions to their state changes in the lexicon from Bosselut et al. (2018). These scores evaluate whether the generated recipe implies the same induced state changes (SCB1), subsequences of consecutive state changes (SCB4), and global state change order (SCR-L) as the gold recipe.

Results Our results in Table 1 show that models optimized on word overlap metrics achieve the greatest improvements for those scores. Optimizing scores such as BLEU-1 encourages the model to output words and phrases that overlap often with reference sequences, but that may not describe main events in the recipe process.

When examining models trained using a neural teacher, we see that the model optimized with

the absolute ordering reward performs worse than most baselines for every word-level score. The relative ordering model, however, raises every word-level score above the cross-entropy baseline, indicating the importance of fine-grained credit assignment at the sentence-level. The model trained with mixed rewards from the teacher and BLEU-4 achieves even higher scores, showing the benefits of training with diverse rewards.

When evaluating these metrics for the action and state change sequence, the models trained with feedback from the relative ordering teacher show large improvement over the baselines, indicating that the models exhibit more understanding of the latent process underlying the task. While optimizing word-level scores teaches the generator to output common sequences of words, the relative ordering reward teaches the model to focus on learning co-occurrences between recipe events.

6.2 Human Evaluation

We perform a human evaluation on 100 recipes sampled from the test set to evaluate our model on four aspects of recipe quality: fluency, ingredient use, title completion, and action ordering. For each example, three judges from Amazon Mechanical Turk are shown a pair of recipes, each generated by a different model and asked to select the recipe that is better according to the criteria above. For ingredient use, judges select the recipe that uses more of the ingredients correctly. For title completion, we ask judges to select the recipe that best completes the dish described in the recipe title. Finally, for action ordering, judges choose the recipe that better links subtasks in the recipes.

Models We use the Relative Ordering + BLEU-4 model (RO + B4) and compared to two baselines, the cross-entropy model (MLE), and the BLEU-1 model, which achieved the best scores on several word-level metrics (§6.1).

Results We report results in Table 2. Our model outperforms the cross-entropy baseline, consistently being preferred on aggregate for every question. Workers preferred the BLEU-1 baseline for the fluency and action order questions, while preferring recipes generated by the teacher-trained model for the ingredient use and title ordering questions. Upon further analysis, we see that the strength of the BLEU-1 model depends on the length of the original reference sequence. In Table 3, we show evaluation scores for recipes where the gold recipe was longer than 100 words. Our model's performance rises compared to the BLEU-1 model for every question, showing that modeling discourse structure as learned reward improves global coherence in long text.

6.3 Insights

Qualitative Analysis In Table 4, we see the effect that the neural teacher has on the recipe generator. The teacher rewards behavior that more closely imitates the actions in the gold recipe. In the first example, the generator learns to complete the actions of placing the mixture into the a *greased casserole* and then *baking* it, which the MLE model misses. The teacher also discourages repetitive phrases, as they provide no increase in reward during training. One weakness of our teacher models, however, is that they encourage common temporal patterns, such as in the third

Title **Ings**	Royale Casserole Broccoli, chopped; butter; flour; salt; black pepper; nutmeg; milk; cheese shredded swiss; lemon juice; cooked cubed turkey; mushrooms; grated parmesan cheese; biscuits, refrigerated
MLE	Cook broccoli according to package directions. Drain. Melt butter in skillet. Add flour, stirring constantly. Cook, stirring constantly, until thickened. Add milk, salt, pepper, and nutmeg. Cook over low heat, stirring constantly, until thickened. Add cheese, salt, pepper and pimento. Cook and stir till thickened. Add cheese, stirring until melted. Add **broccoli and mushrooms**. Cook over low heat for 5 minutes. Add cheese. Cook and stir until cheese melts. Add cheese. Cook and stir until cheese melts. Add cheese. Cook and stir until cheese melts. Add cheese and stir until melted. Serve over hot noodles.
RO	Melt butter in saucepan. Add flour and cook, stirring constantly, until thickened. Add milk, salt, pepper, and nutmeg. Cook, stirring constantly, until thickened. Add cheese, salt and pepper. Cook over low heat, stirring constantly, until mixture is thickened and smooth. Remove from heat. Stir in cheese. Spoon into **greased casserole**. Top with cheese. **Bake in 350 f oven for 30 minutes.** Serves 6.
Gold	Preheat oven to 375. Melt butter in saucepan. Blend in flour, salt, pepper, and nutmeg; cook 1-2 minutes. Gradually add milk; cook, stirring, until slightly thickened. Stir in frozen vegetables. Remove from heat; stir in cheese until melted. Add lemon juice, turkey, mushrooms and broccoli. Pour mixture into a lightly greased baking dish; sprinkle with parmesan and top with biscuits. Bake 20 minutes, or until biscuits are golden brown.
Title **Ings**	Wine Sauerkraut butter; dry white wine; 16 oz drained sauerkraut
MLE	In a saucepan, combine soup, wine, and butter. Heat, uncovered, in microwave oven 2 minutes or until mixture is heated through.
RO	Melt butter in skillet. **Add sauerkraut** and wine; heat to boiling. Reduce heat; cover and simmer 15 minutes. Add wine and heat to boiling; reduce heat. Cover and cook 10 minutes or until mixture is tender. Serve on rice.
Gold	Melt butter in 10-inch skillet over low heat; add sauerkraut. Cover and cook, stirring occasionally, 30 minutes; add wine. Heat to boiling; reduce heat. Cover and simmer until liquid is absorbed, about 45 minutes. Follow directions except simmer until liquid is absorbed, about 1 hour.
Title **Ings**	Strawberry Glazed Pie fresh strawberries; granulated sugar; salt; cornstarch; lemon juice; baked, cooled pie shell
MLE	Combine sugar, cornstarch and salt in top of a double boiler. Cook and stir over medium heat until mixture thickens and boils. Boil and stir 1 minute. Remove from heat and stir in lemon juice. Cool. Add strawberries and lemon juice. Pour into baked pie shell. Top with whipped cream. Serve immediately.
RO	Combine sugar, cornstarch, and salt in a saucepan; cook over medium heat, stirring constantly, until mixture boils and thickens. Remove from heat; stir in lemon juice. Cool. Add strawberries; mix well. Pour into baked pie shell. Bake in preheated 325-degree oven for 10 minutes. Cool. Garnish with whipped cream.
Gold	Wash, drain thoroughly, and hull strawberries. Arrange about 3 cups of whole berries over bottom of baked pastry shell. Crush remaining berries in a saucepan. In a bowl, mix sugar, salt and cornstarch; stir into crushed berries. Heat slowly, stirring constantly, until mixture comes to a boil and thickens. Remove from heat and stir in lemon juice. Cool, then spoon over berries in pie shell chill until glaze is set. Garnish with whipped cream.

Table 4: Example recipe generations from our model and comparative baselines. **Boxed** spans indicate recipe events missed by another model's generation. Red spans indicate superfluous events. The **Ings** row lists the ingredients (separated by semicolons) provided to make the dish in the title.

example in Table 4, where the generator mentions *baking the pie*. The model recognizes pies are generally supposed to be baked, even if it is not appropriate for that particular recipe.

Teacher Feedback Frequency We design the reward functions in Eq. 12 and Eq. 13 to require two passes through the teacher, one comparing the generated sequence to the forward gold sequence, and one comparing it to the reverse gold sequence. With no teacher comparison to the reverse-ordered sequence, the generator learns to *exploit* the teacher for reward with very simple sequences such as "Serve." and "Here's direction." When comparing with both orders, however, this effect is dampened, hinting at the importance of ensembling feedback from multiple sources for robust reward production. Another solution to this effect was mixing policy learning and maximum likelihood learning (Eq. 16) as the underlying language model of the generator did not deteriorate.

Impact of ℓ_{max} and γ Two hyperparameters to tune when training with teacher models are the mixed loss coefficient γ, which balances MLE learning with policy learning, and $[\ell_{min}, \ell_{max}]$, the number of sentences to consider when computing the relative order reward. We fix $\ell_{min} = 3$, and vary $\ell_{max} \in [3, 6]$ and $\gamma \in \{0.95, 0.97, 0.98\}$. Figure 5 shows the importance of tuning γ. A low γ will not allow the teacher to guide the model's learning, while a high γ causes the lan-

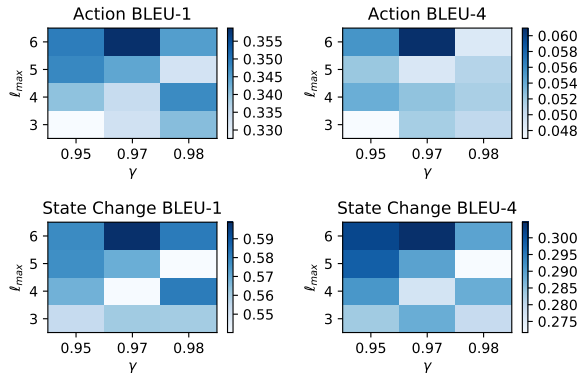

Figure 5: Action and State Change BLEU Metrics for different initializations of ℓ_{max} and γ

guage model to deteriorate. Interestingly, a higher ℓ_{max} leads to better performance on global coherence scores, implying that relative order rewards conditioned on more sentences allow the model to learn longer-range context co-occurrences.

7 Related Work

The field of neural text generation has received considerable attention in tasks such as image captioning (Vinyals et al., 2015; Xu et al., 2015), summarization (Rush et al., 2015; See et al., 2017), machine translation (Bahdanau et al., 2015), and recipe generation (Kiddon et al., 2016). While these works have focused on developing new neural architectures that introduce structural biases for easier *learning*, our work uses a simple architecture and focuses on improving the optimization of the learner (i.e., better *teaching*).

The importance of better teaching for RNN generators was outlined in Bengio et al. (2015), which showed that *exposure* bias from a misaligned train and test setup limited the capabilities of sequence-to-sequence models. This limitation had been addressed in previous work by augmenting training data with examples generated by pretrained models to make models robust to their own errors (Daumé III et al., 2009; Ross et al., 2011).

More recent work on training RNNs for generation has used sequence scores such as ROUGE (Paulus et al., 2018), CIDEr (Rennie et al., 2017; Pasunuru and Bansal, 2017), BLEU (Ranzato et al., 2015) and mixtures of them (Liu et al., 2017) as a global reward to train a policy with the REINFORCE algorithm (Williams, 1992). In contrast, our work uses a neural teacher to reward a model for capturing discourse semantics.

Most similar to our work is work on using neural and embedding rewards to improve dialogue (Li et al., 2016), image captioning (Ren et al., 2017), simplification (Zhang and Lapata, 2017), and paraphrase generation (Li et al., 2017). While these works use single-sentence similarity rewards for short generation tasks, our work designs teachers to reward long-range ordering patterns.

Finally, our teachers can be seen as rewarding generators that approximate script patterns in recipes. Previous work in learning script knowledge (Schank and Abelson, 1975) has focused on extracting scripts from long texts (Chambers and Jurafsky, 2009; Pichotta and Mooney, 2016), with some of that work focusing on recipes (Kiddon et al., 2015; Mori et al., 2014, 2012). Our teachers implicitly learn this script knowledge and reward recipe generators for exhibiting it.

8 Conclusion

We introduce the *absolute ordering* and *relative ordering* teachers, two neural networks that score a sequence's adherence to discourse structure in long text. The teachers are used to compute rewards for a self-critical reinforcement learning framework, allowing a recipe generator to be rewarded for capturing temporal semantics of the cooking domain. Empirical results demonstrate that our teacher-trained generator better models the latent event sequences of cooking recipes, and a human evaluation shows that this improvement is mainly due to maintaining semantic coherence in longer recipes.

A Hyperparameters

A.1 Data

Each recipe is batched based on the number of tokens and number of ingredients it has. We use a minibatch size of 32.

A.2 Teachers

The hidden size of the reward generator is 100, the word embeddings have dimensionality 100. We use dropout with a rate of 0.3 between the bag of words layers and the recurrent layers.

A.3 Pretrained Recipe Generator

We use a hidden size of 256 for the encoder and 256 for the decoder. We initialize three different sets of embeddings for the recipe titles, ingredient lists, and text, each of size 256. All models are trained with a dropout rate of 0.3 and are single-layer. We use a temperature coefficient of $\beta = 2$ to make the output word distribution more peaky (Kiddon et al., 2016), allowing for more controlled exploration during self-critical learning. We use scheduled sampling with a linear decay schedule of 5% every 5 epochs up to a max of 50%. We use a learning rate of $\eta = 0.0003$ and train with the Adam optimizer.

A.4 Policy Learning

We use the same model hyperparameters as during pretraining, but re-initialize the Adam optimizer, use $\eta = 3 \times 10^{-5}$ as the learning rate, and do not train with scheduled sampling.

B Baseline Selection

For each baseline we trained, we report the score of the γ setting that achieved the highest score for the metric on which it was trained. For example, for baselines trained with ROUGE-L reward, we report the results for the model trained with the value of γ that scored the highest ROUGE-L score on the development set. For the models trained with the CIDEr reward, we select the model with value of γ that achieved the highest CIDEr score on the development set. We do the same for models trained with BLEU-1 and BLEU-4 rewards. The values of γ yielding the best performance on the development set were 0.97 for the BLEU-1, ROUGE-L, and CIDEr-trained models, and 0.99 for the BLEU-4 trained baseline. For each baseline, the best model is chosen by selecting the checkpoint that achieves the highest reward (or lowest loss for the MLE model) for the metric it was trained on.

Natural Answer Generation with Heterogeneous Memory

Abstract

Memory augmented encoder-decoder framework has achieved promising progress for natural language generation tasks. Such frameworks enable a decoder to retrieve from a memory during generation. However, less research has been done to take care of the memory contents from different sources, which are often of heterogeneous formats. In this work, we propose a novel attention mechanism to encourage the decoder to actively interact with the memory by taking its heterogeneity into account. Our solution attends across the generated history and memory to explicitly avoid repetition, and introduce related knowledge to enrich our generated sentences. Experiments on the answer sentence generation task show that our method can effectively explore heterogeneous memory to produce readable and meaningful answer sentences while maintaining high coverage for given answer information.

1 Introduction

Most previous question answering systems focus on finding candidate words, phrases or sentence snippets from many resources, and ranking them for their users (Chu-Carroll et al., 2004; Xu et al., 2016). Typically, candidate answers are collected from different resources, such as knowledge base (KB) or textual documents, which are often with heterogeneous formats, e.g., KB triples or semi-structured results from Information Extraction (IE). For factoid questions, a single answer word or phrase is chosen as the response for users, as shown in Table 1 (A1).

However, in many real-world scenarios, users may prefer more natural responses rather than a single word. For example, as A2 in Table 1, *James Cameron directed the Titanic.* is more favorable than the single name *James Cameron.* A straightforward solution to compose an answer sentence is to build a template based model, where the answer word *James Cameron* and topic word in the question *the Titanic* are filled into a pre-defined template (Chu-Carroll et al., 2004). But such systems intrinsically lack variety, hence hard to generalize to new domains.

Q	Who is the director of the Titanic?
A1	**James Cameron**
A2	**James Cameron** directed **the Titanic**.
A3	**James Cameron** directed **it**.
A4	**James Cameron** directed it in **1999**.

Table 1: Answer sentences generated by different QA systems

To produce more natural answer sentences, Yin et al. (2015) proposed GenQA, an encoder-decoder based model to select candidate answers from a KB styled memory during decoding to generate an answer sentence. CoreQA (He et al., 2017b) further extended GenQA with a copy mechanism to learn to copy words from the question. The application of attention mechanism enables those attempts to successfully learn sentence varieties from the memory and training data, such as usage of pronouns (A3 in Table 1). However, since they are within the encoder-decoder framework, they also encounter the well noticed repetition issue: due to loss of temporary decoder state, an RNN based decoder may repeat what has already been said during generation (Tu et al., 2016a,b).

Both GenQA and CoreQA are designed to work with a structured KB as the memory, while in most real-world scenarios, we require knowledge from different resources, hence of different formats. This knowledge may come from structured KBs, documents, or even tables. It is admittedly challenging to leverage a heterogeneous memory in a neural generation framework, and it is not well studied in previous works (Miller et al., 2016). Here in our case, the memory should contain two main formats: KB triples and semi-structured en-

Proceedings of NAACL-HLT 2018, pages 185–195
New Orleans, Louisiana, June 1 - 6, 2018.

tities from IE, forming a heterogeneous memory (HM). The former is usually organized in is a subject-predicate-object form, while, the latter is usually extracted from textual documents, in the form of keywords, sometimes associated with certain categories or tags oriented to specific tasks (Bordes and Weston, 2016).

Miller et al. (2016) discuss different knowledge representations for a simple factoid QA task and show that classic structured KBs organized in a Key-Value Memory style work the best. However, dealing with heterogeneous memory is not trivial. Figure 1 shows an example of generating answer sentences from HM in a Key-Value style, which is indeed more challenging than only using a classic KB memory. Keys and values play different roles during decoding. A *director* key indicates this slot contains the answer. Same *James Cameron* values with different keys indicate duplication. The decoder needs this information to proactively perform memory addressing. Because keys from documents are not canonicalized, e.g., *doc directed* and *doc director*, they may lead to redundancy with the structured KB, e.g., *kb directed_by* and *doc director*. A decoder could repetitively output a director twice simply because there are two different memory slots hit by the query, both indicating the same director. This will make the the repetition issue even worse.

Although many neural generation systems can produce coherent answer sentences, they often focus on how to guarantee the chosen answer words to appear in the output, while ignoring many related or meaningful background information in the memory that can further improve user experiences. In real-world applications like chatbots or personal assistants, users may want to know not only the exact answer word, but also information related to the answers or the questions. This information is potentially helpful to attract users' attention, and make the output sentences more natural. For example in Table 1 (A4), the extra *1999* not only enriches the answer with the movie's release year, but also can act as a clue to help distinguish ambiguous candidate answers, e.g., *Titanic (1999)* and *Titanic (HD, 2016)*.

In this paper, we propose a sequence to sequence model tailing for heterogeneous memory. In order to bridge the gap between decoder states and memory heterogeneity, we split decoder states into separate vectors, which can be used to address

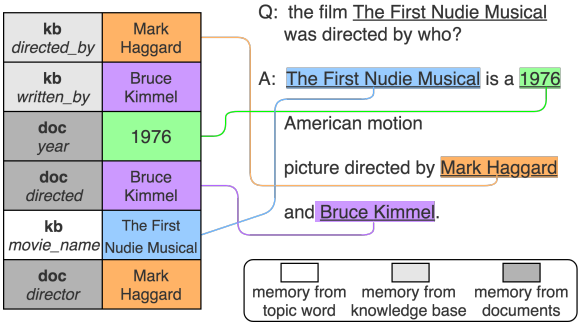

Figure 1: An example qa-pair with heterogeneous memory

different memory components explicitly. To avoid redundancy, we propose the **Cumulative Attention** mechanism, which uses the context of the decoder history to address the memory, thus reduces repetition at memory addressing time. We conduct experiments on two `WikiMovies` datasets, and experimental results show that our model is able to generate natural answer sentences composed of extra related facts about the question.

2 Related Work

Natural Answer Generation with Sequence to Sequence Learning: Sequence to sequence models (with attention) have achieved successful results in many NLP tasks (Cho et al., 2014; Bahdanau et al., 2014; Vinyals et al., 2015; See et al., 2017). Memory is an effective way to equip seq2seq systems with external information (Weston et al., 2014; Sukhbaatar et al., 2015; Miller et al., 2016; Kumar et al., 2015). GenQA (Yin et al., 2015) applies a seq2seq model to generate natural answer sentences from a knowledge base, and CoreQA (He et al., 2017b) extends it with copying mechanism (Gu et al., 2016). But they do not consider the heterogeneity of the memory, only tackle questions with one single answer word, and do not study information enrichment.

Memory and Attention: There are also increasing works focusing on different memory representations and the interaction between the decoder and memory, i.e., attention. Miller et al. (2016) propose the Key-Value style memory to explore textual knowledge (both structured and unstructured) from different sources, but they still utilize them separately, without a uniform addressing and attention mechanism. Daniluk et al. (2017) split the decoder states into key and value representation, and increase language modeling

performance. Multiple variants of attention mechanism have also been studied. Sukhbaatar et al. (2015) introduce multi-hop attention, and extend it to convolutional sequence to sequence learning (Gehring et al., 2017). Kumar et al. (2015) further extend it by using a Gated Recurrent Unit (Chung et al., 2014) between hops. These models show that multiple hops may increase the model's ability to reason. These multi-hop attention is performed within a single homogeneous memory. Our Cumulative Attention is inspired by them, but we utilize it cross different memory, hence can explicitly reason over different memory components.

Conditional Sentence Generation: Controllable sentence generation with external information is wildly studied from different views. From the task perspective, Fan et al. (2017) utilize label information for generation, and tackle information coverage in a summarization task. He et al. (2017a) use recursive Network to represent knowledge base, and Bordes and Weston (2016) track generation states and provide information enrichment, both are in a dialog setting. In terms of network architecture, Wen et al. (2015) equip LSTM with a semantic control cell to improve informativeness of generated sentence. Kiddon et al. (2016) propose the neural checklist model to explicitly track what has been mentioned and what left to say by splitting these two into different lists. Our model is related to these models with respect to information representation and challenges from coverage and redundancy. The most closely related one is the checklist model. But it does not explicitly study information redundancy. Also, the information we track is heterogeneous, and we track it in a different way, i.e. using Cumulative attention.

Due to loss of states across time steps, the decoder may generate duplicate outputs. Attempts have been made to address this problem. Some architectures try to utilize History attention records. See et al. (2017) introduce a coverage mechanism, and Paulus et al. (2017) use history attention weights to normalize new attention. Others are featured in network modules. Suzuki and Nagata (2017) estimate the frequency of target words and record the occurrence. Our model shows that simply attending to history decoder states can reduce redundancy. Then we use the context vector of attention to history decoder states to perform attention to the memory. Doing this enables the decoder to correctly decide what to say at memory addressing time, rather than decoding time, thus increasing answer coverage and information enrichment.

3 Task Definition

Given a question q and a memory M storing related information, our task is to retrieve all the answer words from the memory, generate an answer sentence x, and use the rest information as enrichment.

Answer Coverage is the primary objective of our task. Since many answers contain multiple words, the system needs to cover all the target words.

Information Redundancy is one challenge for this task. It is well noticed that the decoder language model may lose track of its state, thus repeating itself. Also, the decoder needs to reason over the semantic gap between heterogeneous memory slots, figuring out different keys may refer to the same value. These two kinds of redundancy should both be addressed.

Information Enrichment is another challenge. It requires the decoder to interact with the memory effectively and use the right word to enrich the answer.

The tradeoff between redundancy and coverage/enrichment is one of our main considerations. This is because when the decoder generates a word, it either generates a new word or a mentioned word. The more answer words and information enrichment are considered, the more likely the model repeats what it has already generated.

4 Our Model

Our model consists of the question encoder, the heterogeneous memory, and the decoder. The encoder embeds the question into a vector representation. The decoder reads questions, retrieves the memory, and generates answer sentences.

We use a Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) for question encoding and encode the question into an embedding. It takes every word embedding $(q_1, q_2...q_n)$ of question words as inputs, and generates hidden states $s_t = LSTM_{enc}(q_t, s_{t-1})$. These s are later used for decoder's attention. The last hidden state s_n is used as the vector representation of the question, and is later put into the initial hidden state of the decoder.

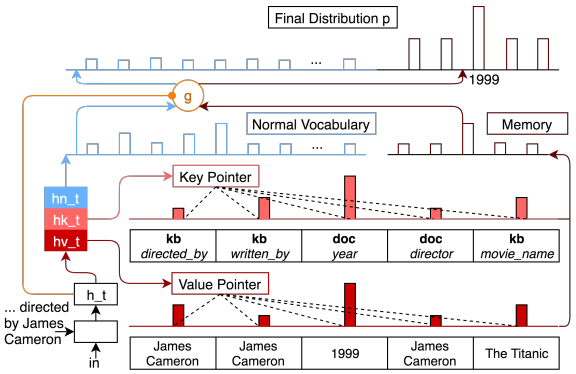

Figure 2: The Decoder with Heterogeneous States

We use a key-value memory M to represent the information heterogeneity. In our experiments, we study information from KB, topic words, and words extracted from documents. The memory is formatted as $((m_0^{\langle K\rangle}, m_0^{\langle V\rangle}), (m_1^{\langle K\rangle}, m_1^{\langle V\rangle})$ ... $(m_n^{\langle K\rangle}, m_n^{\langle V\rangle}))$, where $m_i^{\langle K\rangle}$ and $m_i^{\langle V\rangle}$ are respectively the key embedding and word embedding for the i-th memory slot. The vocabulary for keys V^{key} consists of all predicates in the KB, and all tags we use to classify the value words (e.g: *director, actor, or release_year*). The vocabulary for values V^{val} consists all related words from web documents, subjects and objects from the KB. This memory is later used in two ways: 1. the decoder uses its previous hidden state to perform attention and generate context vectors. 2. the decoder uses the updated hidden states as pointers (Vinyals et al., 2015) to retrieve the memory and copy the memory contents into the decoder's output.

4.1 Decoder with Heterogeneous States

As in the standard encoder-decoder architecture with attention, the word embedding of the decoder's previous time step x_t and context vector c_t is fed as the input of the next time step, and the hidden state h_t is updated then. The initial hidden state is the question embedding concatenated with average memory key and value:

$$h_t = LSTM_{dec}(x_t, c_t, h_{t-1})$$
$$h_0 = [s_n, avg(m^{\langle K\rangle}), avg(m^{\langle V\rangle})]$$

where $[\cdot,\cdot]$ denotes concatenation.

As shown in figure 2, to match the key-value memory representation, we use three linear transformations to convert the decoder's current h_t into $h_t^{\langle N\rangle}$, $h_t^{\langle K\rangle}$, and $h_t^{\langle V\rangle}$:

$$\begin{aligned} h_t^{\langle N\rangle} &= W_n h_t \\ h_t^{\langle K\rangle} &= W_k h_t \\ h_t^{\langle V\rangle} &= W_v h_t \end{aligned}$$

where the Ws are initialized as identity matrix $I = diag(1, 1...1)$. $h_t^{\langle N\rangle}$ will be projected to normal word vocabulary V^{norm} to form a distribution $p_t^{\langle N\rangle}$. $h_t^{\langle K\rangle}$ and $h_t^{\langle V\rangle}$ will be used as pointers to perform attention to memory keys $m^{\langle K\rangle}$ and values $m^{\langle V\rangle}$, respectively, and forms two distributions: $p_t^{\langle MK\rangle}$ and $p_t^{\langle MV\rangle}$. We use the average of the two as distribution over the memory: $p_t^{\langle M\rangle} = (p_t^{\langle MK\rangle} + p_t^{\langle MV\rangle})/2$. By doing this, we bridge the decoder's semantic space with the memory's semantic space, and explicitly maintains heterogeneity.

The decoder then uses a gating mechanism $g = sigmoid(W_g h_t + b_g)$ to decide whether the output x_t comes from the normal vocabulary or the memory. By mixing $p_t^{\langle N\rangle}$ and $p_t^{\langle M\rangle}$ with g, we get the distribution for the next decoder output:

$$\begin{aligned} &P(x_t|q, M, x_0, x_1, ...x_{t-1}) = \\ &\quad g \times P(X_t = w_k|q, M, x_0, x_1...x_{t-1}) + \\ &\quad (1-g) \times P(X_t = m_k|q, M, x_0, x_1...x_{t-1}) \end{aligned} \tag{1}$$

where

$$P(X_t = w_k|q, M, x_0, x_1...x_{t-1}) = p_t^{\langle N\rangle}$$
$$P(X_t = m_k|q, M, x_0, x_1...x_{t-1}) = p_t^{\langle M\rangle}$$

The three hs are then recorded as history states for later decoding time steps to perform the self-attention. We will explain this in the next section.

4.2 Cumulative Attention

As shown in Figure 3, our Cumulative Attention mechanism is exploited similarly to a multi-hop attention (Sukhbaatar et al., 2015). The difference is that the multi-hop attention uses context vector over one single memory at different hops, while our Cumulative Attention utilizes the context vector to query different memories. As shown in the left part of Figure 3, the decoder first performs self-attention to its history $h_t^{\langle N\rangle}$, $h_t^{\langle K\rangle}$, and $h_t^{\langle V\rangle}$, and generates corresponding context vectors c as:

$$\begin{aligned} c_t^{\langle HN\rangle} &= attn(h_{t-1}, hist(h_t^{\langle N\rangle})) \\ c_t^{\langle HK\rangle} &= attn(h_{t-1}, hist(h_t^{\langle K\rangle}) \\ c_t^{\langle HV\rangle} &= attn(h_{t-1}, hist(h_t^{\langle V\rangle})) \end{aligned}$$

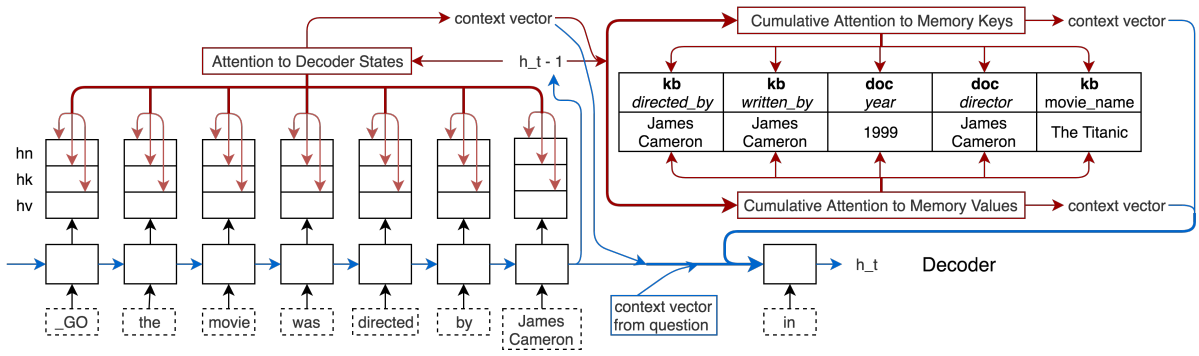

Figure 3: The Cumulative Attention Mechanism

where $c = attn(query, memory)$ denotes the attention function (Bahdanau et al., 2014), and the decoder's history states are defined as:

$$hist(h_t^{\langle N \rangle}) = (h_0^{\langle N \rangle}, h_1^{\langle N \rangle}, ...h_{t-1}^{\langle N \rangle})$$
$$hist(h_t^{\langle K \rangle}) = (h_0^{\langle K \rangle}, h_1^{\langle K \rangle}, ...h_{t-1}^{\langle K \rangle})$$
$$hist(h_t^{\langle V \rangle}) = (h_0^{\langle V \rangle}, h_1^{\langle V \rangle}, ...h_{t-1}^{\langle V \rangle})$$

The overall context vector is obtained through concatenation : $c_t^{\langle H \rangle} = [c_t^{\langle HN \rangle}, c_t^{\langle HK \rangle}, c_t^{\langle HV \rangle}]$, which is then used together with $h^{\langle K \rangle}$ and $h^{\langle V \rangle}$ to perform attention to $m^{\langle K \rangle}$ and $m^{\langle V \rangle}$, respectively:

$$c_t^{\langle MK \rangle} = attn([h_{t-1}^{\langle K \rangle}, c_t^{\langle H \rangle}], m^{\langle K \rangle})$$
$$c_t^{\langle MV \rangle} = attn([h_{t-1}^{\langle V \rangle}, c_t^{\langle H \rangle}], m^{\langle V \rangle})$$

where $m^{\langle K \rangle} = (m_0^{\langle K \rangle}, m_1^{\langle K \rangle}...m_n^{\langle K \rangle})$ and $m^{\langle V \rangle} = (m_0^{\langle V \rangle}, m_1^{\langle V \rangle}...m_n^{\langle V \rangle})$, as shown in the right part of Figure 3.

The decoder also performs attention to the question to get context vector $c_t^{\langle Q \rangle}$, as in the standard seq2seq attention model.

At time step t, all context vectors are concatenated: $c_t = [c_t^{\langle Q \rangle}, c_t^{\langle H \rangle}, c_t^{\langle MK \rangle}, c_t^{\langle MV \rangle}]$ to form the current input to the decoder. The decoder takes the context vector, the previous output, and the previous state to update its state, then generates a distribution for the next token, as shown in Section 4.1. We use the greedy decoding approach and choose the word with the highest probability as the current output.

For optimization, we jointly optimize the negative log-probability of the output sentence and the cross entropy $\mathcal{H}$ for gate g. Since g is the probability about whether the current output comes from the memory or the vocabulary, we can extract the label for g by matching sentence words with the memory. The overall loss function $\mathcal{L}$ can be written as:

$$\mathcal{L} = -\sum_{t=1}^{N} log(P(x_t|q, M, x_0...x_{t-1})) + \mathcal{H}(g, \hat{g})$$

We optimize $\mathcal{L}$ with gradient descent based optimizers.

5 Experiments

Our experiments are designed to answer the following questions: (1) whether our model can properly utilize heterogeneous memories to generate readable answer sentences, (2) whether our model can cover all target answers during generation, (3) whether our model can introduce related knowledge in the output while avoiding repetition.

5.1 Datasets

Our task requires a question, and a memory storing all the answer words and related knowledge as input, and produces a **natural, readable** sentence as the output. Unfortunately, there is no existing dataset that naturally fits to our task. We thus tailor the `WikiMovies`[1] dataset according to our requirements. This `WikiMovies` dataset was originally constructed for answering simple factoid questions, using memory networks with different knowledge representations, i.e., structured KB (**KB entries** in Table 2), raw textual documents (**Doc**), or processed documents obtained through information extraction (**IE**), respectively. The first is in the classic subject-predicate-object format. The second contains sentences from Wikipedia and also sentences automatically generated from predefined templates. The third is in the subject-verb-object format, collected by applying off-the-shell information extractor to all sentences.

The original data format		
Question	Who directed the film Blade Runner?	
KB entries	Blade Runner *directed_by* Ridley Scott Blade Runner *release_year* 1982 Blade Runner *written_by* Philip K. Dick	
IE	*year* 1982 *starred* Harrison Ford	
Doc	Blade Runner is a **1982** American film directed by **Ridley Scott** and starring **Harrison Ford**. It is directed by **Ridley Scott** and written by **Philip K. Dick**. It comes out in **1982**.	
Answer	Ridley Scott	
Our modified data format		
Question	Who directed the film Blade Runner?	
Memory	`Key`	`Value`
	directed_by	Ridley Scott
	release_year	1982
	written_by	Philip K. Dick
	movie	Blade Runner
	year	1982
	starred	Harrison Ford
Answer	Blade Runner is a **1982** American film directed by **Ridley Scott** and starring **Harrison Ford**.	

Table 2: The data format of `WikiMovies` used in our experiment.

As shown in Table 2, we treat each question in `WikiMovies` with its original answer (usually one or more words) as a QA pair, and one of the question's supportive sentences (either from Wikipedia or templates) as its gold-standard answer sentence. For each question, the memory will contain all knowledge triples about the question's topic movie from the **KB entries**, and also include entities and keywords extracted from its **IE** portion. For each entry in **KB entries**, we use the predicate as the key and the object as value to construct a new entry in our memory. For those from **IE**, we keep the extracted tags as the key and entities or other expressions as the value. Given a question, if an entity/expression in the memory is not the answer, it will be treated as information enrichment. According to whether the supportive sentences are generated by predefined templates or not, we split the dataset into `WikiMovies-Synthetic` and `WikiMovies-Wikipedia`.

The resulting `WikiMovies-Synthetic` includes 115 question patterns and 194 answer patterns, covering 10 topics, e.g., director, genre, actor, release year, etc. We follow its original data split, i.e., 47,226 QA-pairs for training, 8,895 for validation and 8,910 for testing.

In `WikiMovies-Wikipedia`, answer sentences are extracted from Wikipedia, admittedly noisy in nature. Note that there are more than 10K Wikipedia sentences that cannot be paired with any questions. We thus left their questions as blank and treat it as a pure generation task from a given memory, which can be viewed as a form of data augmentation to improve sentence variety. We split `WikiMovies-Wikipedia` the dataset randomly into 47,309 cases for training, 4,093 for testing and 3,954 for validation. We treat normal words occurring less than 10 times as `UNK`, and, eventually, have 24,850 normal words and 37,898 entity words. We cut the maximum length of answer sentences to 20, and the maximum memory size to 10, which covers most cases in both synthetic and Wikipedia datasets.

5.2 Metrics

We evaluate our answer sentences in terms of answer **coverage**, information **enrichment**, and **redundancy**. For cases with only one answer word, we design $\mathbf{C}_{single}$ to indicate the percentage of cases being correctly answered. Cases with more than one answer word are evaluated by $\mathbf{C}_{part}$, i.e., the percentage of answer words covered correctly, and $\mathbf{C}_{perfect}$ is the percentage of cases whose answers are perfectly covered. Here, the definition of **coverage** is similar in spirit with the conventional **recall** as both measure how many gold words are included in the output. Specifically, $\mathbf{C}_{part}$ is essentially the same as **recall** with respect to its own cases. Note that perfect coverage is the most difficult, while single coverage is the easiest one. For **Enrich**, we measure the number of none-answer memory items included in the output. Regarding **Redundancy**, we calculate the times of repetition for memory values in the answer sentence. We also compute BLEU scores (Papineni et al., 2002) on the `WikiMovies-Wikipedia`, as an indicator of naturalness, to some extent.

5.3 Comparison Models

We compare our full model (HS-CumuAttn) with state-of-the-art answer generation models and constrained sentence generation models. Our first baseline is GenQA (Yin et al., 2015), a standard encoder-decoder model with attention mechanism. We equip it with our Key-Value style heterogeneous memory. We also compare with its two variants. HS-GenQA: we split its decoder state into heterogeneous representations. The other one,

Model	Redundancy	C_{single}	C_{part}	$C_{perfect}$	Enrich
GenQA	0.1109	91.25%	69.19%	38.92%	0.1535
HS-GenQA	0.1218	94.10%	76.47%	50.10%	0.1951
GenQA-AttnHist	0.1280	95.99%	73.44%	44.94%	0.1903
CheckList	0.1176	93.80%	76.32%	50.04%	0.1963
HS-AttnHist	0.1295	97.17%	**77.90%**	**51.55%**	**0.1996**
HS-CumuAttn	**0.0983**	**98.15%**	**77.28%**	50.79%	0.1665

Table 3: Results on the `WikiMovies-Synthetic` dataset

Model	BLEU	Redundancy	C_{part}	$C_{perfect}$	Enrich
GenQA	42.50	0.2603	62.80%	18.24%	0.5903
CheckList	43.69	0.2744	63.42%	18.23%	0.6094
HS-CumuAttn	**44.97**	**0.2385**	**64.06%**	**19.09%**	**0.6218**

Table 4: Results on the `WikiMovies-Wikipedia` dataset

GenQA-AttnHist, is enhanced with a history attention during decoding.

CheckList (Kiddon et al., 2016) is the state-of-the-art model for generating long sentences with large agenda to mention. It keeps words that have been mentioned and words to mention using two separate records, and updates the records dynamically during decoding. To adapt to our task, we modify CheckList with a question encoder and a KV memory.

We also compare with one variant of our own model, HS-AttnHist, which does not benefit from the Cumulative Attention.

5.4 Implementation

Our model is implemented with the Tensorflow framework[2], version 1.2. We use the Adam optimizer (Kingma and Ba, 2014) with its default setting. The embedding dimension is set to be 256, as is the LSTM state size. We set the batch size to 128 and train the model up to 80 epochs.

As mentioned, there is a tradeoff between Coverage/Enrichment and Redundancy. To set up a more fair comparison for different models, we ask the control group to reach a comparable level of **Redundancy**, i.e., approximately 0.11-0.12 on `WikiMovies-Synthetic` and 0.26-0.27 on `WikiMovies-Wikipedia`. Keeping the **Redundancy** in around the same bucket, we compare their Coverage and Enrichment.

5.5 Results and Discussion

Let us first look at the performance on the `Synthetic` set in Table 3. GenQA is originally proposed to read only one single fact during decoding, so it is not surprising that it has the lowest answer coverage (38.92% $C_{perfect}$) and information enrichment (0.1535). After splitting the decoder state, HS-GenQA obtains significant improvement in both coverage (50.10% $C_{perfect}$) and enrichment (0.1952). When considering history for attention, GenQA-AttnHist achieves even better coverage (+3.% in C_{part} and +5% in $C_{perfect}$). By combining these two mechanisms, HS-AttnHist achieves the best perfect coverage, 51.55%. Although CheckList is not originally designed for our task, it still gives a strong performance (50.04% $C_{perfect}$ and 0.1963 enrichment), at a slightly lower redundancy (0.1176). Finally, our full model, HS-CumuAttn, achieves the best single coverage 98.15%, and comparable partial/perfect coverage, with the lowest redundancy (0.0983). Due to the lower level of redundancy, HS-CumuAttn does not include as much enrichment as other strong models, but still outperforms GenQA.

Question	the movie Torn Curtain starred who?	
Memory	0 *actor*	Julie Andrews
	1 *starred_actors*	Julie Andrews
	2 *starred_actors*	Paul Newman
	3 *movie*	Torn Curtain
	4 *year*	1966
	5 *director*	Alfred Hitchcock
	6 *actor*	Paul Newman
GenQA	It stared **Julie Andrews**$_0$ and **Julie Andrews**$_0$ and and.	
CheckList	**Torn Curtain**$_3$ is a **1966**$_4$ American film starring **Paul Newman**$_2$ and **Julie Andrews**$_0$ and **Julie Andrews**$_1$.	
HS-CumuAttn	**Torn Curtain**$_3$ is a **1966**$_4$ American political thriller film directed by **Alfred Hitchcock**$_5$, starring **Paul Newman**$_2$ and **Julie Andrews**$_0$.	

Table 5: Example sentences generated by different models, where an underlined bold phrase is the value of a memory slot selected from the memory by its corresponding generation model, and its subscript number is the index of this slot in the memory.

Question 1	who starred in Cemetery Man ?			
Memory	0 *ans_actor* 2 *starred_actors* 4 *movie*	Rupert Everett Rupert Everett Cemetery Man	1 *ans_actor* 3 *starred_actors*	Anna Falchi Anna Falchi
Answer	The film stars Rupert Everett$_0$, _UNK , and Anna Falchi$_1$.			
Question 2	who was Dying Breed written by ?			
Memory	0 *ans_release_year* 2 *ans_actor* 4 *written_by*	2008 Nathan Phillips Jody Dwyer	1 *ans_writer* 3 *ans_writer* 5 *movie*	Jody Dwyer Leigh Whannell Dying Breed
Answer	Dying Breed$_5$ is a 2008$_0$ Australian horror film that was directed by Jody Dwyer$_1$ and stars Leigh Whannell$_3$ and Nathan Phillips$_2$.			
Question 3	who is the director that directed Livid ?			
Memory	0 *ans_director* 2 *ans_release_year* 4 *movie* 6 *ans_language*	Julien Maury 2011 Livid French	1 *directed_by* 3 *ans_director* 5 *directed_by*	Alexandre Bustillo Alexandre Bustillo Julien Maury
Answer	Livid$_4$ ( ) is a 2011$_2$ French$_6$ supernatural horror film directed and written by Julien Maury$_0$ and Alexandre Bustillo$_3$.			
Question 4	Drag Me to Hell , when was it released?			
Memory	0 *ans_director* 2 *release_year* 4 *ans_release_year*	Sam Raimi 2009 2009	1 *ans_wiki* 3 *ans_genre* 5 *movie*	Scream Horror Drag Me to Hell
Answer	Scream$_1$ is a 2009$_4$ film			
Question 5	the movie Lights in the Dusk starred who ?			
Memory	0 *starred_actors* 2 *starred_actors* 4 *starred_actors* 6 *ans_actor* 8 *ans_actor*	Janne Hyytiäinen Maria Järvenhelmi Ilkka Koivula Ilkka Koivula Maria Järvenhelmi	1 *ans_language* 3 *ans_actor* 5 *movie* 7 *ans_release_year*	Finnish Janne Hyytiäinen Lights in the Dusk 2006
Answer	Lights in the Dusk$_5$ (,) is a 2006$_7$ Finnish$_1$ drama film starring Janne Hyytiäinen$_3$, Ilkka Koivula$_6$ and Maria Järvenhelmi$_8$.			

Table 6: Example answers generated by our model. In an answer sentence, an underlined phrase is the value of a memory slot selected from the memory by our model, and the subscript number is the index of this slot in the memory.

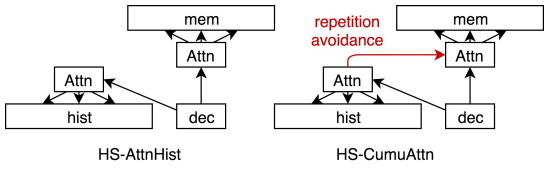

Figure 4: Two methods of using context of history to address the memory

We further break down the contributions from different mechanisms. Compared to vanilla GenQA, HS-GenQA splits the decoder states, thus improves the decoder's memory addressing process by performing attention separately, leading to improvements in both coverage and enrichment. Improvements of GenQA-AttnHist are of a different rationale. Looking at the history enables the decoder to avoid what are already said. Compared with HS-GenQA, GenQA-AttnHist improves Enrichment by avoiding repetition when introducing related information, while, HS-GenQA improves Enrichment by better memory addressing to select proper slots. Combining the two mechanisms together gives HS-AttnHist the best performance in Enrichment. However, HS-AttnHist still suffers from the repetition issue, to certain extent. Because when choosing memory content, there is no explicit mechanism to help the decoder to avoid repetitions according to the history (left of Figure 4). Therefore, a generated word may still be chosen again at the memory addressing step, leaving all the burden of avoiding repetition to the generation step. Our Cumulative Attention mechanism is designed to utilize the context vector of the history to address the memory, thus helps avoid choosing those already mentioned slots at memory addressing time (right of Figure 4), leading to almost the best coverage with the lowest redundancy.

Now we compare the three main models, GenQA, CheckList and our HS-CumuAttn on `WikiMovies-Wikipedia` (Table 4), which is admittedly more challenging than `WikiMovies-Synthetic`. We skip the C_{single} metrics here since most questions in `WikiMovies-Wikipedia` contain more than one answer word. It is not surprising that

CheckList, with a lower redundancy, still outperforms GenQA in almost all metrics, except $C_{perfect}$, since CheckList is originally designed to perform well with larger agenda/memory and longer sentences. On the other hand, our model, HS-CumuAttn, achieves the best performance in all metrics. Although the BLEU score is not designed to fully reflect the naturalness, it still indicates that our model can output sentences that share more n-gram snippets with reference sentences and are more similar to those composed by humans.

Case Study and Error Analysis Table 5 provides the system outputs from different models for an example question. We can see that GenQA may lose track of the decoder history, and repeat itself (*and and*), because there is no explicit mechanism to help avoid repetition. Also, it lacks informativeness and may not utilize other information stored in the memory. CheckList keeps records of what have been said and what are left to mention, thus reaches a good answer coverage. But its decoder is unable to explicitly address separate components within one memory slot, so it may not realize that the two *Julie Andrews*s are essentially the same person. HS-CumuAttn is able to find all the answer words correctly and also include the *director* into the sentence. After generating *Paul Newman*, the Cumulative Attention mechanism enables the model to realize that *Paul Newman* in slot 2 has been said, and *Paul Newman* in slot 6 is the same as slot 2, so it should not choose the 6th slot again. Rather it should move to *Julie Andrews*. Although the decoder may figure out the two *Paul Newman* are the same during decoding, the Cumulative Attention can explicitly help make the clarification during memory addressing. Intuitively, the attention across memory and history induces a stronger signal for the decoder to gather the right information.

Table 6 lists more typical imperfect output from our model. In question 1, there is considerable redundancy in the memory, but our decoder is still able to avoid repeatedly choosing the same entities from difference sources, though it produces a "_UNK" showing a slight incoherence. We think it comes from the gate g as it fails to decide that the current word should come from the memory. In question 2, the model correctly chooses the memory slot, but outputs the word "*directed*" while the correct word should be "*written*". This also shows an word choice inconsistency between the language model and the memory retrieval. Question 3 makes the same mistake, where it indeed chooses the right answer, but adds an incorrect word "*written*". We also observe a pair of additional parentheses, which are often used to accomodate *movie tags*, but we do not see any tags in this memory, so it has to be left blank. Question 4 shows an incorrect memory retrieval, where the decoder should have chosen slot 5 as the movie name. Question 5 is generally good enough, except the same parenthesis error as in question 4.

It is also interesting to see additional descriptions like "*Australian*", "*supernatural*" and "*drama*" in question 2, 3, and 5, introduced by the language model, rather than the memory. Although our model prevents repetition and obtains general naturalness, it cannot guarantee that the decoder can precisely use the right language to describe the memory information. We see the general readability of these sentences, yet they are still not as good as human composed ones. It is fairly subtle for the decoder to collaborate with the memory in different levels of semantics. The semantic coherency and word choice consistency is still a challenge in natural language generation.

6 Conclusion and Future Work

In this paper, we propose a novel mechanism within an encoder-decoder framework to enable the decoder to actively interact with a memory by taking its heterogeneity into account. Our solution can read multiple memory slots from different sources, attend across the generated history and the memory to explicitly avoid repetition, and enrich the answer sentences with related information from the memory. In the future, we plan to extend our work through 1) investigating more sophisticated structures in the memory such as knowledge graph, 2) solving more complex questions, such as those involving deep reasoning over multiple facts.

Abstract

Most recent approaches use the sequence-to-sequence model for paraphrase generation. The existing sequence-to-sequence model tends to memorize the words and the patterns in the training dataset instead of learning the meaning of the words. Therefore, the generated sentences are often grammatically correct but semantically improper. In this work, we introduce a novel model based on the encoder-decoder framework, called Word Embedding Attention Network (WEAN). Our proposed model generates the words by querying distributed word representations (i.e. neural word embeddings), hoping to capturing the meaning of the according words. Following previous work, we evaluate our model on two paraphrase-oriented tasks, namely text simplification and short text abstractive summarization. Experimental results show that our model outperforms the sequence-to-sequence baseline by the BLEU score of 6.3 and 5.5 on two English text simplification datasets, and the ROUGE-2 F1 score of 5.7 on a Chinese summarization dataset. Moreover, our model achieves state-of-the-art performances on these three benchmark datasets.[1]

1 Introduction

Paraphrase is a restatement of the meaning of a text using other words. Many natural language generation tasks are paraphrase-orientated, such as text simplification and short text summarization. Text simplification is to make the text easier to read and understand, especially for poor readers, while short text summarization is to generate a brief sentence to describe the short texts (e.g. posts on the social media). Most recent approaches use sequence-to-sequence model for paraphrase generation (Prakash et al., 2016; Cao et al., 2017). It compresses the source text information into dense vectors with the neural encoder, and the neural decoder generates the target text using the compressed vectors.

Although neural network models achieve success in paraphrase generation, there are still two major problems. One of the problem is that the existing sequence-to-sequence model tends to memorize the words and the patterns in the training dataset instead of the meaning of the words. The main reason is that the word generator (i.e. the output layer of the decoder) does not model the semantic information. The word generator, which consists of a linear transformation and a softmax operation, converts the Recurrent Neural Network (RNN) output from a small dimension (e.g. 500) to a much larger dimension (e.g. 50,000 words in the vocabulary), where each dimension represents the score of each word. The latent assumption of the word generator is that each word is independent and the score is irrelevant to each other. Therefore, the scores of a word and its synonyms may be of great difference, which means the word generator learns the word itself rather than the relationship between words.

The other problem is that the word generator has a huge number of parameters. Suppose we have a sequence-to-sequence model with a hidden size of 500 and a vocabulary size of 50,000. The word generator has up to 25 million parameters, which is even larger than other parts of the encoder-decoder model in total. The huge size of parameters will result in slow convergence, because there are a lot of parameters to be learned. Moreover, under the distributed framework, the more parameters a model has, the more bandwidth and memory it consumes.

To tackle both of the problems, we propose a novel model called Word Embedding Attention Network (WEAN). The word generator of WEAN

[1]The code is available at https://github.com/lancopku/WEAN

Proceedings of NAACL-HLT 2018, pages 196–206
New Orleans, Louisiana, June 1 - 6, 2018.

is attention based, instead of the simple linear softmax operation. In our attention based word generator, the RNN output is a query, the candidate words are the values, and the corresponding word representations are the keys. In order to predict the word, the attention mechanism is used to select the value matching the query most, by means of querying the keys. In this way, our model generates the words according to the distributed word representations (i.e. neural word embeddings) in a retrieval style rather than the traditional generative style. Our model is able to capture the semantic meaning of a word by referring to its embedding. Besides, the attention mechanism has a much smaller number of parameters compared with the linear transformation directly from the RNN output space to the vocabulary space. The reduction of the parameters can increase the convergence rate and speed up the training process. Moreover, the word embedding is updated from three sources: the input of the encoder, the input of the decoder, and the query of the output layer.

Following previous work (Cao et al., 2017), we evaluate our model on two paraphrase-oriented tasks, namely text simplification and short text abstractive summarization. Experimental results show that our model outperforms the sequence-to-sequence baseline by the BLEU score of 6.3 and 5.5 on two English text simplification datasets, and the ROUGE-2 F1 score of 5.7 on a Chinese summarization dataset. Moreover, our model achieves state-of-the-art performances on all of the benchmark datasets.

2 Proposed Model

We propose a novel model based on the encoder-decoder framework, which generates the words by querying distributed word representations with the attention mechanism. In this section, we first present the overview of the model architecture. Then, we explain the details of the word generation, especially the way to query word embeddings.

2.1 Overview

Word Embedding Attention Network is based on the encoder-decoder framework, which consists of two components: a source text encoder, and a target text decoder. Figure 1 is an illustration of our model. Given the source texts, the encoder compresses the source texts into dense representation vectors, and the decoder generates the paraphrased texts. To predict a word, the decoder uses the hidden output to query the word embeddings. The word embeddings assess all the candidate words, and return the word whose embedding matches the query most. The selected word is emitted as the predicted token, and its embedding is then used as the input of the LSTM at the next time step. After the back propagation, the word embedding is updated from three sources: the input of the encoder, the input of the decoder, and the query of the output layer. We show the details of our WEAN in the following subsection.

2.2 Encoder and Decoder

The goal of the source text encoder is to provide a series of dense representation of complex source texts for the decoder. In our model, the source text encoder is a Long Short-term Memory Network (LSTM), which produces the dense representation $\{h_1, h_2, ..., h_N\}$ from the source text $\{x_1, x_2, ..., x_N\}$:

The goal of the target text decoder is to generate a series of paraphrased words from the dense representation of source texts. Fisrt, the LSTM of the decoder compute the dense representation of generated words s_t. Then, the dense representations are fed into an attention layer (Bahdanau et al., 2014) to generate the context vector c_t, which captures context information of source texts. Attention vector c_t is calculated by the weighted sum of encoder hidden states:

$$c_t = \sum_{i=1}^{N} \alpha_{ti} h_i \tag{1}$$

$$\alpha_{ti} = \frac{e^{g(s_t, h_i)}}{\sum_{j=1}^{N} e^{g(s_t, h_j)}} \tag{2}$$

where $g(s_t, h_i)$ is an attentive score between the decoder hidden state s_t and the encoder hidden state h_i.

In this way, c_t and s_t respectively represent the context information of source texts and the target texts at the t^{th} time step.

2.3 Word Generation by Querying Word Embedding

For the current sequence-to-sequence model, the word generator computes the distribution of output words y_t in a generative style:

$$p(y_t) = softmax(W s_t) \tag{3}$$

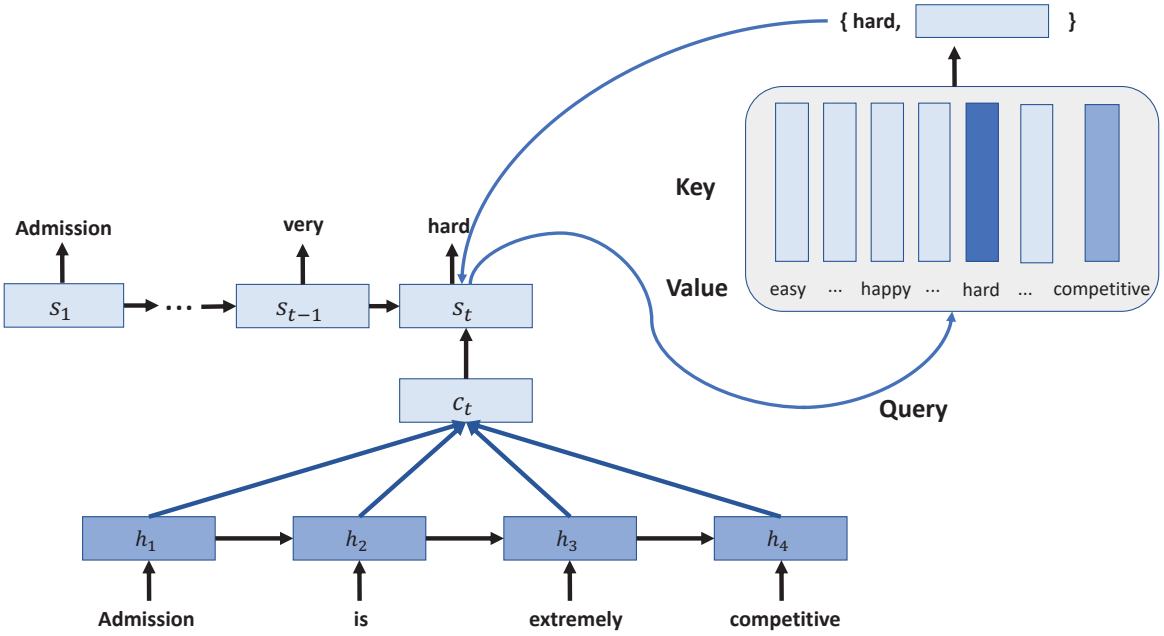

Figure 1: An overview of Word Embedding Attention Network.

where $W \in R^{k \times V}$ is a trainable parameter matrix, k is hidden size, and V is the number of words in the vocabulary. When the vocabulary is large, the number of parameters will be huge.

Our model generates the words in a retrieval style rather than the traditional generative style, by querying the word embeddings. We denote the combination of the source context vector c_t and the target context vector s_t as the query q_t:

$$q_t = \tanh(W_c[s_t; c_t]) \tag{4}$$

The candidate words w_i and their corresponding embeddings e_i are paired as the key-value pairs $\{w_i, e_i\}(i = 1, 2, ..., n)$, where n is the number of candidate words. We give the details of how to determine the set of candidate words in Section 2.4. Our model uses q_t to query the key-value pairs $\{w_i, e_i\}(i = 1, 2, ..., n)$ by evaluating the relevance between the query q_t and each word vector e_i with a score function $f(q_t, e_i)$. The query process can be regarded as the attentive selection of the word embeddings. We borrow the attention energy functions (Luong et al., 2015) as the relevance score function $f(q_t, e_i)$:

$$f(q_t, e_i) = \begin{cases} q_t^T e_i & \text{dot} \\ q_t^T W_a e_i & \text{general} \\ v^T \tanh(W_q q_t + W_e e_i) & \text{concat} \end{cases} \tag{5}$$

where W_q and W_e are two trainable parameter matrices, and v^T is a trainable parameter vector. In implementation, we select the general attention function as the relevance score function, based on the performance on the validation sets. The key-value pair with the highest score $\{w_t, e_t\}$ is selected. At the test stage, the decoder generates the key w_t as the t^{th} predicted word, and inputs the value e_t to the LSTM unit at the $t + 1^{th}$ time step. At the training stage, the scores are normalized as the word probability distribution:

$$p(y_t) = softmax(f(q_t, e_i)) \tag{6}$$

2.4 Selection of Candidate Key-value Pairs

As described in Section 2.3, the model generates the words in a retrieval style, which selects a word according to its embedding from a set of candidate key-value pairs. We now give the details of how to obtain the set of candidate key-value pairs. We extract the vocabulary from the source text in the training set, and select the n most frequent words as the candidate words. We reuse the embeddings of the decoder inputs as the values of the candidate words, which means that the decoder input and the predicted output share the same vocabulary and word embeddings. Besides, we do not use any pretrained word embeddings in our model, so that all of the parameters are learned from scratch.

2.5 Training

Although our generator is a retrieval style, WEAN is as differentiable as the sequence-to-sequence model. The objective of training is to minimize the

cross entropy between the predicted word probability distribution and the golden one-hot distribution:

$$L = -\sum_i \hat{y}_i \log p(y_i) \quad (7)$$

We use Adam optimization method to train the model, with the default hyper-parameters: the learning rate $\alpha = 0.001$, and $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$.

3 Experiments

Following the previous work (Cao et al., 2017), we test our model on the following two paraphrase orientated tasks: text simplification and short text abstractive summarization.

3.1 Text Simplification

3.1.1 Datasets

The datasets are both from the alignments between English Wikipedia website[2] and Simple English Wikipedia website.[3] The Simple English Wikipedia is built for "the children and adults who are learning the English language", and the articles are composed with "easy words and short sentences". Therefore, Simple English Wikipedia is a natural public simplified text corpus.

- **Parallel Wikipedia Simplification Corpus (PWKP).** PWKP (Zhu et al., 2010) is a widely used benchmark for evaluating text simplification systems. It consists of aligned complex text from English WikiPedia (as of Aug. 22nd, 2009) and simple text from Simple Wikipedia (as of Aug. 17th, 2009). The dataset contains 108,016 sentence pairs, with 25.01 words on average per complex sentence and 20.87 words per simple sentence. Following the previous work (Zhang and Lapata, 2017), we remove the duplicate sentence pairs, and split the corpus with 89,042 pairs for training, 205 pairs for validation and 100 pairs for test.

- **English Wikipedia and Simple English Wikipedia (EW-SEW).** EW-SEW is a publicly available dataset provided by Hwang et al. (2015). To build the corpus, they first align the complex-simple sentence pairs, score the semantic similarity between the complex sentence and the simple sentence, and classify each sentence pair as a good, good partial, partial, or bad match. Following the previous work (Nisioi et al., 2017), we discard the unclassified matches, and use the good matches and partial matches with a scaled threshold greater than 0.45. The corpus contains about 150K good matches and 130K good partial matches. We use this corpus as the training set, and the dataset provided by Xu et al. (Xu et al., 2016) as the validation set and the test set. The validation set consists of 2,000 sentence pairs, and the test set contains 359 sentence pairs. Besides, each complex sentence is paired with 8 reference simplified sentences provided by Amazon Mechanical Turk workers.

3.1.2 Evaluation Metrics

Following the previous work (Nisioi et al., 2017; Hu et al., 2015), we evaluate our model with different metrics on two tasks.

- **Automatic evaluation.** We use the BLEU score (Papineni et al., 2002) as the automatic evaluation metric. BLEU is a widely used metric for machine translation and text simplification, which measures the agreement between the model outputs and the gold references. The references can be either single or multiple. In our experiments, the references are single on PWKP, and multiple on EW-SEW.

- **Human evaluation.** Human evaluation is essential to evaluate the quality of the model outputs. Following Nisioi et al. (2017) and Zhang et al. (2017), we ask the human raters to rate the simplified text in three dimensions: Fluency, Adequacy and Simplicity. Fluency assesses whether the outputs are grammatically right and well formed. Adequacy represents the meaning preservation of the simplified text. Both the scores of fluency and adequacy range from 1 to 5 (1 is very bad and 5 is very good). Simplicity shows how simpler the model outputs are than the source text, which ranges from 1 to 5.

3.1.3 Settings

Our proposed model is based on the encoder-decoder framework. The encoder is implemented on LSTM, and the decoder is based on LSTM with Luong style attention (Luong et al., 2015). We

WEAN (our proposal)	**94.45**

Table 2: Automatic evaluation of our model and other related systems on EW-SEW datasets. The results are reported on the test sets.

tune our hyper-parameter on the development set. The model has two LSTM layers. The hidden size of LSTM is 256, and the embedding size is 256. We use Adam optimizer (Kingma and Ba, 2014) to learn the parameters, and the batch size is set to be 64. We set the dropout rate (Srivastava et al., 2014) to be 0.4. All of the gradients are clipped when the norm exceeds 5.

3.1.4 Baselines

We compare our model with several neural text simplification systems.

- **Seq2seq** is our implementation of the sequence-to-sequence model with attention mechanism, which is the most popular neural model for text generation.
- **NTS** and **NTS-w2v** (Nisioi et al., 2017) are two sequence-to-sequence model with extra mechanism like prediction ranking, and NTS-w2v uses a pretrain word2vec.
- **DRESS** and **DRESS-LS** (Zhang and Lapata, 2017) are two deep reinforcement learning sentence simplification models.
- **EncDecA** is a model based on the encoder-decoder with attention, implemented by Zhang and Lapata (2017).
- **PBMT-R** (Wubben et al., 2012) is a phrase based machine translation model which reranks the outputs.
- **Hybrid** (Narayan and Gardent, 2014) is a hybrid approach which combines deep semantics and mono-lingual machine translation.
- **SBMT-SARI** (Xu et al., 2016) is a syntax-based machine translation model which is trained on PPDB dataset (Ganitkevitch et al., 2013) and tuned with SARI.

PWKP	Fluency	Adequacy	Simplicity	All

Table 3: Human evaluation of our model and other related systems on PWKP and EW-SEW datasets. The results are reported on the test sets.

3.1.5 Results

We compare WEAN with state-of-the-art models for text simplification. Table 1 and Table 2 summarize the results of the automatic evaluation. On PWKP dataset, we compare WEAN with PBMT, Hybrid, EncDecA, DRESS and DRESS-LS. WEAN achieves a BLEU score of 54.54, outperforming all of the previous systems. On EW-SEW dataset, we compare WEAN with PBMT-R, Hybrid, SBMT-SARI, and the neural models described above. We do not find any public release code of PBMT-R and SBMT-SARI. Fortunately, Xu et al. (2016) provides the predictions of PBMT-R and SBMT-SARI on EW-SEW test set, so that we can compare our model with these systems.

LCSTS	R-1	R-2	R-L
RNN-W(Hu et al., 2015)	17.7	8.5	15.8
RNN(Hu et al., 2015)	21.5	8.9	18.6
RNN-cont-W(Hu et al., 2015)	26.8	16.1	24.1
RNN-cont(Hu et al., 2015)	29.9	17.4	27.2
SRB(Ma et al., 2017)	33.3	20.0	30.1
CopyNet-W(Gu et al., 2016)	35.0	22.3	32.0
CopyNet(Gu et al., 2016)	34.4	21.6	31.3
RNN-dist(Chen et al., 2016)	35.2	22.6	32.5
DRGD(Li et al., 2017)	37.0	24.2	34.2
Seq2seq	32.1	19.9	29.2
WEAN	**37.8**	**25.6**	**35.2**

Table 4: ROUGE F1 score on the LCSTS test set. R-1, R-2, and R-L denote ROUGE-1, ROUGE-2, and ROUGE-L, respectively. The models with a suffix of 'W' in the table are word-based, while the rest of models are character-based.

It shows that the neural models have better performance in BLEU, and WEAN achieves the best BLEU score with 94.45.

We perform the human evaluation of WEAN and other related systems, and the results are shown in Table 3. DRESS-LS is based on the reinforcement learning, and it encourages the fluency, simplicity and relevance of the outputs. Therefore, it achieves a high score in our human evaluation. WEAN gains a even better score than DRESS-LS. Besides, WEAN generates more adequate and simpler outputs than the reference on PWKP. The predictions of SBMT-SARI are the most adequate among the compared systems on EW-SEW. In general, WEAN outperforms all of the other systems, considering the balance of fluency, adequate and simplicity. We conduct significance tests based on t-test. The significance tests suggest that WEAN has a very significant improvement over baseline, with $p \leq 0.001$ over DRESS-LS in all of the dimension on PWKP, $p \leq 0.05$ over DRESS-LS in the dimension of fluency, $p \leq 0.005$ over NTS-w2v in the dimension of simplicity and $p \leq 0.005$ over DRESS-LS in the dimension of all.

3.2 Large Scale Text Summarization

3.2.1 Dataset

Large Scale Chinese Social Media Short Text Summarization Dataset (LCSTS): LCSTS is constructed by Hu et al. (2015). The dataset consists of more than 2,400,000 text-summary pairs, constructed from a famous Chinese social media website called Sina Weibo.[4] It is split into three parts, with 2,400,591 pairs in PART I, 10,666 pairs in PART II and 1,106 pairs in PART III. All the text-summary pairs in PART II and PART III are manually annotated with relevant scores ranged from 1 to 5. We only reserve pairs with scores no less than 3, leaving 8,685 pairs in PART II and 725 pairs in PART III. Following the previous work (Hu et al., 2015), we use PART I as training set, PART II as validation set, and PART III as test set.

3.2.2 Evaluation Metrics

Our evaluation metric is ROUGE score (Lin and Hovy, 2003), which is popular for summarization evaluation. The metrics compare an automatically produced summary against the reference summaries, by computing overlapping lexical units, including unigram, bigram, trigram, and longest common subsequence (LCS). Following previous work (Rush et al., 2015; Hu et al., 2015), we use ROUGE-1 (unigram), ROUGE-2 (bi-gram) and ROUGE-L (LCS) as the evaluation metrics in the reported experimental results.

3.2.3 Settings

The vocabularies are extracted from the training sets, and the source contents and the summaries share the same vocabularies. We tune the hyper-parameters based on the ROUGE scores on the validation sets. In order to alleviate the risk of word segmentation mistakes, we split the Chinese sentences into characters. We prune the vocabulary size to 4,000, which covers most of the common characters. We set the word embedding size and the hidden size to 512, the number of LSTM layers of the encoder is 2, and the number of LSTM layers of the decoder is 1. The batch size is 64, and we do not use dropout (Srivastava et al., 2014) on this dataset. Following the previous work (Li et al., 2017), we implement a beam search optimization, and set the beam size to 5.

3.2.4 Baselines

We compare our model with the state-of-the-art baselines.

- **RNN** and **RNN-cont** are two sequence-to-sequence baseline with GRU encoder and decoder, provided by Hu et al. (2015).

[4] http://weibo.com

#Param	PWKP	EWSEW	LCSTS
Seq2seq	12.80M	12.80M	2.05M
WEAN	0.13M	0.13M	0.52M

Table 5: The number of the parameters in the output layer. The numbers of rest parameters between Seq2seq and WEAN are the same.

- **RNN-dist** (Chen et al., 2016) is a distraction-based neural model, which the attention mechanism focuses on the different parts of the source content.

- **CopyNet** (Gu et al., 2016) incorporates a copy mechanism to allow part of the generated summary is copied from the source content.

- **SRB** (Ma et al., 2017) is a sequence-to-sequence based neural model with improving the semantic relevance between the input text and the output summary.

- **DRGD** (Li et al., 2017) is a deep recurrent generative decoder model, combining the decoder with a variational autoencoder.

- **Seq2seq** is our implementation of the sequence-to-sequence model with the attention mechanism.

3.2.5 Results

We report the ROUGE F1 score of our model and the baseline models on the test sets. Table 4 summarizes the comparison between our model and the baselines. Our model achieves the score of 37.8 ROUGE-1, 25.6 ROUGE-2, and 35.2 ROUGE-L, outperforming all of the previous models. First, we compare our model with the sequence-to-sequence model. It shows that our model significant outperforms the sequence-to-sequence baseline with a large margin of 5.7 ROUGE-1, 5.7 ROUGE-2, and 6.0 ROUGE-L. Then, we compare our model with other related models. The state-of-the-art model is DRGD (Li et al., 2017), which obtains the score of 37.0 ROUGE-1, 24.2 ROUGE-2, and 34.2 ROUGE-L. Our model has a relative gain of 0.8 ROUGE-1, 1.4 ROUGE-2 and 1.0 ROUGE-L over the state-of-the-art models.

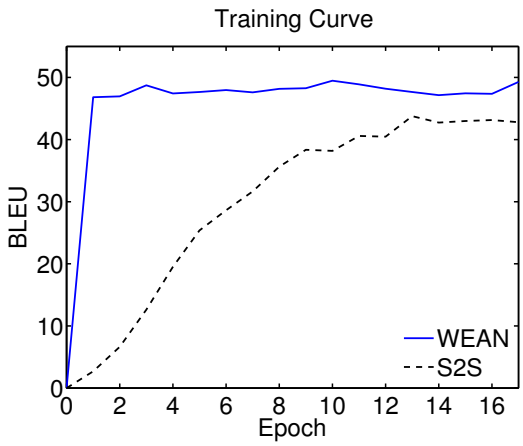

Figure 2: The training curve of WEAN and Seq2seq on the PWKP validation set.

4 Analysis and Discussion

4.1 Reducing Parameters

Our WEAN reduces a large number of the parameters in the output layer. To analyze the parameter reduction, we compare our WEAN model with the sequence-to-sequence model. Table 5 lists the number of the parameters in the output layers of two models. Both PWKP and EWSEWhave the vocabulary size of 50000 words and the hidden size of 256, resulting $50000 \times 256 = 12,800,000$ parameters. LCSTS has a vocabulary size of 4000 and the hidden size of 512, so the seq2seq has $4000 \times 512 = 2,048,000$ parameters in the output layers. WEAN only has two parameter matrices and one parameter vector at most in Equation 5, without regard to the vocabulary size. It has $256 \times 256 \times 2 + 256 = 131,328$ parameters on PWKP and EWSEW, and $512 \times 512 \times 2 + 512 = 524,800$ parameters on LCSTS. Besides, WEAN does not have any extra parameters in the other part of the model.

4.2 Speeding up Convergence

Figure 2 shows the training curve of WEAN and Seq2seq on the PWKP validation set. WEAN achieve near the optimal score in only 2-3 epochs, while Seq2seq takes more than 15 epochs to achieve the optimal score. Therefore, WEAN has much faster convergence rate, compared with Seq2seq. With the much faster training speed, WEAN does not suffer loss in BLEU, and even improve the BLEU score.

Table 6: Two examples of different text simplification system outputs in EW-SEW dataset. Differences from the source texts are shown in bold.

4.3 Case Study

Table 6 shows two examples of different text simplification system outputs on EW-SEW. For the first example, NTS, NTS-w2v and PBMT-R miss some essential constituents, so that the sentences are incomplete and not fluent. SBMT-SARI generates a fluent sentence, but the output does not preserve the original meaning. The predicted sentence of WEAN is fluent, simple, and the same as the reference. For the second example, NTS-w2v omits so many words that it lacks a lot of information. PBMT-R generates some irrelevant words, like 'siemens-martin', '-rrb-', and '-shurba', which hurts the fluency and adequacy of the generated sentence. SBMT-SARI is able to generate a fluent sentence, but the meaning is different from the source text, and even more difficult to understand. Compared with the statistic model, WEAN generates a more fluent sentence. Besides, WEAN can capture the semantic meaning of the word by querying the word embeddings, so the generated sentence is semantically correct, and very close to the original meaning.

5 Related Work

Our work is related to the encoder-decoder framework (Cho et al., 2014) and the attention mechanism (Bahdanau et al., 2014). Encoder-decoder framework, like sequence-to-sequence model, has achieved success in machine translation (Sutskever et al., 2014; Jean et al., 2015; Luong et al., 2015; Lin et al., 2018), text summarization (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Wang et al., 2017; Ma and Sun, 2017), and other natural language processing tasks (Liu et al., 2017). There are many other methods to improve neural attention model (Jean et al., 2015; Luong et al., 2015).

Zhu et al. (2010) constructs a wikipedia dataset, and proposes a tree-based simplification model. Woodsend and Lapata (2011) introduces a data-driven model based on quasi-synchronous grammar, which captures structural mismatches and complex rewrite operations. Wubben et al. (2012)

presents a method for text simplification using phrase based machine translation with re-ranking the outputs. Kauchak (2013) proposes a text simplification corpus, and evaluates language modeling for text simplification on the proposed corpus. Narayan and Gardent (2014) propose a hybrid approach to sentence simplification which combines deep semantics and monolingual machine translation. Hwang et al. (2015) introduces a parallel simplification corpus by evaluating the similarity between the source text and the simplified text based on WordNet. Glavaš and Štajner (2015) propose an unsupervised approach to lexical simplification that makes use of word vectors and require only regular corpora. Xu et al. (2016) design automatic metrics for text simplification. Recently, most works focus on the neural sequence-to-sequence model. Nisioi et al. (2017) present a sequence-to-sequence model, and re-ranks the predictions with BLEU and SARI. Zhang and Lapata (2017) propose a deep reinforcement learning model to improve the simplicity, fluency and adequacy of the simplified texts. Cao et al. (2017) introduce a novel sequence-to-sequence model to join copying and restricted generation for text simplification.

Rush et al. (2015) first used an attention-based encoder to compress texts and a neural network language decoder to generate summaries. Following this work, recurrent encoder was introduced to text summarization, and gained better performance (Lopyrev, 2015; Chopra et al., 2016). Towards Chinese texts, Hu et al. (2015) built a large corpus of Chinese short text summarization. To deal with unknown word problem, Nallapati et al. (2016) proposed a generator-pointer model so that the decoder is able to generate words in source texts. Gu et al. (2016) also solved this issue by incorporating copying mechanism.

6 Conclusion

We propose a novel model based on the encoder-decoder framework, which generates the words by querying distributed word representations. Experimental results show that our model outperforms the sequence-to-sequence baseline by the BLEU score of 6.3 and 5.5 on two English text simplification datasets, and the ROUGE-2 F1 score of 5.7 on a Chinese summarization dataset. Moreover, our model achieves state-of-the-art performances on these three benchmark datasets.

Abstract

Lexical simplification involves identifying complex words or phrases that need to be simplified, and recommending simpler meaning-preserving substitutes that can be more easily understood. We propose a complex word identification (CWI) model that exploits both lexical and contextual features, and a simplification mechanism which relies on a word-embedding lexical substitution model to replace the detected complex words with simpler paraphrases. We compare our CWI and lexical simplification models to several baselines, and evaluate the performance of our simplification system against human judgments. The results show that our models are able to detect complex words with higher accuracy than other commonly used methods, and propose good simplification substitutes in context. They also highlight the limited contribution of context features for CWI, which nonetheless improve simplification compared to context-unaware models.

1 Introduction

Automated text simplification is the process that involves transforming a complex text into one with the same meaning, but can be more easily read and understood by a broader audience (Saggion, 2017). This process includes several subtasks such as complex word and sentence identification, lexical simplification, syntactic simplification, and sentence splitting. In this paper, we focus on lexical simplification, the task of replacing difficult words in a text with words that are easier to understand.

Lexical simplification involves two main processes: identifying complex words within a text, and suggesting simpler paraphrases for these words that preserve their meaning in this context. To identify complex words, we train a model on data manually annotated for complexity. Unlike previous work, our classifier takes into account both lexical and context features. We extract candidate substitutes for the identified complex words from SimplePPDB (Pavlick and Callison-Burch, 2016), a database of 4.5 million English simplification rules linking English complex words to simpler paraphrases. We select the substitutes that best fit each context using a word embedding-based lexical substitution model (Melamud et al., 2015). An example sentence, along with the complex words identified by our model and the proposed replacements, is shown in Figure 1. We show that our complex word identification classifier and substitution model improve over several baselines which exploit other types of information and do not account for context. Our approach proposes highly accurate substitutes that are simpler than the target words and preserve the meaning of the corresponding sentences.

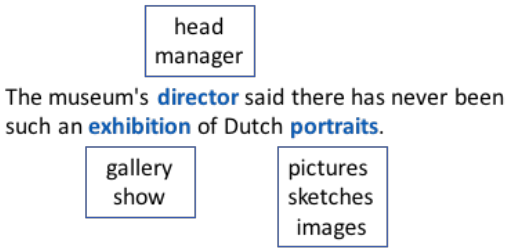

Figure 1: An example sentence with complex words identified by our classifier, and their substitutes proposed by the embedding-based substitution model.

2 Related Work

Prior approaches to text simplification have addressed the task as a monolingual translation problem (Zhu et al., 2010; Coster and Kauchak, 2011; Wubben et al., 2012). The proposed models are trained on aligned sentences extracted from Wikipedia and Simple Wikipedia, a corpus that

Proceedings of NAACL-HLT 2018, pages 207–217
New Orleans, Louisiana, June 1 - 6, 2018.

contains instances of transformation operations needed for simplification such as rewording, reordering, insertion and deletion. Zhu et al. (2010) propose to use a tree-based translation model which covers splitting, dropping, reordering and substitution. Coster and Kauchak (2011) employ a phrase-based Machine Translation system extended to support phrase deletion, and Wubben et al. (2012) augment a phrase-based system with a re-ranking heuristic.

Woodsend and Lapata (2011) view simplification as a monolingual text generation task. They propose a model based on a quasi-synchronous grammar, a formalism able to capture structural mismatches and complex rewrite operations. The grammar is also induced from a parallel Wikipedia corpus, and an integer linear programming model selects the most appropriate simplification from the space of possible rewrites generated by the grammar. The hybrid model of Angrosh et al. (2014) combines a synchronous grammar extracted from the same parallel corpus with a set of hand crafted syntactic simplification rules. In recent work, Zhang and Lapata (2017) propose a reinforcement learning-based text simplification model which jointly models simplicity, grammaticality, and semantic fidelity to the input. In contrast to these methods, Narayan and Gardent (2016)'s sentence simplification approach does not need a parallel corpus for training, but rather uses a deep semantic representation as input for simplification.

The above-mentioned systems support the full range of transformations involved in text simplification. Other works address specific subtasks, such as syntactic or lexical simplification, which involve identifying grammatical or lexical complexities in a text and rewriting these using simpler words and structures. Syntactic simplification might involve operations such as sentence splitting, rewriting of sentences including passive voice and anaphora resolution (Chandrasekar and Srinivas, 1997; Klerke and Søgaard, 2013).[1] Lexical simplification involves complex word identification, substitute generation, context-based substitute selection and simplicity ranking. To identify the words to be simplified, Shardlow (2013a) proposes to use a Support Vector Machine (SVM) that exploits several lexical features, such as frequency, character and syllable length. Our approach also uses a SVM classifier for identifying complex words, but complements this set of features with context-related features that have not been exploited in previous work.[2]

In the lexical simplification subtask, existing methods differ in their decision to include a word sense disambiguation (WSD) step for substitute selection and in the ranking method used. Ranking is often addressed in terms of word frequency in a large corpus since it has been shown that frequent words increase a text's readability (Devlin and Tait, 1998; Kauchak, 2013). Models that include a semantic processing step for substitute selection aim to ensure that the selected substitutes express the correct meaning of words in specific contexts. WSD is often carried out by selecting the correct synset (i.e. set of synonyms describing a sense) for a target word in WordNet (Miller, 1995) and retrieving the synonyms describing that sense. Thomas and Anderson (2012) use WordNet's tree structure (hypernymy relations) to reduce the size of the vocabulary in a document. Biran et al. (2011) perform disambiguation in an unsupervised manner. They learn simplification rules from comparable corpora and apply them to new sentences using vector-based context similarity measures to select words that are the most likely candidates for substitution in a given context. This process does not involve an explicit WSD step, and simplification is addressed as a context-aware lexical substitution task. The SemEval 2012 English Lexical Simplification task (Specia et al., 2012) also addresses simplification as lexical substitution (McCarthy and Navigli, 2007), allowing systems to use external sense inventories or to directly perform in-context substitution.

In our work, we opt for an approach which addresses lexical substitution in a direct way and does not include an explicit disambiguation step. Lexical substitution systems perform substitute ranking in context using vector-space models (Thater et al., 2011; Kremer et al., 2014; Melamud et al., 2015). Recently, Apidianaki (2016) showed that a syntax-based substitution model can successfully filter the paraphrases available in the

[1] For a detailed overview of syntactic simplification works, see (Shardlow, 2014).

[2] Datasets for system training and evaluation have been made available in the SemEval 2016 Complex Word Identification task (Paetzold and Specia, 2016) but present several issues that make system comparison problematic. We explain the drawbacks of the proposed datasets that led to their exclusion from this work in Section 5.

Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) to select the ones that are adequate in specific contexts. In the same line, Cocos et al. (2017) used a word embedding-based substitution model (Melamud et al., 2015) for ranking PPDB paraphrases in context. We extend this work and adapt the Melamud et al. (2015) model to the simplification setting by using candidate paraphrases extracted from the Simple PPDB resource (Pavlick and Callison-Burch, 2016), a subset of the PPDB that contains complex words and phrases, and their simpler counterparts that can be used for in-context simplification.

3 Identifying Complex Words

3.1 Data

The first step for lexical simplification is to identify the complex words that should be simplified. The bulk of prior work on text simplification has addressed the complex word identification problem by training machine learning algorithms on the parallel Wikipedia Simplification (PWKP) corpus (Zhu et al., 2010). The PWKP corpus, however, has several shortcomings, as described in Xu et al. (2015). Namely, it was determined that 50% of the parallel sentences in PWKP were either not aligned correctly, or the simple sentence was not in fact simpler than the complex sentence. Xu et al. (2015) created a more reliably annotated dataset, which uses a corpus consisting of 1,130 articles, manually rewritten by experts at Newsela[3] at four different reading levels. Xu et al. (2015) also aligned sentences from these texts, extracting 141,582 complex/simple sentence pairs.

We use the Newsela corpus to create a gold-standard dataset of complex and simple words for training and testing our models. We do this by hiring crowdsourced annotators through Amazon Mechanical Turk, and asking them to identify complex words in the context of given texts. We randomly select 200 texts from the Newsela corpus, and take the first 200 tokens from each to be labeled by nine annotators. We preprocess the texts using the Stanford CoreNLP suite (Manning et al., 2014) for tokenization, lemmatization, part-of-speech (POS) tagging, and named entity recognition. The annotators are instructed to label at least 10 complex words they deem worth simplifying for young children, people with disabilities, and second language learners. After filtering out stop words (articles, conjunctions, prepositions, pronouns) and named entities, we are left with 17,318 labeled tokens. Tokens identified by at least three annotators are considered as complex, and tokens labeled by less than three or no annotators as simple. This increases the likelihood of complex segments being actually complex; as we can see from Table 1, words identified by only one or two annotators tend to be somewhat noisy.

Annotators	Prevalence	Example Words
0	0.617	heard, sat, feet, shops, town
1	0.118	protests, pump, trial
2	0.062	sentenced, fraction, primary
3	0.047	measures, involved, elite
4	0.035	fore, pact, collapsed
5	0.031	slew, enrolled, widespread
6	0.029	edible, seize, dwindled
7	0.023	perilous, activist, remorse
8	0.023	vintners, adherents, amassed
9	0.015	abdicate, detained, liaison

Table 1: Examples of words identified as difficult to understand within a text by n annotators, where $0 \leq n \leq 9$. Column 2 (Prevalence) shows the proportion of the total number of words identified as complex by n annotators.

3.2 Methods

Following Shardlow (2013a), we use a Support Vector Machine classifier. We also conduct experiments with a Random Forest Classifier. Shardlow (2013a) identified several features that help to determine whether or not a word is complex, including word length, number of syllables, word frequency, number of unique WordNet synsets, and number of WordNet synonyms. Shardlow used word frequencies extracted from SUBTLEX, a corpus of 51 million words extracted from English subtitles.[4] We instead use n-gram frequencies from the Google Web1T corpus Brants and Franz (2006) (henceforth Google n-gram).

Our motivation for using Google n-gram frequencies is based on the hypothesis that word frequency is a strong indicator of word difficulty. More frequent words are more likely to be easy, and less frequent words are more likely to be unknown and therefore hard to understand. The size of the Google n-gram corpus, consisting of a variety of texts across many genres and years, makes

[3]Newsela is a company that provides reading materials for students in elementary through high school. The Newsela corpus can be requested at https://newsela.com/data/

[4]SUBTLEX can be found at: https://www.ugent.be/pp/experimentele-psychologie/en/research/documents/subtlexus

it a good candidate for computing more accurate word frequencies.

In addition to word frequencies and word specific features, we include several context-specific features: average length of words in the sentence, average number of syllables, average word frequency, average number of WordNet synsets, average number of WordNet synonyms, and sentence length. The intuition for including context-specific features is that if a target word is surrounded by simple words, a reader is likely better able to understand the meaning of the target word, which would thus not need it simplified.

4 Lexical Simplification

4.1 Data

For our model and baselines, we consider candidate substitutions from three datasets. The first is WordNet (Miller, 1995), a lexical network encoding manually identified semantic relationships between words, such as synonymy, hypernymy and hyponymy. This resource has been widely used in substitution tasks (McCarthy and Navigli, 2007). We also use paraphrases extracted from the Paraphrase Database (PPDB) and the Simple Paraphrase Database (SimplePPDB). PPDB is a collection of more than 100 million English paraphrase pairs (Ganitkevitch et al., 2013). These pairs were extracted using a bilingual pivoting technique (Bannard and Callison-Burch, 2005), which assumes that two English phrases that translate to the same foreign phrase have the same meaning. PPDB was updated by Pavlick et al. (2015) to assign labels stating the precise entailment relationship between paraphrase pairs (e.g. forward/backward entailment), and new confidence scores (PPDB 2.0 scores) reflecting the strength of paraphrase relations.

SimplePPDB is a subset of PPDB which contains 4.5 million simplification rules, linking a complex word or phrase with a simpler paraphrase with the same meaning. Simplification rules come with both a PPDB 2.0 score and a simplification confidence score (Pavlick and Callison-Burch, 2016), which represent both the strength of the paraphrase relation and how well the replacement word simplifies the target word. These rules were created by sampling 1,000 PPDB phrases, using crowdsourcing to find correct simplifications for each phrase, and building a model to identify rules that simplify the input phrase.

To evaluate the performance of our lexical simplification model, we create a test set from the Newsela corpus. We extract lexical simplification rules from these parallel sentences using two methods. First, we find sentence pairs with only one lexical replacement and use these word pairs as simplification instances. Next, we use a monolingual word alignment software (Sultan et al., 2014) to extract all non-identical aligned word pairs. We only consider word pairs corresponding to different lemmas (i.e. words with different base forms). From this process, we collect a test set of 14,436 word pairs.

4.2 In-context Ranking and Substitution

To accurately replace words in texts with simpler paraphrases and ensure the generated sentences preserve the meaning of the original, we need to take into account the surrounding context. To do this, we adapt the word embedding-based lexical substitution model of Melamud et al. (2015) to the simplification task. Vector-space models have been shown to effectively filter PPDB paraphrases in context while preserving the meaning of the original sentences (Apidianaki, 2016; Cocos et al., 2017).

The Melamud et al. (2015) model (hereafter AddCos) quantifies the fit of substitute word s for target word t in context C by measuring the semantic similarity of the substitute to the target, and the similarity of the substitute to the context:

$$AddCos(s,t,C) = \frac{\cos(s,t)+\sum_{w\in C}\cos(s,w)}{|C|+1} \quad (1)$$

The vectors s and t are word embeddings of the substitute and target generated by the *skip-gram with negative sampling* model (Mikolov et al., 2013b,a). The context C is the set of context embeddings generated by *skip-gram* for words appearing within a fixed-width window of the target t in a sentence. We use a context window of 1; while this seems counter-intuitive, this is the best-performing window found by (Cocos et al., 2017), and we also confirm this result remains true in Section 5.2. We use the AddCos implementation of Cocos et al. (2017)[5], and 300-dimensional word and context embeddings trained over the 4 billion words in the AGiga corpus (Napoles

[5]Available at https://github.com/acocos/lexsub_addcos

et al., 2012) using the gensim word2vec package (Mikolov et al., 2013b,a; Řehůřek and Sojka, 2010). [6]

In our experiments, candidate substitutes for a target word are its paraphrases in the PPDB and SimplePPDB resources. The model needs to select among these candidates the ones that best carry the meaning of target words in specific contexts. We only consider content words (nouns, verbs, adjectives and adverbs) as simplification targets.

For a "target word-substitute" pair, we include in the model the following features which encode the strength of the semantic relationship between them:

- PPDB 1.0 and 2.0 scores, which represent the overall quality of paraphrases.
- Distributional similarity scores calculated by Ganitkevitch et al. (2013) on the Google n-grams and the AGiga corpus.
- Independence probability, that is the probability that there is no semantic entailment relationship between the paraphrase pair, as calculated by Pavlick et al. (2015).
- SimplePPDB score (Pavlick and Callison-Burch, 2016) – when considering SimplePPDB paraphrases – which reflects the confidence in the simplification rule.

5 Evaluation

5.1 Complex Word Identification

Datasets for training and evaluating Complex Word Identification (CWI) systems were created and released in the SemEval 2016 competition (Paetzold and Specia, 2016) but we decided not to use them for several reasons. Although this was a CWI task, surprisingly only 4.7% of the words in the test data were identified as complex, and all the other words were viewed as simple. As a consequence, none of the systems that participated in the SemEval task managed to beat the accuracy of the "All Simple" baseline which labeled all words in the test set as simple (0.953). As noted by Paetzold and Specia (2016), the inverse problem is present in the corpus developed by Shardlow (2013b), where the "All Complex" baseline achieved higher accuracy, recall and F-scores than all other tested systems, suggesting that marking all words in a sentence as complex is the most effective approach for CWI.

Model	Precision	Recall	F-Score
All-Complex	0.500	**1.000**	0.667
Token Length	0.757	0.900	0.822
n-gram Frequency	0.632	0.862	0.729
SVM-word	**0.880**	0.834	**0.857**
SVM-Context	0.871	0.831	0.850
RF-word	0.805	0.840	0.822
RF-Context	0.824	0.851	0.837

Table 2: Cross-validation performance for four different complex words identification classifiers. Comparison to three baselines. Scores are calculated using **unique** words in our training data.

Another problem in the SemEval-2016 dataset is that although the number of complex words is much higher in the training data (32%), 18% of all words were annotated as complex by only one out of 20 annotators and considered as complex. In addition to the highly different number of complex words in the training and test data, the two datasets are also imbalanced in terms of size, with only 2,237 training instances and 88,211 testing instances. These factors make this dataset a dubious choice for system evaluation. Comparison to the participating systems is also extremely difficult, since the best systems are ones that label most of the data as simple. For these reasons, we decided to create and use our crowdsourced data for training and evaluation.[7]

We compare the performance of an SVM classifier with only word features (SVM-word) to one that exploits both word and context features (SVM-context). We use 5-fold cross validation on unique words from the training data collected through Mechanical Turk (see Section 4.1). We also compare a Random Forest classifier with only word features (RF-word) to one with word and context features (RF-context). We consider three baselines:

- labeling all words as complex (All-Complex).
- thresholding for word length (Token Length), considering longer words as complex; the length threshold with the best performance was 7.

[6] The `word2vec` training parameters we use are a context window of size 3, learning rate *alpha* from 0.025 to 0.0001, minimum word count 100, sampling parameter $1e^{-4}$, 10 negative samples per target word, and 5 training epochs.

[7] We have released the new datasets at https://rekriz11.github.io

		Words with ≥1 paraphrase			All words		
Model	**Coverage**	**Top 1**	**Top 5**	**Oracle**	**Top 1**	**Top 5**	**Oracle**
WordNet frequency	0.911	0.141	0.267	0.291	0.129	0.244	0.265
SimplePPDB Score	0.935	0.180	0.403	0.669	0.168	0.377	0.626
AddCos-PPDB	**0.975**	0.196	0.444	**0.962**	0.191	0.433	**0.938**
AddCos-SimplePPDB	0.819	**0.353**	**0.601**	0.643	**0.289**	**0.492**	0.527

Table 3: Performance of the lexical simplification models on the Newsela aligned test set. Columns 3-5 show the performance of each model on only words with at least one paraphrase in the dataset. Columns 6-8 show the performance of each model on all words; this penalizes for the coverage of the databases.

- thresholding for word frequency using Google n-gram counts (n-gram Frequency), considering more frequent words as simple; the frequency threshold with the best performance was 19,950,000.

The results of this experiment are shown in Table 2. While the Token Length and n-gram Frequency baselines have higher recall, both of our models show substantial improvements in terms of precision and increases overall accuracy and F-score, with SVM outperforming Random Forest. The context-based features seem to have an ambiguous impact, in that they do not improve the performance of the SVM classifier, but they do improve that of the Random Forest classifier. While there are indeed some cases where a relatively simple word is more difficult to understand, due to the size of our corpus, these cases are not found that often in our dataset.

5.2 Lexical Simplification Evaluation

We evaluate the performance of the lexical substitution model using Simple PPDB paraphrases on a test set created from the Newsela corpus, described in Section 4.1. Using the complex word and the corresponding sentence, we find the top suggestions made by our word-embedding based substitution model using SimplePPDB. We compare to three baselines:

- WordNet Frequency: We extract all WordNet synonyms for a complex word, and collect the Google n-gram frequencies for each synonym. We then rank the synonyms in decreasing order of frequency (i.e. the most frequent synonym will be ranked first, and the least frequent one will be ranked last.
- SimplePPDB Score: We extract all SimplePPDB synonyms for a complex word. We then rank the synonyms in decreasing order of their SimplePPDB score.

Context Window	**Top 1**	**Top 5**
0	0.180	0.403
1	0.353	0.601
2	0.352	0.596
3	0.334	0.590
4	0.312	0.585
5	0.291	0.581
6	0.269	0.578
7	0.264	0.577

Table 4: Quality of substitutions proposed by AddCos-SimplePPDB with different context window size as measured by Top 1 and Top 5 accuracy on the Newsela aligned test set.

- AddCos-PPDB: We extract all PPDB synonyms for a complex word and rank them using the AddCos model described above.

The performance of AddCos with SimplePPDB paraphrases (AddCos-SimplePPDB) in the lexical simplification task is compared to performance of the baselines in Table 3. For each model, we calculate Top 1 and Top 5 accuracy scores, which show how often the gold-standard simple word was proposed as the best fitting or among the 5 highest-ranked paraphrases. In addition, we calculate the upper bound performance for each dataset (PPDB, SimplePPDB and WordNet), i.e. how often the gold-standard simple word was found as a paraphrase of the target word in the dataset. This is useful in telling us how well we could potentially do, if we could perfectly rank the paraphrases.

When performing this experiment, we also evaluated the impact of the context window size on the quality of the proposed substitutions. We varied the context window used by the AddCos-SimplePPDB model from 0 to 10. The results of this comparison are found in Table 4. As we can see, the largest effect, as expected, is when the model changes from using no context to choosing a window size of 1 word on either side of the word that is being replaced. As the context window in-

Synonym Rank	Substitution	Simplification	Both
1	**0.396**	**0.280**	**0.227**
2	0.311	0.214	0.153
3	0.278	0.184	0.127
4	0.228	0.142	0.093
5	0.193	0.123	0.075
All	**0.622**	**0.553**	**0.435**

Table 5: Performance of our overall lexical simplification system. We give the proportion of substitutes the system ranked at positions 1 to 5 (i.e. from the top ranked to the fifth-ranked paraphrase in context) which was identified by a majority of workers as (a) a good substitute in context (Substitution); (b) simpler than the target word (Simplification); (c) both a good and simpler substitute (Both). We also show the proportion of complex words where at least one of the top 5 paraphrases satisfies these criteria in the last row.

Baseline	Simple	Complex
n-gram Frequency	dug, sled, chart, lakes, push, tight, harm	estimates, frequent, attributed, isolated, preferred, liability
Token Length	nursing, unknown, squares, feeling, teaching, strength	adorns, asylum, myriad, rigors, nutria, edible
RF-Context	malls, hungry, therefore, hears, heavily, rainy	engaging, secular, gridlock, torrent, sanctions, lobbying
SVM-Context	peacefully, favorite, amazing, websites, harmful, somewhat	swelled, entice, tether, chaotic, vessel, midst

Table 6: Examples of words that were incorrectly classified by the two best performing baselines and the RF-Context model, but were correctly classified by the SVM-Context model. The last row shows examples of words that were incorrectly classified by the SVM-Context model.

creases above 2, however, we see a significant decrease in Top 1 accuracy, and a slower decrease in Top 5 accuracy. Thus, in our model, we chose to use a context window of 1.

We experimented with filtering the substitution candidates using SimplePPDB confidence scores, PPDB paraphrase quality scores, and AddCos context similarity scores, but these all resulted in a slight, non-significant increase in performance, and a significant decrease in coverage. We will also explore other ways for promoting high-quality substitutions without hurting the overall coverage of the system in the future.

One thing to note is that just because a model does not find the gold-standard simple word, does not necessarily mean that it does not find any good substitutes in context. Concrete examples of this are shown in Section 6.

5.3 Overall Simplification System

We integrate the best complex word identification classifier (SVM-context) and the substitution model that provided the best ranking in context (AddCos-SimplePPDB), into a simplification pipeline. The input text is a complex text that needs to be simplified and the output consists of simplification suggestions for experts to choose from in order to create simpler versions of texts. The input text is pre-processed using the Stanford CoreNLP suite (Manning et al., 2014) which performs tokenization, sentence splitting, lemmatization, part-of-speech and named entity tagging. The SVM-Context classifier is used to classify each content word that is not part of a named entity as either simple or complex.

The lexical substitution model then gathers the SimplePPDB substitutes available for the complex target word and ranks them according to how well they fit the corresponding context. We only keep the top five suggestions made by the model as final output.

To evaluate the performance of the overall simplification system, we used the 930 texts from the Newsela corpus that were not used in the training of the CWI classifier. Our model identified over 170,000 complex words that also had paraphrases in SimplePPDB. We again asked crowdsourced annotators to evaluate the suggestions made for a random sample of 2,500 complex words on Amazon Mechanical Turk, in order to determine the number of good substitutions in context, the number of suggested paraphrases that are simpler than the target words, and the suggestions that are both simpler paraphrases and good in-context substitutes.

Table 5 shows the quality of the paraphrases ranked by our system in positions from one to five. We can see that the paraphrases our system selects as the best have a higher likelihood of being both good substitutes in context and simpler than the target word. We also show the proportion of target words that had at least one good substitute in context, one simple substitute, and one good and simple substitute.

6 Error Analysis

In this section, we give examples of words for which our models give the correct output and the

Sentence	Gold-Standard	WordNet Frequency	SimplePPDB Score	AddCos-PPDB	AddCos-SimplePPDB
(7.1) Advocates **argue** that including women will help end harassment of female troops.	**say**	reason, fence, debate, contend, indicate	**say**, think, tell, talk, mean	contend, assert, acknowledge, insist, complain	**say**, claim, believe, suggest, debate
(7.2) But in April , detainees covered cameras used to **monitor** them.	**watch**	supervise, proctor, admonisher	find, meet, give, try, allow	track, manipulate, control, analyze, supervise	track, control, check, **watch**, follow
(7.3) Similarly , police can investigate cases and have the **authority** to seize animals.	**power**	agency, potency, bureau, assurance	force, control, permission, office, limit	jurisdiction, discretion, right, prerogative, ability	**power**, responsibility, body, agency

Table 7: Examples of the top-5 substitutes for our three baselines and our best model (AddCos-SimplePPDB). We also provide the gold-standard simplification (Gold-Standard).

Sentence	Bad Substitutions
(8.1)b	basic
(8.2) Russian poultry is more expensive, and U.S. producers enjoy numerous cost **advantages**.	prospect, benefits, revenue, merit, feature
(8.3) Although the calculus may be different with Syrian **refugees**, the parallel for me is politics.	life, right, return, shelter, million
(8.4) He saw them bring in animals to a university, where they'll be cared for and put up for **adoption**.	acceptance, passage, approval, endorsement

Table 8: Examples of words and their context where our model fails to provide any good replacements.

baselines fail to do so. In addition, we give examples of words on which our models perform poorly.

First, we consider examples of words that were incorrectly classified by each of the four best performing CWI models: the RF-Context and SVM-Context models, and the n-gram Frequency and Token Length baselines. (Table 6). In the first three rows, we give words that were correctly identified by SVM-Context, but incorrectly categorized by the two baselines and RF-Context; in the last row, we give examples of words incorrectly classified by SVM-Context. We observe that the n-gram Frequency model tends to incorrectly classify relatively short words that are rare in the Google n-gram corpus as complex. On the other end, the Token Length model shows that using this feature alone leads to incorrectly identifying shorter words such as "adorn" and "myriad" as simple, when these words are relatively complex.

Table 7 presents examples of substitution where the baseline systems did not find the correct paraphrase, but AddCos-SimplePPDB did. As we have mentioned, even when a model did not find the gold-standard paraphrase, they sometimes did find a different paraphrase that works well in the context. In Example 7.2, the top paraphrase identified by both AddCos-PPDB and AddCos-Simple PPDB for the word "monitor" is "track", which is a reasonable substitute. On the other hand, in Example 7.3, AddCos-Simple PPDB model was able to identify a good simple substitute, when none of the other models were able to identify a suitable word with comparable complexity.

Finally, Table 8 shows examples of output of the overall simplification system. Here, the **blue** word is a word that our CWI classifier identified as complex (for simplicity, we only look at one complex word per sentence). From there, we consider the five top-ranked substitutes proposed by AddCos-Simple PPDB, and show which were identified by the majority of annotators as good substitutes for the target word, simpler than the target, good simpler substitutes, and bad substitutes. In row 5 of Table 8, we can see that for the word "adoption", all five words identified by our model are considered to be bad substitutes, since they are all synonyms describing a different sense of adoption. Even though SimplePPDB is quite large, it does not cover all senses of the words represented. Another issue is that SimplePPDB contains some noisy paraphrases, as is the case with all automatically collected synonym banks. We see this with "recognize" being a synonym of "recognition", even though we specified that "recognition" is a noun. Our model does filter out the worst paraphrases (with PPDB2.0 score < 2), but there are still some words that are simply poor substitutes.

We reviewed the examples where our system failed to generate acceptable substitutions for the identified complex words. Below we present the major categories of errors.

- The identified complex term is part of a phrase and no substitution is acceptable. For example, in Example 8.1, Elementary, Mid-

dle or High School is a description of the type of school. *Elementary School* has an alternative name in some cases but *High School* should never become *Tall School*.

- The complex word has no simpler synonym that would be a good substitute. The difficulty of the word might reside in its meaning which can be unknown to the reader. In Example 8.3, it would be more useful to point to the definition of *refugees*.
- The complex word is part of a predicate with arguments that are not accessible to our model. In Example 8.4, the intended meaning of *adoption*, human adoption, is hard to capture in the vicinity of the complex word.
- Finally, in some cases, our annotators were quite strict in admitting a substitute. In Example 8.2, for example, *cost merit* would not be syntactically correct but *cost merits* would be acceptable.

7 Conclusions and Future Work

We present a novel model for simplification that first identifies complex words in text, and then ranks lexical simplification candidates according to their adequacy in these specific contexts. We perform experiments showing that our model makes correct simplification suggestions 35% of the time as measured by top-1 accuracy (versus 20% of the time for the best baseline), and produces a good substitution in its top-5 predictions 60% of the time (versus 44% for the best baseline). We perform a detailed error analysis that suggests future improvements, e.g. not replacing words within collocations like *elementary school*, and extending the context model to include the arguments of words that are going to be simplified.

Achieving high performance on single words is crucial for any system that hopes to adequately holistically simplify a text. Our methods can also be extended to the phrase level. SimplePPDB contains phrasal simplification rules, as well as lexical simplification rules. We can assign a vector representation to phrases to be used by the AddCos model, by applying a vector composition method to the vectors of individual words in the phrase. We plan to extend our method in this direction in future work.

Although our system outperforms simpler baselines on both tasks, the performance of the overall system is relatively low. The filtering mechanisms we have experimented with up to now in order to make high-confidence predictions, increased the quality of the proposed substitutions but significantly decreased the coverage. We will explore other ways for promoting high-quality substitutions without hurting the overall coverage of the system in the future.

The AddCos implementation we used in this work does not rely on syntactic annotations and can be easily applied to new languages. In future work, we plan to experiment with syntactic substitution models and with syntax-based word embeddings like the ones used in the initial AddCos implementation (Melamud et al., 2015). We expect syntactic information to further enhance the quality of the proposed substitutions, ensuring the functional similarity of the lexical substitutions to the target word. Furthermore, we intend to integrate lexical and syntactic simplification, both crucial steps towards text simplification.

8 Data and Software

We release the data that we collected, which is of higher quality than the data used in previous shared tasks on Complex Word Identification. We also release our software for performing context-aware paraphrase substitutions. The dataset and the code can be found at https://rekriz11.github.io

Zero-Shot Question Generation from Knowledge Graphs for Unseen Predicates and Entity Types

Hady Elsahar, Christophe Gravier, Frederique Laforest

Abstract

We present a neural model for question generation from knowledge base triples in a "Zero-Shot" setup, that is generating questions for triples containing predicates, subject types or object types that were not seen at training time. Our model leverages triples occurrences in the natural language corpus in an encoder-decoder architecture, paired with an original part-of-speech copy action mechanism to generate questions. Benchmark and human evaluation show that our model sets a new state-of-the-art for zero-shot QG.

1 Introduction

Questions Generation (QG) from Knowledge Graphs is the task consisting in generating natural language questions given an input knowledge base (KB) triple (Serban et al., 2016). QG from knowledge graphs has shown to improve the performance of existing factoid question answering (QA) systems either by dual training or by augmenting existing training datasets (Dong et al., 2017; Khapra et al., 2017). Those methods rely on large-scale annotated datasets such as SimpleQuestions (Bordes et al., 2015). Building such datasets is a tedious task in practice, especially to obtain an unbiased dataset – i.e. a dataset that covers equally a large amount of triples in the KB. In practice many of the predicates and entity types in KB are not covered by those annotated datasets. For example 75.6% of Freebase predicates are not covered by the SimpleQuestions dataset [1]. Among those we can find important missing predicates such as: `fb:food/beer/country`, `fb:location/country/national_anthem`, `fb:astronomy/star_system/stars`.

One challenge for QG from knowledge graphs is to adapt to predicates and entity types that were *not* seen at training time (Zero-Shot Question Generation). Since state-of-the-art systems in factoid QA rely on the tremendous efforts made to create SimpleQuestions, these systems can only process questions on the subset of 24.4% of freebase predicates defined in SimpleQuestions. Previous works for factoid QG (Serban et al., 2016) claims to solve the issue of small size QA datasets. However encountering an unseen predicate / entity type will generate questions made out of random text generation for those out-of-vocabulary predicates a QG system had never seen. We go beyond this state-of-the-art by providing an original and non-trivial solution for creating a much broader set of questions for unseen predicates and entity types. Ultimately, generating questions to predicates and entity types unseen at training time will allow QA systems to cover predicates and entity types that would not have been used for QA otherwise.

Intuitively, a human who is given the task to write a question on a fact offered by a KB, would read natural language sentences where the entity or the predicate of the fact occur, and build up questions that are aligned with what he reads from both a lexical and grammatical standpoint. In this paper, we propose a model for Zero-Shot Question Generation that follows this intuitive process. In addition to the input KB triple, we feed our model with a set of textual contexts paired with the input KB triple through distant supervision. Our model derives an encoder-decoder architecture, in which the encoder encodes the input KB triple, along with a set of textual contexts into hidden representations. Those hidden representations are fed to a decoder equipped with an attention mechanism to generate an output question.

In the Zero-Shot setup, the emergence of new predicates and new class types during test time requires new lexicalizations to express these pred-

Proceedings of NAACL-HLT 2018, pages 218–228
New Orleans, Louisiana, June 1 - 6, 2018.

icates and classes in the output question. These lexicalizations might not be encountered by the model during training time and hence do not exist in the model vocabulary, or have been seen only few times not enough to learn a good representation for them by the model. Recent works on Text Generation tackle the rare words/unknown words problem using copy actions (Luong et al., 2015; Gülçehre et al., 2016): words with a specific position are copied from the source text to the output text – although this process is blind to the role and nature of the word in the source text. Inspired by research in open information extraction (Fader et al., 2011) and structure-content neural language models (Kiros et al., 2014), in which part-of-speech tags represent a distinctive feature when representing relations in text, we extend these positional copy actions. Instead of copying a word in a specific position in the source text, our model copies a word with a specific part-of-speech tag from the input text – we refer to those as part-of-speech copy actions. Experiments show that our model using contexts through distant supervision significantly outperforms the strongest baseline among six (+2.04 BLEU-4 score). Adding our copy action mechanism further increases this improvement (+2.39). Additionally, a human evaluation complements the comprehension of our model for edge cases; it supports the claim that the improvement brought by our copy action mechanism is even more significant than what the BLEU score suggests.

2 Related Work

QG became an essential component in many applications such as education (Heilman and Smith, 2010), tutoring (Graesser et al., 2004; Evens and Michael, 2006) and dialogue systems (Shang et al., 2015). In our paper we focus on the problem of QG from structured KB and how we can generalize it to unseen predicates and entity types. (Seyler et al., 2015) generate quiz questions from KB triples. Verbalization of entities and predicates relies on their existing labels in the KB and a dictionary. (Serban et al., 2016) use an encoder-decoder architecture with attention mechanism trained on the SimpleQuestions dataset (Bordes et al., 2015). (Dong et al., 2017) generate paraphrases of given questions to increases the performance of QA systems; paraphrases are generated relying on paraphrase datasets, neural machine translation and rule mining. (Khapra et al., 2017) generate a set of QA pairs given a KB entity. They model the problem of QG as a sequence to sequence problem by converting all the KB entities to a set of keywords. None of the previous work in QG from KB address the question of generalizing to unseen predicates and entity types.
Textual information has been used before in the Zero-Shot learning. (Socher et al., 2013) use information in pretrained word vectors for Zero-Shot visual object recognition. (Levy et al., 2017) incorporates a natural language question to the relation query to tackle Zero-Shot relation extraction problem.

Previous work in machine translation dealt with rare or unseen word problem problem for translating names and numbers in text. (Luong et al., 2015) propose a model that generates positional placeholders pointing to some words in source sentence and copy it to target sentence (*copy actions*). (Gülçehre et al., 2016; Gu et al., 2016) introduce separate trainable modules for copy actions to adapt to highly variable input sequences, for text summarization. For text generation from tables, (Lebret et al., 2016) extend positional copy actions to copy values from fields in the given table. For QG, (Serban et al., 2016) use a placeholder for the subject entity in the question to generalize to unseen entities. Their work is limited to unseen entities and does not study how they can generalize to unseen predicates and entity types.

3 Model

Let $F = \{s, p, o\}$ be the input fact provided to our model consisting of a subject s, a predicate p and an object o, and C be the set of textual contexts associated to this fact. Our goal is to learn a model that generates a sequence of T tokens $Y = y_1, y_2, \ldots, y_T$ representing a question about the subject s, where the object o is the correct answer. Our model approximates the conditional probability of the output question given an input fact $p(Y|F)$, to be the probability of the output question, given an input fact and the additional textual context C, modelled as follows:

$$p(Y|F) = \prod_{t=1}^{T} p(y_t|y_{<t}, F, C) \quad (1)$$

where $y_{<t}$ represents all previously generated tokens until time step t. Additional textual contexts are natural language representation of the triples

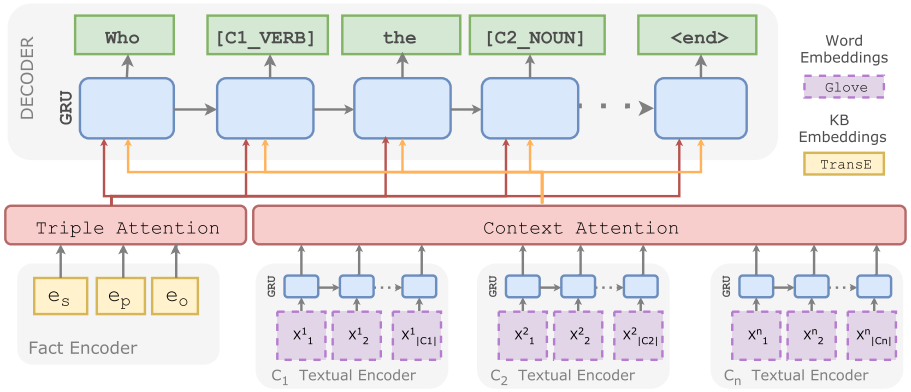

Figure 1: The proposed model for Question Generation. The model consists of a single fact encoder and n textual context encoders, each consists of a separate GRU. At each time step t, two attention vectors generated from the two attention modules are fed to the decoder to generate the next word in the output question.

that can be drawn from a corpus – our model is generic to any textual contexts that can be additionally provided, though we describe in Section 4.1 how to create such texts from Wikipedia.

Our model derives the encoder-decoder architecture of (Sutskever et al., 2014; Bahdanau et al., 2014) with two encoding modules: a feed forward architecture encodes the input triple (sec. 3.1) and a set of recurrent neural network (RNN) to encode each textual context (sec. 3.2). Our model has two attention modules (Bahdanau et al., 2014): one acts over the input triple and another acts over the input textual contexts (sec. 3.4). The decoder (sec. 3.3) is another RNN that generates the output question. At each time step, the decoder chooses to output either a word from the vocabulary or a special token indicating a copy action (sec. 3.5) from any of the textual contexts.

3.1 Fact Encoder

Given an input fact $F = \{s, p, o\}$, let each of e_s, e_p and e_o be a 1-hot vectors of size K. The fact encoder encodes each 1-hot vector into a fixed size vector $h_s = \mathbf{E_f}\, e_s$, $h_p = \mathbf{E_f}\, e_p$ and $h_o = \mathbf{E_f}\, e_o$, where $\mathbf{E_f} \in \mathbb{R}^{H_k \times K}$ is the KB embedding matrix, H_k is the size of the KB embedding and K is the size of the KB vocabulary. The *encoded fact* $h_f \in \mathbb{R}^{3H_k}$ represents the concatenation of those three vectors and we use it to initialize the decoder.

$$h_f = [h_s;\ h_p;\ h_o] \tag{2}$$

Following (Serban et al., 2016), we learn $\mathbf{E_f}$ using *TransE* (Bordes et al., 2015). We fix its weights and do not allow their update during training time.

3.2 Textual Context Encoder

Given a set of n textual contexts $C = \{c_1, c_2, \ldots, c_n\ : c_j = (x_1^j, x_2^j, \ldots, x_{|c_j|}^j)\}$, where x_i^j represents the 1-hot vector of the i^{th} token in the j^{th} textual context c_j, and $|c_j|$ is the length of the j^{th} context. We use a set of n Gated Recurrent Neural Networks (GRU) (Cho et al., 2014) to encode each of the textual concepts separately:

$$h_i^{c_j} = GRU_j\left(\mathbf{E_c}\, x_i^j,\ \ h_{i-1}^{c_j}\right) \tag{3}$$

where $h_i^{c_j} \in \mathbb{R}^{H_c}$ is the hidden state of the GRU that is equivalent to x_i^j and of size H_c . $\mathbf{E_c}$ is the input word embedding matrix. The *encoded context* represents the encoding of all the textual contexts; it is calculated as the concatenation of all the final states of all the encoded contexts:

$$h_c = [h_{|c_1|}^{c_1}; h_{|c_2|}^{c_2}; \ldots; h_{|c_n|}^{c_n}]. \tag{4}$$

3.3 Decoder

For the decoder we use another GRU with an attention mechanism (Bahdanau et al., 2014), in which the decoder hidden state $s_t \in \mathbb{R}^{H_d}$ at each time step t is calculated as:

$$s_t = z_t \circ s_{t-1} + (1 - z_t) \circ \tilde{s}_t\ , \tag{5}$$

Where:

$$\tilde{s}_t = tanh\left(W E_w y_{t-1} + U[r_t \circ s_{t-1}] + A\,[a_t^f; a_t^c]\right) \tag{6}$$

$$z_t = \sigma\left(W_z\, E_w\, y_{t-1} + U_z\, s_{t-1} + A_z\,[a_t^f; a_t^c]\right) \tag{7}$$

$$r_t = \sigma\left(W_r\, E_w\, y_{t-1} + U_r\, s_{t-1} + A_r\,[a_t^f; a_t^c]\right) \tag{8}$$

$W, W_z, W_r \in \mathbb{R}^{m \times H_d}$, $U, U_z, U_r, A, A_z, A_r \in \mathbb{R}^{H_d \times H_d}$ are learnable parameters of the GRU.

$E_w \in \mathbf{R}^{m \times V}$ is the word embedding matrix, m is the word embedding size and H_d is the size of the decoder hidden state. a_t^f, a_t^c are the outputs of the fact attention and the context attention modules respectively, detailed in the following subsection.
In order to enforce the model to pair output words with words from the textual inputs, we couple the word embedding matrices of both the decoder E_w and the textual context encoder E_c (eq.(3)). We initialize them with GloVe embeddings (Pennington et al., 2014) and allow the network to tune them.
The first hidden state of the decoder $s_0 = [h_f;\ h_c]$ is initialized using a concatenation of the encoded fact (eq.(2)) and the encoded context (eq.(4)) .
At each time step t, after calculating the hidden state of the decoder, the conditional probability distribution over each token y_t of the generated question is computed as the $softmax(W_o\, s_t)$ over all the entries in the output vocabulary, $W_o \in \mathbb{R}^{H_d \times V}$ is the weight matrix of the output layer of the decoder.

3.4 Attention

Our model has two attention modules:
Triple attention over the input triple to determine at each time step t an attention-based encoding of the input fact $a_t^f \in \mathbb{R}^{H_k}$:

$$a_t^f = \alpha_{s,t}\, h_s + \alpha_{p,t}\, h_p + \alpha_{s,t}\, h_o \ , \qquad (9)$$

$\alpha_{s,t}, \alpha_{p,t}, \alpha_{o,t}$ are scalar values calculated by the attention mechanism to determine at each time step which of the encoded subject, predicate, or object the decoder should attend to.
Textual contexts attention over all the hidden states of all the textual contexts $a_t^c \in \mathbb{R}^{H_c}$:

$$a_t^c = \sum_{i=1}^{|C|} \sum_{j=1}^{|c_i|} \alpha_{t,j}^{c_i}\, h_j^{c_i} \ , \qquad (10)$$

$\alpha_{t,j}^{c_i}$ is a scalar value determining the weight of the j^{th} word in the i^{th} context c^i at time step t.

Given a set of encoded input vectors $I = \{h_1, h_2, ...h_k\}$ and the decoder previous hidden state s_{t-1}, the attention mechanism calculates $\alpha_t = \alpha_{i,t}, \ldots, \alpha_{k,t}$ as a vector of scalar weights, each $\alpha_{i,t}$ determines the weight of its corresponding encoded input vector h_i.

$$e_{i,t} = \mathbf{v_a}^\top\ tanh(\mathbf{W_a}\, \mathbf{s_{t-1}} + \mathbf{U_a}\, \mathbf{h_i}) \qquad (11)$$

$$\alpha_{i,t} = \frac{exp\,(e_{i,t})}{\sum_{j=1}^{k} exp\,(e_{j,t})} \ , \qquad (12)$$

where $\mathbf{v_a}, \mathbf{W_a}, \mathbf{U_a}$ are trainable weight matrices of the attention modules. It is important to notice here that we encode each textual context separately using a different GRU, but we calculate an overall attention over all tokens in all textual contexts: at each time step the decoder should ideally attend to only one word from all the input contexts.

What caused the `[C1_NOUN]` of the `[C3_NOUN]` `[S]` ?	
C1	`[S]` **`death`** `by [O]`
	`[S]` **`[C1_NOUN]`** `[C1_ADP] [O]`
C2	Disease
	`[C2_NOUN]`
C3	Musical **artist**
	`[C3_ADJ]` **`[C3_NOUN]`**

Table 1: An annotated example of part-of-speech copy actions from several input textual contexts (C1, C2, C3), the words or placeholders in bold are copied in the generated question

3.5 Part-Of-Speech Copy Actions

We use the method of (Luong et al., 2015) by modeling all the copy actions on the data level through an annotation scheme. This method treats the model as a black box, which makes it adaptable to any text generation model. Instead of using positional copy actions, we use the part-of-speech information to decide the alignment process between the input and output texts to the model. Each word in every input textual context is replaced by a special token containing a combination of its context id (e.g. `C1`) and its POS tag (e.g. `NOUN`). Then, if a word in the output question matches a word in a textual context, it is replaced with its corresponding tag as shown in Table 1.
Unlike (Serban et al., 2016; Lebret et al., 2016) we model the copy actions in the input and the output levels. Our model does not have the drawback of losing the semantic information when replacing words with generic placeholders, since we provide the model with the input triple through the fact encoder. During inference the model chooses to either output words from the vocabulary or special tokens to copy from the textual contexts. In

a post-processing step those special tokens are replaced with their original words from the textual contexts.

4 Textual contexts dataset

As a source of question paired with KB triples we use the SimpleQuestions dataset (Bordes et al., 2015). It consists of 100K questions with their corresponding triples from Freebase, and was created manually through crowdsourcing. When asked to form a question from an input triple, human annotators usually tend to mainly focus on expressing the predicate of the input triple. For example, given a triple with the predicate `fb:spacecraft/manufacturer` the user may ask *"What is the manufacturer of `[S]` ?"*. Annotators may specify the entity type of the subject or the object of the triple: *"What is the manufacturer of the **spacecraft** `[S]`?"* or *"Which **company** manufactures `[S]`?"*. Motivated by this example we chose to associate each input triple with three textual contexts of three different types. The first is a phrase containing lexicalization of the predicate of the triple. The second and the third are two phrases containing the entity type of the subject and the object of the triple. In what follows we show the process of collection and preprocessing of those textual contexts.

4.1 Collection of Textual Contexts

We extend the set of triples given in the SimpleQuestions dataset by using the FB5M (Bordes et al., 2015) subset of Freebase. As a source of text documents, we rely on Wikipedia articles.

Predicate textual contexts: In order to collect textual contexts associated with the SimpleQuestions triples, we follow the distant supervision setup for relation extraction (Mintz et al., 2009). The distant supervision assumption has been effective in creating training data for relation extraction and shown to be 87% correct (Riedel et al., 2010) on Wikipedia text.
First, we align each triple in the FB5M KB to sentences in Wikipedia if the subject and the object of this triple co-occur in the same sentence. We use a simple string matching heuristic to find entity mentions in text[2]. Afterwards we reduce the sentence to the set of words that appear on the dependency path between the subject and the object mentions in the sentence. We replace the positions of the subject and the object mentions with `[S]` and `[O]` to the keep track of the information about the direction of the relation. The top occurring pattern for each predicate is associated to this predicate as its textual context. Table 2 shows examples of predicates and their corresponding textual context.

Freebase Relation	Predicate Textual Context
person/place_of_birth	[O] is birthplace of [S]
currency/former_countries	[S] was currency of [O]
dish/cuisine	[O] dish [S]
airliner_accident/flight_origin	[S] was flight from [O]
film_featured_song/performer	[S] is release by [O]
airline_accident/operator	[S] was accident for [O]
genre/artists	[S] became a genre of [O]
risk_factor/diseases	[S] increases likelihood of [O]
book/illustrations_by	[S] illustrated by [O]
religious_text/religion	[S] contains principles of [O]
spacecraft/manufacturer	[S] spacecraft developed by [O]

Table 2: Table showing an example of textual contexts extracted for freebase predicates

Sub-Type and Obj-Type textual contexts: We use the labels of the entity types as the sub-type and obj-type textual contexts. We collect the list of entity types of each entity in the FB5M through the predicate `fb:type/instance`. If an entity has multiple entity types we pick the entity type that is mentioned the most in the first sentence of each Wikipedia article. Thus the textual contexts will opt for entity types that is more natural to appear in free text and therefore questions.

4.2 Generation of Special tokens

To generate the special tokens for copy actions (sec. 3.5) we run POS tagging on each of the input textual contexts[3]. We replace every word in each textual context with a combination of its context id (e.g. `C1`) and its POS tag (e.g. `NOUN`). If the same POS tag appears multiple times in the textual context, it is given an additional id (e.g. `C1_NOUN_2`). If a word in the output question overlaps with a word in the input textual context, this word is replaced by its corresponding tag.
For sentence and word tokenization we use the Regex tokenizer from the NLTK toolkit (Bird, 2006), and for POS tagging and dependency pars-

[2] We map Freebase entities to Wikidata through the Wikidata property P646, then we extract their labels and aliases. We use the Wikidata truthy dump: `https://dumps.wikimedia.org/wikidatawiki/entities/`

[3] For the predicate textual contexts we run pos tagging on the original text not the lexicalized dependency path

		Train	Valid	Test

ing we use the Spacy[4] implementation.

5 Experiments

5.1 Zero-Shot Setups

We develop three setups that follow the same procedure as (Levy et al., 2017) for Zero-Shot relation extraction to evaluate how our model generalizes to: 1) unseen predicates, 2) unseen sub-types and 3) unseen obj-types.

For the unseen predicates setup we group all the samples in SimpleQuestions by the predicate of the input triple, and keep groups that contain at least 50 samples. Afterwards we randomly split those groups to 70% train, 10% valid and 20% test mutual exclusive sets respectively. This guarantees that if the predicate `fb:person/place_of_birth` for example shows during test time, the training and validation set will not contain any input triples having this predicate. We repeat this process to create 10 cross validation folds, in our evaluation we report the mean and standard deviation results across those 10 folds. While doing this we make sure that the number of samples in each fold – not only unique predicates – follow the same 70%, 30%, 10% distribution. We repeat the same process for the subject entity types and object entity types (answer types) individually. Similarly, for example in the unseen object-type setup, the question *"Which **artist** was born in Berlin?"* appearing in the test set means that, there is no question in the training set having an entity of type ***artist***. Table 3 shows the mean number of samples, predicates, sub-types and obj-types across the 10 folds for each experiment setup.

[4]https://spacy.io/

5.2 Baselines

`SELECT` is a baseline built from (Serban et al., 2016) and adapted for the zero shot setup. During test time given a fact F, this baseline picks a fact F_c from the training set and outputs the question that corresponds to it. For evaluating unseen predicates, F_c has the same answer type (obj-type) as F. And while evaluating unseen sub-types or obj-types, F_c and F have the same predicate.

`R-TRANSE` is an extension that we propose for `SELECT`. The input triple is encoded using the concatenation of the TransE embeddings of the subject, predicate and object. At test time, `R-TRANSE` picks a fact from the training set that is the closest to the input fact using cosine similarity and outputs the question that corresponds to it. We provide two versions of this baseline: **`R-TRANSE`** which indexes and retrieves raw questions with only a single placeholder for the subject label, such as in (Serban et al., 2016). And **`R-TRANSE`**$_{\texttt{copy}}$ which indexes and retrieves questions using our copy actions mechanism (sec. 3.5).

`IR` is an information retrieval baseline. Information retrieval has been used before as baseline for QG from text input (Rush et al., 2015; Du et al., 2017). We rely on the textual context of each input triple as the search keyword for retrieval. First, the IR baseline encodes each question in the training set as a vector of TF-IDF weights (Joachims, 1997) and then does dimensionality reduction through LSA (Halko et al., 2011). At test time the textual context of the input triple is converted into a dense vector using the same process and then the question with the closest cosine distance to the input is retrieved. We provide two versions of this baseline: **`IR`** on raw text and **`IR`**$_{\texttt{copy}}$ on text with our placeholders for copy actions.

`Encoder-Decoder.` Finally, we compare our model to the Encoder-Decoder model with a single placeholder, the best performing model from (Serban et al., 2016). We initialize the encoder with TransE embeddings and the decoder with GloVe word embeddings. Although this model was not originally built to generalize to unseen predicates and entity types, it has some generalization abilities represented in the encoded infor-

mation in the pre-trained embeddings. Pretrained KB terms and word embeddings encode relations between entities or between words as translations in the vector space. Thus the model might be able to map new classes or predicates in the input fact to new words in the output question.

5.3 Training & Implementation Details

To train the neural network models we optimize the negative log-likelihood of the training data with respect to all the model parameters. For that we use the RMSProp optimization algorithm with a decreasing learning rate of 0.001, mini-batch size $= 200$, and clipping gradients with norms larger than 0.1. We use the same vocabulary for both the textual context encoders and the decoder outputs. We limit our vocabulary to the top $30,000$ words including the special tokens. For the word embeddings we chose GloVe (Pennington et al., 2014) pretrained embeddings of size 100. We train TransE embeddings of size $H_k = 200$, on the FB5M dataset (Bordes et al., 2015) using the TransE model implementation from (Lin et al., 2015). We set GRU hidden size of the decoder to $H_d = 500$, and textual encoder to $H_c = 200$. The networks hyperparameters are set with respect to the final BLEU-4 score over the validation set. All neural networks are implemented using Tensorflow (Abadi et al., 2015). All experiments and models source code are publicly available[5] for the sake of reproducibility.

5.4 Automatic Evaluation Metrics

To evaluate the quality of the generated question, we compare the original labeled questions by human annotators to the ones generated by each variation of our model and the baselines. We rely on a set of well established evaluation metrics for text generation: BLEU-1, BLEU-2, BLEU-3, BLEU-4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and ROUGE_L (Lin, 2004).

5.5 Human Evaluation

Automatic Metrics for evaluating text generation such as BLEU and METEOR give an measure of how close the generated questions are to the target correct labels. However, they still suffer from many limitations (Novikova et al., 2017). Automatic metrics might not be able to evaluate directly whether a specific predicate was explicitly mentioned in the generated text or not.
As an example, taking a target question and two corresponding generated questions A and B:

	What kind of film is kill bill vol. 2?	**BLEU**
A)	**What is *the name of* the film kill bill vol. 2?**	71
B)	**Which genre is kill bill vol. 2 in?**	55

We can find that the sentence A having a better BLEU score than B although it is not able to express the correct target predicate (*film genre*). For that reason we decide to run two further human evaluations to directly measure the following:
Predicate identification: annotators were asked to indicate whether the generated question contains the given predicate in the fact or not, either directly or implicitly.
Naturalness: following (Ngomo et al., 2013), we measure the comprehensibility and readability of the generated questions. Each annotator was asked to rate each generated question using a scale from 1 to 5, where: (5) perfectly clear and natural, (3) artificial but understandable, and (1) completely not understandable. We run our studies on 100 randomly sampled input facts alongside with their corresponding generated questions by each of the systems using the help of 4 annotators.

6 Results & Discussion

Automatic Evaluation Table 4 shows results of our model compared to all other baselines across all evaluation metrics. Our that encodes the KB fact and textual contexts achieves a significant enhancement over all the baselines in all evaluation metrics, with $+\mathbf{2.04}$ BLEU-4 score than the Encoder-Decoder baseline. Incorporating the part-of-speech copy actions further improves this enhancement to reach $+\mathbf{2.39}$ BLEU-4 points.
Among all baselines, the Encoder-Decoder baseline and the R-TRANSE baseline performed the best. This shows that TransE embeddings encode intra-predicates information and intra-class-types information to a great extent, and can generalize to some extent to unseen predicates and class types.

Similar patterns can be seen in the evaluation on unseen sub-types and obj-types (Table 5). Our model with copy actions was able to outperform

all the other systems. Majority of systems have reported a significantly higher BLEU-4 scores in these two tasks than when generalizing to unseen predicates (+12 and +8 BLEU-4 points respectively). This indicates that these tasks are relatively easier and hence our models achieve relatively smaller enhancements over the baselines.

Human Evaluation Table 6 shows how different variations of our system can express the unseen predicate in the target question with comparison to the Encoder-Decoder baseline.
Our proposed copy actions have scored a significant enhancement in the identification of unseen predicates with up to +40% more than best performing baseline and our model version without the copy actions.

By examining some of the generated questions (Table 7) we see that models without copy actions can generalize to unseen predicates that only have a very similar freebase predicate in the training set. For example `fb:tv_program/language` and `fb:film/language`, if one of those predicates exists in the training set the model can use the same questions for the other during test time.
Copy actions from the sub-type and the obj-type textual contexts can generalize to a great extent to unseen predicates because of the overlap between the predicate and the object type in many questions (Example 2 Table 7). Adding the predicate context to our model has enhanced model performance for expressing unseen predicates by +9% (Table 6). However we can see that it has affected the naturalness of the question. The post processing step does not take into consideration that some verbs and prepositions do not fit in the sentence structure, or that some words are already existing in the question words (Example 4 Table 7). This does not happen as much when having copy actions from the sub-type and the obj-type contexts because they are mainly formed of nouns which are more interchangeable than verbs or prepositions. A post-processing step to reform the question instead of direct copying from the input source is considered in our future work.

7 Conclusion

In this paper we presented a new neural model for question generation from knowledge bases, with a main focus on predicates, subject types or object types that were not seen at the training phase (Zero-Shot Question Generation). Our model is based on an encoder-decoder architecture that leverages textual contexts of triples, two attention layers for triples and textual contexts and

finally a part-of-speech copy action mechanism. Our method exhibits significantly better results for Zero-Shot QG than a set of strong baselines including the state-of-the-art question generation from KB. Additionally, a complimentary human evaluation, helps in showing that the improvement brought by our part-of-speech copy action mechanism is even more significant than what the automatic evaluation suggests. The source code and the collected textual contexts are provided for the community [6]

Abstract

Studies in Social Sciences have revealed that when people evaluate someone else, their evaluations often reflect their biases. As a result, rater bias may introduce highly subjective factors that make their evaluations inaccurate. This may affect automated essay scoring models in many ways, as these models are typically designed to model (potentially biased) essay raters. While there is sizeable literature on rater effects in general settings, it remains unknown how rater bias affects automated essay scoring. To this end, we present a new annotated corpus containing essays and their respective scores. Different from existing corpora, our corpus also contains comments provided by the raters in order to ground their scores. We present features to quantify rater bias based on their comments, and we found that rater bias plays an important role in automated essay scoring. We investigated the extent to which rater bias affects models based on hand-crafted features. Finally, we propose to rectify the training set by removing essays associated with potentially biased scores while learning the scoring model.

1 Introduction

Automated Essay Scoring (AES) aims at developing models that can grade essays automatically or with reduced involvement of human raters (Page, 1967). AES systems may rely not only on grammars, but also on more complex features such as semantics, discourse and pragmatics (Davis and Veloso, 2016; Song et al., 2014; Farra et al., 2015; Somasundaran et al., 2014). Thus, a prominent approach to AES is to learn scoring models from previously graded samples, by modeling the scoring process of human raters. When given the same set of essays to evaluate and enough graded samples, AES systems tend to achieve high agreement levels with trained human raters (Taghipour and Ng, 2016).

While research in AES has focused on designing scoring models that maximize the agreement with human raters(Chen and He, 2013; Alikaniotis et al., 2016), there is a lack of discussion on how biased are human ratings. Despite making judgments on a common dimension, raters may be influenced by their attitudes, their cultural background, and their political and economic views (Guerra et al., 2011). Since AES models are designed to learn by analyzing human-graded essays, AES models could inherit rating biases present in the scores from human raters, and this may result in systematic errors. Thus, our objective in this paper is to examine the extent to which rater bias affects the effectiveness of state-of-the-art AES models. A deeper understanding of such factors may help mitigating the effects of rater bias, enabling AES models to achieve greater objectivity.

In order to study the effects of rater bias in essay scoring, we created an annotated corpus containing essays written by high school students as part of a standardized Brazilian national exam. Our corpus contains a number of essays, written in Portuguese, along with their respective scores. Further, raters must also provide a comment for each essay in order to ground their scores. As in (Recasens et al., 2013) we built subjectivity and sentiment lexicons that serve as features to represent the comments, that is, rater comments are represented according to the subjectivity distribution as given by specific subjectivity cues in our lexicons. We present empirical evidence suggesting that the subjectivity distribution within rater comment is a proxy for the score that is given to the essay. More specifically, very low (or very high) scores are associated with essays for which rater comments showed a very particular subjectivity distribution. We also investigated the relationship be-

Proceedings of NAACL-HLT 2018, pages 229–237
New Orleans, Louisiana, June 1 - 6, 2018.

tween subjectivity distribution and the misalignment between human raters and AES models. Interestingly, the subjectivity distribution becomes very characteristic as the misalignment increases.

Our main contributions are three-fold:

- We built subjectivity lexicons for the Portuguese language. These lexicons include words and phrases associated with different subjectivity dimensions – sentiments, factive verbs, entailments, intensifiers and hedges. We identify biased language within rater comments by calculating the word mover's distance (Kusner et al., 2015) between comments and the lexicons. This approach benefits from large unsupervised corpora, that can be used to learn effective word embeddings (Mikolov et al., 2013). By identifying biased language, we observed that biases can work to inflate essay scores or to deflate them.

- We employ a set of linguistic features in order to learn different AES models, and we evaluate the effects of biased ratings in the efficacy of these models. In summary, biased ratings affect AES models in different ways, but in general the misalignment between human rater and the AES model is more acute when the rater shows biased language in their comments.

- We propose simple ways of preventing and reducing the negative effects of biased ratings while learning AES models. Results in a controlled experimental setting revealed that detecting and removing biased ratings from the training set lead to significant improvements in automated essay scoring.

In the remainder of this paper, Section 2 discusses related work on automated essay scoring. Section 3 describes the features used for learning AES models, as well as the features used for identifying biased language in rater comments. Further, our debiasing approach is also discussed in Section 3. Section 4 describes the data, the setup and the results of our empirical evaluation. Finally, Section 5 provides our conclusions.

2 Related Work

Research in cognitive science, psychology and other social studies offer a great amount of work on (conscious and unconscious) biases and their effects on a variety of human activities (Kaheman and Tversky, 1972; Tversky and Kaheman, 1974). Biases can create situations that lead us to make decisions that project our experiences and values onto others (Baron, 2007; Ariely, 2008). While there is sizeable literature on rater effects in general settings (Myford and Wolfe, 2003), it remains unknown how biased ratings affect automated essay scoring models. Rather, works on automated essay scoring are mainly focused on designing AES models by maximizing the agreement with human raters, despite the assertiveness of the ratings.

Typically, AES systems are built on the basis of predefined linguistic features that are then given to a machine learning algorithm (Amorim and Veloso, 2017). Works that fall into this approach include (Srihari et al., 2008, 2007; Cummins et al., 2016; McNamaraa et al., 2015). Further, authors in (Dong and Zhang, 2016) presented an empirical analysis of features typically used for learning AES models. Authors in (Crossley et al., 2015) studied a broader category of features that can also be used to build AES models. There are also more recent approaches for learning AES models that do not assume a set of predefined features. These approaches are based on deep architectures, and include (Alikaniotis et al., 2016; Taghipour and Ng, 2016; Riordan et al., 2017; Dong et al., 2017). Finally, there also models based on domain adaptation (Phandi et al., 2015) and unsupervised learning (Chen et al., 2010).

Few works have investigated the subjective nature of essay scoring. An interesting exception is (Allen et al., 2015), in which the authors investigated the misalignment between students' and teachers' ratings of essay. Results revealed that students who were less accurate in their self-assessments produced essays that were more causal, contained less meaningful words, and had less argument overlap between sentences.

The work in this paper builds upon prior work on building subjectivity lexicons (Klebanov et al., 2012) and subjectivity detection (Recasens et al., 2013), but in our case applied to score agreement. In this respect, our work is more comparable to (Klebanov and Beigman, 2009; Beigman and Klebanov, 2009), where authors discussed and investigated the problem of learning in the presence of biased annotators. Other works that are also

close to ours include (Farra et al., 2015; Somasundaran et al., 2016; Song et al., 2014), in which the authors studied the problem of scoring persuasive and argumentative essays.

3 Method

Our aim in this work is to learn AES models that are less prone to the effects of biased ratings, that is, models that are able to perform highly objective and impartial judgements. Thus, we start this section by proposing features that are useful for building AES models. Then, we propose another set of features that are useful for identifying biased ratings based on subjectivity cues. Finally, we propose an approach to remove biased ratings from the training set, thus learning more objective AES models.

3.1 Features for Essay Scoring

As most existing AES systems, our models are built on the basis of predefined features (e.g. number of words, average word length, and number of spelling errors) that are given to a machine learning algorithm. The features used to build our AES models are discussed and evaluated in (Amorim and Veloso, 2017). They may fall into two broad categories:

Domain features: These are simple linguistic features, including the number of first-person pronouns, demonstrative pronouns and verbs. Features also include the number of pronouns and verbs normalized by the number of tokens in the corresponding sentence.

General features: Most of the general features are based on (Attali and Burstein, 2006). However, due to lack of tools for processing the Portuguese language, we implemented the following features, which are sub-divided as follows:

Grammar and style: Features include the number of grammar errors and misspellings. These numbers are also normalized by the number of tokens in the corresponding sentence. In order to evaluate style, we designed features based on the style rules suggested in (Martins, 2000). Features include the number of style errors and the number of style of errors per sentence.

Organization and development: Features include the number of discourse markers from the Portuguese grammar, and the number of discourse markers per sentence. Discourse markers are linguistic units that establish connections between sentences to build coherent and knit discourse.

Lexical complexity: Features include the Portuguese version for the Flesh score (Martins et al., 1996), the average word length (i.e., the number of syllables), the number of tokens in an essay, and the number of different words in an essay.

Prompt-specific vocabulary usage: Features include different distances between prompt and essay (i.e., cosine distance). In this case, both the prompt and the essay are treated as frequency vectors of words.

3.2 Features for Identifying Biased Ratings

We assume a scenario in which essay raters must ground the provided scores with specific comments. We also assume that we can identify biased ratings by detecting comments with biased language. In order to detect biased language, we developed subjectivity lexicons for the Portuguese language. Specifically, a linguist built a list of Portuguese lexicons based on the analysis of expressions that seem to express some subjectivity of the human evaluator. Our subjectivity lexicons are categorized into the following groups:

Argumentation: This lexicon includes markers of argumentative discourse. Argumentative markers include lexical expressions and connectives, such as: "even" (*até*), "by the way" (*aliás*), "as a consequence" (*como consequência*), "or else" (*ou então*), "as if" (*como se*), "rather than" (*em vez de*), "somehow" (*de certa forma*), "despite" (*apesar de*), among others.

Presupposition: This lexicon includes markers that suggest the rater assumes something is true. Some examples of such markers include: "nowadays" (*hoje em dia*), "to keep on doing" (*continuar a*), and factive verbs.

Modalization: This lexicon indicates that the writer exhibits a stance towards its own state-

ment. Some examples of such markers are adverbs, auxiliary verbs, modality clauses, and some type of verbs.

Sentiment: This lexicon also includes markers that indicate a state of mind or a sentiment of the rater while evaluating the essay. Some examples of such markers include: "with regret" (*infelizmente*), "with pleasure" (*felizmente*), and "it is preferable" (*preferencialmente*).

Valuation: This lexicon assigns a value to facts. Usually, adjectives are employed as valuation, but as adjectives are context dependent we use only in this class the markers related to intensification, such as: "absolutely" (*absolutamente*), "highly" (*altamente*), and "approximately" (*aproximadamente*).

3.3 Debiasing the Training Set

Bias is generally defined as a deviation from a norm. If the norm is unknown to us, then bias is hard to identify. Thus, our approach for debiasing the training set starts by finding the norm (in terms of the subjectivity within rater comments) for each score value. Intuitively, the amount of subjectivity within a comment should be similar to the amount of subjectivity within another comment, given that the scores associated with the corresponding essays are close to each other. So, we should not expect to find essays having discrepant scores, but for which the corresponding comments show a similar amount of subjectivity. Our debiasing approach is divided into three steps:

1. Rater comments are represented according to the amount of subjectivity cues. In order to represent a comment, we calculate the distance between it and each of the five subjectivity lexicons. More specifically, we learn word embeddings (Mikolov et al., 2013) for the Portuguese language, and then we employed the Word Mover's Distance function (Kusner et al., 2015) between a comment and the five subjectivity lexicons. As a result, each comment is finally represented by a five-dimensional subjectivity vector, where each dimension corresponds to the amount of a specific type of subjectivity. This results in a subjectivity space, where comments are placed according to their amount of subjectivity.

2. We group subjectivity vectors according to the score misalignment associated with the corresponding essay. Then, we calculate centroids for each group in order to find the prototypical subjectivity vector for each group (or misalignment level).

3. The distance to the prototypical subjectivity vector is used as a measure of deviation from the norm. Specifically, we sort essays according to the distance between the subjectivity vector and the corresponding centroid. Then, we define a number of essays to be removed from the training set. The relative number of essays to be removed from the training set is controlled by hyper-parameter α.

4 Experiments

In this section, we present the data we used to learn and evaluate different AES models. Then, we discuss our evaluation procedure and report the results obtained with our debiasing approach. In particular, our experiments aim to answer the following research questions:

RQ1: How scores are distributed across the essays? How aligned with human raters are different AES models?

RQ2: Does subjectivity in rater comments vary depending on the given score?

RQ3: Does subjectivity in rater comments vary depending on the misalignment between the AES model and the human rater?

RQ4: Can we mitigate the effects of biased ratings?

4.1 Corpus

Our corpus is composed of essays ($n = 1,840$) that were written by high-school students as part of a standardized Brazilian national exam. Each essay is evaluated according to the following five objective aspects:

Formal language: Mastering of the formal Portuguese language.

Relevance to the prompt: Understanding of essay prompt and application of concepts from different knowledge fields, to develop the theme in an argumentative dissertation format.

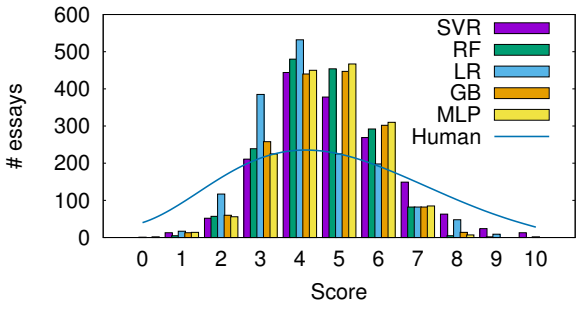

Figure 1: Distribution of the scores given by human raters. Also, distribution of the scores given by different AES models.

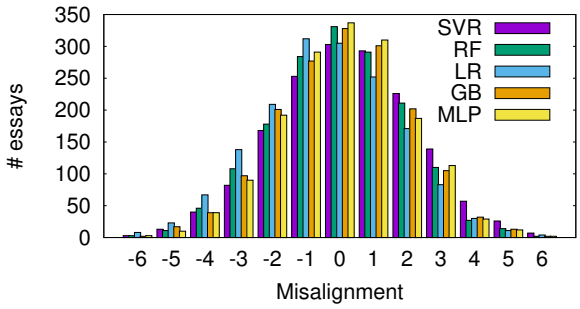

Figure 2: Distribution of misalignment for the different AES models.

Organization of information: Selecting, connecting, organizing, and interpreting information.

Argumentation: Demonstration of knowledge of linguistic mechanisms required to construct arguments.

Solution proposal: Formulation of a proposal to the problem presented.

The final score is given as the sum of the scores associated with each aspect. Raters are supposed to perform impartial and objective evaluations, and they must enter specific comments in order to ground their scores. Also, each essay was assessed by one rater.

Bias-free ratings: We also separate a number of essays ($n = 50$) which received similar scores by three expert raters who were directly instructed to perform impartial, objective, and unbiased evaluations. These raters are PhD-level in Linguistics with unlimited time to provide their ratings, and they do not participate on the creation of the training set. We assume the ratings given to these essays were not contaminated by biased judgements, and we will use these essays for evaluating the efficacy of AES models learned after the training set is debiased.

4.2 Setup

We implemented the different AES models using scikit-learn (Pedregosa et al., 2011). Specifically, we learn AES models using Support Vector Regression (SVR), Random Forests (RF), Logistic Regression (LR), Gradient Boosting (GB), and Multi-Layer Perceptron (MLP). All models are based on the same set of features, previously described in Section 3.1, and all models are trained in regression mode. The measure used to evaluate the effectiveness of the different models is the quadratic weighted kappa (κ) which measures the inter-agreement between human raters and AES models (Cohen, 1960). We conducted five-fold cross validation, where the dataset is arranged into five folds with approximately the same number of examples. At each run, four folds are used as training set, and the remaining fold is used as test set. We also kept a separate validation set. The training set is used to learn the models, the validation set is used to tune hyper-parameters and the test set is used to estimate κ numbers for the different the models. Unless otherwise stated, the results reported are the average of the five runs, and are used to assess the overall effectiveness of each model. To ensure the relevance of the results, we assess the statistical significance of our measurements by comparing each pair of models using a Welch's t-test with $\text{p}-\text{value} \leq 0.01$.

4.3 Results and Discussion

Next we report results obtained from the execution of the experiments, and discuss these results in the light of our research questions.

Score distribution: The first experiment is concerned with RQ1. Figure 1 shows how scores are distributed over the essays in our corpus. Although the distribution differs for each AES model, scores are centered around 4, and few essays received extreme scores. The LR model seems to have a preference for lower scores. The scores provided by the GB and MLP models are better distributed.

Figure 2 shows how aligned with human raters are the different AES models. For most of the essays, AES models are well aligned with human

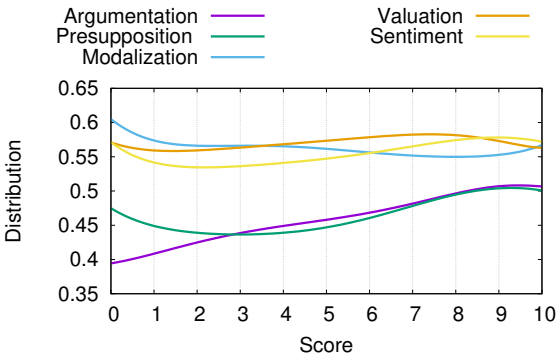

Figure 3: Subjectivity distribution for human raters.

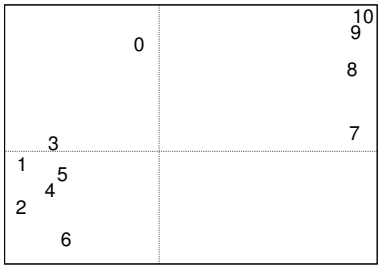

Figure 4: t-SNE representation for subjectivity vectors. Numbers correspond to the scores assigned to corresponding essays.

raters, showing misalignments that vary from -2 to $+2$. For some essays, the LR model tends to give scores that are much smaller than the score given by the human rater. The GB and MLP models perform very similary, but the MLP model shows a slightly better alignment.

Subjectivity vectors and biased ratings: The second experiment is concerned with RQ2. Figure 3 shows the average subjectivity vector grouped according to the score given to the corresponding essay (i.e., the centroid or prototypical vector of a score). More specifically, we first grouped subjectivity vectors according to the score associated with the corresponding essay, and then we calculated the average subjectivity vector for each group. As shown in Figure 3, the argumentation dimension increases with the score, while modalization tends to decrease. Presupposition, valuation and sentiment dimensions show a very similar trend with varying score values.

Figure 4 shows t-SNE representations (van ter Maaten and Hinton, 2008) for the average subjectivity vectors (centroids for each group of score). Three larger clusters emerged: subjectivity vectors associated with score 0, subjectivity vectors associated with scores between 1 and 6, and subjectivity vectors associated with scores between 6 and 10.

Subjectivity vectors and misalignment: The third experiment is concerned with RQ3. Figure 5 shows the average subjectivity vector considering different levels of misalignment. More specifically, we grouped essays according to the misalignment between the score provided by the AES model and the human rater. Then, we calculated the average subjectivity vector for each group. As we can see, subjectivity affects AES models in different ways. In general, however, subjectivity vectors within groups of essays associated with extreme misalignments are very different from subjectivity vectors associated with mild misalignments.

Figure 6 shows t-SNE representations for subjectivity vectors grouped by misalignment levels. Each cluster contains $\approx 80\%$ of the vectors associated with one of the misalignment levels inside the cluster. That is, 20% of the essays will be removed from the training set (i.e., $\alpha = 0.2$).

Debiasing the training set: The last experiment is concerned with RQ4. As described in Section 3.3, our debiasing approach works by removing from the training set a number of essays (controlled by α) that are more likely to be associated with biased ratings. Table 1 shows κ numbers for different α values. Clearly, the inter-agreement decreases as we remove essays with potentially biased ratings from the training set. This happens because the test set remains with essays that are potentially associated with biased ratings. In this case, removing biased ratings from the training set is always detrimental to the efficacy of AES models.

In order to properly evaluate our debiasing approach, we employ the 50 separate essays with bias-free ratings as our test set. In this case, biased ratings are removed from the training set, and the test set is composed by unbiased ratings. Table 2 shows κ numbers for different α values. As expected, the inter-agreement increases significantly with α, until a point in which keeping removing essays from the training set becomes detrimental. This happens either because we start to remove unbiased ratings, or the training set becomes too small. In all cases, the MLP model showed to be

statistically superior than the other models.

5 Conclusions

In this paper, we investigated the problem of automated essay scoring in the presence of biased ratings. Most of the existing work on automated essay scoring is devoted to maximize the agreement with the human rater. This is fairly dangerous, since human ratings may be biased. Overall, discussion about the quality of the ratings in automated essay scoring is lacking, and this was a central interest in this paper. Specifically, we create a subjectivity space from which potentially biased scores/ratings can be identified. We showed that removing biased scores from the training set results in improved AES models. Finally, the essay data as well as the subjectivity lexicons that we will release as part of this research could prove useful in other bias related tasks.

Abstract

We present a content-based method for recommending citations in an academic paper draft. We embed a given query document into a vector space, then use its nearest neighbors as candidates, and rerank the candidates using a discriminative model trained to distinguish between observed and unobserved citations. Unlike previous work, our method does not require metadata such as author names which can be missing, e.g., during the peer review process. Without using metadata, our method outperforms the best reported results on PubMed and DBLP datasets with relative improvements of over 18% in F1@20 and over 22% in MRR. We show empirically that, although adding metadata improves the performance on standard metrics, it favors self-citations which are less useful in a citation recommendation setup. We release an online portal for citation recommendation based on our method,[1] and a new dataset `OpenCorpus` of 7 million research articles to facilitate future research on this task.

1 Introduction

Due to the rapid growth of the scientific literature, conducting a comprehensive literature review has become challenging, despite major advances in digital libraries and information retrieval systems. Citation recommendation can help improve the quality and efficiency of this process by suggesting published scientific documents as likely citations for a query document, e.g., a paper draft to be submitted for ACL 2018. Existing citation recommendation systems rely on various information of the query documents such as author names and publication venue (Ren et al., 2014; Yu et al., 2012), or a partial list of citations provided by the author (McNee et al., 2002; Liu et al., 2015; Jia and Saule, 2017) which may not be available, e.g., during the peer review process or in the early stage of a research project.

Our method uses a neural model to embed all available documents into a vector space by encoding the textual content of each document. We then select the nearest neighbors of a query document as candidates and rerank the candidates using a second model trained to discriminate between observed and unobserved citations. Unlike previous work, we can embed new documents in the same vector space used to identify candidate citations based on their text content, obviating the need to re-train the models to include new published papers. Further, unlike prior work (Yang et al., 2015; Ren et al., 2014), our model is computationally efficient and scalable during both training and test time.

We assess the feasibility of recommending citations when some metadata for the query document is missing, and find that we are able to outperform the best reported results on two datasets while only using papers' textual content (i.e. its title and abstract). While adding metadata helps further improve the performance of our method on standard metrics, we found that it introduces a bias for self-citation which might not be desirable in a citation recommendation system. See §5 for details of our experimental results.

Our main contributions are:

- a content-based method for citation recommendation which remains robust when metadata are missing for query documents,
- large improvements over state of the art results on two citation recommendation datasets despite omitting the metadata,
- a new dataset of seven million research papers, addressing some of the limitations in

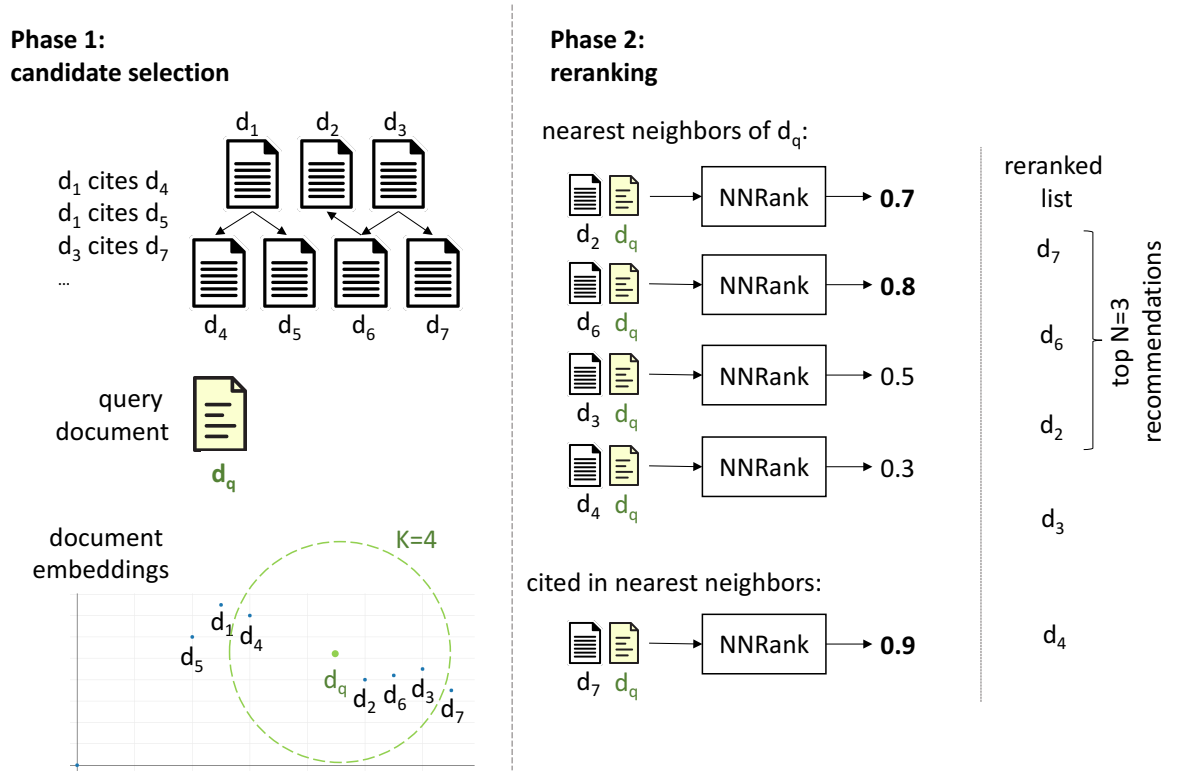

Figure 1: An overview of our Citation Recommendation system. In Phase 1 (`NNSelect`), we project all documents in the corpus (7 in this toy example) in addition to the query document d_q into a vector space, and use its (K=4) nearest neighbors: d_2, d_6, d_3, and d_4 as candidates. We also add d_7 as a candidate because it was cited in d_3. In Phase 2 (`NNRank`), we score each pair $(d_q, d_2), (d_q, d_6), (d_q, d_3), (d_q, d_4)$, and (d_q, d_7) separately to rerank the candidates and return the top 3 candidates: d_7, d_6 and d_2.

previous datasets used for citation recommendation, and

- a scalable web-based literature review tool based on this work.[2]

2 Overview

We formulate citation recommendation as a ranking problem. Given a query document d_q and a large corpus of published documents, the task is to rank documents which should be referenced in d_q higher than other documents. Following previous work on citation recommendation, we use standard metrics (precision, recall, F-measure and mean reciprocal rank) to evaluate our predictions against gold references provided by the authors of query documents.

Since the number of published documents in the corpus can be large, it is computationally expensive to score each document as a candidate reference with respect to d_q. Instead, we recommend citations in two phases: (i) a fast, recall-oriented candidate selection phase, and (ii) a feature rich, precision-oriented reranking phase. Figure 1 provides an overview of the two phases using a toy example.

Phase 1 - Candidate Selection: In this phase, our goal is to identify a set of candidate references for d_q for further analysis without explicitly iterating over all documents in the corpus.[3] Using a trained neural network, we first project all published documents into a vector space such that a document tends to be close to its references. Since the projection of a document is independent of the query document, the entire corpus needs to be embedded only once and can be reused for subsequent queries. Then, we project each query document d_q to the same vector space and identify its nearest neighbors as candidate references. See §3 for more details about candidate selection.

[2] https://github.com/allenai/citeomatic

[3] In order to increase the chances that all references are present in the list of candidates, the number of candidates must be significantly larger than the total number of citations of a document, but also significantly smaller than the number of documents in the corpus.

Phase 2 - Reranking: Phase 1 yields a manageable number of candidates making it feasible to score each candidate d_i by feeding the pair (d_q, d_i) into another neural network trained to discriminate between observed and unobserved citation pairs. The candidate documents are sorted by their estimated probability of being cited in d_q, and top candidates are returned as recommended citations. See §4 for more details about the reranking model and inference in the candidate selection phase.

3 Phase 1: Candidate Selection (`NNSelect`)

In this phase, we select a pool of candidate citations for a given query document to be reranked in the next phase. First, we compute a dense embedding of the query document d_q using the document embedding model (described next), and select K nearest neighbor documents in the vector space as candidates.[4] Following Strohman et al. (2007), we also include the outgoing citations of the K nearest neighbors as candidates.

The output of this phase is a list of candidate documents d_i and their corresponding scores $\texttt{NNSelect}(d_q, d_i)$, defined as the cosine similarity between d_q and d_i in the document embedding space.

Document embedding model. We use a supervised neural model to project any document d to a dense embedding based on its textual content. We use a bag-of-word representation of each textual field, e.g., $d[\text{title}] = \{\text{'content-based'}, \text{'citation'}, \text{'recommendation'}\}$, and compute the feature vector:

$$\mathbf{f}_{d[\text{title}]} = \sum_{t \in d[\text{title}]} w_t^{\text{mag}} \frac{\mathbf{w}_t^{\text{dir}}}{\|\mathbf{w}_t^{\text{dir}}\|_2}, \quad (1)$$

where $\mathbf{w}_t^{\text{dir}}$ is a dense direction embedding and w_t^{mag} is a scalar magnitude for word type t.[5] We then normalize the representation of each field and compute a weighted average of fields to get the document embedding, $\mathbf{e}_d$. In our experiments, we use the title and abstract fields of a document d:

$$\mathbf{e}_d = \lambda^{\text{title}} \frac{\mathbf{f}_{d[\text{title}]}}{\|\mathbf{f}_{d[\text{title}]}\|_2} + \lambda^{\text{abstract}} \frac{\mathbf{f}_{d[\text{abstract}]}}{\|\mathbf{f}_{d[\text{abstract}]}\|_2},$$

where λ^{title} and $\lambda^{\text{abstract}}$ are scalar model parameters.

Training. We learn the parameters of the document embedding model (i.e., $\lambda^*, w_*^{\text{mag}}, \mathbf{w}_*^{\text{dir}}$) using a training set $\mathcal{T}$ of triplets $\langle d_q, d^+, d^- \rangle$ where d_q is a query document, d^+ is a document cited in d_q, and d^- is a document not cited in d_q. The model is trained to predict a high cosine similarity for the pair (d_q, d^+) and a low cosine similarity for the pair (d_q, d^-) using the per-instance triplet loss (Wang et al., 2014):

$$\text{loss} = \max\big(\alpha + s(d_q, d^-) - s(d_q, d^+), 0\big), \quad (2)$$

where $s(d_i, d_j)$ is defined as the cosine similarity between document embeddings $\text{cos-sim}(\mathbf{e}_{d_i}, \mathbf{e}_{d_j})$. We tune the margin α as a hyperparameter of the model (see Appendix B for more details). Next, we describe how negative examples are selected.

Selecting negative examples. Defining positive examples is straight-forward; we use any (d_q, d^+) pair where a document d_q in the training set cites d^+. However, a careful choice of negative training examples is critical for model performance. We use three types of negative examples:

1. **Random:** any document not cited by d_q.
2. **Negative nearest neighbors:** documents that are close to d_q in the embedding space, but are not cited in it.[6]
3. **Citation-of-citation:** documents referenced in positive citations of d_q, but are not cited directly in d_q.

Negative examples belong to at least one of these types that serve different, and complementary purposes. Selecting a paper from the corpus at random as a negative example typically results in easy negative examples. Selecting nearest neighbor documents in the embedding space used for candidate selection enables the re-ranking phase (described in §4) to fix some of the mistakes made in the candidate selection step. Finally, using citations-of-citations as negative examples is based on the assumption that the authors would have included them as positive examples if they were relevant for the query paper. In Appendix §A, we describe the number of negative examples of each type used for training. Next, we describe how to rerank the candidate documents.

[4] We tune K as a hyperparameter of our method.

[5] The magnitude-direction representation is based on Salimans and Kingma (2016) and was found to improve results in preliminary experiments, compared to the standard "direction-only" word representation.

[6] Since the set of approximate neighbors depend on model parameters, we recompute a map from each query document to its K nearest neighbors before each epoch while training the document embedding model.

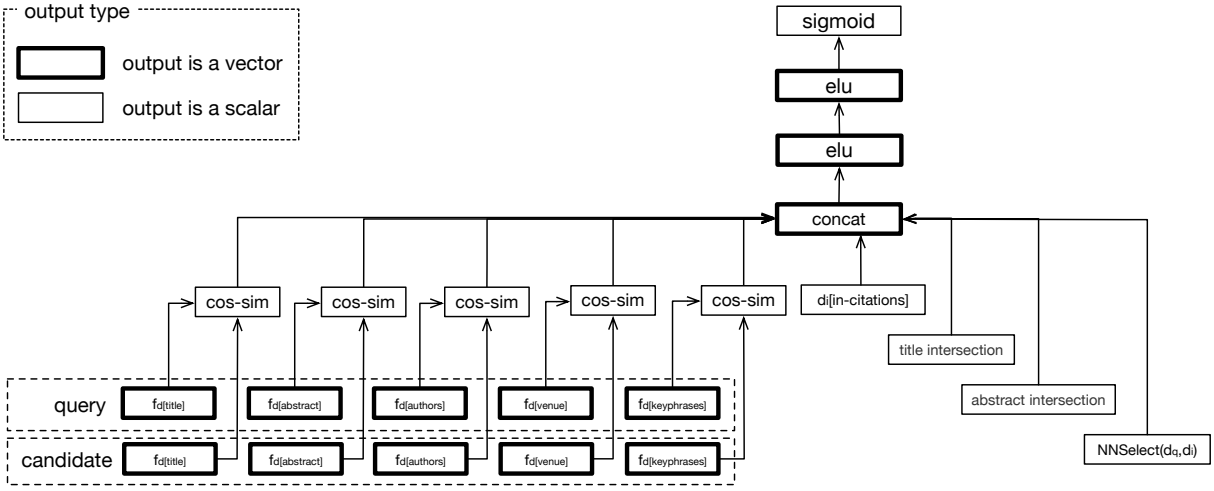

Figure 2: NNRank architecture. For each of the textual and categorical fields, we compute the cosine similarity between the embedding for d_q and the corresponding embedding for d_i. Then, we concatenate the cosine similarity scores, the numeric features and the summed weights of the intersection words, followed by two dense layers with ELU non-linearities The output layer is a dense layer with sigmoid non-linearity, which estimates the probability that d_q cites d_i.

4 Phase 2: Reranking Candidates (NNRank)

In this phase, we train another model which takes as input a pair of documents (d_q, d_i) and estimates the probability that d_i should be cited in d_q.

Input features. A key point of this work is to assess the feasibility of recommending citations without using metadata, but we describe all features here for completeness and defer this discussion to §5. For each document, we compute dense feature vectors $\mathbf{f}_{d[\text{field}]}$ as defined in Eq. 1 for the following fields: title, abstract, authors, venue and keyphrases (if available). For the title and abstract, we identify the subset of word types which appear in both documents (intersection), and compute the sum of their scalar weights as an additional feature, e.g., $\sum_{t \in \cap \text{title}} w_t^{\cap}$. We also use *log* number of times the candidate document d_i has been cited in the corpus, i.e., $log(d_i[\text{in-citations}])$. Finally, we use the cosine similarity between d_q and d_i in the embedding space, i.e., cos-sim$(\mathbf{e}_{d_q}, \mathbf{e}_{d_i})$.

Model architecture. We illustrate the NNRank model architecture in Figure 2. The output layer is defined as:

$$s(d_i, d_j) = \text{FeedForward}(\mathbf{h}), \quad (3)$$

$$\mathbf{h} = \Big[\mathbf{g}_{\text{title}}; \mathbf{g}_{\text{abstract}}; \mathbf{g}_{\text{authors}}; \mathbf{g}_{\text{venue}}; \mathbf{g}_{\text{keyphrases}}; \text{cos-sim}(\mathbf{e}_{d_q}, \mathbf{e}_{d_i}); \textstyle\sum_{t \in \cap_{\text{title}}} w_t^{\cap}; \sum_{t \in \cap_{\text{abstract}}} w_t^{\cap}; d_i[\text{in-citations}]\Big],$$

$$\mathbf{g}_{\text{field}} = \text{cos-sim}(\mathbf{f}_{d_q[\text{field}]}, \mathbf{f}_{d_i[\text{field}]}),$$

where 'FeedForward' is a three layer feed-forward neural network with two exponential linear unit layers (Clevert et al., 2015) and one sigmoid layer. ';' indicates concatenation.

Training. The parameters of the NNRank model are $w_*^{\text{mag}}, \mathbf{w}_*^{\text{dir}}, w_*^{\cap}$ and parameters of the three dense layers in 'FeedForward'. We reuse the triplet loss in Eq. 2 to learn these parameters, but redefine the similarity function $s(d_i, d_j)$ as the sigmoid output described in Eq. 3.

At test time, we use this model to recommend candidates d_i with the highest $s(d_q, d_i)$ scores.

5 Experiments

In this section, we describe experimental results of our citation recommendation method and compare it to previous work.

Datasets. We use the DBLP and PubMed datasets (Ren et al., 2014) to compare with previous work on citation recommendation. The DBLP

dataset contains over 50K scientific articles in the computer science domain, with an average of 5 citations per article. The PubMed dataset contains over 45K scientific articles in the medical domains, with an average of 17 citations per article. In both datasets, a document is accompanied by its title, abstract, venue (i.e. journal or conference where the document was published), authors, citations (i.e. other documents in the corpus that are referenced in the given document) and keyphrases (i.e. phrases considered important by automated extraction methods). We replicate the experimental setup of Ren et al. (2014) by excluding papers with fewer than 10 citations and using the standard train, dev and test splits.[7]

We also introduce `OpenCorpus`,[8] a new dataset of 7 million scientific articles primarily drawn from the computer science and neuroscience domain. Due to licensing constraints, documents in the corpus do not include the full text of the scientific articles, but include the title, abstract, year, author, venue, keyphrases and citation information. The mutually exclusive training, development, and test splits were selected such that no document in the development or test set has a publication year less than that of any document in the training set. Papers with zero citations were removed from the development and test sets. We describe the key characteristics of `OpenCorpus` in Table 1.

Statistic	Value
# of documents in corpus	6.9 million
# of unique authors	8.3 million
# of unique keyphrases	823,677
# of unique venues	23,672
avg. # of incoming citations	7.4 ($\pm$ 38.1)
avg. # of outgoing citations	8.4 ($\pm$ 14.4)
size of training set [years 1991 to 2014]	5.5 million
size of dev set [years 2014 to 2015]	689,000
size of test set [years 2015 to 2016]	20,000

Table 1: Characteristics of the `OpenCorpus`.

Baselines. We compare our method to two baseline methods for recommending citations: ClusCite and BM25. ClusCite (Ren et al., 2014) clusters nodes in a heterogeneous graph of terms, authors and venues in order to find related documents which should be cited. We use the ClusCite results as reported in Ren et al. (2014), which compared it to several other citation recommendation methods and found that it obtains state of the art results on the PubMed and DBLP datasets. The BM25 results are based on our implementation of the popular ranking function Okapi BM25 used in many information retrieval systems. See Appendix §D for details of our BM25 implementation.

Evaluation. We use Mean Reciprocal Rank (MRR) and F1@20 to report the main results in this section. In Appendix §F, we also report additional metrics (e.g., precision and recall at 20) which have been used in previous work. We compute F1@20 as the harmonic mean of the corpus-level precision and recall at 20 (P@20 and R@20). Following (Ren et al., 2014), precision and recall at 20 are first computed for each query document then averaged over query documents in the test set to compute the corpus-level P@20 and R@20.

Configurations. To find candidates in `NNSelect`, we use the approximate nearest neighbor search algorithm `Annoy`[9], which builds a binary-tree structure that enables searching for nearest neighbors in $O(\log n)$ time. To build this tree, points in a high-dimensional space are split by choosing random hyperplanes. We use 100 trees in our approximate nearest neighbors index, and retrieve documents using the cosine distance metric.

We use the `hyperopt` library[10] to optimize various hyperparameters of our method such as size of hidden layers, regularization strength and learning rate. To ensure reproducibility, we provide a detailed description of the parameters used in both `NNSelect` and `NNRank` models, our hyperparameter optimization method and parameter values chosen in Appendix §A.

Main results. Table 2 reports the F1@20 and MRR results for the two baselines and three variants of our method. Since the `OpenCorpus` dataset is much bigger, we were not able to train the ClusCite baseline for it. Totti et al. (2016) have also found it difficult to scale up ClusCite to larger datasets. Where available, we report the mean $\pm$ standard deviation based on five trials.

The first variant, labeled "`NNSelect`," only uses the candidate selection part of our method (i.e., phase 1) to rank candidates by their cosine

[7] The dataset characteristics reported here are different from those in Table 3 in (Ren et al., 2014) because we report the size of the filtered datasets while they report the size of the datasets before filtering.

Method	DBLP		PubMed		OpenCorpus	
	F1@20	MRR	F1@20	MRR	F1@20	MRR
BM25	0.119	0.425	0.209	0.574	0.058	0.218
ClusCite	0.237	0.548	0.274	0.578	–	–
NNSelect	0.282±0.002	0.579±0.007	0.309±0.001	0.699±0.001	0.109	0.221
+ NNRank	0.302±0.001	0.672±0.015	0.325±0.001	0.754±0.003	**0.126**	0.330
+ metadata	**0.303**±0.001	**0.689**±0.011	**0.329**±0.001	**0.771**±0.003	0.125	**0.330**

Table 2: F1@20 and MRR results for two baselines and three variants of our method. BM25 results are based on our implementation of this baseline, while ClusCite results are based on the results reported in Ren et al. (2014). "NNSelect" ranks candidates using cosine similarity between the query and candidate documents in the embedding space (phase 1). "NNSelect + NNRank" uses the discriminative reranking model to rerank candidates (phase 2), without encoding any of the metadata features. "+ metadata" encodes the metadata features (i.e., keyphrases, venues and authors), achieving the best results on all datasets. Mean and standard deviations are reported based on five trials.

similarity to the query document in the embedding space as illustrated in Fig. 1. Although the document embedding space was designed to efficiently select candidates for further processing in phase 2, recommending citations directly based on the cosine distance in this space outperforms both baselines.

The second variant, labeled "NNSelect + NNRank," uses the discriminative model (i.e., phase 2) to rerank candidates selected by NNSelect, without encoding metadata (venues, authors, keyphrases). Both the first and second variants show that improved modeling of paper text can significantly outperform previous methods for citation recommendation, without using metadata.

The third variant, labeled "NNSelect + NNRank + metadata," further encodes the metadata features in the reranking model, and gives the best overall results. On both the DBLP and PubMed datasets, we obtain relative improvements over 20% (for F1@20) and 25% (for MRR) compared to the best reported results of ClusCite.

In the rest of this section, we describe controlled experiments aimed at analyzing different aspects of our proposed method.

Choice of negative samples. As discussed in §3, we use different types of negative samples to train our models. We experimented with using only a subset of the types, while controlling for the total number of negative samples used, and found that using negative nearest neighbors while training the models is particularly important for the method to work. As illustrated in Table 3, on the PubMed dataset, adding negative nearest neighbors while training the models improves the F1@20 score from 0.306 to 0.329, and improves the MRR score from 0.705 to 0.771. Intuitively, using nearest neighbor negative examples focuses training on the harder cases on which the model is more likely to make mistakes.

	F1@20	Δ	MRR	Δ
Full model	0.329		0.771	
without intersection	0.296	**0.033**	0.653	**0.118**
without -ve NNs	0.306	0.016	0.705	0.066
without numerical	0.314	0.008	0.735	0.036

Table 3: Comparison of PubMed results of the full model with model without (i) intersection features, (ii) negative nearest neighbors in training samples, and (iii) numerical features.

Valuable features. We experimented with different subsets of the optional features used in NNRank in order to evaluate the contribution of various features. We found intersection features, NNSelect scores, and the number of incoming citations to be the most valuable feature. As illustrated in Table 3, the intersection features improves the F1@20 score from 0.296 to 0.329, and the MRR score from 0.653 to 0.771, on the PubMed dataset. The numerical features (NNSelect score and incoming citations) improve the F1@20 score from 0.314 to 0.329, and improves the MRR score from 0.735 to 0.771. This shows that, in some applications, feeding engineered features to neural networks can be an effective strategy to improve their performance.

Performance across venues We studied the variability of performance of our model for papers from different venues. Figure 3 shows the F1@20 score of NNRank for papers belonging to the top

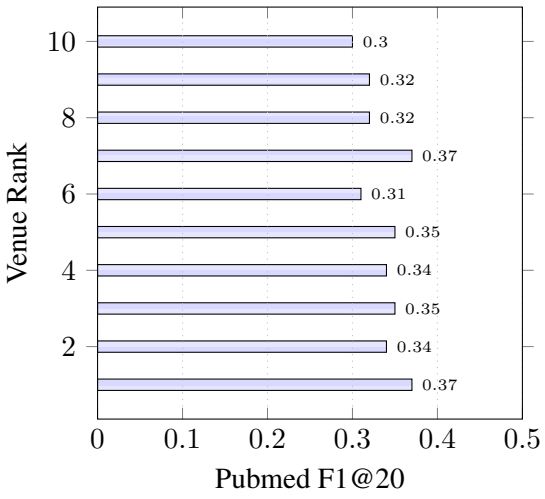

Figure 3: F1@20 of NNRank on the Pubmed dataset across top ten venues

ten venues (by their paper count) in the Pubmed corpus. NNRank's performance is robust across venues.

Encoding textual features. We also experimented with using recurrent and convolutional neural network to encode the textual fields of query and candidate documents, instead of using a weighted sum as described in Eq. 1. We found that recurrent and convolutional encoders are much slower, and did not observe a significant improvement in the overall performance as measured by the F1@20 and MRR metrics. This result is consistent with previous studies on other tasks, e.g., Iyyer et al. (2015).

Number of nearest neighbors. As discussed in §3, the candidate selection step is crucial for the scalability of our method because it reduces the number of computationally expensive pairwise comparisons with the query document at runtime. We did a controlled experiment on the OpenCorpus dataset (largest among the three datasets) to measure the effect of using different numbers of nearest neighbors, and found that both P@20 and R@20 metrics are maximized when NNSelect fetches five nearest neighbors using the approximate nearest neighbors index (and their out-going citations), as illustrated in Table 4.

Self-citation bias. We hypothesized that a model trained with the metadata (e.g., authors) could be biased towards self-citations and other well-cited authors. To verify this hypothesis, we compared two NNRank models – one with metadata, and one without. We measured the mean and max rank of predictions that had at least one author in common with the query document. This experiment was performed with the OpenCorpus dataset.

# of neighbors	R@20	P@20	Time(ms)
1	0.123	0.079	131
5	**0.142**	**0.080**	144
10	0.138	0.069	200
50	0.081	0.040	362

Table 4: OpenCorpus results for NNSelect step with varying number of nearest neighbors on 1,000 validation documents.

A lower mean rank for NNRank + Metadata indicates that the model trained with metadata tends to favor documents authored by one of the query document's authors. We verified the prevalence of this bias by varying the number of predictions for each model from 1 to 100. Figure 4 shows that the mean and max rank of the model trained with metadata is always lower than those for the model that does not use metadata.

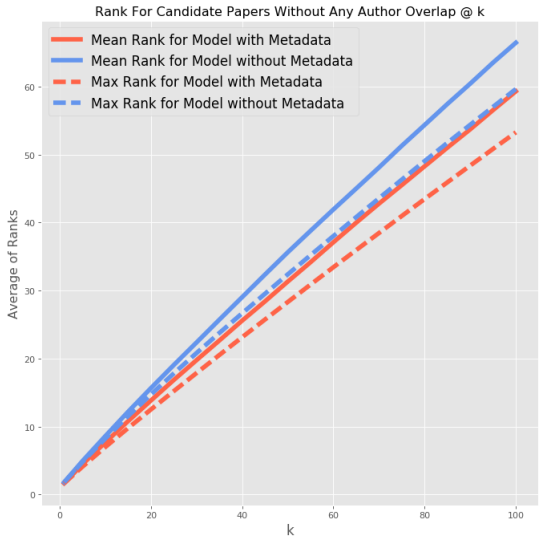

Figure 4: Mean and Max Rank of predictions with varying number of candidates.

6 Related Work

Citation recommendation systems can be divided into two categories – *local* and *global*. A local citation recommendation system takes a few sentences (and an optional placeholder for the candidate citation) as input and recommends citations based on the local context of the input sen-

tences (Huang et al., 2015; He et al., 2010; Tang and Zhang, 2009; Huang et al., 2012; He et al., 2011). A global citation recommendation system takes the entire scholarly article as input and recommends citations for the paper (McNee et al., 2002; Strohman et al., 2007; Nallapati et al., 2008; Kataria et al., 2010; Ren et al., 2014). We address the global citation recommendation problem in this paper.

A key difference of our proposed method compared to previous work is that our method is content-based and works well even in the absence of metadata (e.g. authors, venues, key phrases, seed list of citations). Many citation recommendation systems crucially rely on a query document's metadata. For example, the collaborative filtering based algorithms of McNee et al. (2002); Jia and Saule (2017); Liu et al. (2015) require seed citations for a query document. (Ren et al., 2014; Yu et al., 2012) require authors, venues and key terms of the query documents to infer interest groups and to extract features based on paths in a heterogeneous graph. In contrast, our model performs well solely based on the textual content of the query document.

Some previous work (e.g. (Ren et al., 2014; Yu et al., 2012)) have addressed the citation recommendation problem using graph-based methods. But, training graph-based citation recommendation models has been found to be expensive. For example, the training complexity of the ClusCite algorithm (Ren et al., 2014) is cubic in the number of edges in the graph of authors, venues and terms. This can be prohibitively expensive for datasets as large as `OpenCorpus`. On the other hand our model is a neural network trained via batched stochastic gradient descent that scales very well to large datasets (Bottou, 2010).

Another crucial difference between our approach and some prior work in citation prediction is that we build up a document representation using its constituent words only. Prior algorithms (Huang et al., 2015, 2012; Nallapati et al., 2008; Tanner and Charniak, 2015) learn an explicit representation for each training document separately that isn't a deterministic function of the document's words. This makes the model effectively transductive since a never-before-seen document does not have a ready-made representation. Similarly, Huang et al. (2012)'s method needs a candidate document to have at least one in-coming citation to be eligible for citation – this disadvantages newly published documents. Liu et al. (2015) form document representations using citation relations, which are not available for unfinished or new documents. In contrast, our method does not need to be re-trained as the corpus of potential candidates grows. As long as the new documents are in the same domain as that of the model's training documents, they can simply be added to the corpus and are immediately available as candidates for future queries.

While the citation recommendation task has attracted a lot of research interest, a recent survey paper (Beel et al., 2016) has found three main concerns with existing work: (i) limitations in evaluation due to strongly pruned datasets, (ii) lack of details for re-implementation, and (iii) variations in performance across datasets. For example, the average number of citations per document in the DBLP dataset is 5, but Ren et al. (2014) filtered out documents with fewer than 10 citations from the test set. This drastically reduced the size of the test set. We address these concerns by releasing a new large scale dataset for future citation recommendation systems. In our experiments on the `OpenCorpus` dataset, we only prune documents with zero outgoing citations. We provide extensive details of our system (see Appendix §A) to facilitate reproducibility and release our code[11]. We also show in experiments that our method consistently outperforms previous systems on multiple datasets.

Finally, recent work has combined graph node representations and text-based document representations using CCA (Gupta and Varma, 2017). This sort of approach can enhance our text-based document representations if a technique to create graph node representations at test-time is available.

7 Conclusion

In this paper, we present a content-based citation recommendation method which remains robust when metadata is missing for query documents, enabling researchers to do an effective literature search early in their research cycle or during the peer review process, among other scenarios. We show that our method obtains state of the art results on two citation recommendation datasets, even without the use of metadata available to the

[11] https://github.com/allenai/citeomatic

baseline method. We make our system publicly accessible online. We also introduce a new dataset of seven million scientific articles to facilitate future research on this problem.

Acknowledgements

We would like to thank Oren Etzioni, Luke Zettlemoyer, Doug Downey and Iz Beltagy for participating in discussions and for providing helpful comments on the paper draft; Hsu Han and rest of the Semantic Scholar team at AI2 for creating the OpenCorpus dataset. We also thank Xiang Ren for providing the data used in their experiments on the DBLP and Pubmed datasets. Finally, we thank the anonymous reviewers for insightful comments on the draft.

A Hyperparameter Settings

Neural networks are complex and have a large number of hyperparameters to tune. This makes it challenging to reproduce experimental results. Here, we provide details of how the hyperparameters of the `NNSelect` and `NNRank` models were chosen or otherwise set. We chose a subset of hyperparameters for tuning, and left the rest at manually set default values. Due to limited computational resources, we were only able to perform hyperparameter tuning on the development split of the smaller DBLP and Pubmed datasets.

For DBLP and PubMed, we first ran Hyperopt[12] with 75 trials. Each trial was run for five epochs of 500,000 triplets each. The ten top performing of these models were trained for a full 50 epochs, and the best performing model's hyperparameters are selected. Hyperparameters for `NNSelect` were optimized for Recall@20 and those for the `NNRank` model were optimized for F1@20 on the development set. The selected values for DBLP are reported in Table 6 and for PubMed are reported in Table 7.

`OpenCorpus` hyperparameters were set via informal hand-tuning, and the results are in Table 9. A few miscellaneous parameters (not tuned) that are necessary for reproducibility are in Table 8.

We briefly clarify the meaning of some parameters below:

- **Margin Multiplier** - The triplet loss has variable margins for the three types of negatives: $0.1\gamma, 0.2\gamma$, and 0.3γ. We treat γ as a hyperparameter and refer to it as the margin multiplier.
- **Use Siamese Embeddings** - For the majority of our experiments, we use a *Siamese* model (Bromley et al., 1993). That is, the textual embeddings for the query text and abstract share the same weights. However, we had a significantly larger amount of data to train `NNRank` on `OpenCorpus`, and found that non-Siamese embeddings are beneficial.
- **Use Pretrained** - We estimate word embeddings on the titles and abstracts of `OpenCorpus` using Word2Vec implemented by the gensim Python package[13].

[12]https://github.com/hyperopt/hyperopt
[13]https://radimrehurek.com/gensim/

B Margin Loss Details

When computing the margins for the triplet loss, we use a boosting function for highly cited documents. The full triplet loss function is as follows:

$$\max\big(\gamma\alpha(d^-) + s(d_q, d^-) + B(d^-) - s(d_q, d^+) - B(d^+), 0\big)$$

where γ is the margin multiplier, and $\alpha(d^-)$ varies based on the type of negative document:

- $\alpha(d^-) = 0.3$ for random negatives
- $\alpha(d^-) = 0.2$ for nearest neighbor negatives
- $\alpha(d^-) = 0.1$ for citation-of-citation negatives.

The boosting function is defined as follows:

$$B(d) = \frac{\sigma\left(\frac{d[\text{in-citations}]}{100}\right)}{50}$$

where σ is the sigmoid function and $d[\text{in-citations}]$ is the number of times document d was cited in the corpus. The boosting function allows the model to slightly prefer candidates that are cited more frequently, and the constants were set without optimization.

C Nearest Neighbors for Training Details

When obtaining nearest neighbors for negative examples during training, we use a heuristic to find a subset of the fetched nearest neighbors that are sufficiently wrong. That is, these are non-citation samples that look dissimilar in the original text but similar in the embedding space. This procedure is as follows for each training query:

1. Compute the Jaccard similarities between a training query and all of its true citations using the concatenation of title and abstract texts.
2. Compute the bottom fifth percentile Jaccard similarity value. I.e. the value below which only the bottom 5% most least textually similar true citations fall. For example, if the Jaccard similarities range from 0.2 to 0.9, the fifth percentile might plausibly be 0.3.
3. Use the Annoy index computed at the end of the previous epoch to fetch nearest neighbors for the query document.

4. Compute the textual Jaccard similarity between all of the nearest neighbors and the query document.

5. Retain nearest neighbors that have a smaller Jaccard similarity than the fifth percentile. Using the previous example, retain the nearest neighbors that have a lower Jaccard similarity than 0.3.

D BM25 Details

BM25 Implementation	DBLP		PubMed	
	F@20	MRR	F@20	MRR
Ren et al. (2014)	0.111	0.411	0.153	0.497
Our approximation	0.119	0.425	0.209	0.574

Table 5: Results of our BM25 implementation on DBLP and Pubmed datasets.

Okapi-BM25 is a popular ranking function. We use BM25 as an IR-based baseline for the task of citation recommendation. For the DBLP and Pubmed datasets, BM25 performance is provided in Ren et al. (2014). To create a competitive BM25 baseline for `OpenCorpus`, we first created indexes for the DBLP and Pubmed datasets and tuned the query to approximate the performance reported in previous work. We used Whoosh[14] to create an index. We extract the key terms (using Whoosh's `key_terms_from_text` method) from the title and abstract of each query document. The key terms from the document are concatenated to form the query string. Table 5 shows that our BM25 is a close approximation to the BM25 implementation of previous work and can be reliably used as a strong IR baseline for `OpenCorpus`. In Table 2, we report results on all three datasets using our BM25 implementation.

E Key Phrases for `OpenCorpus`

In the `OpenCorpus` dataset, some documents are accompanied by automatically extracted key phrases. Our implementation of automatic key phrase extraction is based on standard key phrase extraction systems – e.g. (Caragea et al., 2014a,b; Lopez and Romary, 2010). We first extract noun phrases using the Stanford CoreNLP package (Manning et al., 2014) as candidate key phrases. Next, we extract corpus level and document level features (e.g. term frequency, document frequency, n-gram probability etc.) for each candidate key phrase. Finally, we rank the candidate key phrases using a ranking model that is trained on author-provided key phrases as gold labels.

F Detailed Experimental Results

Table 10 compares `NNRank` with previous work in detail on DBLP and Pubmed datasets. ClusCite (Ren et al., 2014) clusters nodes in a heterogeneous graph of terms, authors and venues in order to find related documents which should be cited. ClusCite obtains the previous best results on these two datasets. L2-LR (Yu et al., 2012) uses a linear combination of meta-path based linear features to classify candidate citations. We show that `NNRank` (with and without metadata) consistently outperforms ClusCite and other baselines on all metrics on both datasets.

Abstract

We present a reading comprehension challenge in which questions can only be answered by taking into account information from multiple sentences. We solicit and verify questions and answers for this challenge through a 4-step crowdsourcing experiment. Our challenge dataset contains $\sim 6k$ questions for $+800$ paragraphs across 7 different domains (elementary school science, news, travel guides, fiction stories, etc) bringing in linguistic diversity to the texts and to the questions wordings. On a subset of our dataset, we found human solvers to achieve an F1-score of 86.4%. We analyze a range of baselines, including a recent state-of-art reading comprehension system, and demonstrate the difficulty of this challenge, despite a high human performance. The dataset is the first to study multi-sentence inference at scale, with an open-ended set of question types that requires reasoning skills.

1 Introduction

Machine Comprehension of natural language text is a fundamental challenge in AI and it has received significant attention throughout the history of AI (Greene, 1959; McCarthy, 1976; Reiter, 1976; Winograd, 1980). In particular, in natural language processing (NLP) it has been studied under various settings, such as multiple-choice Question-Answering (QA) (Green Jr. et al., 1961), Reading Comprehension (RC) (Hirschman et al., 1999), Recognizing Textual Entailment (RTE) (Dagan et al., 2013) etc. The area has seen rapidly increasing interest, thanks to the existence of sizable datasets and standard benchmarks. CNN/Daily Mail (Hermann et al., 2015), SQuAD (Rajpurkar et al., 2016) and NewsQA (Trischler et al., 2016) to name a few, are some of the datasets that were released recently with the goal of facilitating research in machine comprehension. Despite all the excitement fueled by that large data sets and the ability to directly train statistical learning models, current QA systems do not have capabilities comparable to elementary school or younger children (Clark and Etzioni, 2016). For many of these datasets, researchers point out that models neither need to 'comprehend' in order to correctly predict an answer, nor do they learn to 'reason' in a way that generalizes across datasets. For example, Khashabi et al. (2016) showed that adversarial perturbation in candidate answers results in a significant drop in performance of a few state-of-art science QA systems. Similarly, Jia and Liang (2017) show that adding an adversarially selected sentence to the instances in the SQuAD datasets drastically reduces the performance of many of the existing baselines. Chen et al. (2016) show that in the CNN/Daily Mail datasets, "the required reasoning and inference level ... is quite simple" and that a relatively simple algorithm can get almost close to the upper-bound. We believe that one key reason that simple algorithms can deal with the existing large datasets but, nevertheless, fail at generalization, is that the datasets do not actually require a deep understanding.

We propose to address this shortcoming by developing a reading comprehension challenge in which answering each of the questions requires reasoning over multiple sentences.

There is evidence that answering 'single-sentence questions', i.e. questions that can be answered from a single sentence of the given paragraph, is easier than answering multi-sentence questions', which require multiple sentences to answer a given question. For example, Richardson et al. (2013) released a reading comprehension dataset that contained both single-sentence and multi-sentence questions; models proposed for this task yielded considerably better performance on the single-sentence questions than on the multi-

Proceedings of NAACL-HLT 2018, pages 252–262
New Orleans, Louisiana, June 1 - 6, 2018.

sentence questions (according to Narasimhan and Barzilay (2015) accuracy of about 83% and 60% on these two types of questions, respectively).

There could be multiple reasons for this. First, multi-sentence reasoning seems to be inherently a difficult task. Research has shown that while complete-sentence construction emerges as early as first grade for many children, their ability to integrate sentences emerges only in fourth grade (Berninger et al., 2011). Answering multi-sentence questions might be more challenging for an automated system because it involves more than just processing individual sentences but rather combining linguistic, semantic and background knowledge across sentences—a computational challenges in itself. Despite these challenges, multi-sentence questions can be answered by humans and hence present an interesting yet reasonable goal for AI systems (Davis, 2014).

In this work, we propose a multi-sentence QA challenge in which questions can be answered only using information from multiple sentences. Specifically, we present MultiRC (Multi-Sentence Reading Comprehension)[1]—a dataset of short paragraphs and multi-sentence questions that can be answered from the content of the paragraph. Each question is associated with several choices for answer-options, out of which *one or more* correctly answer the question. Figure 1 shows two examples from our dataset. Each instance consists of a multi-sentence paragraph, a question, and answer-options. All instances were constructed such that it is not possible to answer a question correctly without gathering information from multiple sentences. Due to space constraints, the figure shows only the relevant sentences from the original paragraph. The entire corpus consists of 871 paragraphs and about $\sim$ 6k multi-sentence questions.

The goal of this dataset is to encourage the research community to explore approaches that can do more than sophisticated lexical-level matching. To accomplish this, we designed the dataset with three key challenges in mind. (i) The number of correct answer-options for each question is not pre-specified. This removes the over-reliance of current approaches on answer-options and forces them to decide on the correctness of each candidate answer independently of others. In other words, unlike previous work, the task here is not to simply identify the best answer-option, but to evaluate the correctness of each answer-option individually. For example, the first question in Figure 1 can be answered by combining information from sentences 3, 5, 10, 13 and 15. It requires not only understanding that the stalker's name is Timothy but also that he is the man who Mary had hit. (ii) The correct answer(s) is not required to be a span in the text. For example, the correct answer, A, of the second question in Figure 1 is not present in the paragraph verbatim. It is instead a combination of two spans from 2 sentences: 12 and 13. Such answer-options force models to process and understand not only the paragraph and the question but also the answer-options. (iii) The paragraphs in our dataset have diverse provenance by being extracted from 7 different domains such as news, fiction, historical text etc., and hence are expected to be more diverse in their contents as compared to single-domain datasets. We also expect this to lead to diversity in the types of questions that can be constructed from the passage.

Overall, we introduce a reading comprehension dataset that significantly differs from most other datasets available today in the following ways:

S3: Hearing noises in the garage, Mary Murdock finds a bleeding man, mangled and impaled on her jeep's bumper.
S5: Panicked, she hits him with a golf club.
S10: Later the news reveals the missing man is kindergarten teacher, Timothy Emser.
S12: It transpires that Rick, her boyfriend, gets involved in the cover up and goes to retrieve incriminatory evidence off the corpse, but is killed, replaced in Emser's grave.
S13: It becomes clear Emser survived.
S15: He stalks Mary many ways.

Who is stalking Mary?

A)* Timothy	D) Rick
B) Timothy's girlfriend	E) Murdock
C)* The man she hit	F) Her Boyfriend

S1: Most young mammals, including humans, play.
S2: Play is how they learn the skills that they will need as adults.
S6: Big cats also play.
S8: At the same time, they also practice their hunting skills.
S11: Human children learn by playing as well.
S12: For example, playing games and sports can help them learn to follow rules.
S13: They also learn to work together.

What do human children learn by playing games and sports?
A)* They learn to follow rules and work together
B) hunting skills
C)* skills that they will need as adult

Figure 1: Examples from our MultiRCcorpus. Each example shows relevant excerpts from a paragraph; multi-sentence question that can be answered by combining information from multiple sentences of the paragraph; and corresponding answer-options. The correct answer(s) is indicated by a *. Note that there can be multiple correct answers per question.

[1] http://cogcomp.org/multirc/

- $\sim 6k$ high-quality multiple-choice RC questions that are generated (and manually verified via crowdsourcing) to require integrating information from multiple sentences.
- The questions are not constrained to have a *single* correct answer, generalizing existing paradigms for representing answer-options.
- Our dataset is constructed using 7 different sources, allowing more diversity in content, style, and possible question types.
- We show a significant performance gap between current solvers and human performance, indicating an opportunity for developing sophistical reasoning systems.

2 Relevant Work

Automated reasoning is arguably one of the major problems in contemporary AI research. Brachman et al. (2005) suggest challenges for developing AI program that can pass the SAT exams. In similar spirit Clark and Etzioni (2016) advocate elementary-school tests as a new test for AI. Davis (2014) proposes hand-construction of multiple-choice challenge sets that are easy for children but difficult for computers. Despite Davis' claim on simplicity of his target questions, it is not clear how easy it is to generate such questions, as he doesn't provide any reasonably-sized dataset matching his proposal. Weston et al. (2015) present a relatively small dataset of 10 reasoning categories, and propose to build a system that uses a world model and a linguistic model. The fundamental limitation of the dataset is that it is generated according to a restricted set of reasoning categories, which possibly limits the complexity and diversity of questions.

Some other recent datasets proposed for machine comprehension also pay attention to type of questions and reasoning required. For example, RACE (Lai et al., 2017) attempts to incorporate different types of reasoning phenomena, and MCTest (Richardson et al., 2013) attempted to contain at least 50% multi-sentence reasoning questions. However, since the crowdsourced workers who created the dataset were only encouraged, and not required, to write such questions, it is not clear how many of these questions actually require multi-sentence reasoning (see Sec. 3.5). Similarly, only about 25% of question in the RACE dataset require multi-sentence reasoning as reported in their paper. Remedia (Hirschman et al., 1999) also contains 5 different types of questions (based on question words) but is a much smaller dataset. Other datasets which do not deliberately attempt to include multi-sentence reasoning, like SQuAD (Rajpurkar et al., 2016) and the CNN/Daily Mail dataset (Hermann et al., 2015), suffer from even lower percentage of such questions (12% and 2% respectively (Lai et al., 2017)). There are several other corpora which do not guarantee specific reasoning types, including MS MARCO (Nguyen et al., 2016), WikiQA (Yang et al., 2015), and TriviaQA (Joshi et al., 2017).

The complexity of reasoning required for a reading comprehension dataset would depend on several factors such as the source of questions or paragraphs; the way they are generated; and the order in which they are generated (i.e. questions from paragraphs, or the reverse). Specifically, paragraphs' source could influence the complexity and diversity of the language of the paragraphs and questions, and hence the required level of reasoning capabilities. Unlike most current datasets which rely on only one or two sources for their paragraphs (e.g. CNN/Daily Mail and SQuAD rely only on news and Wikipedia articles respectively) our dataset uses 7 different domains.

Another factor that distinguishes our dataset from previously proposed corpora is the way answers are represented. Several datasets represent answers as multiple-choices with a single correct answer. While multiple-choice questions are easy to grade, coming up with non-trivial correct and incorrect answers can be challenging. Also, assuming exactly one correct answer (e.g., as in MCTest and RACE) inadvertently changes the task from choosing the correct answer to choosing the most likely answer. Other datasets (e.g MS-MARCO and SQuAD) represent answers as a contiguous substring within the passage. This assumption of the answer being a span of the paragraph, limits the questions to those whose answer is contained verbatim in the paragraph. Unfortunately, it rules out more complicated questions whose answers are only implied by the text and hence require a deeper understanding. Because of these limitations, we designed our dataset to use multiple-choice representations, but without specifying the number of correct answers for each question.

3 Construction of MultiRC

In this section we describe our principles and methodology of dataset collection. This includes automatically collecting paragraphs, composing questions and answer-options through crowdsourcing platform, and manually curating the collected data. We also summarize a pilot study that helped us design this process, and end with a summary of statistics of the collected corpus.

3.1 Principles of design

Questions and answers in our dataset are designed based on the following key principles:

Multi-sentenceness. Questions in our challenge require models to use information from multiple sentences of a paragraph. This is ensured through explicit validation. We exclude any question that can be answered based on a single sentence from a paragraph.

Open-endedness. Our dataset is not restricted to questions whose answer can be found verbatim in a paragraph. Instead, we provide a set of handcrafted answer-options for each question. Notably, they can represent information that is not explicitly stated in the text but is only inferable from it (e.g. implied counts, sentiments, and relationships).

Answers to be judged independently. The total number of answer options per question is variable in our data and we explicitly allow multiple correct and incorrect answer options (e.g. 2 correct and 1 incorrect options). As a consequence, correct answers cannot be guessed solely by a process of elimination or by simply choosing the best candidates out of the given options.

Through these principles, we encourage users to explicitly model the semantics of text beyond individual words and sentences, to incorporate extra-linguistic reasoning mechanisms, and to handle answer options independently of one another.

Variability. We encourage variability on different levels. Our dataset is based on paragraphs from multiple domains, leading to linguistically diverse questions and answers. Also, we do not impose any restrictions on the questions, to encourage different forms of reasoning.

3.2 Sources of documents

The paragraphs used in our dataset are extracted from various sources. Here is the complete list of the text types and sources used in our dataset, and the number of paragraphs extracted from each category (indicated in square brackets on the right):

1. News: [121]
   - CNN (Hermann et al., 2015)
   - WSJ (Ide et al., 2008)
   - NYT (Ide et al., 2008)
2. Wikipedia articles [92]
3. Articles on society, law and justice (Ide and Suderman, 2006) [91]
4. Articles on history and anthropology (Ide et al., 2008) [65]
5. Elementary school science textbooks [2] [153]
6. 9/11 reports (Ide and Suderman, 2006) [72]
7. Fiction: [277]
   - Stories from the Gutenberg project
   - Children stories from MCTest (Richardson et al., 2013)
   - Movie plots from CMU Movie Summary corpus (Bamman et al., 2013)

From each of the above-mentioned sources we extracted paragraphs that had enough content. To ensure this we followed a 3-step process. In the first step we selected top few sentences from paragraphs such that they contained 1k-1.5k characters. To ensure coherence, all sentences were contiguous and extracted from the same paragraph. In this process we also discarded paragraphs that seemed to deviate too much from third person narrative style. For example, while processing Gutenberg corpus we considered files that had at least 5k lines because we found that most of them were short poetic texts. In the second step, we annotated (Khashabi et al., 2018b) the paragraphs and automatically filtered texts using conditions such as the average number of words per sentence; number of named entities; number of discourse connectives in the paragraph. These were designed by the authors of this paper after reviewing a small sample of paragraphs. A complete set of conditions is listed in Table 1. Finally in the last step, we manually verified each paragraph and filtered out the ones that had formatting issues or other concerns that seemed to compromise their usability.

Condition	bound
Number of sentences	≥ 6 & ≤ 18
Number of NER(CoNLL) mentions	≥ 2
Avg. number of NER(CoNLL) mentions	≥ 0.2
Number of NER(Ontonotes) mentions	≥ 4
Avg. number of NER(Ontonotes) mentions	≥ 0.25
Avg. number of words per sentence	≥ 5
Number of coreference mentions	≥ 3
Avg. number of coreference mentions	≥ 0.1
Number of coreference relations	≥ 3
Avg. number of coreference relations	≥ 0.08
Number of coreference chains	≥ 2
Avg. number of coreference chains	≥ 0.1
Number of discourse markers	≥ 2

Table 1: Bounds used to select paragraphs for dataset creation.

3.3 Pipeline of question extraction

In this section, we delineate details of the process for collecting questions and answers. Figure 2 gives a high-level idea of the process. The first two steps deal with creating multi-sentence questions, followed by two steps for construction of candidate answers. Interested readers can find more details on set-ups of each step in Appendix I.

Step 1: Generating questions. The goal of the first step of our pipeline is to collect multi-sentence questions. We show each paragraph to 5 turkers and ask them to write 3-5 questions such that: (1) the question is answerable from the passage, and (2) only those questions are allowed whose answer cannot be determined from a single sentence. We clarify this point by providing example paragraphs and questions. In order to encourage turkers to write meaningful questions that fit our criteria, we additionally ask them for a correct answer and for the sentence indices required to answer the question. To ensure the grammatical quality of the questions collected in this step, we limit the turkers to the countries with English as their major language. After the acquisition of questions in this step, we filter out questions which required less than 2 or more than 4 sentences to be answered; we also run them through an automatic spell-checker[3] and manually correct questions regarding typos and unusual wordings.

Step 2: Verifying multi-sentenceness of questions. In a second step, we verify that each question can only be answered using more than one sentence. For each question collected in the previous step, we create question-sentence pairs by pairing it with each of the sentences necessary for answering it as indicated in the previous step. For a given question-sentence pair, we then ask turkers to annotate if they could answer the question from the sentence it is paired with (binary annotation). The underlying idea of this step is that a multi-sentence question would not be answerable from a single sentence, hence turkers should not be able to give a correct answer for any of the question-sentence pair. Accordingly, we determine a question as requiring multiple sentences only if the correct answer cannot be guessed from any single question-sentence pair. We collected at least 3 annotations per pair, and to avoid sharing of information across sentences, no two pairs shown to a turker came from the same paragraph. We aggregate the above annotations for each question-answer pair and retain only those questions for which no pair was judged as answerable by a majority of turkers.

Step 3: Generating answer-options. In this step, we collect answer-options that will be shown with each question. Specifically, for each verified question from the previous steps, we ask 3 turkers to write as many correct and incorrect answer options as they can think of. In order to not curb creativity, we do not place a restriction on the number of options they have to write. We explicitly ask turkers to design difficult and non-trivial incorrect answer-options (e.g. if the question is about a person, a non-trivial incorrect answer-option would be other people mentioned in the paragraph).

After this step, we perform a light clean up of the candidate answers by manually correcting minor errors (such as typos), completing incomplete sentences and rephrasing any ambiguous sentences. We further make sure there is not much repetition in the answer-options, to prevent potential exploitation of correlation between some candidate answers in order to find the correct answer. For example, we drop obviously duplicate answer-options (i.e. identical options after lower-casing, lemmatization, and removing stop-words).

Step 4: Verifying quality of the dataset. This step serves as the final quality check for both questions and the answer-options generated in the previous steps. We show each paragraph, its questions, and the corresponding answer-options to 3 turkers, and ask them to indicate if they find any errors (grammatical or otherwise), in the questions and/or answer-options. We then manually review,

[3]Grammarly: www.grammarly.com

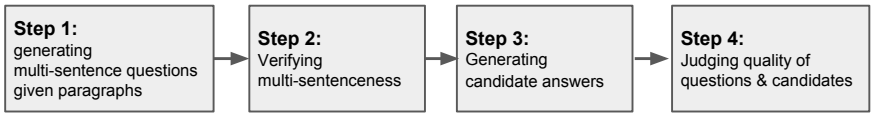

Figure 2: Pipeline of our dataset construction.

and correct if needed, all erroneous questions and answer-options. This ensures that we have meaningful questions and answer-options. In this step, we also want to verify that the correct (or incorrect) options obtained from Step 3 were indeed correct (or incorrect). For this, we additionally ask the annotators to select all correct answer-options for the question. If their annotations did not agree with the ones we had after Step 3 (e.g. if they unanimously selected an 'incorrect' option as the answer), we manually reviewed and corrected (if needed) the annotation.

3.4 Pilot experiments

The 4-step process described above was a result of detailed analysis and substantial refinement after two small pilot studies.

In the first pilot study, we ran a set of 10 paragraphs extracted from the CMU Movie Summary Corpus through our pipeline. Our then pipeline looked considerably different from the one described above. We found the steps that required turkers to write questions and answer-options to often have grammatical errors, possibly because a large majority of turkers were non-native speakers of English. This probslem was more prominent in questions than in answer-options. Because of this, we decided to limit the task to native speakers. Also, based on the results of this pilot, we overhauled the instructions of these steps by including examples of grammatically correct—but undesirable (not multi-sentence)—questions and answer-options, in addition to several minor changes.

Thereafter, we decided to perform a manual validation of the verification steps (current Steps 2 and 4). For this, we (the authors of this paper) performed additional annotations ourselves on the data shown to turkers, and compared our results with those provided by the turkers. We found that in the verification of answer-options, our annotations were in high agreement (98%) with those obtained from mechanical turk. However, that was not the case for the verification of multi-sentence questions. We made several further changes to the first two steps. Among other things, we clarified in the instructions that turkers should not use their background knowledge when writing and verifying questions, and also included negative examples of such questions. Additionally, when turkers judged a question to be answerable using a single sentence, we decided to encourage (but not require) them to guess the answer to the question. This improved our results considerably, possibly because it forced annotators to think more carefully about what the answer might be, and whether they *actually* knew the answer or they just *thought* that they knew it (possibly because of background knowledge or because the sentence contained a lot of information relevant to the question). Guessed answers in this step were only used to verify the validity of multi-sentence questions. They were not used in the dataset or subsequent steps.

After revision, we ran a second pilot study in which we processed a set of 50 paragraphs through our updated pipeline. This second pilot confirmed that our revisions were helpful, but thanks to its larger size, also allowed us to identify a couple of borderline cases for which additional clarifications were required. Based on the results of the second pilot, we made some additional minor changes and then decided to apply the pipeline for creating the final dataset.

3.5 Verifying multi-sentenceness

While collecting our dataset, we found that, even though Step 1 instructed turkers to write multi-sentence questions, not all generated questions indeed required multi-sentence reasoning. This happened even after clarifications and revisions to the corresponding instructions, and we attribute it to honest mistakes. Therefore, we designed the subsequent verification step (Step 2).

There are other datasets which aim to include multi-sentence reasoning questions, especially MCTest. Using our verification step, we systematically verify their multi-sentenceness. For this, we conducted a small pilot study on about 60 multi-sentence questions from MCTest. As for our own verification, we created question-sentence pairs for each question and asked annotators to judge whether they can answer a question from the single sentence shown. Because we did not know

which sentences contain information relevant to a question, we created question-sentence pairs using all sentences from a paragraph. After aggregation of turker annotations, we found that about half of the questions annotated as multi-sentence could be answered from a single sentence of the paragraph. This study, though performed on a subset of the data, underscores the necessity of rigorous verification step for multi-sentence reasoning when studying this phenomenon.

3.6 Statistics on the dataset

We now provide a brief summary of MultiRC. Overall, it contains roughly $\sim 6k$ multi-sentence questions collected for about $+800$ paragraphs.[4] The median number of correct and total answer options for each question is 2 and 5, respectively. Additional statistics are given in Table 2.

In Step 1, we also asked annotators to identify sentences required to answer a given question. We found that answering each question required 2.4 sentences on average. Also, required sentences are often not contiguous, and the average distance between sentences is 2.4. Next, we analyze the types of questions in our dataset. Figure 4 shows the count of first word(s) for our questions. We can see that while the popular question words (*What*, *Who*, etc.) are very common, there is a wide variety in the first word(s) indicating a diversity in question types. About 28% of our questions require binary decisions (true/false or yes/no).

We randomly selected 60 multi-sentence questions from our corpus and asked two independent annotators to label them with the type of reasoning phenomenon required to answer them.[5] During this process, the annotators were shown a list of common reasoning phenomena (shown below), and they had to identify one or more of the phenomena relevant to a given question. The list of phenomena shown to the annotators included the following categories: mathematical and logical reasoning, spatio-temporal reasoning, list/enumeration, coreference resolution (including implicit references, abstract pronouns, event coreference, etc.), causal relations, paraphrases and contrasts (including lexical relations such as synonyms, antonyms), commonsense knowledge, and 'other'. The categories were selected after a manual inspection of a subset of questions by two of the authors. The annotation process revealed that answering questions in our corpus requires a broad variety of reasoning phenomena. The left plot in Figure 3 provides detailed results.

The figure shows that a large fraction of questions require coreference resolution, and a more careful inspection revealed that there were different types of coreference phenomena at play here. To investigate these further, we conducted a follow-up experiment in which manually annotated all questions that required coreference resolution into finer categories. Specifically, each question was shown to two annotators who were asked to select one or more of the following categories: entity coreference (between two entities), event coreference (between two events), set inclusion coreference (one item is part of or included in the other) and 'other'. Figure 3 (right) shows the results of this experiment. We can see that, as expected, entity coreference is the most common type of coreference resolution needed in our corpus. However, a significant number of questions also require other types of coreference resolution. We provide some examples of questions along with the required reasoning phenomena in Appendix II.

Parameter	Value
# of paragraphs	871
# of questions	9,872
# of multi-sentence questions	5,825
avg # of candidates (per question)	5.44
avg # of correct answers (per question)	2.58
avg paragraph length (in sentences)	14.3 (4.1)
avg paragraph length (in tokens)	263.1 (92.4)
avg question length (in tokens)	10.9 (4.8)
avg answer length (in tokens)	4.7 (5.5)
% of yes/no/true/false questions	27.57%
avg # of sent. used for questions	2.37 (0.63)
avg distance between the sent.'s used	2.4 (2.58)
% of correct answers verbatim in paragraph	34.96%
% of incorrect answers verbatim in paragraph	25.84%

Table 2: Various statistics of our dataset. Figures in parentheses represent standard deviation.

4 Analysis

In this section, we provide a quantitative analysis of several baselines for our challenge.

Evaluation Metrics. We define precision and recall for a question q as: $\text{Pre}(q) = \frac{|A(q) \cap \hat{A}(q)|}{|\hat{A}(q)|}$ and $\text{Rec}(q) = \frac{|A(q) \cap \hat{A}(q)|}{|A(q)|}$, where $A(q)$ and $\hat{A}(q)$ are the sets of correct and selected answer-options.

[4] We will also release the $3.7k$ questions that did not pass Step 2. Though not multi-sentence questions, they could be a valuable resource on their own.

[5] The annotations were adjudicated by two authors of this paper.

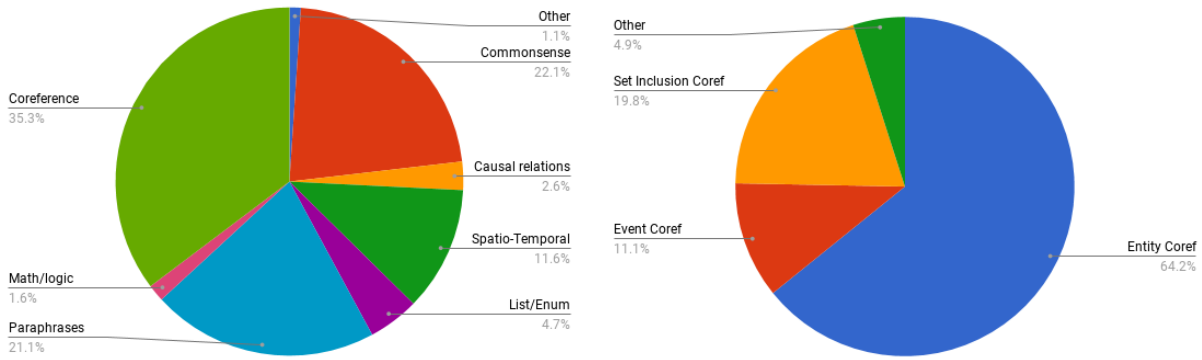

Figure 3: Distribution of (left) general phenomena; (right) variations of the "coreference" phenomena.

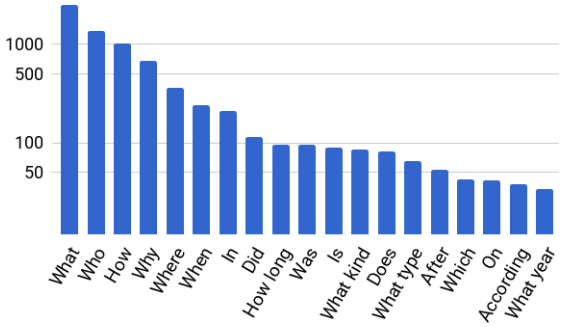

Figure 4: Most frequent first chunks of the questions (counts in log scale).

We define (macro-average) F1_m as the harmonic mean of average-precision $avg_{q \in Q}(\text{Pre}(q))$ and average-recall $avg_{q \in Q}(\text{Rec}(q))$ with Q as the set of all questions.

Since by design, each answer-option can be judged independently, we consider another metric, F1_a, evaluating binary decisions on all the answer-options in the dataset. We define F1_a to be the harmonic mean of $\text{Pre}(Q)$ and $\text{Rec}(Q)$, with $\text{Pre}(Q) = \frac{|A(Q) \cap \hat{A}(Q)|}{|\hat{A}(Q)|}$; $A(Q) = \bigcup_{q \in Q} A(q)$; and similar definitions for $\hat{A}(Q)$ and $\text{Rec}(Q)$.

4.1 Baselines

Human. Human performance provides us with an estimate of the best achievable results on datasets. Using mechanical turk, we ask 4 people (limited to native speakers) to solve our data. We evaluate score of each label by averaging the decision of the individuals.

Random. To get an estimate on the lower-bound we consider a random baseline, where each answer option is selected as correct with a probability of 50% (an unbiased coin toss). The numbers reported for this baseline represent the expected outcome (statistical expectation).

IR (information retrieval baseline). This baseline selects answer-options that best match sentences in a text corpus (Clark et al., 2016). Specifically, for each question q and answer option a_i, the IR solver sends $q + a_i$ as a query to a search engine (we use Lucene) on a corpus, and returns the search engine's score for the top retrieved sentence s, where s must have at least one non-stopword overlap with q, and at least one with a_i.

We create two versions of this system. In the first variation IR(paragraphs) we create a corpus of sentences extracted from all the paragraphs in the dataset. In the second variation, IR(web) in addition to the knowledge of the paragraphs, we use extensive external knowledge extracted from the web (Wikipedia, science textbooks and study guidelines, and other webpages), with 5×10^{10} tokens (280GB of plain text).

SurfaceLR (logistic regression baseline). As a simple baseline that makes use of our small training set, we reimplemented and trained a logistic regression model using word-based overlap features. As described in (Merkhofer et al., 2018), this baseline takes into account the lengths of a text, question and each answer candidate, as well as indicator features regarding the (co-)occurrences of any words in them.

SemanticILP (semi-structured baseline). This state-of-the-art solver, originally proposed for science questions and biology tests, uses a semi-structured representation to formalize the scoring problem as a subgraph optimization problem over multiple layers of semantic abstrac-

	Dev		Test	
	$F1_m$	$F1_a$	$F1_m$	$F1_a$
Random	44.3	43.8	47.1	47.6
IR(paragraphs)	64.3	60.0	54.8	53.9
SurfaceLR	66.1	63.7	66.7	63.5
Human	86.4	83.8	84.3	81.8

Table 3: Performance comparison for different baselines tested on a subset of our dataset (in percentage). There is a significant gap between the human performance and current statistical methods.

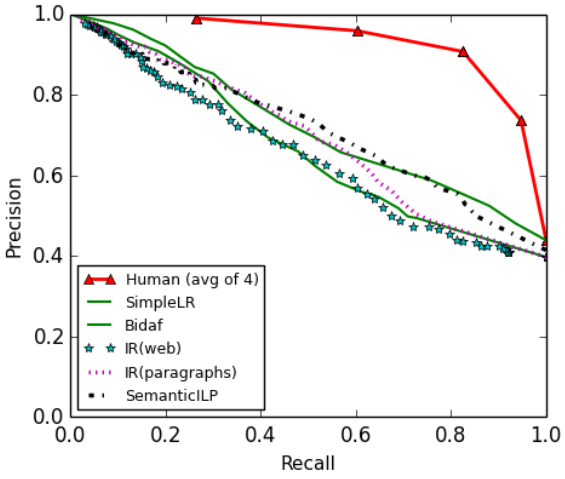

Figure 5: PR curve for each of the baselines. There is a considerable gap with the baselines and human.

tions (Khashabi et al., 2018a). Since the solver is designed for multiple-choice with single-correct answer, we adapt it to our setting by running it for each answer-option. Specifically for each answer-option, we create a single-candidate question, and retrieve a real-valued score from the solver.

BiDAF (neural network baseline). As a neural baseline, we apply this solver by Seo et al. (2017), which was originally proposed for SQuAD but has been shown to generalize well to another domain (Min et al., 2017). Since BiDAF was designed for cloze style questions, we apply it to our multiple-choice setting following the procedure by Kembhavi et al. (2017): Specifically, we score each answer-option by computing the similarity value of it's output span with each of the candidate answers, computed by phrasal similarity tool of Wieting et al. (2015).

4.2 Results

To get a sense of our dataset's hardness, we evaluate both human performance and multiple computational baselines. Each baseline scores an answer-option with a real-valued score, which we threshold to decide whether an answer option is selected or not, where the threshold is tuned on the development set. Table 3 shows performance results for different baselines. The significantly high human performance shows that humans do not have much difficulties in answering the questions. Similar observations can be made in Figure 5 where we plot $avg_{q \in Q}(\text{Pre}(q))$ vs. $avg_{q \in Q}(\text{Rec}(q))$, for different threshold values.

5 Conclusion

In this paper we have presented MultiRC, a reading comprehension dataset in which questions require reasoning over multiple sentences to be answered. Our dataset contains $\sim 6k$ questions extracted from about +800 paragraphs. For each question, it contains multiple answer-options out of which one or more can be correct. The paragraphs (and questions) originate from different domains and hence are amenable to a wide variety and complexity of required reasoning phenomena. We found human performance on this corpus to be about 88% while state-of-the-art machine comprehension models do not exceed a F1-score of 60%. We hope that this significant difference in performance will encourage the community to work towards more sophisticated reasoning systems.

Abstract

We demonstrate that current state-of-the-art approaches to Automated Essay Scoring (AES) are not well-suited to capturing adversarially crafted input of grammatical but incoherent sequences of sentences. We develop a neural model of local coherence that can effectively learn connectedness features between sentences, and propose a framework for integrating and jointly training the local coherence model with a state-of-the-art AES model. We evaluate our approach against a number of baselines and experimentally demonstrate its effectiveness on both the AES task and the task of flagging adversarial input, further contributing to the development of an approach that strengthens the validity of neural essay scoring models.

1 Introduction

Automated Essay Scoring (AES) focuses on automatically analyzing the quality of writing and assigning a score to the text. Typically, AES models exploit a wide range of manually-tuned shallow and deep linguistic features (Shermis and Hammer, 2012; Burstein et al., 2003; Rudner et al., 2006; Williamson et al., 2012; Andersen et al., 2013). Recent advances in deep learning have shown that neural approaches to AES achieve state-of-the-art results (Alikaniotis et al., 2016; Taghipour and Ng, 2016) with the additional advantage of utilizing features that are automatically learned from the data. In order to facilitate interpretability of neural models, a number of visualization techniques have been proposed to identify textual (superficial) features that contribute to model performance (Alikaniotis et al., 2016).

To the best of our knowledge, however, no prior work has investigated the robustness of neural AES systems to adversarially crafted input that is designed to trick the model into assigning desired missclassifications; for instance, a high score to a low quality text. Examining and addressing such validity issues is critical and imperative for AES deployment. Previous work has primarily focused on assessing the robustness of "standard" machine learning approaches that rely on manual feature engineering; for example, Powers et al. (2002); Yannakoudakis et al. (2011) have shown that such AES systems, unless explicitly designed to handle adversarial input, can be susceptible to subversion by writers who understand something of the systems' workings and can exploit this to maximize their score.

In this paper, we make the following contributions:

i. We examine the robustness of state-of-the-art neural AES models to adversarially crafted input,[1] and specifically focus on input related to *local coherence*; that is, grammatical but incoherent sequences of sentences.[2] In addition to the superiority in performance of neural approaches against "standard" machine learning models (Alikaniotis et al., 2016; Taghipour and Ng, 2016), such a setup allows us to investigate their potential superiority / capacity in handling adversarial input without being explicitly designed to do so.

ii. We demonstrate that state-of-the-art neural AES is not well-suited to capturing adversarial input of grammatical but incoherent sequences of sentences, and develop a neural model of local coherence that can effectively learn connectedness features between sentences.

[1] We use the terms 'adversarially crafted input' and 'adversarial input' to refer to text that is designed with the intention to trick the system.

[2] Coherence can be assessed locally in terms of transitions between adjacent sentences.

Proceedings of NAACL-HLT 2018, pages 263–271
New Orleans, Louisiana, June 1 - 6, 2018.

iii. A local coherence model is typically evaluated based on its ability to rank coherently ordered sequences of sentences higher than their incoherent / permuted counterparts (e.g., Barzilay and Lapata (2008)). We focus on a stricter evaluation setting in which the model is tested on its ability to rank coherent sequences of sentences higher than *any* incoherent / permuted set of sentences, and not just its own permuted counterparts. This supports a more rigorous evaluation that facilitates development of more robust models.

iv. We propose a framework for integrating and jointly training the local coherence model with a state-of-the-art AES model. We evaluate our approach against a number of baselines and experimentally demonstrate its effectiveness on both the AES task and the task of flagging adversarial input, further contributing to the development of an approach that strengthens AES validity.

At the outset, our goal is to develop a framework that strengthens the validity of state-of-the-art neural AES approaches with respect to adversarial input related to local aspects of coherence. For our experiments, we use the Automated Student Assessment Prize (ASAP) dataset,[3] which contains essays written by students ranging from Grade 7 to Grade 10 in response to a number of different prompts (see Section 4).

2 Related Work

AES Evaluation against Adversarial Input One of the earliest attempts at evaluating AES models against adversarial input was by Powers et al. (2002) who asked writing experts – that had been briefed on how the e-Rater scoring system works – to write essays to trick e-Rater (Burstein et al., 1998). The participants managed to fool the system into assigning higher-than-deserved grades, most notably by simply repeating a few well-written paragraphs several times. Yannakoudakis et al. (2011) and Yannakoudakis and Briscoe (2012) created and used an adversarial dataset of well-written texts and their random sentence permutations, which they released in the public domain, together with the grades assigned by a human expert to each piece of text. Unfortunately, however, the dataset is quite small, consisting of 12 texts in total. Higgins and Heilman (2014) proposed a framework for evaluating the susceptibility of AES systems to gaming behavior.

Neural AES Models Alikaniotis et al. (2016) developed a deep bidirectional Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) network, augmented with score-specific word embeddings that capture both contextual and usage information for words. Their approach outperformed traditional feature-engineered AES models on the ASAP dataset. Taghipour and Ng (2016) investigated various recurrent and convolutional architectures on the same dataset and found that an LSTM layer followed by a Mean over Time operation achieves state-of-the-art results. Dong and Zhang (2016) showed that a two-layer Convolutional Neural Network (CNN) outperformed other baselines (e.g., Bayesian Linear Ridge Regression) on both in-domain and domain-adaptation experiments on the ASAP dataset.

Neural Coherence Models A number of approaches have investigated neural models of coherence on news data. Li and Hovy (2014) used a window approach where a sliding kernel of weights was applied over neighboring sentence representations to extract local coherence features. The sentence representations were constructed with recursive and recurrent neural methods. Their approach outperformed previous methods on the task of selecting maximally coherent sentence orderings from sets of candidate permutations (Barzilay and Lapata, 2008). Lin et al. (2015) developed a hierarchical Recurrent Neural Network (RNN) for document modeling. Among others, they looked at capturing coherence between sentences using a sentence-level language model, and evaluated their approach on the sentence ordering task. Tien Nguyen and Joty (2017) built a CNN over entity grid representations, and trained the network in a pairwise ranking fashion. Their model outperformed other graph-based and distributed sentence models.

We note that our goal is not to identify the "best" model of local coherence on randomly permuted grammatical sentences in the domain of AES, but rather to propose a framework that strengthens the validity of AES approaches with respect to adversarial input related to local aspects of coherence.

[3] https://www.kaggle.com/c/asap-aes/

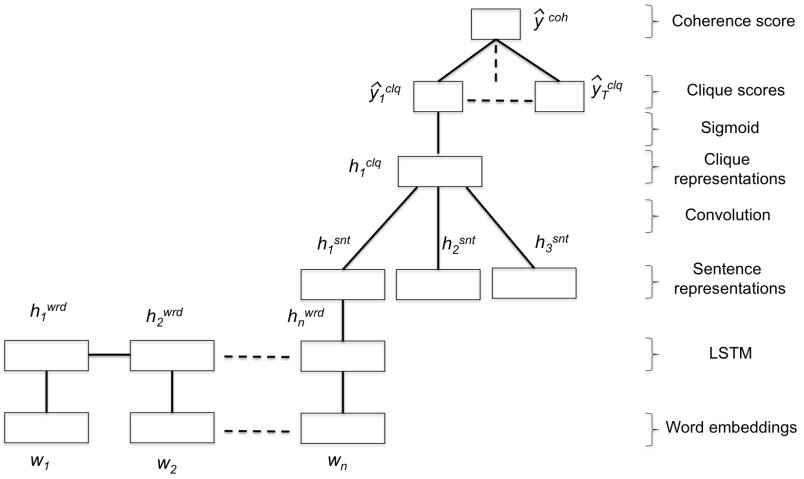

Figure 1: Local Coherence (LC) model architecture using a window of size 3. All h^{snt} representations are computed the same way as h_1^{snt}. The figure depicts the process of predicting the first clique score, which is applied to all the cliques in the text. The output coherence score is the average of all the clique scores. T is the number of cliques.

3 Models

3.1 Local Coherence (LC) Model

Our local coherence model is inspired by the model of Li and Hovy (2014) which uses a window approach to evaluate coherence.[4] Figure 1 presents a visual representation of the network architecture, which is described below in detail.

Sentence Representation This part of the model composes the sentence representations that can be utilized to learn connectedness features between sentences. Each word in the text is initialized with a k-dimensional vector w from a pre-trained word embedding space. Unlike Li and Hovy (2014), we use an LSTM layer[5] to capture sentence compositionality by mapping words in a sentence $s = \{w_1, w_2, ..., w_n\}$ at each time step t (w_t, where $t \leq n$) onto a fixed-size vector $h_t^{wrd} \in \mathbb{R}^{d_{lstm}}$ (where d_{lstm} is a hyperparameter). The sentence representation h^{snt} is then the representation of the last word in the sentence:

$$h^{snt} = h_n^{wrd} \tag{1}$$

Clique Representation Each window of sentences in a text represents a clique $q = \{s_1, ..., s_m\}$, where m is a hyperparameter indicating the window size. A clique is assigned a score of 1 if it is coherent (i.e., the sentences are *not* shuffled) and 0 if it is incoherent (i.e., the sentences are shuffled). The clique embedding is created by concatenating the representations of the sentences it contains according to Equation 1. A convolutional operation – using a filter $W^{clq} \in \mathbb{R}^{m \times d_{lstm} \times d_{cnn}}$, where d_{cnn} denotes the convolutional output size – is then applied to the clique embedding, followed by a non-linearity in order to extract the clique representation $h^{clq} \in \mathbb{R}^{d_{cnn}}$:

$$h_j^{clq} = \tanh([h_j^{snt}; ..; h_{j+m-1}^{snt}] * W^{clq}) \tag{2}$$

Here, $j \in \{1, ..., N - m + 1\}$, N is the number of sentences in the text, and $*$ is the linear convolutional operation.

Scoring The cliques' predicted scores are calculated via a linear operation followed by a sigmoid function to project the predictions to a $[0, 1]$ probability space:

$$\hat{y}_j^{clq} = \text{sigmoid}(h_j^{clq}.V) \tag{3}$$

where $V \in \mathbb{R}^{d_{cnn}}$ is a learned weight. The network optimizes its parameters to minimize the negative log-likelihood of the cliques' gold scores y^{clq}, given the network's predicted scores:

$$L_{local} = \frac{1}{T}\sum_{j=1}^{T}[-y_j^{clq}\log(\hat{y}_j^{clq}) - (1 - y_j^{clq})\log(1 - \hat{y}_j^{clq})] \tag{4}$$

[4] We note that Li and Jurafsky (2017) also present an extended version of the work by Li and Hovy (2014), evaluated on different domains.

[5] LSTMs have been shown to produce state-of-the-art results in AES (Alikaniotis et al., 2016; Taghipour and Ng, 2016).

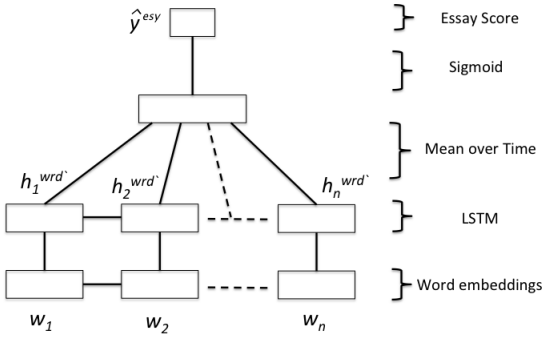

Figure 2: AES $\text{LSTM}_{\text{T\&N}}$ model of Taghipour and Ng (2016). The $\hat{y}^{esy}$ is the final predicted essay score.

where $T = N - m + 1$ (number of cliques in text). The final prediction of the text's coherence score is calculated as the average of all of its clique scores:

$$\hat{y}^{coh} = \frac{1}{T} \sum_{j=1}^{T} \hat{y}_j^{clq} \quad (5)$$

This is in contrast to Li and Hovy (2014), who multiply all the estimated clique scores to generate the overall document score. This means that if only one clique is misclassified as incoherent and assigned a score of 0, the whole document is regarded as incoherent. We aim to soften this assumption and use the average instead to allow for a more fine-grained modeling of degrees of coherence.[6]

We train the LC model on synthetic data automatically generated by creating random permutations of highly-scored ASAP essays (Section 4).

3.2 LSTM AES Model

We utilize the LSTM AES model of Taghipour and Ng (2016) shown in Figure 2 ($\text{LSTM}_{\text{T\&N}}$), which is trained, and yields state-of-the-art results on the ASAP dataset. The model is a one-layer LSTM that encodes the sequence of words in an essay, followed by a Mean over Time operation that averages the word representations generated from the LSTM layer.[7]

[6] Our experiments showed that using the multiplicative approach gives poor results, as presented in Section 6.

[7] We note that the authors achieve slightly higher results when averaging ensemble results of their LSTM model together with CNN models. We use their main LSTM model which, for the purposes of our experiments, does not affect our conclusions.

3.3 Combined Models

We propose a framework for integrating the $\text{LSTM}_{\text{T\&N}}$ model with the Local Coherence (LC) one. Our goal is to have a robust AES system that is able to correctly flag adversarial input while maintaining a high performance on essay scoring.

3.3.1 Baseline: Vector Concatenation (VecConcat)

The baseline model simply concatenates the output representations of the pre-prediction layers of the trained $\text{LSTM}_{\text{T\&N}}$ and LC networks, and feeds the resulting vector to a machine learning algorithm (e.g., Support Vector Machines, SVMs) to predict the final overall score. In the $\text{LSTM}_{\text{T\&N}}$ model, the output representation (hereafter referred to as the *essay representation*) is the vector produced from the Mean Over Time operation; in the LC model, we use the generated clique representations (Figure 1) aggregated with a max operation;[8] (hereafter referred to as the *clique representation*). Although the LC model is trained on permuted ASAP essays (Section 4) and the $\text{LSTM}_{\text{T\&N}}$ model on the original ASAP data, essay and clique representations are generated for both the ASAP and the synthetic essays containing reordered sentences.

3.3.2 Joint Learning

Instead of training the $\text{LSTM}_{\text{T\&N}}$ and LC models separately and then concatenating their output representations, we propose a framework where both models are trained jointly, and where the final network has then the capacity to predict AES scores and flag adversarial input (Figure 3).

Specifically, the $\text{LSTM}_{\text{T\&N}}$ and LC networks predict an essay and coherence score respectively (as described earlier), but now they both share the word embedding layer. The training set is the aggregate of both the ASAP and permuted data to allow the final network to learn from both simultaneously. Concretely, during training, for the ASAP essays, we assume that both the gold essay and coherence scores are the same and equal to the gold ASAP scores. This is not too strict an assumption, as overall scores of writing competence tend to correlate highly with overall coherence. For the synthetic essays, we set the "gold" coher-

[8] We note that max aggregation outperformed other aggregation functions.

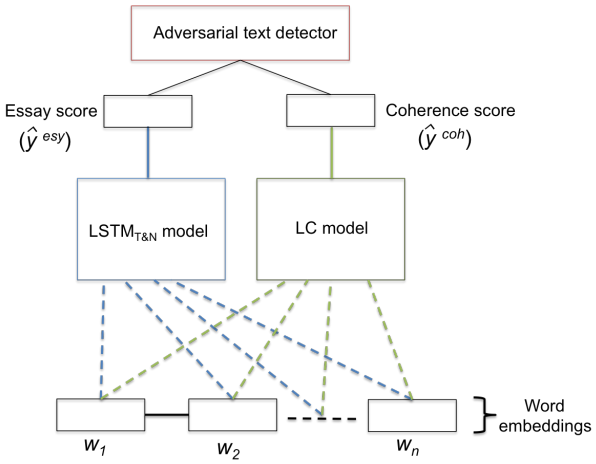

Figure 3: A joint network for scoring essays as well as detecting adversarial input. The LSTM$_{T\&N}$ model is the one depicted in Figure 2, and the LC in Figure 1.

ence scores to zero, and the "gold" essay scores to those of their original non-permuted counterparts in the ASAP dataset. The intuition is as follows: firstly, setting the "gold" essay scores of synthetic essays to zero would bias the model into over-predicting zeros; secondly, our approach reinforces the LSTM$_{T\&N}$'s inability to detect adversarial input, and forces the overall network to rely on the LC branch to identify such input.[9]

The two sub-networks are trained together and the error gradients are back-propagated to the word embeddings. To detect whether an essay is adversarial, we further augment the system with an *adversarial text detection* component that simply captures adversarial input based on the difference between the predicted essay and coherence scores. Specifically, we use our development set to learn a threshold for this difference, and flag an essay as adversarial if the difference is larger than the threshold. We experimentally demonstrate that this approach enables the model to perform well on both original ASAP and synthetic essays. During model evaluation, the texts flagged as adversarial by the model are assigned a score of zero, while the rest are assigned the predicted essay score ($\hat{y}^{esy}$ in Figure 3).

4 Data and Evaluation

We use the ASAP dataset, which contains 12,976 essays written by students ranging from Grade 7 to Grade 10 in response to 8 different prompts. We follow the ASAP data split by Taghipour and Ng (2016), and apply 5-fold cross validation in all experiments using the same train/dev/test splits. For each prompt, the fold predictions are aggregated and evaluated together. In order to calculate the overall system performance, the results are averaged across the 8 prompts.

To create adversarial input, we select high scoring essays per prompt (given a pre-defined score threshold, Table 1)[10] that are assumed coherent, and create 10 permutations per essay by randomly shuffling its sentences. In the joint learning setup, we augment the original ASAP dataset with a subset of the synthetic essays. Specifically, we randomly select 4 permutations per essay to include in the training set,[11] but include all 10 permutations in the test set. Table 1 presents the details of the datasets.

We test performance on the ASAP dataset using Quadratic Weighted Kappa (QWK), which was the official evaluation metric in the ASAP competition, while we test performance on the synthetic dataset using pairwise ranking accuracy (PRA) between an original non-permuted essay and its permuted counterparts. PRA is typically used as an evaluation metric on coherence assessment tasks on other domains (Barzilay and Lapata, 2008), and is based on the fraction of correct pairwise rankings in the test data (i.e., a coherent essay should be ranked higher than its permuted counterpart). Herein, we extend this metric and furthermore evaluate the models by comparing each original essay to all adversarial / permuted essays in the test data, and not just its own permuted counterparts – we refer to this metric as *total pairwise ranking accuracy* (TPRA).

5 Model Parameters and Baselines

Coherence models We train and test the LC model described in Section 3.1 on the synthetic dataset and evaluate it using PRA and TPRA. During pre-processing, words are lowercased and initialized with pre-trained word embeddings (Zou et al., 2013). Words that occur only once in the training set are mapped to a special *UNK* embed-

[9] We note that, during training, the scores are mapped to a range between 0 and 1 (similarly to Taghipour and Ng (2016)), and then scaled back to their original range during evaluation.

[10] We note that this threshold is different than the one mentioned in Section 3.3.2.

[11] This is primarily done to keep the data balanced: initial experiments showed that training with all 10 permutations per essay harms AES performance, but has negligible effect on adversarial input detection.

Prompt	#ASAP essays	Score Range	Synthetic Dataset		
			threshold	#ASAP essays	total size
1	1,783	2–12	10	472	5,192
2	1,800	1–6	5	82	902
3	1,726	0–3	3	407	4,477
4	1,772	0–3	3	244	2,684
5	1,805	0–4	4	258	2,838
6	1,800	0–4	4	367	4,037
7	1,569	0–30	23	179	1,969
8	723	0–60	45	72	792

Table 1: Statistics for each dataset per prompt. For the synthetic dataset, the high scoring ASAP essays are selected based on the indicated score threshold (inclusive). "total size" refers to the number of the ASAP essays selected + their 10 different permutations.

ding. All network weights are initialized to values drawn randomly from a uniform distribution with scale $= 0.05$, and biases are initialized to zeros. We apply a learning rate of 0.001 and RMSProp (Tieleman and Hinton, 2012) for optimization. A size of 100 is chosen for the hidden layers (d_{lstm} and d_{cnn}), and the convolutional window size (m) is set to 3. Dropout (Srivastava et al., 2014) is applied for regularization to the output of the convolutional operation with probability 0.3. The network is trained for 60 epochs and performance is monitored on the development sets – we select the model that yields the highest PRA value.[12]

We use as a baseline the LC model that is based on the multiplication of the clique scores (similarly to Li and Hovy (2014)), and compare the results (LC_{mul}) to our averaged approach. As another baseline, we use the entity grid (EGrid) (Barzilay and Lapata, 2008) that models transitions between sentences based on sequences of entity mentions labeled with their grammatical role. EGrid has been shown to give competitive results on similar coherence tasks in other domains. Using the Brown Coherence Toolkit (Eisner and Charniak, 2011),[13] we construct the entity transition probabilities with length = 3 and salience = 2. The transition probabilities are then used as features that are fed as input to an SVM classifier with an *RBF* kernel and penalty parameter $C = 1.5$ to predict a coherence score.

$\text{LSTM}_{\text{T\&N}}$ model We replicate and evaluate the LSTM model of Taghipour and Ng (2016)[14] on ASAP and our synthetic data.

Combined models After training the LC and $\text{LSTM}_{\text{T\&N}}$ models, we concatenate their output vectors to build the **Baseline: Vector Concatenation (VecConcat)** model as described in Section 3.3.1, and train a Kernel Ridge Regression model.[15]

The **Joint Learning** network is trained on both the ASAP and synthetic dataset as described in Section 3.3.2. Adversarial input is detected based on an estimated threshold on the difference between the predicted essay and coherence scores (Figure 3). The threshold value is empirically calculated on the development sets, and set to be the average difference between the predicted essay and coherence scores in the synthetic data:

$$\text{threshold} = \frac{\sum_{i=1}^{M} \hat{y}_i^{esy} - \hat{y}_i^{coh}}{M}$$

where M is the number of synthetic essays in the development set.

We furthermore evaluate a baseline where the joint model is trained *without* sharing the word embedding layer between the two submodels, and report the effect on performance ($\text{Joint Learning}_{\text{no\_layer\_sharing}}$). Finally, we evaluate a baseline where for the joint model we set the "gold" essay scores of synthetic data to zero ($\text{Joint Learning}_{\text{zero\_score}}$), as opposed to our proposed approach of setting them to be the same as the score of their original non-permuted counterpart in the ASAP dataset.

6 Results

The state-of-the-art $\text{LSTM}_{\text{T\&N}}$ model, as shown in Table 2, gives the highest performance on the ASAP data, but is not robust to adversarial input and therefore unable to capture aspects of local coherence, with performance on synthetic data that is less than 0.5. On the other hand, both

[13] https://bitbucket.org/melsner/browncoherence

[14] https://github.com/nusnlp/nea

[15] We use scikit-learn with the following parameters: alpha=0.1, coef0=1, degree=3, gamma=0.1, kernel='rbf'.

Model	ASAP	Synthetic	
	QWK	PRA	TPRA
EGrid	–	0.718*	0.706*
LC	–	0.946*	0.689*
LC_{mul}	–	**0.948***	0.620*
$LSTM_{T\&N}$	**0.739**	0.430	0.473
VecConcat	0.719	0.614*	0.567*
Joint Learning	0.724	0.770*	**0.777***

Table 2: Model performance on ASAP and synthetic test data. Evaluation is based on the average QWK, PRA and TRPA across the 8 prompts. * indicates significantly different results compared to $LSTM_{T\&N}$ (two-tailed test with $p < 0.01$).

our LC model and the EGrid significantly outperform $LSTM_{T\&N}$ on synthetic data. While EGrid is slightly better in terms of TPRA compared to LC (0.706 vs. 0.689), LC is substantially better on PRA (0.946 vs. 0.718). This could be attributed to the fact that LC is optimised using PRA on the development set. The LC_{mul} variation has a performance similar to LC in terms of PRA, but is significantly worse in terms of TPRA, which further supports the use of our proposed LC model.

Our Joint Learning model manages to exploit the best of both the $LSTM_{T\&N}$ and LC approaches: performance on synthetic data is significantly better compared to $LSTM_{T\&N}$ (and in particular gives the highest TPRA value on synthetic data compared to all models), while manages to maintain the high performance of $LSTM_{T\&N}$ on ASAP data (performance slighly drops from 0.739 to 0.724 though not significantly). When the Joint Learning model is compared against the VecConcat baseline, we can again confirm its superiority on both datasets, giving significant differences on synthetic data.

7 Further Analysis

We furthermore evaluate the performance of the the Joint Learning model when trained using different parameters (Table 3). When assigning "gold" essay scores of zero to adversarial essays ($\text{Joint Learning}_{\text{zero\_score}}$), AES performance on the ASAP data drops to 0.449 QWK, and the results are statistically significant.[16] This is partly explained by the fact that the model, given the training data gold scores, is biased towards predicting zeros. The result, however, further supports our hypothesis that forcing the Joint Learning model to rely on the coherence branch for adversarial input detection further improves performance. Importantly, we need something more than just training a state-of-the-art AES model (in our case, $LSTM_{T\&N}$) on both original and synthetic data.

Model	ASAP	Synthetic	
	QWK	PRA	TPRA
Joint Learning	**0.724**	**0.770**	**0.777**
$\text{Joint Learning}_{\text{no\_layer\_sharing}}$	0.720	0.741	0.753*
$\text{Joint Learning}_{\text{zero\_score}}$	0.449*	–	–

Table 3: Evaluation of different Joint Learning model parameters. * indicates significantly different results compared to our Joint Learning approach.

We also compare Joint Learning to $\text{Joint Learning}_{\text{no\_layer\_sharing}}$ in which the the two sub-models are trained separately without sharing the first layer of word representations. While the difference in performance on the ASAP test data is small, the differences are much larger on synthetic data, and are significant in terms of TPRA. By examining the false positives of both systems (i.e., the coherent essays that are misclassified as adversarial), we find that when the embeddings are not shared, the system is biased towards flagging long essays as adversarial, while interestingly, this bias is not present when the embeddings are shared. For instance, the average number of words in the false positive cases of $\text{Joint Learning}_{\text{no\_layer\_sharing}}$ on the ASAP data is 426, and the average number of sentences is 26; on the other hand, with the Joint Learning model, these numbers are 340 and 19 respectively.[17] A possible explanation for this is that training the words with more contextual information (in our case, via embeddings sharing), is advantageous for longer documents with a large number of sentences.

Ideally, no essays in the ASAP data should be flagged as adversarial as they were not designed to trick the system. We calculate the number of ASAP texts incorrectly detected as adversarial, and find that the average error in the Joint Learning model is quite small (0.382%). This increases with $\text{Joint Learning}_{\text{no\_layer\_sharing}}$ (1%), although still remains relatively small.

[16] Note that we do not report performance of this model on synthetic data. In this case, the thresholding technique cannot be applied as both sub-models are trained with the same "gold" scores and thus have very similar predictions on synthetic data.

[17] Adversarial texts in the synthetic dataset have an average number of 306 words and an average number of 18 sentences.

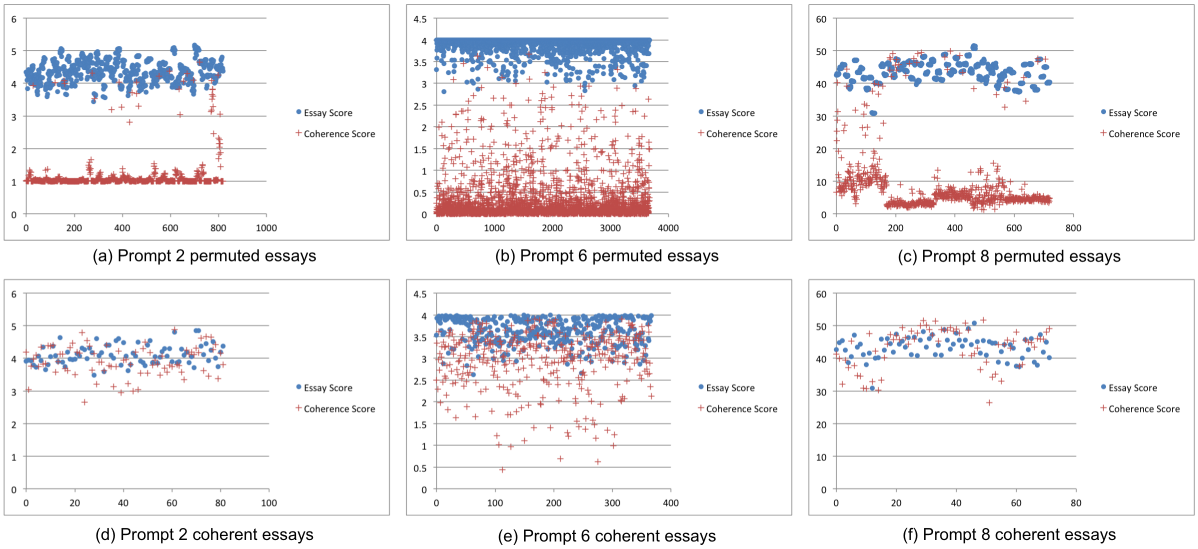

Figure 4: Joint Learning model predictions on the synthetic test set for 3 randomly selected prompts. The upper graphs ((a), (b) and (c)) show the predicted essay and coherence scores on adversarial text, while the bottom ones ((d), (e) and (f)) show the predicted scores for highly scored / coherent ASAP essays. The blue circles represent the essay scores, and the red pluses the coherence scores. All predicted scores are mapped to their original scoring scale.

We further investigate the essay and coherence scores predicted by our best model, Joint Learning, for the permuted and original ASAP essays in the *synthetic* dataset (for which we assume that the selected, highly scored ASAP essays are coherent, Section 4), and present results for 3 randomly selected prompts in Figure 4. The graphs show a large difference between predicted essay and coherence scores on permuted / adversarial data ((a), (b) and (c)), where the system predicts high essay scores for permuted texts (as a result of our training strategy), but low coherence scores (as predicted by the LC model). For highly scored ASAP essays ((d), (e) and (f)), the system predictions are less varied and positively contributes to the performance of our proposed approach.

8 Conclusion

We evaluated the robustness of state-of-the-art neural AES approaches on adversarial input of grammatical but incoherent sequences of sentences, and demonstrated that they are not well-suited to capturing such cases. We created a synthetic dataset of such adversarial examples and trained a neural local coherence model that is able to discriminate between such cases and their coherent counterparts. We furthermore proposed a framework for jointly training the coherence model with a state-of-the-art neural AES model, and introduced an effective strategy for assigning "gold" scores to adversarial input during training. When compared against a number of baselines, our joint model achieves better performance on randomly permuted sentences, while maintains a high performance on the AES task. Among others, our results demonstrate that it is not enough to simply (re-)train neural AES models with adversarially crafted input, nor is it sufficient to rely on "simple" approaches that concatenate output representations from different neural models. Finally, our framework strengthens the validity of neural AES approaches with respect to adversarial input designed to trick the system.

QuickEdit: Editing Text & Translations by Crossing Words Out

David Grangier **Michael Auli**
Facebook AI Research
Menlo Park, CA

Abstract

We propose a framework for computer-assisted text editing. It applies to translation post-editing and to paraphrasing. Our proposal relies on very simple interactions: a human editor modifies a sentence by marking tokens they would like the system to change. Our model then generates a new sentence which reformulates the initial sentence by avoiding marked words. The approach builds upon neural sequence-to-sequence modeling and introduces a neural network which takes as input a sentence along with change markers. Our model is trained on translation bitext by simulating post-edits. We demonstrate the advantage of our approach for translation post-editing through simulated post-edits. We also evaluate our model for paraphrasing through a user study.

1 Introduction

Computers can help humans edit text more efficiently. In particular, statistical models are used for that purpose, for instance to help correct spelling mistakes (Brill and Moore, 2000) or suggest likely completions of a sentence (Bickel et al., 2005). In this work, we rely on statistical learning to enable a computer to rephrase a sentence by only pointing at words that should be avoided. Specifically, we consider the task of reformulating either a sentence, i.e. *paraphrasing* (Quirk et al., 2004), or a translation, i.e. *translation post-editing* (Koehn, 2009b). Paraphrasing reformulates a sentence with different words preserving its meaning, while translation post-editing takes a candidate translation along with the corresponding source sentence and improves it.

Our proposal relies on very simple interactions: a human editor modifies a sentence by selecting tokens they would like the system to replace and no other feedback. Our system then generates a new sentence which reformulates the initial sentence by avoiding the word types from the selected tokens. Our approach builds upon neural sequence-to-sequence and introduces a neural network which takes as input a sentence along with token markers. We introduce a novel attention-based architecture suited to this goal and propose a training procedure based on simulated post-edits on translation bitext (§3). This approach allows to get substantial modifications of the initial sentence – including deletion, reordering and insertion of multiple words – with limited user effort.

Our experiments (§4) relies on large scale simulated post-edits. They show that our model outperforms our post-editing baseline by up to 5 BLEU points on WMT'14 English-German and WMT'14 German-English translation. The advantage of our method is also highlighted in monolingual settings, where we analyze the quality of the paraphrases generated by our model in a user study.

Before introducing our method (§3) and its empirical evaluation (§4), we describe related work in the next section.

2 Related Work

Our work builds upon previous research on neural machine translation, machine translation post-editing, and computer-assisted editing.

2.1 Neural Machine Translation

Statistical machine translation systems models automatically translate text relying on large corpora of bitext, i.e. corresponding pairs of sentences in the source and target language (Koehn, 2009a). Recently, machine translation systems based on neural networks have emerged as an effective approach to this problem (Sutskever et al., 2014). Neural networks are a departure from count-based translation systems, e.g. phrase-based systems, which used to dominate the field (Koehn, 2009a).

Research in Neural Machine Translation (NMT) focuses notably on identifying appropri-

Proceedings of NAACL-HLT 2018, pages 272–282
New Orleans, Louisiana, June 1 - 6, 2018.

ate neural architecture. Cho et al. (2014) and Suskever et al. (2014) proposed encoder/decoder models. These models consist of a Recurrent Neural Network (RNN) mapping the source sentence sentence into a latent vector (encoder). This vector conditions an RNN language model (decoder) which generates the target sentence (Mikolov et al., 2010; Graves, 2013). Bahdanau et al. (2014) adds attention to these models, which leverages that the explanation for a given target word in generally localized around a few source words. Recently, new architectures have proposed to replace recurrent modules with convolutions (Gehring et al., 2017) or self-attention (Vaswani et al., 2017) to further increase accuracy. These architecture also perform attention at more than one decoder layer, allowing for more complex attention patterns. In this work, we build upon the architecture of Gehring et al. (2017) since this model offers a good trade-off between high accuracy and fast decoding.

2.2 Translation Post-Editing

Post-editing leverages a machine translation system and enable human translators to edit its output with different levels of computer assistance. This enables improving machine translation outputs with lesser effort than purely manual translation.

Green et al. (2014) implement such a system relying on a phrase-based translation system. The system presents an initial translation to the user who can accept a prefix and select among the most likely postfix iteratively. Similar ideas relying on decoding with prefix constrains are common in post-translation (Langlais et al., 2000; Koehn, 2009b; Barrachina et al., 2009). Recently, these approaches based on left-to-right decoding have been extended to neural machine translation (Peris et al., 2017).

Closer to our work, Marie and Max (2015) propose light-weight interactions based on accepting/rejecting spans from the output of a statistical machine translation system. The user labels each span that should appear in the final translation. Unmarked spans are assumed to be undesirable and the system removes any entries that could generate those spans from the phrase table. The phrase table is modified such that only positively marked target spans are allowed to explain the corresponding source phrases.

Compared to their work, we rely on similar interactions but we do not require the user to label every token as either accepted or rejected. The user only needs to mark a few rejections. Also, we build on a more accurate neural translation model which is not amenable to phrase table editing. Finally, our method is equally applicable to the monolingual editing of regular text.

Automatic post-editing (APE) (Lagarda et al., 2009), i.e. a process which automatically modifies an MT output without human guidance (Lagarda et al., 2009), is also an active area of research. Although APE shares similarities to classical post-editing, it is beyond the scope of this paper.

2.3 Computer-Assisted Text Editing

Computer assisted text editing has been introduced with interactive computer terminals (Irons and Djorup, 1972). Its first achievement was to simplify the insertion, deletion, and copy of text compared to typewriters. Computers then enabled the emergence of computerized language assistance tools such as spelling correctors (Brill and Moore, 2000) or next word suggestions (Bickel et al., 2005).

More recently, research has focused on generating paraphrases (Bannard and Callison-Burch, 2005; Mallinson et al., 2017), compressing sentences (Rush et al., 2015) or simplifying sentences (Nisioi et al., 2017). This type of work expands the possibilities for *interactive* text generation tools, like our work.

Related to our work, Filippova et al. (2015) considers the task of predicting which tokens can be removed from a sentence without modifying its meaning relying on a recurrent neural network. Our work pursues a different goal since our model does not predict which token to remove, as the user provides this information. Our generation is more involved as our model rephrases the sentences, which includes introducing new words, reordering text, inflecting nouns and verbs, etc. Guu et al. (2017) considers generating text with latent edits. Their goal is not to enable users to control which words need to be changed in an initial sentence but to enable sampling valid English sentences with high lexical overlap around a starting sentence. Contrary to paraphrasing, such samples might introduce negations and other changes impacting meaning.

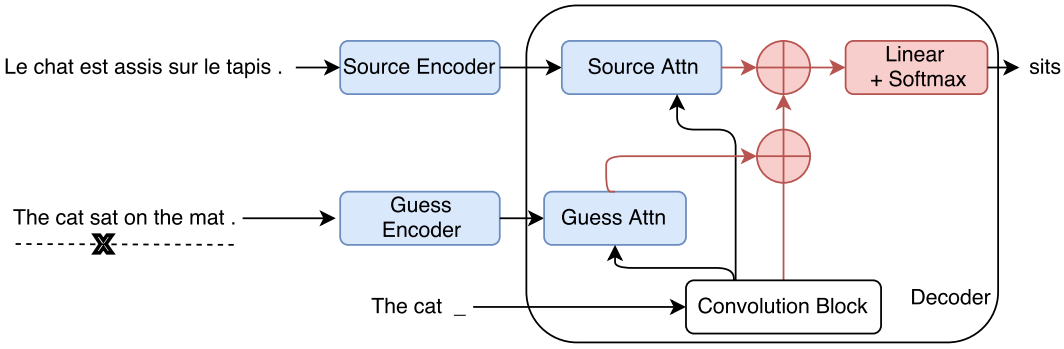

Figure 1: QuickEdit architecture for translation post-editing. The decoder attends to both encodings, one for the source and one for the initial translation (guess) with deletion markers (X on the diagram). Our simplified schema shows one convolutional block and single-hop attention for readability.

3 QuickEdit

QuickEdit is our sequence-to-sequence model for post-editing via delete actions. This model takes as input a *source* sentence and an initial *guess* target sentence annotated with change markers. It then aims to improve upon the guess by generating a better target sentence which avoids the marked tokens.

3.1 Model Architecture

Our model builds upon the architecture of Gehring et al. (2017). This model is a sequence to sequence neural model with attention. Both the encoder and decoder are deep convolutional networks with residual connections. The model performs *multi-hop* attention, i.e. each layer of the decoder attends to the encoder outputs. Our architecture choice is motivated by the accuracy of this model along with its computational efficiency.

QuickEdit adds a *second* encoder to represent the annotated guess sentence. It also duplicates every attention layer to allow the decoder to attend both to the source and the guess sentences. Dual attention has been introduced recently in the context of automatic post-editing (Novak et al., 2016; Libovický and Helcl, 2017). Our work is however the first work to introduce dual attention in a multi-hop architecture. Figure 1 illustrates our architecture.

The encoder of the initial guess takes as input a target sentence t annotated with binary change labels c, i.e.

$$g = \{g_i\}_{i=1}^{l_g} \text{ where } \forall i, g_i = (t_i, c_i)$$

in which l_g denotes the length of the guess, t_i is an index in the target vocabulary and c_i is a binary variable with 1 indicating a request to change the token by the user and 0 indicating no user preference. The first layer of the encoder maps this sequence to two embedding sequences, i.e. a sequence of target word embeddings and a sequence of positional embeddings. Compared to (Gehring et al., 2017), we extend the positional embedding to contain two types of vectors, positional vectors associated with positions i where $c_i = 0$ and positional vectors associated with positions i where $c_i = 1$. Like all parameters in the system, both sets of embeddings are learned to maximize the log-likelihood of the training reference sentences conditioned on the source, annotated guess pairs.

The attention over two sentences is simple. Both source and guess encoders produce a sequence of key and value pairs. We denote the output of the source encoder as $\{(k_i^s, v_i^s)\}_{i=1}^{l_s}$ and the output of the guess encoder as $\{(k_i^g, v_i^g)\}_{i=1}^{l_g}$. At each decoder layer k and time step j, the decoder produces a latent state vector h_j^k, this vector attends to the output of the source encoder,

$$a_i^s = \exp\left(h_j^k \cdot k_i^s\right) / \sum_l \exp\left(h_j^k \cdot k_l^s\right)$$

and the guess encoder,

$$a_i^g = \exp\left(h_j^k \cdot k_i^g\right) / \sum_l \exp\left(h_j^k \cdot k_l^g\right).$$

This attention weights are used to summarize the values of the source $\sum_i a_i^s v_i^s$ and the guess $\sum_i a_i^s v_i^g$ respectively. The attention module then averages these two vectors $\frac{1}{2}\sum_i a_i^s v_i^s + \frac{1}{2}\sum_i a_i^g v_i^g$ and uses this average instead of the source attention output in the next layer (Gehring et al., 2017).

3.2 Training & Inference

Our model is trained on translation bitext by simulating post-edits. Given a bitext corpus, we first train an initial translation system and we then rely on this system to translate the training corpus. This strategy results in three sentences for each example: the source, the guess (i.e. the sentence decoded from the initial system) and the reference sentence. Post-edits are simulated by marking guess tokens which do not appear in the corresponding reference sentence.

The dual attention model presented in the above section is then trained. We maximize the log-likelihood of the training reference sentences y given each corresponding source sentence x and the annotated guess g, i.e. we maximize

$$\mathcal{L}_{\text{Train}} : \theta \rightarrow \sum_{(x,y,g) \in \text{Train}} \log P(y|x, g, \theta)$$

where y refers to the reference sentence, x refers to the source sentence and g is the annotated guess sentence as defined above. Training relies on stochastic gradient descent (Bottou, 1991), using Nesterov's accelerated gradient with momentum (Nesterov, 1983; Sutskever et al., 2013). At inference time, we decode through standard left-to-right beam search (Sutskever et al., 2014). Our decoding strategy for QuickEdit also incorporates hard constraints that prevent the decoder from outputting tokens which are marked in the guess.

3.3 Extension to Monolingual Editing

The extension of QuickEdit to a monolingual setting is straightforward: we remove the source encoder and the corresponding attention path. This results in a single encoder model which takes only an annotated guess as input. This model can be trained from pairs of sentences consisting of a machine translation output along with the corresponding reference sentence. Although machine translation bitext are used to create this model training data, it operates solely on target language sentences without requiring a source sentence at test time. In our experiments, we train distinct models for the monolingual setting. We do not consider sharing parameters with the translation models at this point.

4 Experiments & Results

We evaluate on three translation datasets of increasing size and we report results in both language directions: IWSLT'14 German-English (Cettolo et al., 2014), WMT'14 German-English (Luong et al., 2015), and WMT'14 English-French (Bojar et al., 2014). Our post-editing baseline is our initial neural translation system, complemented with decoding constraints to disallow marked guess words to be considered in the beam. For paraphrasing, we compare our model trained on WMT'14 fr-en to the model of (Mallinson et al., 2017) on the MTC dataset (Huang et al., 2002) following their setup. We relied on WMT'14 fr-en training data motivated by its size[1].

For IWSLT'14 we train on 160K sentence pairs and we validate on a random subset of 7,250 sentence-pairs held-out from the original training corpus. We test on the concatenation of *tst2010, tst2011, tst2012, tst2013, dev2010* and *dev2012* comprising 6,750 sentence pairs. The vocabulary for this dataset is 24k for English and 36k for German. For WMT'14 English to German and German to English, we use the same setup as Luong et al. (2015) which comprises 4.5M sentence pairs for training and we test on newstest2014.[2] We took 45k sentences out of the training set for validation purpose. As vocabulary, we learn a joint source and target byte-pair encoding (BPE) with 44k types from the training set (Sennrich et al., 2016b,a). Note that even when using BPE, we solely rely on full word markers, i.e. all the BPE tokens of a given word carry the same binary indication (to be changed/no preference). For WMT'14 English to French and French to English (Bojar et al., 2014), we also rely on BPE with 44k types. This dataset is larger with 35.4M sentences for training and 26k sentences for validation. We rely on newstest2014 for testing[3].

The model architecture settings are borrowed from (Gehring et al., 2017). For IWSLT'14 de-en and IWSLT'14 en-de, we rely on 4-layer encoders and 3-layer decoders, both with 256 hidden units and kernel width 3. The word embedding for source and target as well as the output matrix have 256 dimensions. For WMT'14 en-de and WMT'14 de-en, both encoders and decoders have 15 layers (9 layers with 512 hidden units, 4

[1] Posterior to our experiments, (Wieting and Gimpel, 2017) released an even large dataset that might be used in our setting.

[2] http://nlp.stanford.edu/projects/nmt

[3] http://www.statmt.org/wmt14/translation-task.html

layers with 1,024 units followed by 2 layers with 2,048 units). Input embeddings have 768 dimensions, output embedding have 512. For WMT'14 en-fr and WMT'14 fr-en, both encoders and decoders have 15 layers (6 layers with 512 hidden units, 4 layers with 768 units, 3 layers with 1024 units, followed by two larger layers with 2048 and 4096 units). Similar to the German model, input embeddings have 768 dimensions, output embedding have 512 dimensions. For all datasets, we decode using beam search with a beam of size 5.

4.1 Post-editing

Our study is based on simulated post-edits, i.e. simulated token deletion actions. We start from machine translation outputs from an initial system in which we label tokens to change automatically. For initial translation, we rely on the convolutional translation system from (Gehring et al., 2017)[4] learned from the training portion of the dataset. For each system output, any word which does not belong to the reference translation is marked to be changed. We perform this operation for the train, validation and test portion of each dataset. The training and validation portion can be used for learning and developing our post-editing system. The test portion is used for evaluation.

Table 1 reports our result on this task. Our QuickEdit method strongly outperforms the baseline post-editing system. Both systems access the same information, i.e. a list of deleted word types, which constrains the decoding. QuickEdit adds attention over the initial sentence with rejection marks. This has a big impact on BLEU. On the larger WMT'14 en-de benchmark, the advantage is over 5 BLEU point for both directions. We conjecture that the improvement is lower on the smaller IWSLT data due to over-fitting, i.e. the base system is excellent on the training set which reduces the post-editing opportunities on the training data, therefore limiting the amount of supervised data for training our post-editing system. We show examples of post-editing from the test set of WMT-14 de-en in Table 2. These examples show the ability of the model to rephrase sentences avoiding the marked tokens while preserving the source meaning. Similar to our experiments on WMT'14 en-de, QuickEdit also reports large improvement with respect to the baseline model on WMT'14 en-fr, with $+5.6$ points (53.4 vs 47.8).

One should note that the simulated edits rely on gold information, i.e. crossed-out words are always absent from the reference. Our aim is to simulate a post-editor which might have a sentence close to the reference in mind. This evaluation method allows to conduct large scale experiments without labeling burden. Conducting an interactive post-editing study requires trained editors and interface consideration beyond the scope of this initial work.

4.2 Partial Feedback

So far, our post-editing setting marked all incorrect words in the guess. We now consider a setting where the simulated post-editor performs less work by marking only a subset of these tokens. This is analogous to a hypothetical online translation service which offers a feature enabling the user to mark parts of a translation to be improved. In addition to marking only a subset of the incorrect tokens at inference time, we also train new models for which the training data also only had a subset of incorrect tokens marked. Specifically, we train three models QE25, QE50, QE100 for which either 25%, 50% or 100% of incorrect guess tokens were marked.

In this setting, we also compare with the baseline model, i.e. the initial translation system augmented with decoding constraints to avoid marked words. Figure 2 plots BLEU as a function of the number of marked words on the validation set of WMT'14 German to English. This curve is obtained by marking at most 1, 2, ..., 8 words to be changed per sentence, taking into account that the actual number of marked word in a sentence cannot be higher than the number of guess words not present in the reference sentence.

Compared to the baseline, there is a small advantage for QuickEdit for 1-2 marked words and a larger improvement when more words are marked. Unsurprisingly, the model trained with fewer marked words (QE25, QE50) performs better when tested with fewer marked words, while QE100 gives the largest improvement with 4 or more marked words.

4.3 Monolingual Editing

Table 1 also reports monolingual results. In that case, the system is not given the source sentence, only a sentence in the target language along with change markers. Even if the model is not given the

source, it manages to generate sentences which are closer to the reference than the initial sentences, as shown by the BLEU improvement. This shows the ability of the model to paraphrase from deletion constraints. Table 3 shows examples of the system in action from the English test set of WMT-14 fr-en. This examples show that the model can provide synonyms, e.g. *essential* → *vital*, or *came after* → *followed*. The model can also replace tenses when appropriate, e.g. *have not waited* → *did not wait*, or *wrote* → *had written*.

4.4 Paraphrasing

Although it is not our primary goal, monolingual QuickEdit can also be used for paraphrasing by pairing it with another model to automatically generate change markers. In that case, the generative model of edit markers replaces the human instructions. Basically, given an input sentence x, the edit model generate a sequence c of binary variables, which indicates whether each word x_i of x should

Table 5: Paraphrasing experiments on news data from the MTC dataset. Bold indicates tokens introduced by the the models, i.e. tokens which are not in the human source given as input.

edited out $P(c_i = 1|x_i = w)$ on the QuickEdit training data based on relative frequency counts. For inference, we simply threshold this probability $P(c_i = 1|x_i = w) > \tau$ to assign change markers. τ is selected to control how *bold* paraphrasing should be, i.e. large τ would yield minor changes, while small τ would edit the input sentence substantially.

We compare our paraphrasing approach with ParaNet (Mallinson et al., 2017), a paraphrasing neural model based on translation pivoting[5]. We conduct our evaluation on the MTC dataset (Huang et al., 2002) following the setup introduced in the ParaNet paper. This setup consists of 75 human paraphrase pairs (excluding duplicate MTC sentences as well as erroneous paraphrases). The evaluation considers each pair of human paraphrases (x, y). Each paraphrasing model (QuickEdit and ParaNet) generates a paraphrase given x. Then human judgments are collected by showing y and three versions of x, i.e. the original version x, its paraphrase from ParaNet $x^{(p)}$ and its paraphrase from QuickEdit $x^{(q)}$. For each example, the three sentences $x, x^{(p)}, x^{(q)}$ are shuffled and do not carry any information about their origin. The assessor should label whether each version of x is a valid paraphrase of y and should rank them by fluency from 1 most fluent to 3 least fluent.

We can evaluate paraphrasing performance at various levels of boldness which we control with the parameter τ. Bold paraphrasing means that the model needs to generate sentences which differ more from the input x than conservative paraphrasing. In this work, our evaluation relies on a level of boldness comparable to ParaNet

[5]We are thankful to the authors of ParaNet for sharing their generations for our evaluation.

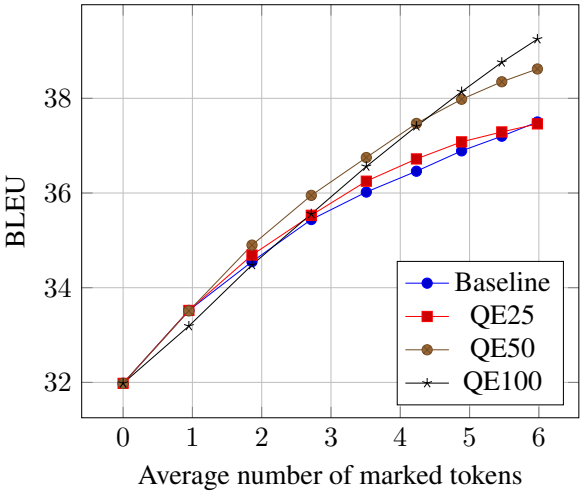

Figure 2: Post-editing results as a function of the average number of marked tokens per sentence on WMT'14 de-en validation set (45k sentences). QE25, QE50, QE100 refer to QuickEdit models trained with data where respectively 25, 50 or 100% of the guess tokens not present in the reference were marked to be changed.

from (Mallinson et al., 2017). Table 4 reports the results of this experiment. Accuracy measures the fraction of sentences considered valid paraphrases. Fluency measures the number of cases the paraphrase was considered more fluent or as fluent as the source sentence. Boldness measure the fraction of paraphrase tokens that were not in the source.

The results highlight the advantages of QuickEdit. The paraphrases from QuickEdit are accurate for 72% of the sentences versus 56% for ParaNet. The fluency of the generation from QuickEdit ranks equally or higher than the human source sentence for 53% of the examples, which compares to 37% for ParaNet. Table 5 shows a few paraphrases from both models. These examples highlight that the boldness operating point chosen by the authors of ParaNet is rather conservative, with few edits per sentence. Nevertheless, QuickEdit advantage is clear, showing that ParaNet often forgets part of the source sentence while QuickEdit does not, e.g. *could futher develop* in the first example is not expressed by ParaNet but QuickEdit proposes *would continue*. This tendency to shorten the input can yield an opposite meaning, e.g. in the second example, ParaNet rephrases *cause minimum threat* as *endanger* while QuickEdit proposes correctly *pose a minimum threat*. Examples with less conservative paraphrasing are shown in Table 3.

5 Conclusions

This work proposes QuickEdit, a neural sequence to sequence model that allows one to edit text by simply requesting few initial tokens to be changed. From a marked sentence, the model can generate an edited sentence both in the context of machine translation post-editing (a source sentence is also provided), or in a monolingual setting. In both cases, we assess the impact of the change requests. We show that marking words not present in a hidden reference sentence allow the model to generate text closer to this reference. In the context of post-editing, we conduct simulated post-edits, i.e. we mark words absent from the reference as rejected. We show that crossing out a few words per sentence can drastically improve BLEU, even on top of a strong MT system, e.g. BLEU on WMT'14-en-fr moves from 40.2 to 53.4 with QuickEdit post-editing as opposed to 47.8 for the post-editing baseline. In the context of monolingual editing, we show that our system both allow text editing and paraphrasing. For paraphrasing, we outperform a strong model (Mallinson et al., 2017) in a human evaluation on the MTC dataset, both in terms of accuracy (72% vs 53%) and fluency of the generation (53% vs 37%).

Our work opens several future directions of research. First, we want to extend our evaluation from simulated post-edits to a genuine interactive editing scenario. QuickEdit currently allows only to reject word forms for a whole sentence, not reject them in a specific context. We plan to explore this possibility. Also, QuickEdit could be a good basis for an automatic post-editing system (Chatterjee et al., 2015). QuickEdit can be applied for multi-step editing, letting the user refine their sentence multiple time. In that case, attending to all previous versions of the sentence would be relevant. Finally, we could also consider offering a richer set of simple edit actions. For instance, we could propose span substitutions to the user, which requires a decoding stage proposing a short list of promising spans and candidate replacements.

Acknowledgments

We thank Marc'Aurelio Ranzato, Sumit Chopra, Roman Novak for helpful discussions. We thank Sergey Edunov, Sam Gross, Myle Ott for writing the fairseq-py toolkit used in our experiments. We thank Jonathan Mallinson, Rico Sennrich, Mirella Lapata, for sharing ParaNet data.

Abstract

Search task extraction in information retrieval is the process of identifying search intents over a set of queries relating to the same topical information need. Search tasks may potentially span across multiple search sessions. Most existing research on search task extraction has focused on identifying tasks within a single session, where the notion of a session is defined by a fixed length time window. By contrast, in this work we seek to identify tasks that span across multiple sessions. To identify tasks, we conduct a global analysis of a query log in its entirety without restricting analysis to individual temporal windows. To capture inherent task semantics, we represent queries as vectors in an abstract space. We learn the embedding of query words in this space by leveraging the temporal and lexical contexts of queries. To evaluate the effectiveness of the proposed query embedding, we conduct experiments of clustering queries into tasks with a particular interest of measuring the cross-session search task recall. Results of our experiments demonstrate that task extraction effectiveness, including cross-session recall, is improved significantly with the help of our proposed method of embedding the query terms by leveraging the temporal and temp-lexical contexts of queries.

1 Introduction

A complex search task is defined as a "a multi-aspect or a multi-step information need consisting of a set of related subtasks, each of which might recursively be complex" (Hassan Awadallah et al., 2014). For example, a task of making arrangements for travel to a conference qualifies as a complex search task because there are several choices that a user needs to make in order to plan his entire trip, e.g. selecting flight, hotel, making arrangements for local transport, finding the conference venue, finding good places to eat around, finding local sight-seeing options after the conference etc. All these sub-tasks are likely to take place within their own search sessions, where a session is defined as a set comprised of queries executed during a time period of a specific length, usually about half-an-hour (Lucchese et al., 2013).

In this paper, we address the problem of automatically predicting whether search sessions, focused on specific activities, are a part of a broader complex search task, which we refer to as the *cross-session search task extraction problem*. Cross-session search task extraction can potentially find applications in designing more proactive search engines, which may suggest relevant information about specific subsequent subtasks along a timeline, e.g. suggesting places to eat around a conference venue without the user needing to execute these queries.

To see why cross-session search task extraction is a challenging problem, firstly, note that it is likely that a query session for flight booking and one for local sightseeing around a conference venue may be far apart in time, as a result of which simple approaches of grouping queries by their timestamps, e.g. (Lucchese et al., 2013), are not likely to yield satisfactory outcomes. Secondly, the term overlap between the queries of these two sessions is also likely to be low, indicating that using lexical similarity for clustering cross-session queries into a single group, e.g. (Lucchese et al., 2013; Wang et al., 2013), is unlikely to be effective.

As an illustrative example of term mismatch, consider the two queries 'Eric Harris', 'Reb Vodka' from the AOL query log[1]. Although these two queries do not share any common terms between them, they refer to the task of finding infor-

New Orleans, Louisiana, June 1 - 6, 2018.

mation on the Columbine high school massacre, the first query referring to the name of the first murderer while the second one refers to their nickname.

Our Contributions. To alleviate the identified problems with attempting to group queries by their timestamps or lexical similarities, we propose to embed queries in a task-based semantic space in a manner that will give two similar queries in this space a high likelihood of pertaining to the same underlying task. Word embedding algorithms, such as 'word2vec' (Mikolov et al., 2013), make use of the lexical context in learning vector representations of words. We propose to *transform* these word vectors into a task-oriented semantic space with the objective of making two words that are likely to be a part of the same search task closer to each other.

To learn the transformation function, we make use of average session duration and lexical similarities between within-session queries. Our method thus provides a unifying framework for addressing tempo-lexical similarity, in contrast to previous approaches that treat these two separately. Another important contribution of our proposed method is that we are able to empirically demonstrate that our proposed method is more effective than existing algorithms (Lucchese et al., 2013; Mehrotra and Yilmaz, 2017) in extracting cross-session search tasks without the application of any external information for estimating task relatedness. For instance, the work in (Lucchese et al., 2013) relies on Wikipedia to contextualize queries, while the one in (Verma and Yilmaz, 2014) uses Wikipedia-based entity recognition to estimate task relatedness.

The rest of the paper is organized as follows. In Section 2 we overview previous work in task extraction and query embedding. In Section 3, we introduce our semantic context driven transformation-based word vector embedding algorithm to enhance cross-session query similarity matching. Section 4 then describes how the transformed query vectors are clustered into search tasks. Section 5 describes our experimental setup. Section 6 presents the results of our experiments. Section 7 concludes the paper with suggestions for future work.

2 Related Work

In this section we review existing work in search task extraction and query embedding and contrast this with the method introduced in this paper. We look first at work on unsupervised task extraction and then consider work on supervised methods, and final briefly consider a study introducing a query embedding method.

2.1 Unsupervised Task Extraction

A method for extracting tasks within each search session is proposed in (Lucchese et al., 2013). A session is defined with fixed length time windows. After investigating a wide range of time length values, the optimum is reported to be 26 minutes, which is what we also use in our work. The study reported in (Lucchese et al., 2013) also investigated a number of clustering techniques to group together related queries from each session into tasks. A wide range of features were investigated to define the similarity between a pair of queries, e.g. edit distance, cosine-similarity and Jaccard coefficient of character level trigrams. In contrast to (Lucchese et al., 2013; Wang et al., 2013), we investigate the use of embedded query vectors to compute similarity, rather than depending on character and word level lexical similarity features, e.g. edit distance, term overlap, trigram character overlap etc. Another difference of our method from (Lucchese et al., 2013) is that instead of restricting clustering to each session, we cluster the entire dataset globally, which implies that our method is not limited by variations in session duration. We also evaluate the effectiveness of clustering the entire dataset rather than on aggregating clustering effectiveness separately for each session as in (Lucchese et al., 2013).

Extraction of task hierarchies was investigated in (Mehrotra et al., 2016). Given a set of task related queries, they composed query vectors as weighted combinations of the constituent query term vectors, the weights being the maximum likelihood estimates from query-task relationships. A Chinese Restaurant Process (CRP) based posterior inference process was then used to extract the tasks from individual queries. In an extension of this work (Mehrotra and Yilmaz, 2017), the authors proposed a Bayesian non-parametric approach for extracting task hierarchies. The main difference between our approach and (Mehrotra et al., 2016; Mehrotra and Yilmaz, 2017) is that

our focus is on finding cross-session tasks from a query log, rather than finding hierarchies of tasks. Further, instead of using similarities between embedded query vectors as one of the features to estimate the relatedness between two queries, we propose a task semantics driven embedding technique to transform a query in close proximity to its task-related counterpart.

An entity extraction method was applied in (Verma and Yilmaz, 2014) to estimate similarities between queries for the purpose of task extraction. In contrast to this, our method does not rely on an entity extractor to extract cross-session tasks.

2.2 Supervised Task Extraction

A supervised approach for automatically segmenting queries into task hierarchies was proposed in (Jones and Klinkner, 2008). They trained logistic regression models to determine whether two queries belong to same task or not. According to (Wang et al., 2013), the disadvantage of using a classifier based approach for extracting tasks is that with the binary predictions of the classifier it is difficult to model the transitive task dependence between the queries, e.g. if query pairs (q_1, q_2) and (q_2, q_3) are predicted to be part of the same task, the classifier may not predict that q_1 and q_3 are also a part of the same task. Graph-based clustering on the binary adjacency matrix between query pairs (obtained from logistic regression output) is also likely to introduce noise during clustering (Wang et al., 2013). The limitations of (Jones and Klinkner, 2008) were alleviated in the work reported in (Wang et al., 2013), which employs a structural SVM framework for estimating the weights of different lexical features to measure the similarity between two queries.

The difference between the studies reported in (Jones and Klinkner, 2008; Wang et al., 2013) and our work is that we propose a completely unsupervised approach for clustering queries. This implies that our method does not rely on the availability of training data, the construction of which requires considerable manual effort.

2.3 Query Embedding

A relevance-based word embedding technique was developed in (Zamani and Croft, 2017). This method uses the top documents retrieved for each query to learn the association between the query terms and those occurring in the retrieved documents. In contrast to retrieving ranked lists for every query as in (Zamani and Croft, 2017), we capture the semantic context of query words with the help of other useful cues for task-relatedness, e.g. the time-gap between queries.

3 Embedding Query Words

'Word2vec' is a standard approach to obtain embedded words vectors (Mikolov et al., 2013). The word2vec approach aims to create similar vector representations of words that have similar context, and are thus assumed to be significantly semantically related. In this section, we explain why the standard word2vec method may not be suitable for embedding queries in an abstract space of task-semantics for the purpose of using these vectors to extract cross-session search tasks. To address this problem, we propose a method of word embedding that is able to capture larger semantic contexts for better estimation of the word vectors.

3.1 Problems with Short Documents

Let $\mathbf{w} \in \mathbb{R}^d$ denote the vector representation of a word $w \in V$, V and d being the vocabulary and the dimension of the embedded vectors, respectively. Let W be a $d \times V$ matrix, where each d dimensional column vector represents a word vector. Let D be an indicator random variable denoting semantic relatedness of a word with its context. Given a pair of words, (w, c), the probability that the word c is observed in the context of word w is given by $\sigma(\exp(-(\mathbf{w} \cdot \mathbf{c})))$. Word embedding for a given corpus is obtained by sliding a window along with its context through each word position in the corpus maximizing the objective function shown in Equation 1.

$$J(\theta) = \sum_{w_t, c_t \in D^+} \sum_{c \in c_t} log(P(D = 1 | \mathbf{w_t}, \mathbf{c_t})) - \sum_{w_t, c'_t \in D^-} \sum_{c \in c'_t} log(P(D = 1 | \mathbf{w_t}, \mathbf{c'_t})) \quad (1)$$

In Equation 1, w_t is the word in the t^{th} position in a training document corpus, c_t is the set of observed context words of word w_t within a word window, c'_t is the set of randomly sampled words from outside the context of w_t. D^+ denotes the set of all observed word-context pairs (w_t, c_t), whereas D^- consists of pairs (w_t, c'_t).

The word2vec algorithm respects document boundaries by not extending the context vector

across them. In the context of our empirical study, we aim to learn word vector embedding from a query log, where each document in the 'word2vec' terminology refers to a single query. In the case of keyword-based search queries, often comprising 2-3 words, the average number of context vectors is much lower than the number of contexts available for the standard word embedding scenario of full length documents, e.g. news articles and web pages. Consequently, this may result in ineffective estimation of the word-context semantic relations for the queries.

3.2 Word Vector Transformation with Semantic Contexts

To alleviate the problems of short contexts when embedding queries, we propose to learn a transformation matrix to transform a set of word vectors to, generally speaking, another abstract space. The aim is to transform a word vector $\mathbf{w}$ so that it is close to a set of other words that *respects* the characteristics of this abstract space. In the context of our problem, the abstract space refers to the embedding space of task-relatedness with the characteristics that queries that are a part of the same search task should be embedded close to each other.

We adopt a general terminology of referring to the desired similarity in the abstract space as *semantic similarity*, which in the context of our problem refers to task-relatedness and is not to be confused with linguistic semantics. Formally, the set of words similar to the word w is represented by the set $\Phi(w)$ shown in Equation 2,

$$\Phi(w) = \{v : (w, v) \in S\}, \tag{2}$$

where S denotes the semantic relation between a pair of words. In particular, the set $\Phi(w)$ depends on the definition of the semantic relation S between two words, which we will describe in Section 3.3.

Assuming the existence of a pre-defined semantic relation S between word pairs, we define the loss function for a word vector $\mathbf{w}$ as shown in Equation 3.

$$l(\mathbf{w};\theta) = \sum_{\mathbf{v}:v\in\Phi(w)} \sum_{\mathbf{u}:u\notin\Phi(w)} \max\big(0, m - ((\theta\mathbf{w})^T\mathbf{v} - (\theta\mathbf{w})^T\mathbf{u})\big) \tag{3}$$

Equation 3 defines a hinge loss function with margin m (set to 1 in our experiments). The loss function is parameterized by the transformation matrix $\theta \in \mathbb{R}^{d\times d}$, and is learned by iterating with stochastic gradient descent. The word vectors used in learning the parameter matrix θ are obtained by the word2vec skip-gram algorithm. After training, each word vector $\mathbf{w}$ is transformed to $\mathbf{w}'$ in Equation 4.

$$\mathbf{w}' = \theta \cdot \mathbf{w} \tag{4}$$

Informally speaking, the objective function aims to maximize the similarity between two word vectors $\mathbf{w}$ and $\mathbf{v}$ that are members of the same semantic context. On the other hand, it minimizes the similarity between the word vector $\mathbf{w}$ and a word vector $\mathbf{u}$ randomly sampled from outside its context, as defined by the semantic relation S of Equation 2. In principle, the objective function of Equation 3 is similar to the word2vec objective function of Equation 1, the difference being in the definition of the context vector. While the word2vec algorithm relies on an adjacent sequence of words to define a context, in our proposed approach, we rely on a pre-defined set of binary relations between words.

Another analogy of Equation 3 can be drawn with the multi-modal embedding loss function proposed in (Frome et al., 2013), where the words from the caption of an image constitute the notion of the 'semantic context' of the image vector used to transform it. For our problem, we make use of this context to associate the task-specific relationship between query words.

3.3 Temporal Semantic Context

In the particular context of query logs, temporal similarity is likely to play an important role in topically grouping queries. This is because queries in the same search session are usually related to the same topic, as observed in previous studies (Lucchese et al., 2013; Wang et al., 2013). For example, it can be observed from the AOL query log that the words 'reb' and 'vodka' belong to the same search session as the words 'eric' and 'harris' (see example in Section 1). In this case, the semantic relationship S, as described in Section 3.2, considers terms u (e.g. 'vodka') and v (e.g. 'harris') from the same query session to be semantically related. To define the semantic relation S, we take into account a temporal context specified by a time window of 26 minutes as reported in (Lucchese et al., 2013). Specifically, if two queries belong to the same search session, as defined by a fixed length time window, then each

constituent word pair within them is considered to be members of the set S.

3.4 Tempo-Lexical Semantic Context

In real-life settings, even within a session of a specified time length, users often multi-task their activities (possibly by using multiple browser tabs or windows) (Lucchese et al., 2013; Wang et al., 2013; Mehrotra and Yilmaz, 2017). To address this issue, we further cluster the queries of each search session into mutually disjoint groups. Our hypothesis is that this grouping of the queries of a single search session into multiple clusters may improve word embedding of the query terms further by restricting the semantic relationship S (Equation 2) to consider terms from related queries within each cluster separately.

Our clustering approach is based on a weighted graph of query similarities computed by a linear combination of content-based similarity (Sim_r) and retrieved document list based similarity (Sim_r) as described in Section 4 and Section 5.3. The clusters then provide the tempo-lexical contexts which are subsequently used to improve the quality of embedding of the query words.

4 Clustering of Embedded Queries

In this section, we describe our unsupervised approach to identifying cross-session tasks by clustering the query vectors, where the constituent query word vectors are obtained using the word embedding approaches described in Section 3.

4.1 Query Vector Embedding

We hypothesize that the modified word vector embedding approach of Section 3.2 will be more effective in capturing the session specific semantics of query terms since it takes into account the temporal context of query session information from query logs. We adopt a standard word vector combination method to form embedded query vectors. Because of the compositionality property of word vectors (Mikolov et al., 2013), the simple method of averaging over the constituent word vectors has been reported to work well for various tasks such as term re-weighting and query reformulation (Zheng and Callan, 2015; Grbovic et al., 2015).

4.2 Clustering of Query Vectors

Unlike previous approaches of grouping together queries according to fixed time windows, and then clustering the queries within each time window separately (Lucchese et al., 2013; Wang et al., 2013), we take a more general approach of clustering the overall set of query vectors.

Since the number of query clusters cannot be known a priori, the number of clusters is estimated by adopting a clustering approach that does not require the number of clusters to be specified. We adopt the best performing clustering method identified in (Lucchese et al., 2013) referred to as QC-$_{WCC}$. This is a graph based clustering algorithm that extracts the weighted connected components of a graph after constructing a complete graph and then pruning off the edges that are below a predefined threshold, η.

In QC-$_{WCC}$, the weights between the graph edges are defined by a linear combination of two types of similarities: i) content-based (Sim_c), and ii) retrieval based (Sim_r), as shown in Equation 5, in which the overall similarity is controlled by the linear combination parameter α.

$$Sim(q_i, q_j) = \alpha Sim_c(q_i, q_j) + (1 - \alpha) Sim_r(q_i, q_j) \quad (5)$$

- *Content-based* similarity: Measured with the help of character trigrams and normalized Levenshtein similarity between query pairs.
- *Retrieval-based* similarity: Each query is contextualized with a Wikipedia collection. More specifically, two queries are considered similar if the top 1000 documents retrieved by them are also similar.

In contrast to the experimental setup of (Lucchese et al., 2013), a) we conduct clustering globally instead of clustering each individual query session separately; and b) the edge weights of the graph-based clustering in our case refers to the cosine-similarity values computed between the embedded query vectors and cosine similarity values between the vectors obtained from top 1000 documents retrieved from Clueweb12B, a publicly available web collection[2].

5 Experimental Setup

In this section we describe the setup for our experimental study. We begin with an overview of our datasets, then introduce the experimental baselines used and the objectives of our experiments, finally

[2] http://boston.lti.cs.cmu.edu/clueweb12/

we set out the parameter settings used in our experiments.

5.1 Dataset

Similar to previous reported studies (Lucchese et al., 2013; Mehrotra and Yilmaz, 2017; Mehrotra et al., 2016; Verma and Yilmaz, 2014), we use the AOL query log for our experiments. In order to compare our results with these studies, we use the same subset of 1424 queries from the AOL query log for the evaluation of task extraction effectiveness as used in these earlier studies. However, since the purpose of these studies was only to extract tasks from a single session, in its annotation scheme two queries only qualified as part of the same task if they appeared within the same session.

In contrast, since we investigate cross-session task extraction, the time length threshold is not applicable to our annotation scheme, as a result of which, we re-annotated the task labelled dataset of (Lucchese et al., 2013). In particular, our annotation scheme was solely based on the underlying search intent of the query.

While re-annotating the dataset of (Lucchese et al., 2013), the annotators were instructed not to change the task labels within each session. Instead, the annotators were asked to re-label task identifiers spanning across different query sessions. For example, the annotation of (Lucchese et al., 2013) considered 'robert f kennedy jr' and 'robert francis kennedy' to belong to two different tasks since these queries were executed during different sessions. However, our annotation scheme considers them to be a part of the same task.

Two persons were employed to carry out our annotation step of the set of 1424 queries in two different batches. They were asked to come to a consensus when trying to merge the task labels across their individual batches. The annotators were instructed to use a commercial search engine (e.g. Google), if required, to determine if two queries from different search sessions could potentially relate to the same underlying task. Table 1 provides an overview of our annotated task labels; this shows that there are a considerable number of sessions that contain queries spanning across session boundaries. It can be seen from Table 1 that after post-processing the single session task labels, the total number of distinct tasks is reduced. This is indicative of the fact that the modified dataset is able to consider queries from different search sessions as a part of the same search task (there are 36,768 of them as shown in Table 1). The post-processed dataset with cross-session task labels that we use for our experiments is publicly available[3].

	Task label granularity	
Item	Within-session	Cross-session
#Queries	1424	1424
#Tasks annotated	554	224
#Sessions	307	307
#Sessions with cross-session tasks	0	239
#Query pairs across sessions judged in the same task	0	36768

Table 1: Dataset statistics of task annotated queries from the AOL query log. Cross-session task labels are post-processed annotations of the dataset prepared by (Lucchese et al., 2013).

5.2 Baselines and Experiment Objectives

Since our proposed task extraction method is unsupervised, for a fair comparison we only employ unsupervised approaches as baselines. More specifically, we did not consider the supervised approaches reported in (Jones and Klinkner, 2008; Wang et al., 2013) as our baselines.

As our first baseline, we re-implemented QC-WCC, the best performing approach (Lucchese et al., 2013) (briefly described in Section 4.2). This study investigated a wide range of features, clustering methods and parameter settings. We adopt the same linear combination of similarities in our study as shown in Equation 5.

Our re-implementation of this work involves a slight change to the original one. Instead of using a Wikipedia document collection, we employ a much larger collection of crawled web documents, namely the ClueWeb12B collection, comprising of nearly $52M$ documents[4]. Our reasons for using the ClueWeb collection are as follows. Firstly, our study is carried out using queries from a Web search log and hence it is reasonable to expect that a web collection will provide better estimates of semantic similarities between the queries. Secondly, a number of our queries in our dataset are not of expository type, and hence the num-

[3] https://github.com/procheta/AOLTaskExtraction/blob/master/Task.csv

[4] http://boston.lti.cs.cmu.edu/clueweb12/

ber of matching Wikipedia articles is expected to be low for them due to vocabulary mismatch. On the other hand, the web collection, being diverse, is expected to retrieve more matching articles for these types of queries. To compare the performance of our implementation of QC-$_{WCC}$ with ClueWeb12B with the original one, we adopted an experimental and evaluation setup identical to that of (Lucchese et al., 2013), the only difference being in the collection used for deriving the semantic similarities. For the retrieval model we used the LM-JM (Language Model with Jelineck-Mercer smoothing) with the smoothing parameter set to 0.6 as suggested in (Lavrenko and Croft, 2001).

To demonstrate the potential benefits of our proposed tempo and tempo-lexical context-driven word embedding based approaches for the query terms, we employed the following three baselines.

1. **Qry vec skip-gram**: In this approach, query vectors were obtained by summing over the constituent word vectors obtained using the standard skip-gram (Mikolov et al., 2013).
2. **Qry vec (All-in-one Session Context)**: We hypothesized that additional context is likely to capture task-specific semantics of the query terms. A boundary condition arises when the entire query log is assumed to belong to one session. To show that the temporal context needs to be focused, in this approach, we investigate the effect of setting the context set S to the entire vocabulary of query terms.
3. **Qry vec (Pre-trained Google news vectors)** We hypothesized that additional context is likely to be useful to learn the vector representations of constituent words of short documents (in this case, queries). To see if pre-trained word vectors from an external generic corpus can be useful to alleviate the problem of short documents, we employ pre-trained word vectors from the Google news corpus to obtain the vector representation of the queries.

The objective of the experiments is to show that our proposed query term embedding method can outperform the above mentioned baselines, thus indicating that within-session adjacency information can be useful to learn task specific semantics.

5.3 Parameters and Evaluation Metrics

Parameters. In our method, we use the cosine similarity between the embedded query vectors instead of using character 3-grams and Levenshtein similarity, as used in (Lucchese et al., 2013)), to compute $Sim_c(q_i, q_j)$ between any two query pairs q_i and q_j. We employ three different embedding strategies for our experiments: i) standard word2vec, ii) transformed vectors with temporal context, and iii) transformed vectors with tempo-lexical contexts. In all our experiments, we tune α from 0 to 1 in steps of 0.1. The second parameter common to all the methods, the threshold η, which is used in QC-$_{WCC}$ clustering to prune off edges from the weighted similarity graph between query pairs. We tuned η in the range 0.1 to 1 in steps of 0.1 for each method separately.

For our word vector based experiments, we used the skip-gram model to train the word vectors using the entire AOL query log comprising over 6M queries. The dimensionality of the word vectors was set to 200. The initially obtained word vectors were used as starting inputs to learn the temporal and tempo-lexical transformations. For the tempo-lexical based transformation method, we used the optimal value of η as obtained from the QC-$_{WCC}$ baseline, to cluster the queries in each temporal window of 26 minutes.

Evaluation Metrics. Since we use weighted clustering to extract cross-session search tasks, we used standard clustering evaluation metrics to evaluate the effectiveness of the task extraction. Clustering is typically evaluated with the effectiveness of the pair-wise decisions of assigning data points to the same or different clusters. In our case, the number of true positives was given by the number of query pairs in the ground-truth that were judged to belong to the same task and were also predicted by the system to be a part of the same task. Similarly, we computed the false positives and the true negatives. Based on these counts, we computed the standard metrics of precision, recall, and F-score (similar to (Lucchese et al., 2013)).

Additionally, to measure how many of the total number of cross-session queries that were part of the same search tasks were discovered by these approaches, we computed the cross-session recall (denoted as 'CS-Recall'). This metric was computed as the ratio of the number of correctly identified cross-session similar-task query pairs against

Query Similarity	Parameters		Metrics			
	α	η	F-score	Prec	Recall	CS-Recall
QC-$_{WCC}$(3gram+ Levenestine) (Lucchese et al., 2013)	0.8	0.4	0.471	0.387	0.603	0.1930
Qry vec skip-gram	0.7	0.8	0.524*	**0.465***	0.602	0.7161*
Qry vec (All-in-one Session Context)	0.7	0.5	0.499	0.430	0.595	0.6400
Qry vec (Pre-trained Google news vectors)	0.6	0.5	0.473	0.410	0.558	0.6400
Qry vec with temporal context	1.0	0.7	0.536*†	0.461*	0.643*†	0.7393*†
Qry vec with tempo-lexical context	0.6	0.7	**0.538***†	0.441*	**0.691***†‡	**0.7395***†‡

Table 2: Comparison between the best results obtained after parameter tuning on different unsupervised approaches of task extraction. For all methods, $1-\alpha$ represents the weight of the semantic similarity estimated from ClueWeb12B. *†‡ indicates statistical significance (paired t-test with 95% confidence) with respect to (Lucchese et al., 2013), 'Qry vec skip-gram' and 'Qry vec with temporal context' respectively.

Task extraction method	Session-F-socre
QC-$_{WCC}$ on trigram+Levenshtein with Wikipedia (Lucchese et al., 2013)	0.812*
QC-$_{WCC}$ on trigram+Levenshtein with ClueWeb12B	0.834
Non-parametric clustering on average query term vectors (Mehrotra et al., 2016)	0.845†
QC-$_{WCC}$ on average of baseline skip-gram query word vectors	0.837

QC-$_{WCC}$ on transformed word vectors with tempo-lexical context	0.840

Table 3: Within-session Task Extraction effectiveness.

the total number of them (36,768 as reported in Table 1).

In order to extend evaluation of our proposed approach to within-session task extraction, for comparison with existing studies, we computed the clustering metrics for each individual session and then computed the weighted average of these values over each session as reported in (Lucchese et al., 2013; Mehrotra and Yilmaz, 2017). Although these earlier studies refer to this weighted measure as F-score, we refer to this version of F-score as 'Session-F-score'.

6 Results

In this section, we report the results of our investigations of our proposed query vector based cross-session search task extraction. We first investigate the effectiveness of our proposed approach on the cross-session search task extraction and then report and compare results with existing approaches for within-session task extraction.

6.1 Cross-Session Task Extraction

Table 2 shows the results of weighted clustering QC-$_{WCC}$ with optimal α and η settings for each individual method. It can be seen that the first baseline approach QC-$_{WCC}$ performs poorly because trigram and Levenshtein similarities lack the semantic information required to effectively cluster task-related queries into the same cluster. Clustering effectiveness improves considerably when weighted clustering is conducted using the cosine similarities between the query vectors, i.e. the 'Qry vec skip-gram' approach. This suggests that the word vectors are better able to capture the semantic relatedness between the task-related query terms.

It can be seen that using the entire query log as one context, i.e. the approach 'Qry vec (All-in-one Sesion Context)' yields worse results than the baseline skip-gram approach, which shows that a focused context is required for effectively embedding the query terms. Results with pre-trained word vectors on a large news corpora, i.e. the approach 'Qry vec (Pre-trained Google news vectors)', show that additional out-of-domain and generic context is not helpful for improving the quality of the embedded query term vectors.

Transformation of the word vectors leveraging the semantic contexts (i.e. our proposed method in Section 3) outperforms the clustering effectiveness obtained with the baseline approaches. The most important observation is that the use of temporal context in learning word vectors results in best performance for $\alpha = 1$, i.e. when no retrieval-based similarity is used (see Equation 5). This suggests that optimally trained word vectors can produce effective task clusters without the use of external collections in contextualizing the queries. The use of tempo-lexical contexts, i.e. when the semantic context used to learn the transformation matrix for the word vectors is restricted to sim-

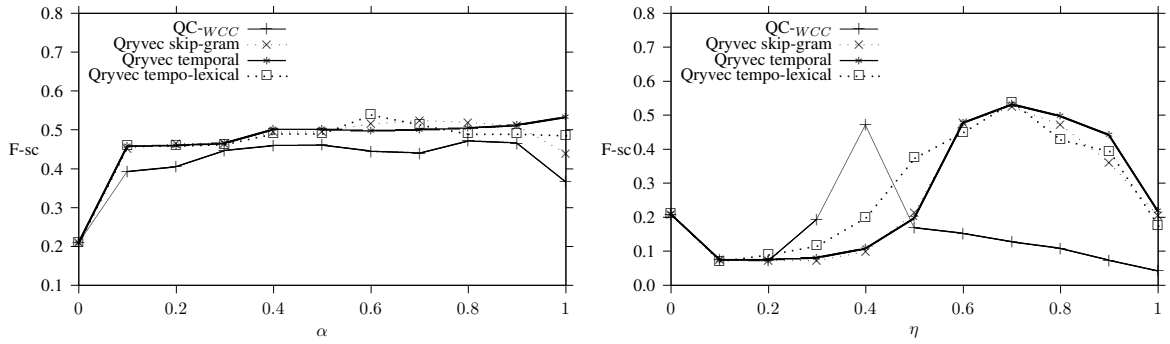

Figure 1: Sensitivity of task clustering with variations in α (left) and η (right).

ilar queries within search sessions, the effectiveness improves further. In particular, Table 2 shows that both tempo and tempo-lexical transformations are able to improve recall significantly suggesting that the transformation helps to group more truly task-related queries into the same cluster.

Next, we show the effect of varying the parameters α and η separately in Figure 1. The values of η for each corresponding method in the left graph of Figure 1 are those reported in Table 2. Similarly, for the plot on the right of Figure 1, the α values correspond to those reported in Table 2. A value of $\alpha = 1$ considers only the content based similarity (see Equation 5). It can be observed from Figure 1 (left) that at $\alpha = 1$, the F-score values for all the query embedding based approaches are higher than the baseline method of QC-$_{WCC}$. This indicates that the query embedding based approaches perform well without relying on similarity-based retrieval using an external collection. In general, it can be observed that over a wide range of α and η settings, the F-score values of the embedding based methods outperform the QC-$_{WCC}$ method.

6.2 Within-session task extraction

In this experimental setup, we make use of the session duration span of 26 minutes, similar to (Lucchese et al., 2013), to restrict query clustering to each individual session. Similar to (Lucchese et al., 2013; Mehrotra and Yilmaz, 2017), we employ the session averaged clustering metrics for measuring the effectiveness of the different approaches (see Section 5.3). We use the within-session ground-truth of (Lucchese et al., 2013) to evaluate the task extraction effectiveness.

Table 3 reports the results for various within-session task clustering approaches. The results with * and † are taken from the results reported in (Lucchese et al., 2013) and (Mehrotra et al., 2016). The following observations can be made with regard to Table 3. Firstly, the use of ClueWeb12B contributed to an improvement in task extraction effectiveness, thus demonstrating that our re-implementation of (Lucchese et al., 2013) is comparable with that of the original. Secondly, an important observation is that the use of average query term vectors along with contextual information from ClueWeb12B outperforms the approach of trigram and Levenshtein based similarity computation of (Lucchese et al., 2013). Thirdly, it can be observed that results improve with the application of transformation based word vector embedding of the query terms. The temporal context proves more effective than the tempo-lexical one.

7 Conclusions and Future Work

In this paper, we studied the problem of cross-session task extraction. We proposed a transformation based word embedding approach that takes into account the temporal and tempo-lexical contexts of queries to learn task-specific semantics. Our experiments on the AOL query log indicate that the proposed temporal and tempo-lexical query embedding method significantly outperform the baseline word2vec embedding. As future work, we would like to investigate supervised methods for cross-session task extraction.

Abstract

Can attention- or gradient-based visualization techniques be used to infer token-level labels for binary sequence tagging problems, using networks trained only on sentence-level labels? We construct a neural network architecture based on soft attention, train it as a binary sentence classifier and evaluate against token-level annotation on four different datasets. Inferring token labels from a network provides a method for quantitatively evaluating what the model is learning, along with generating useful feedback in assistance systems. Our results indicate that attention-based methods are able to predict token-level labels more accurately, compared to gradient-based methods, sometimes even rivaling the supervised oracle network.

1 Introduction

Sequence labeling is a structured prediction task where systems need to assign the correct label to every token in the input sequence. Many NLP tasks, including part-of-speech tagging, named entity recognition, chunking, and error detection, are often formulated as variations of sequence labeling. Recent state-of-the-art models make use of bidirectional LSTM architectures (Irsoy and Cardie, 2014), character-based representations (Lample et al., 2016), and additional external features (Peters et al., 2017). Optimization of these models requires appropriate training data where individual tokens are manually labeled, which can be time-consuming and expensive to obtain for each different task, domain and target language.

In this paper, we investigate the task of performing sequence labeling without having access to any training data with token-level annotation. Instead of training the model directly to predict the label for each token, the model is optimized using a sentence-level objective and a modified version of the attention mechanism is then used to infer labels for individual words.

While this approach is not expected to outperform a fully supervised sequence labeling method, it opens possibilities for making use of text classification datasets where collecting token-level annotation is not possible or cost-effective.

Inferring token-level labels from a text classification network also provides a method for analyzing and interpreting the model. Previous work has used attention weights to visualize the focus of neural models in the input data. However, these analyses have largely been qualitative examinations, looking at only a few examples from the datasets. By formulating the task as a zero-shot labeling problem, we can provide quantitative evaluations of what the model is learning and where it is focusing. This will allow us to measure whether the features that the model is learning actually match our intuition, provide informative feedback to end-users, and guide our development of future model architectures.

2 Network Architecture

The main system takes as input a sentence, separated into tokens, and outputs a binary prediction as the label of the sentence. We use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) architecture for sentence classification, with dynamic attention over words for constructing the sentence representations. Related architectures have been successful for machine translation (Bahdanau et al., 2015), sentence summarization (Rush and Weston, 2015), entailment detection (Rocktäschel et al., 2016), and error correction (Ji et al., 2017). In this work, we modify the attention mechanism and training objective in order to make the resulting network suitable for

Proceedings of NAACL-HLT 2018, pages 293–302
New Orleans, Louisiana, June 1 - 6, 2018.

also inferring binary token labels, while still performing well as a sentence classifier.

Figure 1 contains a diagram of the network architecture. The tokens are first mapped to a sequence of word representations $[w_1, w_2, w_3, ..., w_N]$, which are constructed as a combination of regular word embeddings and character-based representations, following Lample et al. (2016). These word representations are given as input to a bidirectional LSTM which iteratively passes through the sentence in both directions. Hidden representations from each direction are concatenated at every token position, resulting in vectors h_i that are focused on a specific word but take into account the context on both sides of that word. We also include a transformation with $tanh$ activation, which helps map the information from both directions into a joint feature-space:

$$\overrightarrow{h_i} = LSTM(w_i, \overrightarrow{h_{i-1}}) \quad (1)$$

$$\overleftarrow{h_i} = LSTM(w_i, \overleftarrow{h_{i+1}}) \quad (2)$$

$$\widetilde{h_i} = [\overrightarrow{h_i}; \overleftarrow{h_i}] \qquad h_i = tanh(W_h \widetilde{h_i} + b_h) \quad (3)$$

where W_h is a parameter matrix and b_h is a parameter vector, optimized during training.

Next, we include an attention mechanism that allows the network to dynamically control how much each word position contributes to the combined representation. In most attention-based systems, the attention amount is calculated in reference to some external information. For example, in machine translation the attention values are found based on a representation of the output that has already been generated (Bahdanau et al., 2015); in question answering, the attention weights are calculated in reference to the input question (Hermann et al., 2015). In our task there is no external information to be used, therefore we predict the attention values directly based on h_i, by passing it through a separate feedforward layer:

$$e_i = tanh(W_e h_i + b_e) \quad (4)$$

$$\widetilde{e_i} = W_{\widetilde{e}} e_i + b_{\widetilde{e}} \quad (5)$$

where $W_{\widetilde{e}}$, $b_{\widetilde{e}}$, W_e and b_e are trainable parameters and $\widetilde{e_i}$ results in a single scalar value. This method is equivalent to calculating the attention weights in reference to a fixed weight vector, which is optimized during training. Shen and Lee (2016) proposed an architecture for dialogue act detection where the attention values are found based on a separate set of word embeddings. We found that the method described above was consistently equivalent or better in development experiments, while requiring a smaller number of parameters.

The values of $\widetilde{e_i}$ are unrestricted and should be normalized before using them for attention, to avoid sentences of different length having representations of different magnitude. The common approach is to use an exponential function to transform the value, and then normalize by the sum of all values in the sentence:

$$a_i = \frac{exp(\widetilde{e_i})}{\sum_{k=1}^{N} exp(\widetilde{e_k})} \quad (6)$$

The value a_i is now in a range $0 \leq a_i \leq 1$ and higher values indicate that the word at position i is more important for predicting the sentence class. The network learns to predict informative values for a_i based only on the sentence objective, without receiving token-level supervision. Therefore, we can use these attention values at each token in order to infer an unsupervised sequence labeling output.

The method in Equation 6 is well-suited for applications such as machine translation – the exponential function encourages the attention to prioritize only one word in the sentence, resulting in a word-word alignment. However, the same function is less suitable for our task of unsupervised sequence labeling, as there is no reason to assume that exactly one word has a positive label. An input sentence can contain more than one tagged token, or it can contain no tokens of interest, and this should be reflected in the predictions.

Instead of the exponential function, we make use of the logistic function σ for calculating soft attention weights:

$$\widetilde{a_i} = \sigma(\widetilde{e_i}) \qquad a_i = \frac{\widetilde{a_i}}{\sum_{k=1}^{N} \widetilde{a_k}} \quad (7)$$

where each $\widetilde{a_i}$ has an individual value in the range $0 \leq \widetilde{a_i} \leq 1$ and a_i is normalized to sum up to 1 over all values in the sentence. The normalized weights a_i are used for combining the context-conditioned hidden representations from Equation

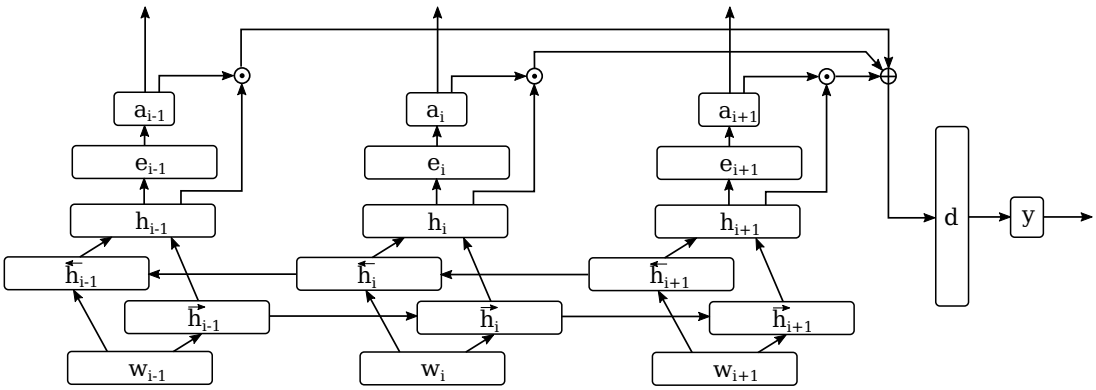

Figure 1: The neural network architecture for zero-shot sequence labeling. The soft attention values a_i are used for weighting hidden representations h_i as well as providing a binary label for each token. The network is only optimized through the sentence classification objective, predicting the sentence-level label y.

3 into a single sentence representation:

$$c = \sum_{i=1}^{N} a_i h_i \tag{8}$$

In addition, we can use the pre-normalization value $\widetilde{a_i}$ as a score for sequence labeling, with a natural decision boundary of 0.5 – higher values indicate that the token at position i is important and should be labeled positive, whereas lower values suggest the token is largely ignored for sentence classification and can receive a negative label. Attention weights with sigmoid activation have been shown to also improve performance on classification tasks (Shen and Lee, 2016), which indicates that this architecture has the benefit of being both accurate and interpretable on the token level.

Finally, we pass the sentence representation c through a feedforward layer and predict a binary label for the overall sentence:

$$d = tanh(W_d c + b_d) \tag{9}$$

$$y = \sigma(W_y d + b_y) \tag{10}$$

where d is a sentence vector and y is a single value between $0 \leq y \leq 1$, with values higher than 0.5 indicating a positive class and lower values indicating a negative prediction.

In order to optimize the model, we use several different loss functions. The first is the squared loss which optimizes the sentence-level score prediction to match the gold label in the annotation:

$$L_1 = \sum_j (y^{(j)} - \widetilde{y}^{(j)})^2 \tag{11}$$

where $y^{(j)}$ is the predicted score for the j-th sentence, and $\widetilde{y}^{(j)}$ is the true binary label $(0, 1)$ for the j-th sentence.

In addition, we want to encourage the model to learn high-quality token-level labels as part of the attention weights. While the model does not have access to token-level annotation during training, there are two constraints that we can take advantage of:

1. Only some, but not all, tokens in the sentence can have a positive label.

2. There are positive tokens in a sentence only if the overall sentence is positive.

We can then construct loss functions that encourage the model to optimize for these constraints:

$$L_2 = \sum_j (min_i(\widetilde{a_i}) - 0)^2 \tag{12}$$

$$L_3 = \sum_j (max_i(\widetilde{a_i}) - \widetilde{y}^{(j)})^2 \tag{13}$$

where $min_i(\widetilde{a_i})$ is the minimum value of all the attention weights in the sentence and $max_i(\widetilde{a_i})$ is the corresponding maximum value. Equation 12 optimizes the minimum unnormalized attention weight in a sentence to be 0, satisfying the constraint that all tokens in a sentence should not have a positive token-level label. Equation 13 then optimizes for the maximum unnormalized attention weight in a sentence to be equal to the gold label for that sentence, which is either 0 or 1, incentivizing the network to only assign large attention

weights to tokens in positive sentences. These objectives do not provide the model with additional information, but serve to push the attention scores to a range that is suitable for binary classification.

We combine all of these loss objectives together for the main optimization function:

$$L = L_1 + \gamma(L_2 + L_3) \tag{14}$$

where γ is used to control the importance of the auxiliary objectives.

3 Alternative Methods

We compare the attention-based system for inferring sequence labeling with 3 alternative methods.

3.1 Labeling Through Backpropagation

We experiment with an alternative method for inducing token-level labels, based on visualization methods using gradient analysis. Research in computer vision has shown that interpretable visualizations of convolutional networks can be obtained by analyzing the gradient after a single backpropagation pass through the network (Zeiler and Fergus, 2014). Denil et al. (2014) extended this approach to natural language processing, in order to find and visualize the most important sentences in a text. Recent work has also used the gradient-based approach for visualizing the decisions of text classification models on the token level (Li et al., 2016; Alikaniotis et al., 2016). In this section we propose an adaptation that can be used for sequence labeling tasks.

We first perform a forward pass through the network and calculate the predicted sentence-level score y. Next, we define a pseudo-label $y^* = 0$, regardless of the true label of the sentence. We then calculate the gradient of the word representation w_i with respect to the loss function using this pseudo-label:

$$g_i = \frac{\partial L_1}{\partial w_i}\Big|_{(y^*,y)} \tag{15}$$

where L_1 is the squared loss function from Equation 11. The magnitude of g_i, $|g_i|$ can now be used as an indicator of how important that word is for the positive class. The intuition behind this approach is that the magnitude of the gradient indicates which individual words need to be changed the most in order to make the overall label of the sentence negative. These are the words that are contributing most towards the positive class and should be labeled as such individually.

An obstacle in using this score for sequence labeling comes from the fact that there is no natural decision boundary between the two classes. The magnitude of the gradient is not constrained to a specific range and can vary quite a bit depending on the sentence length and the predicted sentence-level score. In order to map this magnitude to a decision, we analyze the distribution of magnitudes in a sentence. Intuitively, we want to detect outliers – scores that are larger than expected. Therefore, we map all the magnitudes in a sentence to a Gaussian distribution and set the decision boundary at 1.5 standard deviations. Any word that has a gradient magnitude higher than that will be tagged with a positive class for sequence labeling. If all the magnitudes in a sentence are very similar, none of them will cross this threshold and therefore all words will be labeled as negative.

We calculate the gradient magnitude using the same network architecture as described in Section 2, at word representation w_i after the character-based features have been included. The attention-based architecture is not necessary for this method, therefore we also report results using a more traditional bidirectional LSTM, concatenating the last hidden states from both directions and using the result as a sentence representation for the main objective.

3.2 Relative Frequency Baseline

The system for producing token-level predictions based on sentence-level training data does not necessarily need to be a neural network. As the initial experiment, we trained a Naive Bayes classifier with n-gram features on the annotated sentences and then used it to predict a label only based on a window around the target word. However, this did not produce reliable results – since the classifier is trained on full sentences, the distribution of features is very different and does not apply to a window of only a few words.

Instead, we calculate the relative frequency of a feature occurring in a positive sentence, normalized by the overall frequency of the feature, and calculate the geometric average over all features that contain a specific word:

$$r_k = \frac{c(X_k = 1, Y = 1)}{\sum_{z \in (0,1)} c(X_k = 1, Y = z)} \tag{16}$$

$$score_i = \sqrt[|F_i|]{\prod_{k \in F_i} r_k} \quad (17)$$

where $c(X_k = 1, Y = 1)$ is the number of times feature k is present in a sentence with a positive label, F_i is the set of n-gram features present in the sentence that involve the i-th word in the sentence, and $score_i$ is the token-level score for the i-th token in the sentence. We used unigram, bigram and trigram features, with extra special tokens to mark the beginning and end of a sentence.

This method will assign a high score to tokens or token sequences that appear more often in sentences which receive a positive label. While it is not able to capture long-distance context, it can memorize important keywords from the training data, such as modal verbs for uncertainty detection or common spelling errors for grammatical error detection.

3.3 Supervised Sequence Labeling

Finally, we also report the performance of a supervised sequence labeling model on the same tasks. This serves as an indicator of an upper bound for a given dataset – how well the system is able to detect relevant tokens when directly optimized for sequence labeling and provided with token-level annotation.

We construct a bidirectional LSTM tagger, following the architectures from Irsoy and Cardie (2014), Lample et al. (2016) and Rei (2017). Character-based representations are concatenated with word embeddings, passed through a bidirectional LSTM, and the hidden states from both direction are concatenated. Based on this, a probability distribution over the possible labels is predicted and the most probable label is chosen for each word. While Lample et al. (2016) used a CRF on top of the network, we exclude it here as the token-level scores coming from that network do not necessarily reflect the individual labels, since the best label sequence is chosen globally based on the combined sentence-level score. The supervised model is optimized by minimizing cross-entropy, training directly on the token-level annotation.

4 Datasets

We evaluate the performance of zero-shot sequence labeling on 3 different datasets. In each experiment, the models are trained using only sentence-level annotation and then evaluated based on token-level annotation.

4.1 CoNLL 2010 Uncertainty Detection

The CoNLL 2010 shared task (Farkas et al., 2010) investigated the detection of uncertainty in natural language texts. The use of uncertain language (also known as hedging) is a common tool in scientific writing, allowing scientists to guide research beyond the evidence without overstating what follows from their work. Vincze et al. (2008) showed that 19.44% of sentences in the biomedical papers of the BioScope corpus contain hedge cues. Automatic detection of these cues is important for downstream tasks such as information extraction and literature curation, as typically only definite information should be extracted and curated.

The dataset is annotated for both hedge cues (keywords indicating uncertainty) and scopes (the area of the sentence where the uncertainty applies). The cues are not limited to single tokens, and can also consist of several disjoint tokens (for example, *"either ... or ..."*). An example sentence from the dataset, with bold font indicating the hedge cue and curly brackets marking the scope of uncertainty:

> Although IL-1 has been reported to contribute to Th17 differentiation in mouse and man, it remains to be determined {**whether** therapeutic targeting of IL-1 will substantially affect IL-17 in RA}.

The first subtask in CoNLL 2010 was to detect any uncertainty in a sentence by predicting a binary label. The second subtask required the detection of all the individual cue tokens and the resolution of their scope. In our experiments, we train the system to detect sentence-level uncertainty, use the architecture to infer the token-level labeling and evaluate the latter on the task of detecting uncertainty cues. Since the cues are defined as keywords that indicate uncertainty, we would expect the network to detect and prioritize attention on these tokens. We use the train/test data from the second task, which contains the token-level annotation needed for evaluation, and randomly separate 10% of the training data for development.

4.2 FCE Error Detection

Error detection is the task of identifying tokens which need to be edited in order to produce a

	CoNLL 2010					FCE

Table 1: Results for different system configurations on the CoNLL 2010 and FCE datasets. Reporting sentence-level F_1, token-level Mean Average Precision (MAP), and token-level precision/recall/F_1.

grammatically correct sentence. The task has numerous applications for writing improvement and assessment, and recent work has focused on error detection as a supervised sequence labeling task (Rei and Yannakoudakis, 2016; Kaneko et al., 2017; Rei, 2017).

Error detection can also be performed on the sentence level – detecting whether the sentence needs to be edited or not. Andersen et al. (2013) described a practical tutoring system that provides sentence-level feedback to language learners. The 2016 shared task on Automated Evaluation of Scientific Writing (Daudaravicius et al., 2016) also required participants to return binary predictions on whether the input sentence needs to be corrected.

We evaluate our system on the First Certificate in English (FCE, Yannakoudakis et al. (2011)) dataset, containing error-annotated short essays written by language learners. While the original corpus is focused on aligned corrections, Rei and Yannakoudakis (2016) converted the dataset to a sequence labeling format, which we make use of here. An example from the dataset, with bold font indicating tokens that have been annotated as incorrect given the context:

> When the show started the person who was acting **it** was not Danny Brook and **he seemed not** to be an actor.

We train the network as a sentence-level error detection system, returning a binary label and a confidence score, and also evaluate how accurately it is able to recover the locations of individual errors on the token level.

4.3 SemEval Sentiment Detection in Twitter

SemEval has been running a series of popular shared tasks on sentiment analysis in text from social media (Nakov et al., 2013; Rosenthal et al., 2014, 2015). The competitions have included various subtasks, of which we are interested in two: Task A required the polarity detection of individual phrases in a tweet, and Task B required sentiment detection of the tweet as a whole. A single tweet could contain both positive and negative phrases, regardless of its overall polarity, and was therefore separately annotated on the tweet level.

In the following example from the dataset, negative phrases are indicated with a bold font and positive phrases are marked with italics, whereas the overall sentiment of the tweet is annotated as negative:

> They may *have* a *SuperBowl* in Dallas, but Dallas **ain't winning** a SuperBowl. **Not with that** quarterback and owner. @S4NYC @RasmussenPoll

Sentiment analysis is a three-way task, as the system needs to differentiate between positive, negative and neutral sentences. Our system relies on a binary signal, therefore we convert this dataset into two binary tasks – one aims to detect positive sentiment, the other focuses on negative sentiment. We train the system as a sentiment classifier, using the tweet-level annotation, and then evaluate the system on recovering the individual positive or negative tokens. We use the train/dev/test splits of the original SemEval 2013 Twitter dataset, which contains phrase-level sentiment annotation.

5 Implementation Details

During pre-processing, tokens are lowercased while the character-level component still retains access to the capitalization information. Word embeddings were set to size 300, pre-loaded from publicly available Glove (Pennington et al., 2014)

	SemEval Negative					SemEval Positive				
	Sent F_1	MAP	P	R	F_1	Sent F_1	MAP	P	R	F_1

Table 2: Results for different system configurations on the SemEval Twitter sentiment dataset, separated into positive and negative sentiment detection. Reporting sentence-level F_1, token-level Mean Average Precision (MAP), and token-level precision/recall/F_1.

embeddings and fine-tuned during training. Character embeddings were set to size 100. The recurrent layers in the character-level component have hidden layers of size 100; the hidden layers $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ are size 300. The hidden combined representation h_i was set to size 200, and the attention weight layer e_i was set to size 100. Parameter γ was set to 0.01 based on development experiments.

The model was implemented using Tensorflow (Abadi et al., 2016). The network weights were randomly initialized using the uniform Glorot initialization method (Glorot and Bengio, 2010) and optimization was performed using AdaDelta (Zeiler, 2012) with learning rate 1.0. Dropout (Srivastava et al., 2014) with probability 0.5 was applied to word representations w_i and the composed representations h_i after the LSTMs. The training was performed in batches of 32 sentences. Sentence-level performance was observed on the development data and the training was stopped if performance did not improve for 7 epochs. The best overall model on the development set was then used to report performance on the test data, both for sentence classification and sequence labeling. In order to avoid random outliers, we performed each experiment with 5 random seeds and report here the averaged results.

The code used for performing these experiments is made available online.[1]

6 Evaluation

Results for the experiments are presented in Tables 1 and 2. We first report the sentence-level F-measure in order to evaluate the performance on the general text classification objective. Next, we report the Mean Average Precision (MAP) at returning the active/positive tokens. This measure rewards systems that assign higher scores to positive tokens as opposed to negative ones, evaluating this as a ranking problem. It disregards a specific classification threshold and therefore provides a more fair evaluation towards systems that could be improved simply by choosing a different decision boundary. Finally, we also report token-level precision, recall and F-measure for evaluating the accuracy of this model as a sequence labeler.[2]

We report five different system configurations: **Relative freq** is the n-gram based approach described in Section 3.2. **Supervised** is the fully supervised sequence labeling system described in Section 3.3. **LSTM-LAST-BP** is using the last hidden states from the word-level LSTMs for constructing a sentence representation, and the backpropagation-based method from Section 3.1 for inducing token labels. **LSTM-ATTN-BP** is using the attention-based network architecture together with the backpropagation-based labeling method. **LSTM-ATTN-SW** is the method described in Section 2, using soft attention weights for sequence labeling and additional objectives for optimizing the network.

The method using attention weights achieves the best performance on all datasets, compared to other methods not using token-level supervision. On the CoNLL 2010 uncertainty detection dataset the system reaches 73.26% F-score, which is 93% of the supervised upper bound. The alternative methods using backpropagation and relative fre-

[1] http://www.marekrei.com/projects/mltagger

[2] The CoNLL 2010 shared task on uncertainty detection comes with an official scorer which requires additional steps and the detection of both cues and scopes, whereas the binary labels from the zero-shot systems are not directly applicable to this format. Similarly, error detection is commonly evaluated using $F_{0.5}$, which is motivated by end-user experience, but in this case we wish to specifically measure the tagging accuracy. Therefore we use the regular F_1 score as the main evaluation metric for both of these tasks.

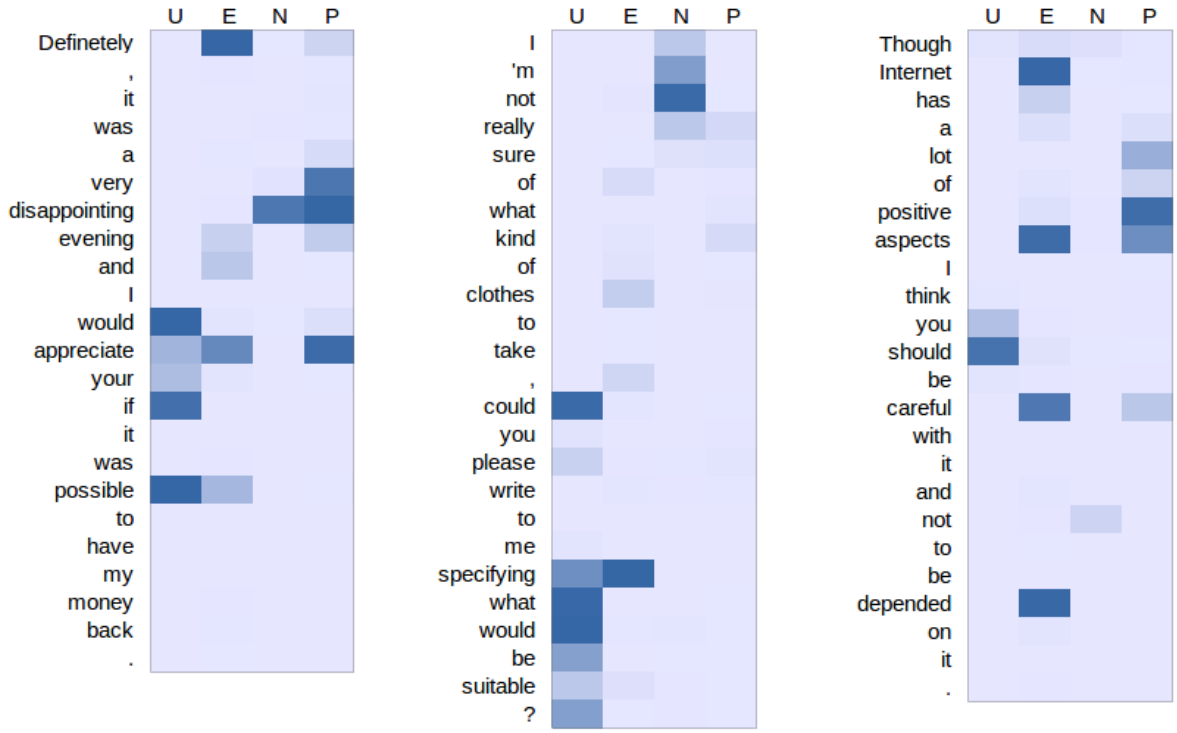

Figure 2: Example output from each of the zero-shot sequence labeling models, trained on 4 different tasks. **U**: uncertainty detection, **E**: error detection, **N**: negative sentiment detection, **P**: positive sentiment detection. Darker blue indicates higher predicted values.

quency achieve high recall values, but comparatively lower precision. On the FCE dataset, the F-score is considerably lower at 28.27% – this is due to the difficulty of the task and the supervised system also achieves only 34.76%. The attention-based system outperforms the alternatives on both of the SemEval evaluations. The task of detecting sentiment on the token level is quite difficult overall as many annotations are context-specific and require prior knowledge. For example, in order to correctly label the phrase *"have Superbowl"* as positive, the system will need to understand that organizing the Superbowl is a positive event for the city.

Performance on the sentence-level classification task is similar for the different architectures on the CoNLL 2010 and FCE datasets, whereas the composition method based on attention obtains an advantage on the SemEval datasets. Since the latter architecture achieves competitive performance and also allows for attention-based token labeling, it appears to be the better choice. Analysis of the token-level MAP scores shows that the attention-based sequence labeling model achieves the best performance even when ignoring classification thresholds and evaluating the task through ranking.

Figure 2 contains example outputs from the attention-based models, trained on each of the four datasets. In the first example, the uncertainty detector correctly picks up *"would appreciate if"* and *"possible"*, and the error detection model focuses most on the misspelling *"Definetely"*. Both the positive and negative sentiment models have assigned a high weight to the word *"disappointing"*, which is something we observed in other examples as well. The system will learn to focus on phrases that help it detect positive sentiment, but the presence of negative sentiment provides implicit evidence that the overall label is likely not positive. This is a by-product of the 3-way classification task and future work could investigate methods for extending zero-shot classification to better match this requirement.

In the second example, the system correctly labels the phrase *"what would be suitable?"* as uncertain, and part of the phrase *"I'm not really sure"* as negative. It also labels *"specifying"* as an error, possibly expecting a comma before it. In the third example, the error detection model labels *"Internet"* for the missing determiner, but also captures a more difficult error in *"depended"*,

which is an incorrect form of the word given the context.

7 Conclusion

We investigated the task of performing sequence labeling without having access to any training data with token-level annotation. The proposed model is optimized as a sentence classifier and an attention mechanism is used for both composing the sentence representations and inferring individual token labels. Several alternative models were compared on three tasks – uncertainty detection, error detection and sentiment detection.

Experiments showed that the zero-shot labeling system based on attention weights achieved the best performance on all tasks. The model is able to automatically focus on the most salient areas of the sentence, and additional objective functions along with the soft attention mechanism encourage it to also perform well as a sequence labeler. The zero-shot labeling task can provide a quantitative evaluation of what the model is learning, along with offering a low-cost method for creating sequence labelers for new tasks, domains and languages.

Abstract

Information about the meaning of mathematical variables in text is useful in NLP/IR tasks such as symbol disambiguation, topic modeling and mathematical information retrieval (MIR). We introduce *variable typing*, the task of assigning one *mathematical type* (multi-word technical terms referring to mathematical concepts) to each variable in a sentence of mathematical text. As part of this work, we also introduce a new annotated data set composed of 33,524 data points extracted from scientific documents published on arXiv. Our intrinsic evaluation demonstrates that our data set is sufficient to successfully train and evaluate current classifiers from three different model architectures. The best performing model is evaluated on an extrinsic task: MIR, by producing a *typed formula index*. Our results show that the best performing MIR models make use of our typed index, compared to a formula index only containing raw symbols, thereby demonstrating the usefulness of variable typing.

1 Introduction

Scientific documents, such as those from Physics and Computer Science, rely on mathematics to communicate ideas and results. Written mathematics, unlike general text, follows strong domain-specific conventions governing how content is presented. According to Ganesalingam (2008), the sense of mathematical text is conveyed through the interaction of two contexts: the textual context (flowing text) and the mathematical (or symbolic) context (mathematical formulae).

In this work, we introduce a new task that focuses on one particular interaction: the assignment of meaning to variables by surrounding text in the same sentence[1]. For example, in the sentence

> *Let P be a parabolic subgroup of $GL(n)$ with Levi decomposition $P = MN$, where N is the unipotent radical.*

the variables P and N in the symbolic context are assigned the meaning "parabolic subgroup" and "unipotent radical" by the textual context surrounding them respectively.

We will refer to the task of assigning one *mathematical type* to each variable in a sentence as *variable typing*. We use mathematical types (Stathopoulos and Teufel, 2016) as variable denotation labels. Types are multi-word phrases drawn from the technical terminology of the mathematical discourse that label mathematical objects (e.g., "set"), algebraic structures (e.g., "monoid") and instantiable notions (e.g., "cardinality of a set"). In the sentence presented earlier, the phrases "parabolic subgroup", "Levi decomposition" and "unipotent radical" are examples of types.

Typing variables may be beneficial to other natural language processing (NLP) tasks, such as topic modeling, to group documents that assign meaning to variables consistently (e.g., "E" is "energy" consistently in some branches of Physics). In mathematical information retrieval (MIR), for instance, enriching formulae with types may improve precision. For example, the formulae $x + y$ and $a + b$ can be considered α-equivalent matches. However, if a and b are matrices while x and y are vectors, the match is likely to be a false positive. Typing information may be helpful in reducing such instances and improving retrieval precision.

Variable typing differs from similar tasks in three fundamental ways. First, meaning – in the form of mathematical types – is explicitly assigned to variables, rather than arbitrary mathematical expressions. Second, variable typing is carried out at the sentential level, with valid type assignments for variables drawn from the sentences in which

[1]Data for the task is available at https://www.cst.cam.ac.uk/~yas23/

Proceedings of NAACL-HLT 2018, pages 303–312
New Orleans, Louisiana, June 1 - 6, 2018.

they occur, rather than from larger contexts, such as documents. Third, denotations are drawn from a pre-determined list of types, rather than from free-form text in the surrounding context of each variable.

As part of our work, we have constructed a new data set for variable typing that is suitable for machine learning (Section 4) and is distributed under the Open Data Commons license. We propose and evaluate three models for typing variables in mathematical documents based on current machine learning architectures (Section 5). Our intrinsic evaluation (Section 6) suggests that our models significantly outperform the state-of-the-art SVM model by Kristianto et al. (2012, 2014) (originally developed for description extraction) on our data set. More importantly, our intrinsic evaluation demonstrates that our data set is sufficient to successfully train and evaluate classifiers from three different architectures. We also demonstrate that our variable typing task and data are useful in MIR in our extrinsic evaluation (Section 7).

2 Related Work

The task of extracting semantics for variables from the linguistic context was first proposed by Grigore et al. (2009) with the intention of disambiguating symbols in mathematical expressions. Grigore et al. took operators listed in OpenMath content dictionaries (CDs) as concepts and used term clusters to model their semantics. A bag of nouns is extracted from the operator description in the dictionary and enriched manually using terms taken from online lexical resources. The cluster that maximises the similarity (based on Pointwise Mutual Information (PMI) and DICE) between nouns in the cluster and the local context of a target formula is taken to represent its meaning.

Wolska et al. (2011) used the Cambridge dictionary of mathematics and the mathematics subject classification hierarchy to manually construct taxonomies used to assign meaning to *simple expressions*. Simple expressions are defined by the authors to be mathematical formulae taking the form of an identifier, which may have super/subscripted expressions of arbitrary complexity. Lexical features surrounding simple expressions are used to match the context of candidate expressions to suitable taxonomies using a combination of PMI and DICE (Wolska et al., 2011). Wolska et al. report a precision of 66%.

Quoc et al. (2010) used a rule-based approach to extract descriptions for formulae (phrases or sentences) from surrounding context. In a similar approach, Kristianto et al. (2012) applied pattern matching on sentence parse trees and a "nearest noun" approach to extract descriptions. These rule-based methods have been shown to perform well for recall but poorly for precision (Kristianto et al., 2012). However, Kristianto et al. (2012) note that domain-agnostic parsers are confused by mathematical expressions making rule-based methods sensitive to parse tree errors. Both rule-based extraction methods were outperformed by Support Vector Machines (SVMs) (Kristianto et al., 2012, 2014).

Schubotz et al. (2016) use hierarchical named topic clusters, referred to as *namespaces*, to model the semantics of mathematical identifiers. Namespaces are derived from a document collection of 22,515 Wikipedia articles. A vector-space approach is used to cluster documents into namespaces using mini-batch K-means clustering. Clusters beyond a certain purity threshold are selected and converted into namespaces by extracting phrases that assign meaning to identifiers in the selected clusters. Schubotz et al. (2016) take a ranked approach at determining the phrase that best assigns meaning to a particular identifier. The authors report F_1 scores of 23.9% and 56.6% for their definition extraction methods.

In contrast, we assign meaning exclusively to variables, using denotations from a pre-computed dictionary of mathematical types, rather than free-form text. Types as pre-identified, compositionally constructed denotational labels enable efficient determination of relatedness between mathematical concepts. In our extrinsic MIR experiment (Section 7), the mathematical concept that two or more types are derived from is identified by locating their common parent type – the supertype – on a suffix trie. Topically related types that do not share a common supertype can be identified using an automatically constructed type embedding space (Stathopoulos and Teufel (2016), Section 5.1), rather than manually curated namespaces or fuzzy term clusters.

3 The Variable Typing Task

We define the task of variable typing as follows. Given a sentence containing a pre-identified set of

variables V and types T, variable typing is the task of classifying all edges $V \times T$ as either existent (positive) or non-existent (negative).

However, not all elements of $V \times T$ are valid edges. Invalid edges are usually instances of *type parameterisation*, where some type is parameterised by what appears to be a variable. For example, the set of candidate edges for the sentence

> *We now consider the* $\boldsymbol{q}$*-exterior algebras of* $\boldsymbol{V}$ *and* $\boldsymbol{V^*}$*, cf. [21].*

would include $(\boldsymbol{V}, \text{exterior algebra})$ and $(\boldsymbol{V^*}, \text{exterior algebra})$ but *not* $(\boldsymbol{q}, \text{exterior algebra})$. Such edges are identified using pattern matching (Java regular expressions) and are not presented to annotators or recorded in the data set.

Our definition of "variable" mirrors that of "simple expression" proposed by Grigore et al. (2009): instances of formulae in the discourse are considered to be "typeable variables" if they are only composed of a single, potentially scripted base identifier.

Variable typing, as defined in this work, is based on four assumptions: (1) typings occur at the sentential level and variables in a sentence can only be assigned a type phrase occurring in that sentence, (2) variables and types in the sentence are known a priori, (3) edges in each sentence are independent of one another, and (4) edges in one sentence are independent of those in other sentences – given a variable v in sentence s, type assignment for v is agnostic of other typings involving v from other sentences.

The decision to constrain variable typing at the sentential level is motivated by empirical studies (Grigore et al., 2009; Gödert, 2012). Grigore et al. (2009) have shown that the majority of variables are introduced and declared in the same sentence. In addition, mathematical text tends to be composed of local contexts, such as theorems, lemmas and proofs (Ganesalingam, 2008).

The assumptions introduced above simplify the task of variable typing without sacrificing the generalisability of the task. For example, cases where the same variable is assigned multiple conflicting types from different sentences within a document can be collected and resolved using a *type disambiguation* algorithm.

4 Variable Typing Data Set

We have constructed an annotated data set of sentences for building variable typing classifiers. The sentences in our corpus are sourced from the Mathematical REtrieval Corpus (MREC) (Líška et al., 2011), a subset of arXiv (over 439,000 papers) with all LaTeX formulae converted to MathML.

	Train	Dev	Test	Total
Sentences	5,273	841	1,689	**7,803**
Positive edges	1,995	457	1,049	**3,501**
Negative edges	15,164	4,386	10,473	**30,023**
Total edges	17,159	4,843	11,522	**33,524**

Table 1: Data set statistics.

The data set is split into a standard training/development/test machine learning partitioning scheme as outlined in Table 1. The idea behind this scheme is to train and evaluate new models on standardised data partitions so that results can be directly comparable.

4.1 Sentence Sampling

The structure and role of sentences in mathematical papers may vary according to their location in the discourse. For example, sentences in the "Introduction" – intended to introduce the subject matter – can be expected to differ in structure from those in a proof, which tend to be short, formal statements. Our sampling strategy is designed to control for this diversity in sentence structure. First, we sentence-tokenised and transformed each document in the MREC into a graph that encodes its section structure. Document graphs also take into account blocks of text unique to the mathematical discourse such as theorems, proofs and definitions. Then, we sampled sentences for our data set by distribution according to their location in the source arXiv document.

Variables in each MREC document are identified via a parser that recognises the variable description given in Section 3. Our variable parser is designed to operate on *symbol layout trees* (SLTs) (Schellenberg et al., 2012) – trees representing the 2-dimensional presentation layout of mathematical formulae. We identified 28.6 million sentences that contain variables.

The distribution of sentences according to (a) the type of discourse/math block of origin and (b) the number of unique types in the sentence is reconstructed by putting sentences into bins based

on the value of these features. Sentences are selected from the bins at random in proportion to their size. The training, development and test samples have been produced via repeated application of this sample-by-distribution strategy over the set of all sentences that contain variables.

4.2 Extended Type Dictionary

The type dictionary distributed by Stathopoulos and Teufel (2016) contains 10,601 automatically detected types from the MREC. However, the MREC contains 2.9 million distinct technical terms, many of which might also be types. Therefore, the seed dictionary is too small to be used with variable typing at scale since types from the seed dictionary will be sparsely present in sampled sentences. To overcome this problem, we used the *double suffix trie algorithm* (DSTA) to automatically expand the type dictionary. The algorithm makes use of the fact that most types are compositional (Stathopoulos and Teufel, 2016): longer subtypes can be constructed out of shorter supertypes by attaching pre-modifiers (e.g., a "Riemannian manifold" can be considered a subtype of "manifold").

The DSTA takes two lists of technical terms as input – the seed dictionary of types and the MREC master list (2.9 million technical terms). First, technical terms on both lists are word-tokenised. Then, all technical terms in the seed dictionary (the known types) are placed onto the *known types suffix trie* (KTST). Additional types are generated from single word types on the KTST by expanding them with one of 40 prefixes observed in the corpus. For example, the type "algebra" might generate the supertype "coalgebra". These are also added on the KTST as known types.

Technical terms in the KTST are copied onto the *candidate type suffix trie* (CTST) and are labeled as types. Next, the technical terms on the master list are inserted into the CTST. Technical terms in the master list that have known types from the seed dictionary as their suffix on the CTST are also marked as types. A new dictionary of types (in the form of a list of technical terms) is produced by traversing the CTST and recording all phrases that have a known type as their suffix. This way, we have expanded the type dictionary from 10,601 types to approximately 1.23 million technical terms, from which an updated KTST can be produced.

4.3 Human Annotation and Agreement

Two of the authors jointly developed the annotation scheme and guidelines using sentences sampled by distribution as discussed in Section 4.1. Sentences sampled for this purpose are excluded from subsequent sampling. The labeling scheme, presented in Table 2, implements the assumptions of the variable typing task – each variable in a sentence is assigned exactly one label: either one type from the sentence or one of six fixed labels for special situations.

An annotation experiment was carried out using two authors as annotators to investigate (a) how intuitive the task of typing is to humans and (b) the reliability of the annotation scheme. For this purpose, a further 1,000 sentences were sampled (and removed) from the pool and organised into two subsamples each with 554 sentences. The subsamples have an overlap of 108 sentences with a total of 182 edges, which are used to measure inter-annotator agreement.

We report annotator agreement for three separate cases. The first case reflects whether annotators agree that a variable can be typed or not by its context. A variable falls into the first category if it is assigned a type from the sentential context and in the latter category if it is assigned one of the six fixed labels from Table 2. In this case, agreement is substantial (Cohen's $K = 0.80$, $N = 182$, $k = 2$, $n = 2$). The second case is for instances where both annotators believe a variable can be typed by its sentential context – the variable is assigned a type by both annotators. In this case, Cohen's Kappa is not applicable because the number of labels varies: there are as many labels as there are types in the sentence. Instead, we report accuracy as the proportion of decisions where annotators agree over all decisions: 90.9%. In the last case where both annotators agree that a variable is not a type (i.e., is assigned one of the six fixed labels), agreement has been found to be moderate (Fleiss' $K = 0.61$, $N = 123$, $k = 2$, $n = 6$).

The bulk of the annotation was carried out by one of the author-annotators and was produced by repeated sampling by distribution (as described in Section 4.1). Sentences in the bulk sample are combined with the 554 sentences annotated by the author during the annotation experiment to produce a final data set composed of 7,803 sentences. The training, test and development sets have been produced using the established 70% for training,

Label	Description
One label per type instance	One label per instance of any type in the sentence.
Type Unknown	The type of the variable is not in the scope of the sentence.
Type Present but Undetected	The type of the variable is in the scope of the sentence but is not in the dictionary.
Parameterisation	Variable is part of an instance of parameterisation.
Index	Variable is an instance of indexing (numeric or non-numeric).
Number	Variable is implied to be a number by the textual context (e.g., "the n-th element...").
Formula is not a variable	Label used to mark data errors. For example, in some instances end-of-proof symbols are encoded as identifiers in the corpus and are mistaken for variables.

Table 2: Labels for special typing situations.

20% for test and 10% for development data set partitioning strategy. Each partition is sampled by distribution in order to model training and predicting typings over complete discourse units, such as documents.

5 Experiments

We compare three models for variable typing to two baselines: the "nearest type" baseline and the SVM proposed by Kristianto et al. (2014). One of our models is an extension of the latter baseline with both type and variable-centric features. The other two models are based on deep neural networks: a convolutional neural network and a bidirectional LSTM.

We treat the task of typing as binary classification: every possible typing in a sentence is presented to a classifier which, in turn, is expected to make a "type" or "not-type" decision. We say that an edge is *positive* if it connects a variable to a type in the sentence and *negative* otherwise.

5.1 Computing a Type Embedding Space

We use the extended dictionary of types (Section 4.2) to pre-train a *type embedding space*. Computed over the MREC, a type embedding space includes embeddings for both words and types (as atomic lexical tokens). These vectors are used by our deep neural networks to model the distributional meaning of words and types. The type embedding space is constructed using the process described by Stathopoulos and Teufel (2016): occurrences of extended dictionary type phases in the MREC are substituted with unique atomic lexical units before the text is passed on to `word2vec`.

5.2 Models for Variable Typing

Nearest Type baseline (NT) Given a variable v, the nearest type baseline takes the edge that minimises the word distance between v and some type in the sentence to be the positive edge. This baseline is intended to approximate the "nearest noun" baseline (Kristianto et al., 2012, 2014) which we cannot directly compute due to the fact that noun phrases in the text become parts of types.

Support Vector Machine (Kristianto et al.) (SVM) This is an implementation of the features and linear SVM described by Kristianto et al. (2012). Furthermore, we use the same value for hyperparameter C (the soft margin cost parameter) used by Kristianto et al. (2012). Due to the class imbalance in our data set we have used inversely proportional class weighting (as implemented in scikit-learn). L2-normalisation is also applied.

Extended Support Vector Machine (SVM+) We have extended the SVM proposed by Kristianto et al. (2012) with the features that are type and variable-centric, such as the 'base symbol of a candidate variable' and 'first letter in the candidate type'. A description of these extended features are listed in Table 4. We applied automatic class weighting and L2-normalisation. We have found that $C = 2$ is optimal for this model by fine-tuning over the development set.

Convolutional Neural Network (Convnet) We use a Convnet to classify each of the $V \times T$ assignment edges as either positive or negative, where V are the variables in the input text and T are the types. Unlike the SVM models, we do not use any hand-crafted features, but only the inputs (Table 3), and the pre-trained embeddings (Section 5.1).

The input is a tensor that encodes the input described in Table 3. We use the embeddings to represent the input tokens. In addition, we concatenate two dimensions to the input for each token : one dimension to denote (using 1 or 0) whether a given token is a type and another dimension to denote if a token is a variable.

The model has a set of different sized filters, and each filter size has an associated number of filters to be applied (all are hyperparameters to

Name	Description
Token	A word in the sentence. If the token is a formula (including a variable), the token is '@@@'. Types are represented by the key of their embedding vector.
Token class	An integer – 0 for normal word, 1 for type, 2 for variable and 3 to indicate that a variable token is part of the edge being considered.
Type of Interest	If the token is a type and it is part of the edge being considered, this field takes the value 'TYPE' or '-' otherwise.

Table 3: Input and features to neural network typing models.

Orientation	Description
Type	Number of words in the candidate type.
Type	The base type of each candidate type.
Type and Variable	The first letter in the type and base symbol of the candidate variable.
Type	The grammatical number of the type as it appears in the sentence.
Variable	The variables and symbols in the candidate variable layout graph (one string per symbol).
Variable	The number of distinct symbols in the candidate variable layout graph.
Variable	The base symbol of the candidate variable layout graph.
Variable	The directions (Above, Below,Up-left, Up-right, Down-left, Down-right, Next) in which a candidate symbol has neigbouring symbols.
Variable	Operators in the mathematical context of the candidate variable layout graph.
Sentence	Prefix sequence: tokens from start of sentence to a (exclusive)
Sentence	Middle sequence: tokens between a and b (exclusive)
Sentence	Suffix sequence: tokens between b (exclusive) and end of sentence.

Table 4: SVM+ features. For each edge e, let a be the position of its left-most component (variable or type) and b the position of its rightmost component (variable or symbol).

the model). The filters are applied to the input text (i.e. convolutions), and then max-pooled, flattened, concatenated, and a dropout layer ($p = 0.5$) is then applied before being fed into a multilayer perceptron (MLP), with the number of hidden layers and their hidden units as hyperparameters. Finally, a softmax layer is used to output a binary decision.

The model is implemented using the Keras library using binary cross-entropy as loss function, and the ADAM optimizer (Kingma and Ba, 2014). We tune the aforementioned hyperparameters on the development data and we use balanced oversampling with replacement in order to adjust for the class imbalance in the data.

Our tuned hyperparameters are as follows: filter window sizes (2 to 12, then 14,16,18,20) with an associated number of filters (300 for the first five, 200 for the next four, 100 for the next three, then 75,70,50). One hidden layer of the MLP with 512 units is used with batch size 50.

Bidirectional LSTM (BiLSTM) The architecture takes as input a sequence of words, which are then mapped to word embeddings. For each token in the input sentence, we also include the inputs described in Table 3. In addition, the model uses one string feature we refer to as "supertype". If the token is a type, then this feature is the string key of the embedding vector of its supertype or "NONE" otherwise.

These features are mapped to a separate embedding space and then concatenated with the word embedding to form a single task-specific word representation. This allows us to capture useful information about each word, and also designate which words to focus on when processing the sentence.

We use a neural sequence labeling architecture, based on the work of Lample et al. (2016) and Rei and Yannakoudakis (2016). The constructed word representations are given as input to a bidirectional LSTM (Hochreiter and Schmidhuber, 1997), and a context-specific representation of each word is created by concatenating the hidden representations from both directions.

A hidden layer is added on top to combine the features from both directions. Finally, we use a softmax output layer that predicts a probability distribution over positive or negative assignment for a given edge.

We also make use of an extension of neural sequence labeling that combines character-based word representations with word embeddings using a predictive gating operation (Rei et al., 2016). This allows our model to capture character-level patterns and estimate representations for previously unseen words.

In this framework, an alternative word repre-

sentation is constructed from individual characters, by mapping characters to an embedding space and processing them with a bidirectional LSTM. This representation is then combined with a regular word embedding by dynamically predicting element-wise weights for a weighted sum, allowing the model to choose for each feature whether to take the value from the word-level or character-level representation.

The LSTM layer size was set to 200 in each direction for both word- and character-level components; the hidden layer d was set to size 50. During training, sentences were grouped into batches of size 64. Performance on the development set was measured at every epoch and training was stopped when performance had not improved for 10 epochs; the best-performing model on the development set was then used for evaluation on the test set.

6 Intrinsic Evaluation

Evaluation is performed over edges, rather than sentences, in the test set. We measure performance using precision, recall and F_1-score. We use the non-parametric *paired randomisation test* to detect significant differences in performance across classifiers.

The convnet and BiLSTM models are trained and evaluated with as many sentences as there are edges: the source sentence is copied for each input edge, with inputs modified to reflect the relation of interest. We employed early stopping and dropout to avoid overfitting with these models.

Table 5 shows the performance results of all classifiers considered. All three proposed models have significantly outperformed the NT baseline and Kristianto et al.'s (Kristianto et al., 2014) state-of-the-art SVM. The best performing model is the bidirectional LSTM ($F_1 = 78.98\%$) which has significantly outperformed all other models ($\alpha = 0.01$).

According to the results in Table 5, both deep neural network models have significantly outperformed classifiers based on other paradigms. This is consistent with the intuition that the language of mathematics is formulaic: we expect deep neural networks to effectively recognise patterns and identify correlations between tokens.

The neural models outperform SVM+ despite the fact that the latter is a product of laborious manual feature engineering. In contrast, no manual feature engineering has been performed on the Convnet model (or indeed on any of the deep neural network models).

	Precision (%)	Recall (%)	F_1-score (%)
NT	30.30	82.94	44.39
SVM	55.39	76.36	64.21
SVM+	71.11	72.74	71.91
Convnet	80.11	70.26	74.86
BiLSTM	83.11	74.77	78.98

Table 5: Model performance summary. All figures are statistically significant ($p < 0.01$) according to the randomisation test.

The nearest type (NT) baseline demonstrates high recall but low precision. This is not surprising since the NT baseline is not capable of making a negative decision: it always assigns some type to all variables in a given sentence.

7 Extrinsic Evaluation

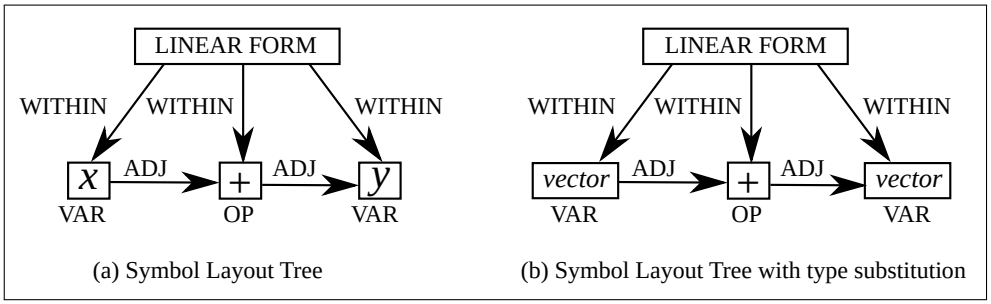
We demonstrate that our data set and variable typing task are useful using a mathematical information retrieval (MIR) experiment. The hypothesis for our MIR experiment is two-fold: (a) types identified in the textual context for the variable typing task are also useful for text-based mathematical retrieval and (b) substituting raw symbols with types in mathematical expressions will have an observable effect to MIR.

In order to motivate the second hypothesis, consider the following natural language query:

> *Let x be a vector. Is there another vector y such that $x + y$ will produce the zero element?*

In the context of MIR, mathematical expressions are represented using SLTs (Pattaniyil and Zanibbi, 2014) that are constructed by parsing presentation MathML. The expression "$x + y$" is represented by the SLT in figure 1(a). The variable typing classifier and the type disambiguation algorithm determine the types of the variables x and y as "vector". Thus, the variable nodes in figure 1(a) will be substituted with their type, producing the SLT in figure 1(b).

The example query can be satisfied by identifying a vector y such that when added to x will produce the zero vector. This operation is abstract in mathematics and extends to objects beyond vectors, including integers. In an untyped formula index, there is no distinction between instances of $x + y$ where the variables are integers or vectors. As a result, documents where both variables are integers might also be returned. In contrast,



(a) Symbol Layout Tree (b) Symbol Layout Tree with type substitution

Figure 1: (a) SLT representation of the expression $x + y$, (b) typed SLT for the expression $x + y$.

a typed formula index will return instances of the typed SLT in figure 1(b) where the variables are vectors, as opposed to integers. Therefore, a typed index can reduce the number of false positives and increase precision.

Four MIR retrieval models are introduced in Section 7.3 designed to control for text indexing/retrieval so that the effects of type-aware vs type-agnostic formula indexing and scoring can be isolated. These models make use of the Tangent formula indexing and scoring functions (Pattaniyil and Zanibbi, 2014), which we have implemented.

We use the Cambridge University Math IR Test Collection (CUMTC) (Stathopoulos and Teufel, 2015) which is composed of 120 research-level mathematical information needs and 160 queries. The CUMTC is ideal for our evaluation for two reasons. First, topics in the CUMTC are expressed in natural language and are rich in mathematical types. This allows us to directly apply our best performing variable typing model (BiLSTM) in our retrieval experiment in order to extract variable typings for documents and queries. Second, the CUMTC uses the MREC as its underlying document collection, which enables downstream evaluation in an optimal setting for variable typing.

7.1 Tangent Formula Indexing and Scoring

Given a mathematical formula, the Tangent indexing algorithm starts from the root node of an SLT and generates symbol pair tuples in a depth-first manner. Symbol pair tuples record parent/child relationships between SLT nodes, the distance (number of edges) and vertical offset between them. At each step in the traversal, the index is updated to record one tuple representing the relationship between the current node and every node in the path to the SLT root. We have also implemented Tangent's method of indexing matrices, but we refer the reader to Pattaniyil and Zanibbi (2014) for further details.

Tangent scoring proceeds as follows. For each query formula, the symbol pair tuples are generated and matched exactly to those in the document index. Let C denote the set of matched index formulae and $|s|$ the number of symbol pairs in any given expression s in C. For each s in C, recall (R) is said to be $\frac{|C|}{|Q|}$, where $|C|$ and $|Q|$ are the numbers of tuples in C and the query formula Q respectively, and precision (P) is $\frac{|C|}{|s|}$. Candidate s is assigned the F score of these precision and recall values. The mathematical context score for a given document d and query with formulae $e_1, \ldots, e_n$ is

$$m(d, e_1, \ldots, e_n) = \sum_{j=1}^{n} \frac{|e_j| \cdot t1(d, e_j)}{\sum_{i=1}^{n} |e_i|}$$

where $|e_j|$ represents the number of tuples in expression e_j and $t1(d, e_j)$ represents the top F-score for expression e_i in document d. The final score for document d is a linear combination of the math context score above and its Lucene text score (L(d)):

$$\lambda \times L(d) + (1 - \lambda) \times m(d, e_1, \ldots, e_n)$$

7.2 Typed Tangent Indexing and Scoring

We have applied the BiLSTM variable typing model to obtain variable typings for all symbols in the documents in the MREC. For each document in the collection our adapted Tangent formula indexer first groups the variable typing edges for that document according to the variable identifier involved. Subsequently, our typed indexing process applies a type disambiguation algorithm to determine which of the candidate types associated with the variable will be designated as its type.

For a variable v in document d, our type disambiguation algorithm first looks at the known types suffix trie (KTST) containing all 1.23 million types in order to find a common parent be-

tween the candidate types. If a common supertype T is discovered, then v is said to be of type T. Otherwise, the type disambiguation algorithm uses simple majority vote amongst the candidates to determine the final type for variable v.

The type disambiguation algorithm is applied to every typing group until all variable typings have been processed. Variable groups with no type candidates (e.g., no variable typings have been extracted for a variable) are assigned a missing type symbol ("*"). Subsequently, variables in the SLT of each formula in d are replaced with their type or the missing type symbol. An index, referred to as the typed index, is generated by applying the tangent indexing process on the modified SLTs.

The same process is applied to query formulae during query time in order to facilitate typed matching and scoring.

7.3 Results

We have replicated runs of the Lucene vector-space model (VSM) and BM25 models presented by Stathopoulos and Teufel (2016) on the CUMTC. Furthermore, we introduce four models based on Tangent indexing and scoring that represent different strategies in handling types in text and formulae. We refer to a model as *typed* if it uses the type-substituted version of the Tangent index and *untyped* otherwise.

Text with types removed (RT): The Lucene score $L(d)$ is computed over a text index with type phrases completely removed. This model is intended to isolate the performance of retrieval on the formula index alone. We consider both typed and untyped instances of this model.

Text with types(TY): The Lucene score is computed over a text index that treats type phrases as atomic lexical tokens. This model is intended to simulate type-aware text that enables the application of variable typing. Both typed and untyped instances of this model are considered.

Optimal values for the linear combination parameter λ are obtained using 13 queries in the "development set" of the CUMTC. We report mean average precision (MAP) for our models computed over all 160 queries in the main CUMTC. MAPs obtained over the CUMTC are low due to the difficulty of the queries rather than an unstable evaluation (Stathopoulos and Teufel, 2016). The paired randomisation test is used to test for significance in retrieval performance gains between the models.

	VSM	**BM25**		
MAP	.076	.079		
	RT typed	**RT untyped**	**TY typed**	**TY untyped**
MAP	.046	.052	.139	.083
λ_{opt}	.9	.9	.9	.4

Table 6: MIR model performance summary.

The results of our MIR experiments are presented in Table 6. The best performing model is TY/typed which significantly outperforms all other baselines ($p - value < 0.05$ for comparison with BM25 and $p - value < 0.01$ with all other models). The TY/typed model yields almost double the MAP performance of its untyped counterpart (TY/untyped, .083 MAP). In contrast, the RT/typed and RT/untyped models perform comparably (no significant difference) but poorly. This drop in MAP performance suggests that type phrases are beneficial for text-based retrieval of mathematics. Retrieval models employing formula indexing seem to be affected by both the presence of types in the text as well as in the formula index. The TY/typed model outperforms the TY/untyped model, which in turn outperforms RT/untyped. This suggests that gains in retrieval performance are strongest when types are used in both text and formula retrieval – models using either approach alone do not perform as well. These results demonstrate that variable typing is a valuable task in MIR.

8 Conclusions

This work introduces the new task of variable typing and an associated data set containing 33,524 labeled edges in 7,803 sentences. We have constructed three variable typing models and have shown that they outperform the current state-of-the-art methods developed for similar tasks. The BiLSTM model is the top performing model achieving 79% F_1-score. This model is then evaluated in an extrinsic downstream task–MIR, where we augmented Tangent formula indexing with variable typing. A retrieval model employing the typed Tangent index outperforms all considered retrieval models demonstrating that our variable typing task, data and trained model are useful in downstream applications. We make our variable typing data set available through the Open Data Commons license.

Abstract

Machine Learning has been the quintessential solution for many AI problems, but learning models are heavily dependent on specific training data. Some learning models can be incorporated with prior knowledge using a Bayesian setup, but these learning models do not have the ability to access any organized world knowledge on demand. In this work, we propose to enhance learning models with *world knowledge* in the form of Knowledge Graph (KG) fact triples for Natural Language Processing (NLP) tasks. Our aim is to develop a deep learning model that can extract relevant prior support facts from *knowledge graphs* depending on the task using attention mechanism. We introduce a *convolution-based model* for learning representations of knowledge graph entity and relation clusters in order to reduce the attention space. We show that the proposed method is highly scalable to the amount of prior information that has to be processed and can be applied to any generic NLP task. Using this method we show significant improvement in performance for text classification with 20Newsgroups (News20) & DBPedia datasets, and natural language inference with Stanford Natural Language Inference (SNLI) dataset. We also demonstrate that a deep learning model can be trained with substantially less amount of labeled training data, when it has access to organized world knowledge in the form of a knowledge base.

1 Introduction

Today, machine learning is centered around algorithms that can be trained on available task-specific labeled and unlabeled training samples. Although learning paradigms like Transfer Learning (Pan and Yang, 2010) attempt to incorporate knowledge from one task into another, these techniques are limited in scalability and are specific to the task at hand. On the other hand, humans have the intrinsic ability to elicit required past knowledge from the world on demand and infuse it with newly learned concepts to solve problems.

The question that we address in this paper is the following: Is it possible to develop learning models that can be trained in a way that it is able to infuse a general body of world knowledge for prediction apart from learning based on training data?

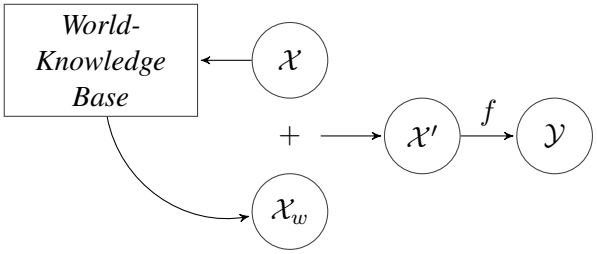

Figure 1: The Basic Idea: $\mathcal{X}$ is the feature input and $\mathcal{Y}$ is the prediction. The relevant world knowledge for the task $\mathcal{X}_w$, is retrieved and augmented with the feature input before making the final prediction

By world knowledge, we mean structured general purpose knowledge that need not be domain specific. Knowledge Graphs (Nickel et al., 2016a) are a popular source of such structured world knowledge. Knowledge Graphs represent information in the form of fact triplets, consisting of a subject entity, relation and object entity (example: *<Italy, capital, Rome>*). The entities represent the nodes of the graph and their relations act as edges. A fact triple (subject entity, relation, object relation) is represented as (h, r, t). Practical knowledge bases congregate information from secondary databases or extract facts from unstructured text using various statistical learning mechanisms, examples of such systems are NELL (Mitchell et al., 2015) and DeepDive (Niu

New Orleans, Louisiana, June 1 - 6, 2018.

et al., 2012). There are human created knowledge bases as well, like Freebase (FB15k) (Bollacker et al., 2008) and WordNet (Miller et al., 1990). The knowledge present in these knowledge bases includes common knowledge and partially covers common-sense knowledge and domain knowledge (Song and Roth, 2017). Knowledge Graphs and Knowledge Bases are conceptually equivalent for our purpose and we will use the name interchangeably in this paper.

We illustrate the significance of world knowledge using a few examples. For the example of a Natural Language Inference (NLI) problem (MacCartney, 2009), consider the two following statements, A: `The couple is walking on the sea shore` and B: `The man and woman are wide awake`. Here, for a learning model to infer B from A, it should have access to the common knowledge that "*The man and woman* and *The couple* means the same" since this information may not be specific for a particular inference. Further, it is not possible for a model to learn all such correlations from just the labeled training data available for the task.

Consider another example of classifying the news snippet, `Donald Trump offered his condolences towards the hurricane victims and their families in Texas`. We cannot classify it as a political news unless we know the facts <*Donald Trump, president, United States*> and <*Texas, state, United States*>. We posit that machine learning models, apart from training them on data with the ground-truth can also be trained to fetch relevant information from structured knowledge bases in order to enhance their performance.

In this work, we propose a deep learning model that can extract relevant support facts on demand from a knowledge base (Mitchell et al., 2015) and incorporate it in the feature space along with the features learned from the training data (shown in Figure 1). This is a challenging task, as knowledge bases typically have millions of fact triples. Our proposed model involves a deep learning mechanism to jointly model this look-up scheme along with the task specific training of the model. The look-up mechanism and model is generic enough so that it can be augmented to any task specific learning model to boost the learning performance. In this paper, we have established superior performance of the proposed KG-augmented models over vanilla model on text classification and natural language inference.

Although there is a plethora of work on knowledge graph representation (Nickel et al., 2016a) (Mitchell et al., 2015) (Niu et al., 2012) from natural language text, no attempt to augment learning models with knowledge graph information have been done. To the best of our knowledge this is the first attempt to incorporate world knowledge from a knowledge base for learning models.

2 Knowledge Graph Representations

Knowledge Graph entities/relations need to be encoded into a numerical representation for processing. Before describing the model, we provide a brief overview of graph encoding techniques. Various KG embedding techniques can be classified at a high level into: *Structure-based embeddings* and *Semantically-enriched embeddings*.

Structure-based embeddings: TransE (Bordes et al., 2013) is the introductory work on knowledge graph representation, which translated subject entity to object entity using one-dimensional relation vector $(h + r = t)$. Variants of the TransE (Bordes et al., 2013) model uses translation of the entity vectors over relation specific subspaces. TransH (Wang et al., 2014b) introduced the relation-specific hyperplane to translate the entities. Similar work utilizing only the structure of the graph include ManifoldE (Xiao et al., 2015b), TransG (Xiao et al., 2015a), TransD (Ji et al., 2015), TransM (Fan et al., 2014), HolE (Nickel et al., 2016b) and ProjE (Shi and Weninger, 2017).

Semantically-enriched embeddings: These embedding techniques learn to represent entities/relations of the KG along with its semantic information. Neural Tensor Network(NTN) (Socher et al., 2013) was the pioneering work in this field which initialized entity vectors with the average word embeddings followed by tensor-based operations. Recent works involving this idea are "Joint Alignment" (Zhong et al., 2015) and SSP (Xiao et al., 2017). DKRL (Xie et al., 2016) is a KG representation technique which also takes into account the descriptive nature of text keeping the simple structure of TransE model. Pretrained word2vec (Mikolov et al., 2013) is used to form the entity representation by passing through a Convolutional Neural Network (CNN) (Kim, 2014) architecture constraining the relationships to hold.

In our experiments we have used the DKRL (Xie et al., 2016) encoding scheme as it emphasizes on the semantic description of the text. Moreover, DKRL fundamentally uses TransE (Bordes et al., 2013) method for encoding structural information. Therefore, we can retrieve relevant entities & relation and obtain the complete the fact using $t = h + r$. This reduces the complexity of fact retrieval as the number of entities/relations is much less compared to the number of facts, thus making the retrieval process faster.

3 The Proposed Model

Conventional supervised learning models with parameters Θ, given training data x and label y, tries to maximize the following function

$$\max_{\Theta} P(y|x, \Theta)$$

The optimized parameters Θ are given as,

$$\Theta = \underset{\Theta}{\operatorname{argmax}} \log P(y|x, \Theta)$$

In this work, we propose to augment the supervised learning process by incorporation of world knowledge features x_w. The world knowledge features are retrieved using the data x, using a separate model where, $x_w = F(x, \Theta^{(2)})$. Thus, our modified objective function can be expressed as

$$\max_{\Theta} P(y|x, x_w, \Theta^{(1)})$$

where, $\Theta = \{\Theta^{(1)}, \Theta^{(2)}\}$. The optimized parameters can be obtained using the equation

$$\Theta = \underset{\Theta}{\operatorname{argmax}} \log P(y|x, F(x, \Theta^{(2)}), \Theta^{(1)})$$

The subsequent sections focus on the formulation of the function F which is responsible for fact triple retrieval using the data sample x. Here it is important to note that, we are not assuming any structural form for P based on F. So the method is generic and applicable to augment any supervised learning setting with any form for P, only constraint being P should be such that the error gradient can be computed with respect to F. In the experiments we have used softmax using the LSTM (Greff et al., 2015) encodings of the input as the form for P. As for F, we use soft attention (Luong et al., 2015; Bahdanau et al., 2014) using the LSTM encodings of the input and appropriate representations of the fact(s). Based on the representation used for the facts, we propose two models (a) Vanilla Model (b) Convolution-based entity/relation cluster representation, for fact retrieval in the subsequent sections.

3.1 Vanilla Model

The entities and relationships of KG are encoded using DKRL, explained earlier. Let $e_i \in \mathbb{R}^m$ stand for the encoding of the entity i and $r_j \in \mathbb{R}^m$ stands for j^{th} relationship in the KG. The input text in the form of concatenated word vectors, $\boldsymbol{x} = (x_1, x_2, \ldots, x_T)$ is first encoded using an LSTM (Greff et al., 2015) module as follows,

$$h_t = f(x_t, h_{t-1})$$

and

$$o = \frac{1}{T}\sum_{t=1}^{T} h_t,$$

$h_t \in \mathbb{R}^n$ is the hidden state of the LSTM at time t, f is a non-linear function and T is the sequence length. Then a context vector is formed from o as follows,

$$C = \text{ReLU}(o^T W),$$

where, $W \in \mathbb{R}^{n \times m}$ represent the weight parameters. The same procedure is duplicated with separate LSTMs to form two seperate context vectors, one for entity retrieval (C_E) and one for relationship retrieval (C_R).

As the number of fact triples in a KG is in the order of millions in the vanilla model, we resort to generating attention over the entity and relation space separately. The fact is then formed using the retrieved entity and relation. The attention for the entity, e_i using entity context vector is given by

$$\alpha_{e_i} = \frac{\exp(C_E^T e_i)}{\sum_{j=0}^{|E|} \exp(C_E^T e_j)}$$

where $|E|$ is the number of entities in the KG.

Similarly the attention for a relation vector r_i is computed as

$$\alpha_{r_i} = \frac{\exp(C_R^T r_i)}{\sum_{j=0}^{|R|} \exp(C_R^T r_j)}$$

where $|R|$ is the number of relations in the KG. The final entity and relation vector retrieval is computed by the weighted sum with the attention

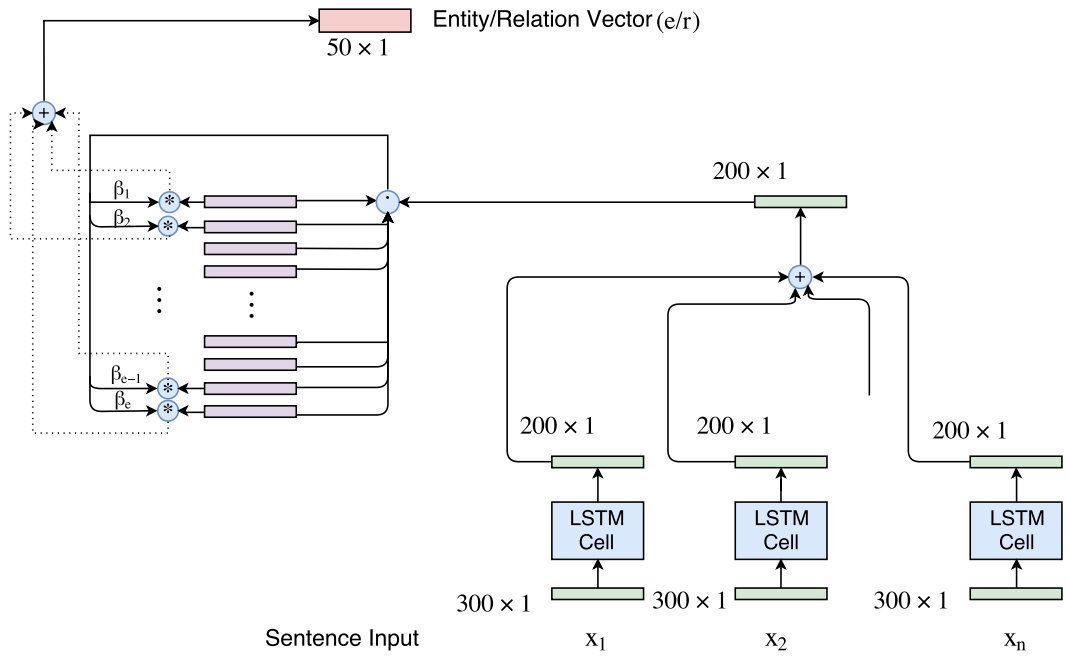

Figure 2: Vanilla Entity/Relationship Retrieval Block Diagram

values of individual retrieved entity/relation vectors.

$$e = \sum_{i=0}^{|E|} \alpha_{e_i} e_i \qquad r = \sum_{i=0}^{|R|} \alpha_{r_i} r_i$$

Figure 2 shows the schematic diagram for entity/relation retrieval. After the final entity and relation vectors are computed, we look forward to completion of the fact triple. The KG embedding technique used for the experiment is DKRL which inherently uses the TransE model assumption ($h+r \approx t$). Therefore, using the subject entity and relation we form the object entity as $t = e+r$. Thus the fact triplet retrieved is $\mathcal{F} = [e, r, e+r]$, where $\mathcal{F} \in \mathbb{R}^{3m}$. This retrieved fact information is concatenated along with the context vector (C) of input x obtained using LSTM module. The final classification label $\mathbf{y}$ is computed as follows,

$$\mathcal{F}^{'} = \mathrm{ReLU}(\mathcal{F}^{T} V)$$

$$\mathbf{y} = \mathrm{softmax}([\mathcal{F}^{'} : C]^{T} U)$$

where, $V \in \mathbb{R}^{3m \times u}$ and $U \in \mathbb{R}^{2u \times u}$ are model parameters to be learned. $\mathbf{y}$ is used to compute the cross entropy loss. We minimize this loss averaged across the training samples, to learn the various model parameters using stochastic gradient descent (Bottou, 2012). The final prediction $\mathbf{y}$, now includes information from both dataset specific samples and world knowledge to aid in enhanced performance. While jointly training the attention mechanism tunes itself to retrieve relevant facts that are required to do the final classification.

3.2 Pre-training KG Retrieval

The vanilla model attends over the entire entity/relation space which is not a good approach as we observe that the gradient for each attention value gets saturated easily. While training the classification and retrieval module together, the model tends to ignore the KG part and gradient propagates only through the classification module. This is expected to an extent as the most pertinent information for the task at hand comes from the training samples, only background aiding information comes from KG. After few epochs of training, the KG retrieved fact always converged to a fixed vector. To overcome this problem, we attempted pre-training KG retrieval part separately. A pre-trained KG model is used to retrieve the facts and then concatenate with the classification module, while we allow error to be propagate through the pre-trained model, at the time of joint training. We infer that KG doesn't return noise and has essential information for the task as the separate KG part alone shows significant performance (59% for News20 & 66% for SNLI). Figure 3 depicts the entire training scheme. This procedure solved the issue of gradient saturation in the KG retrieval part

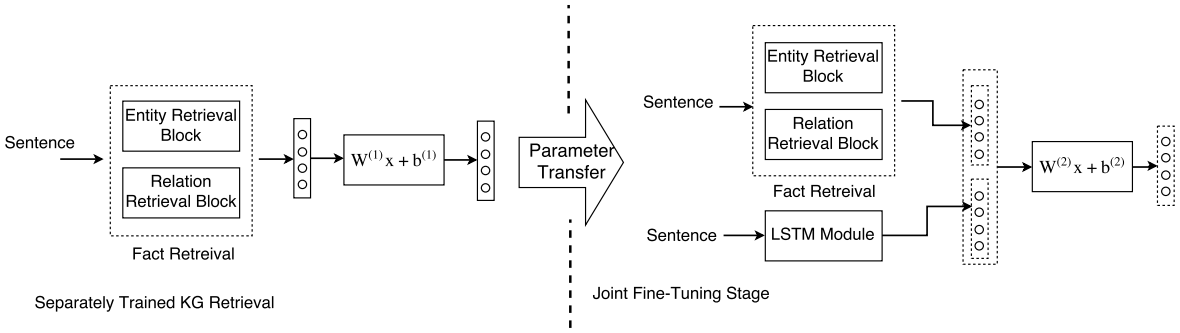

Figure 3: Separately Training Knowledge Graph Retrieval and Jointly Training the Full Model

at the time of joint training. However, the key problem of attention mechanism having to cover a large span of entities/relation, remained.

3.3 Convolution-based Entity and Relation Cluster Representation

In this section, we propose a mechanism to reduce the large number of entities/relationships over which attention has to be generated in the knowledge graph. We propose to reduce the attention space by learning the representation of similar entity/relation vectors and attending over them.

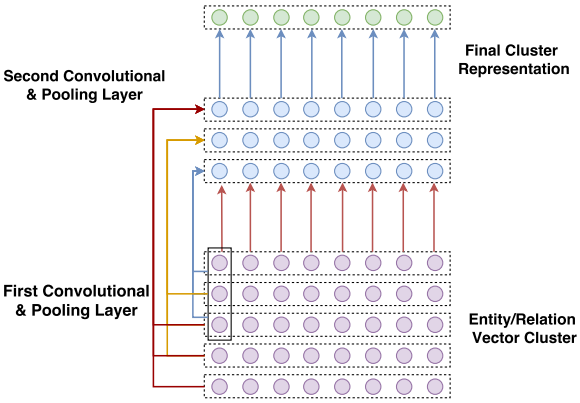

Figure 4: Convolution model cluster representation

In order to cluster similar entity/relation vectors, we used k-means clustering (Bishop, 2006) and formed l clusters with equal number of entity/relation vectors in each cluster. Each of the clusters were then encoded using convolutional filters. The output of the k-means clustering is a sequence of entity/relation vectors $\{e_1^T, e_2^T, \cdots, e_q^T\}$, where $e_i \in \mathbb{R}^m$. For each cluster these vectors were stacked to form $\mathcal{E}$ as the 2-D input to the CNN encoder, where $\mathcal{E} \in \mathbb{R}^{m \times q}$. During experimentation for finding a suitable filter shape, it was observed that using 2-D filters the model failed to converge at all. Therefore, we inferred that the latent representation of two different indices in the vector e_i, should not be tampered using convolution. We then resorted to use 1-D convolution filters which slide along only the columns of $\mathcal{E}$, as shown Figure 4. The stride length along y-axis is the window length k. The output of the convolution layer is expressed as,

$$\mathcal{E}'(i,j) = W^T[e_{i,j}, e_{i+1,j}, \ldots, e_{i+k-1,j}]^T$$

where, $\mathcal{E}'(i,j)$ is the $(i,j)^{th}$ element of the output matrix $\mathcal{E}'$ and $W \in \mathbb{R}^k$ is the convolution weight filter. A pooling layer followed the convolution layer in order to reduce the parameter space, we used 1-D window only along the y-axis similar to the convolutional kernel mentioned above. We used a two layered convolution network with the stride length k & max-pool windows n is adjusted to obtain output $E_i \in \mathbb{R}^m$, where i is the cluster index. Similar procedure of clustering followed by the encoding of the cluster entities is done for relations as well. Thus both the entity and relation space were reduced to contain fewer elements, one each for each cluster. After the compact entity space E and relation space R is formed, we followed the same steps as earlier for forming the attention, but now the training was more effective as the gradient was propagating effectively and was not choked by the large space. As the convolution architecture is also simultaneously trained, attention mechanism was not burdened as before, to learn over the large space of entities and relations.

Another point that needs to be mentioned here is regarding ranking/ordering items in the clusters, we have done experiments to verify the ordering does not affect the final result. We have verified this by randomly shuffling the entities/relationships in every clusters and the ac-

curacy output remained within an error bound of $\pm 0.5\%$. In various permutations, the representations learned by the convolution operator for clusters varies, but it does not affect the overall results. Regarding the interpretation of what convolution operator learns, the operator is applied along each dimension of the entity/relationship vector, to learn a representation of the clusters. This representation includes information from relevant entities in the cluster, as the relevant entities varies across tasks, the representation learned using convolution also adapts accordingly. It is analogous to learning relevant features from an image, in our case the convolution layer learns the features focusing on relevant entities/relations in a cluster pertaining to the task.

4 Experiments and Evaluations

Our experiments were designed to analyze whether a deep learning model is being improved when it has access to KG facts from a relevant source. The selection of knowledge graph has to be pertinent to the task at hand, as currently there is no single knowledge base that contains multiple kinds of information and can cater to all tasks. We illustrate with results that the performance of a deep learning model improves when it has access to relevant facts. We also illustrate that as the model learns faster with access to knowledge bases, we can train deep learning models with substantially less training data, without compromising on the accuracy. In the subsequent section we briefly describe the datasets and associated Knowledge Bases used.

Datasets and Relevant Knowledge Graphs

In our experiments, we have mainly used the popular text classification dataset 20Newsgroups (Lichman, 2013) and the Natural Language Inference dataset, Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015). We have also done experiments on DBPedia ontology classification dataset[1], with a very strong baseline. These datasets are chosen as they share domain knowledge with two most popular knowledge bases, Freebase (FB15k) (Bollacker et al., 2008) and WordNet (WN18) (Bordes et al., 2013). The training and test size of the datasets are mentioned in Table 1.

[1] http://wiki.dbpedia.org/services-resources/dbpedia-data-set-2014

Dataset	Train Size	Test Size	# Classes
News20	16000	2000	20
SNLI	549367	9824	3
DBPedia	553,000	70,000	14

Table 1: Dataset Specifications

Freebase (FB15k) (Bollacker et al., 2008) contains facts about people, places and things (contains 14904 entities, 1345 relations & 4.9M fact triples), which is useful for text classification in 20Newsgroups (Lichman, 2013) dataset. On the other hand, WordNet (WN18) (Bordes et al., 2013) (has 40943 entities, 18 relations & 1.5M fact triples) contains facts about common day-to-day things (example: furniture includes bed), which can help in inference tasks like SNLI. Both the knowledge bases are directed graphs, due to fewer number of relations WN18 the entities are more likely to be connected using the same type of relations. For experiments relating to both the datasets 20Newsgroups & SNLI we used the standard LSTM as the classification module. As iterated earlier, our KG based fact retrieval is independent of the base model used. We show improvement in performance using the proposed models by KG fact retrieval. We use classification accuracy of the test set as our evaluation metric.

4.1 Experimental Setup

All experiments were carried on a Dell Precision Tower 7910 server with Quadro M5000 GPU with 8 GB of memory. The models were trained using the Adam's Optimizer (Kingma and Ba, 2014) in a stochastic gradient descent (Bottou, 2012) fashion. The models were implemented using TensorFlow (Abadi et al., 2015). The relevant hyperparameters are listed in Table 2. The word embeddings for the experiments were obtained using the pre-trained GloVe (Pennington et al., 2014)[2] vectors. For words missing in the pre-trained vectors, the local GloVe vectors which was trained on the corresponding dataset was used.

4.2 Results & Discussion

Table 3 shows the results of test accuracy of the various methods proposed on the datasets News20 & SNLI. We observe that incorporation of KG facts using the basic vanilla model improves the performance slightly, as the retrieval model was

[2] http://nlp.stanford.edu/data/glove.840B.300d.zip

Hyper-parameter	News20	SNLI
Batch size	256	1024
Learning rate	0.05	0.05
Word Vector Dimension	300	300
Sequence Length	300	85
LSTM hidden-state Dimension	200	200
KG Embedding Dimension	50	50
# Clusters	20	20
# Epochs	20	20

Table 2: Hyper-parameters which were used in experiments for News20 & SNLI datasets

not getting trained effectively. The convolution-based model shows significant improvement over the normal LSTM classification. While tuning the parameters of the convolution for clustered entities/relations it was observed that smaller stride length and longer max-pool window improved performance. For News20 dataset we show an improvement of almost 3% and for SNLI an improvement of almost 5%.

The work is motivated more from the perspective of whether incorporation of world knowledge will improve any deep learning model rather than beating the state-of-the-art performance. Although LSTM is used to encode the input for the model as well as the retrieval vector, as mentioned earlier, these two modules need not be same. For encoding the input any complex state-of-the-art model can be used. LSTM has also been used to generate the retrieval vector. For DBPedia ontology classification dataset, we have used a strong baseline of 98.6%, and after augmenting it with KG (Freebase) using convolution based model we saw an improvement of ∼0.2%. As the baseline is stronger, the improvement quantum has decreased. This is quite intuitive as complex models are self-sufficient in learning from the data by itself and therefore the room available for further improvement is relatively less. The improvement as observed in the experiments is significant in weaker learning models, however it is also capable of improving stronger baselines as is evident from the results of DBPedia dataset.

4.3 Reducing Dataset Size Requirements for Training Deep Learning Models

We hypothesized that as Knowledge Graph is feeding more information to the model, we can achieve better performance with less training data.

Model	Accuracy	
	News20	SNLI
Plain LSTM	66.75%	68.73%
Vanilla KG Retrieval	67.30%	69.20%
Convolution-based KG	**69.34%**	**73.10%**

Table 3: Test accuracy of approaches in News20 using FB15K & SNLI datasets using WN18

To verify this we have performed experiments on varying dataset fractions for 20Newsgroups dataset as shown in Figure 5. From the plot, we observe that KG augmented LSTM with 70% data outperforms the baseline model with full dataset support, thereby reducing the dependency on labeled data by 30%.

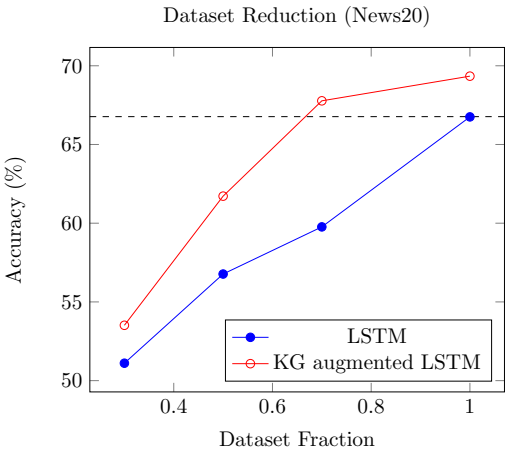

Figure 5: Accuracy Plot over dataset fractions for baseline and KG augmented model for News20

We also designed an experiment to compare the accuracy of the baseline model trained on full training data and compared it with the accuracy of the KG augmented model trained with just 70% of the training data for 20Newsgroups and SNLI datasets. The accuracy and training loss plots across training epochs is given in Figure 6. Even with just 70% of the data, KG augmented model is able to achieve better accuracy compared to the vanilla LSTM model trained on the full data. This clearly indicates that relevant information pertaining to the task is retrieved from the knowledge graph and the training loss reduction is not due to lesser data only. Also note that training loss is substantially less for KG LSTM compared to normal LSTM when the dataset size is reduced. This result is very promising, to reduce the large labeled training data requirement of large deep learning

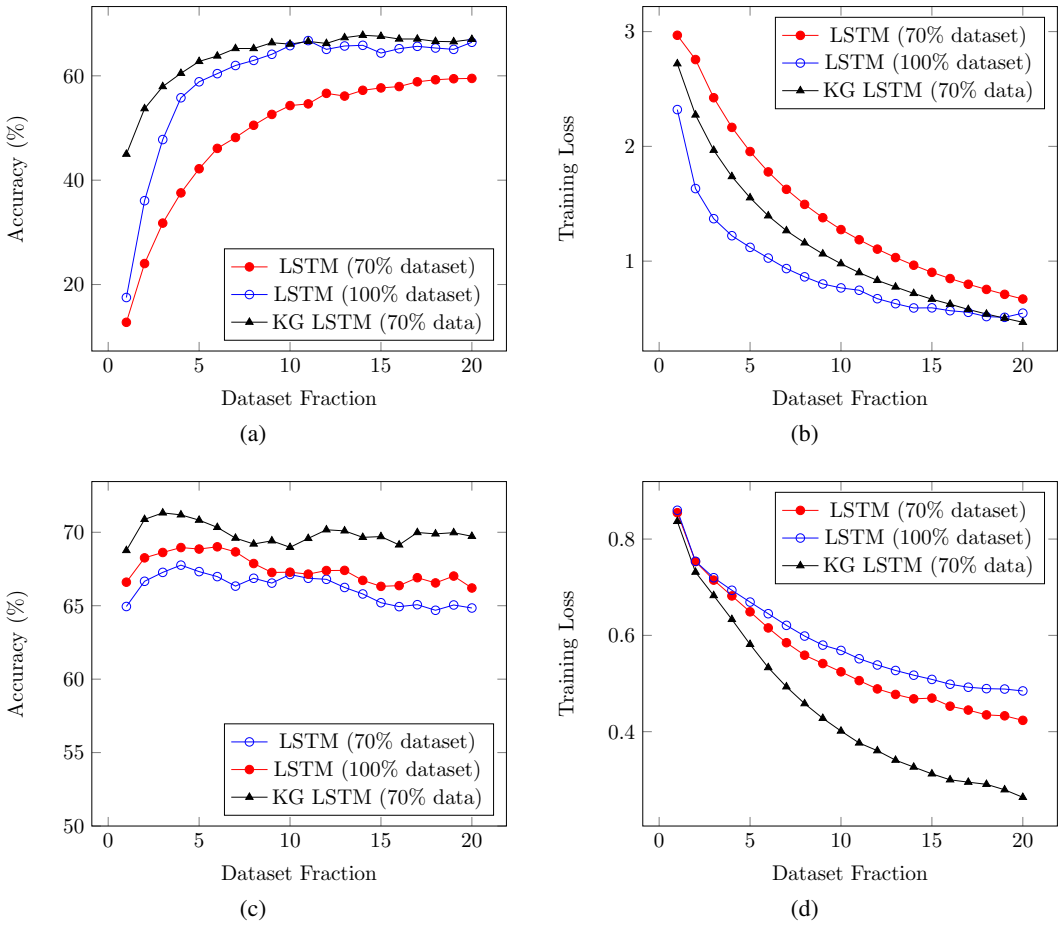

Figure 6: (a) Accuracy Plot over training epochs for LSTM (using full & 70% dataset) and KG augmented LSTM (using 70% dataset) for News20 task (b) Corresponding Training Loss plots for the aforementioned methods using News20 dataset (c) Accuracy Plot over training epochs for LSTM (using full & 70% dataset) and KG augmented LSTM (using 70% dataset) for SNLI task (d) Corresponding Training Loss plots for the aforementioned methods using SNLI dataset

models, which is hard to come by.

5 Relevant Previous Work

The basic idea of infusing general world knowledge for learning tasks, especially for natural language processing, has not been attempted before. For multi-label image classification, the use of KGs has been pursued recently by (Marino et al., 2016). In this work, they first obtain labels of the input data (using a different model), use these labels to populate features from the KG and in turn use these features back for the final classification. For NLP tasks the information needed may not necessarily depend on the final class, and we are directly using all the information available in the input for populating the relevant information from the knowledge graphs. Our attempt is very different from Transfer Learning (Pan and Yang, 2010). In Transfer Learning the focus is on training the model for one task and tuning the trained model to use it for another task. This is heavily dependent on the alignment between source task and destination task and transferred information is in the model. In our case, general world knowledge is being infused into the learning model for any given task. By the same logic, our work is different from domain adaptation (Glorot et al., 2011) as well. There has been attempts to use world knowledge (Song and Roth, 2017) for creating more labeled training data and providing distant supervision etc. Incorporating Inductive Biases (Ridgeway, 2016) based on the known information about a domain onto the structure of the learned models, is an active area of research. However our motivation and approach is fundamentally different from these works.

6 Conclusion & Future Work

In this work we have illustrated the need for incorporating world knowledge in training task specific models. We presented a novel convolution-based architecture to reduce the attention space over entities and relations that outperformed other models. With significant improvements over the vanilla baselines for two well known datasets, we have illustrated the efficacy of our proposed methods in enhancing the performance of deep learning models. We showcased that the proposed method can be used to reduce labeled training data requirements of deep learning models. Although in this work we focused only on NLP tasks and using LSTM as the baseline model, the proposed approach is applicable for other domain tasks as well, with more complicated deep learning models as baseline. To the best of our knowledge this is the first attempt at infusing general world knowledge for task specific training of deep learning models.

Being the first work of its kind, there is a lot of scope for improvement. A more sophisticated model which is able to retrieve facts more efficiently from millions of entries can be formulated. Currently we have focused only on a flat attention structure, a hierarchical attention mechanism would be more suitable. The model uses soft attention to enable training by simple stochastic gradient descent. Hard attention over facts using reinforcement learning can be pursued further. This will further help in selection of multi-facts, that are not of similar type but relevant to the task. The convolution based model, helped to reduce the space over entities and relationships over which attention had to be generated. However more sophisticated techniques using similarity based search (Wang et al., 2014a; Mu and Liu, 2017) can be pursued towards this purpose. The results from the initial experiments illustrates the effectiveness of our proposed approach, advocating further investigations in these directions.

Comparing Constraints for Taxonomic Organization

Abstract

Building a taxonomy from the ground up involves several sub-tasks: selecting terms to include, predicting semantic relations between terms, and selecting a subset of relational instances to keep, given constraints on the taxonomy graph. Methods for this final step – taxonomic organization – vary both in terms of the constraints they impose, and whether they enable discovery of synonymous terms. It is hard to isolate the impact of these factors on the quality of the resulting taxonomy because organization methods are rarely compared directly. In this paper, we present a head-to-head comparison of six taxonomic organization algorithms that vary with respect to their structural and transitivity constraints, and treatment of synonymy. We find that while transitive algorithms out-perform their non-transitive counterparts, the top-performing transitive algorithm is prohibitively slow for taxonomies with as few as 50 entities. We propose a simple modification to a non-transitive optimum branching algorithm to explicitly incorporate synonymy, resulting in a method that is substantially faster than the best transitive algorithm while giving complementary performance.

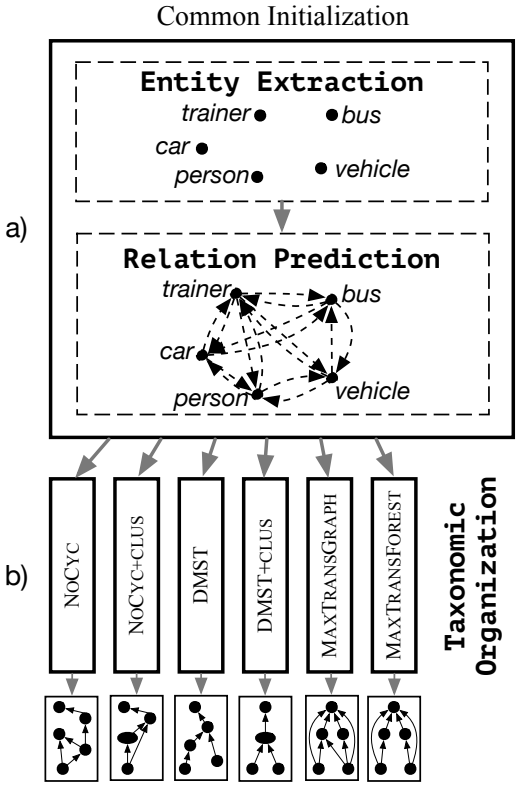

Figure 1: In this study we compare algorithms for taxonomic organization. We first (a) run entity extraction and pairwise relation prediction as a common initialization; we then (b) feed the resulting graphs as identical input to six taxonomic organization algorithms. We evaluate the impact of varied structural constraints between algorithms.

1 Introduction

Many words and phrases fit within a natural semantic hierarchy: a *mobile* is a type of *telephone*, which in turn is a *communications device* and an *object*. Taxonomies, which encode this knowledge, are important resources for natural language understanding systems.

There is ongoing interest in developing methods to build taxonomic resources automatically (Bordea et al., 2015, 2016). Although several widely-used general ontologies (e.g. WordNet (Miller, 1995)) and domain-specific ontologies (e.g. Unified Medical Language System (UMLS) (Bodenreider, 2004)) exist, these resources are handcrafted and therefore expensive to update or expand. Automatic taxonomy induction enables the construction of taxonomic resources at scale in new languages and domains. Further, there is evidence that it is useful to build dynamic or context-specific taxonomies extemporaneously for some applications (Do and Roth, 2010).

Proceedings of NAACL-HLT 2018, pages 323–333
New Orleans, Louisiana, June 1 - 6, 2018.

Taxonomy induction involves three sub-tasks: *entity extraction*, *relation prediction*, and *taxonomic organization*. In many cases these subtasks are undertaken sequentially to build a taxonomy from the ground up. While many works directly compare methods for relation prediction (e.g. Turney and Mohammad (2015), Shwartz et al. (2017) and others), none directly compare methods for the final taxonomic organization step with varying constraints. Each paper that proposes a taxonomic organization method starts with its own set of predicted relations, making it impossible to determine – even with benchmark datasets – the extent to which improvements in identifying ground-truth relations are due to (a) better relation prediction, or (b) better taxonomic organization.

In this work, we present an empirical apples-to-apples comparison of six algorithms for unsupervised taxonomic organization. The algorithms vary along three axes: whether they impose transitivity constraints on the taxonomic graph, whether they specify that the final graph structure be a directed acyclic graph (DAG) or tree/forest, and whether they identify 'clusters' of synonymous terms. In each case we begin with the same sets of terms and predicted relations (see Figure 1). This makes it possible to address several research questions. First, which combination of these factors produces a taxonomy that most closely mirrors a set of ground-truth taxonomic relations? Second, which algorithms are efficient enough in practice to run on large term sets? And third, how robust is each algorithm to noise in the predicted relations used as input?

We find that while transitive algorithms perform better than non-transitive algorithms given the same constraints on graph structure, the best-performing transitive algorithm is prohibitively slow to use on input with as few as 50 nodes. By modifying a commonly-used optimum branching algorithm to consolidate clusters of predicted synonyms into a single graph node, we show that it is possible to achieve complementary performance levels with an average runtime that is faster by orders of magnitude.

2 General Framework for Taxonomy Induction

The problem of taxonomy induction can be summarized via three core sub-tasks. While all systems that build taxonomies automatically must address each of these tasks, the sequence and manner in which they are addressed varies. In the most straightforward case, the core tasks are viewed as orthogonal and carried out sequentially. They are:

1. **Entity Extraction:** Identify a set of entities E (i.e. word types, synsets, etc) that will become nodes in the eventual taxonomy graph.

2. **Relation Prediction:** Predict the presence or absence of a directed semantic relation (hypernymy or entailment) between each pair of nodes, $(e_i, e_j) \in E \times E$. The outputs are (a) a set of potential edges $R \subseteq E \times E$, where we use the notation $r_{ij} \in R$ to signify the relational instance, or edge, (e_i, e_j), and (b) relation scores $s(r_{ij})$ for each edge derived from the classifier's predicted likelihood that the relational instance exists.

3. **Taxonomic Organization:** Select a subset of the predicted edges, $\hat{R} \subseteq R$, that produces a high sum of scores, $\sum_{r \in \hat{R}} s(r_{ij})$, subject to structural constraints. The final output is the graph $\hat{G}(E, \hat{R})$.

Structural constraints dictate what can be considered a *valid* or *invalid* combination of edges in a taxonomic graph (Do and Roth, 2010). Two structural constraints frequently imposed are that the final graph be a DAG, or that the final graph be a tree/forest.[1] Examples of algorithms that produce DAG structures are the longest-path algorithm of Kozareva and Hovy (2010), the *ContrastMedium* approach of Faralli et al. (2017), and the random cycle-breaking method used in (Panchenko et al., 2016) and Faralli et al. (2015). We experiment with a variation of the last one here, which we call NoCyc. To produce tree-structured taxonomies, most researchers (including us) use algorithms for finding the maximally-weighted rooted tree spanning a directed graph (DMST). Examples of prior work following this approach are Navigli et al. (2011) and Bansal et al. (2014).

Another dimension along which taxonomy organization approaches differ is whether they explicitly require the set of chosen relational instances $\hat{R}$ to be fully transitive. The transitivity constraint dictates that if (*beetle* IS-A *insect*) is selected as part of $\hat{R}$, and (*insect* IS-A *organism*) is

[1] WLOG, the tree and forest constraints are identical, as a dummy root node can be attached to the root of each component in a forest to produce a tree.

selected as part of $\hat{R}$, then (*beetle* IS-A *organism*) must also be selected. Two methods that impose such transitivity constraints are the MAXTRANSGRAPH and MAXTRANSFOREST methods of Berant et al. (2015), both of which we experiment with here.

A final consideration when choosing a taxonomy organization algorithm is whether the method should enable the consolidation of synonyms into a single taxonomic entity. Synonym sets, or *synsets*, are present as nodes in the WordNet graph (Miller, 1995). Potential advantages to using synonym sets, rather than individual terms, as nodes include the ability to model polysemy (*horse* means one thing when grouped with its synonym *cavalry* and another entirely when grouped with *sawhorse*), and the ability to be more precise in defining relations. A few early taxonomy induction approaches incorporated synonym clustering (e.g. Lin and Pantel (2002) and Pantel and Ravichandran (2004)). The two transitive algorithms that we analyze here, MAXTRANSGRAPH and MAXTRANSFOREST, also consolidate equivalent terms into a single node.

3 Taxonomic Organization Algorithms

The six algorithms that we compare differ along the three dimensions just described, namely, the structural constraints imposed (DAG or tree), whether transitivity is required, and whether synonyms are combined into a single taxonomy node (Figure 2). Here we provide a short description of each.

	No Transitivity	**Transitivity**
DAG	NOCYC NOCYC+CLUS	MAXTRANSGRAPH
Tree / Forest	DMST* DMST+CLUS	MAXTRANSFOREST

Figure 2: Classification of the algorithms compared in our study. The starred DMST algorithm is the only one that does not support consolidation of synonyms into clusters.

3.1 NOCYC: Organizing a DAG

The no-cycles method, which we abbreviate as NOCYC, is a simple method for constructing a **DAG** with high score from a set of predicted relational edges. It is **not transitive**.

The algorithm works as follows. From the set R of all predicted hypernym relations, we first filter out of the graph $G(E, R)$ any edges with score $s(r_{ij})$ less than a tunable threshold τ. Next, we break any cycles by finding strongly connected components (SCC) in the graph (i.e. a subset of nodes such that each node in the subset has a path to every other node in the subset), and iteratively removing the lowest-scoring edge from each SCC until all cycles are broken. This implementation is slightly different from that of Faralli et al. (2015) and Panchenko et al. (2016), where cycles were broken by removing cycle edges randomly. The search for SCCs in each iteration is linear using Tarjan's algorithm (Tarjan, 1972).

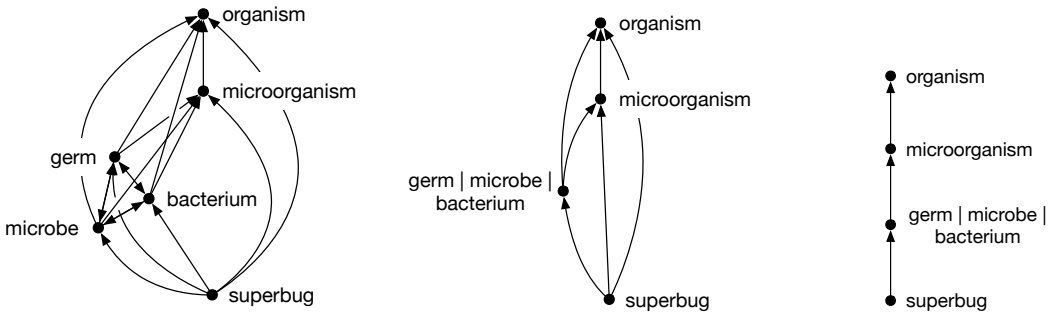
The NOCYC algorithm does not explicitly cluster synonyms, but we can find synonyms in the resulting graph implicitly as follows. If we assume all synonymous terms share the same direct hypernyms and direct hyponyms, we can find such pairs by taking the transitive reduction[2] of the resulting graph $\hat{G} = (E, \hat{R})$, and grouping all pairs of terms that have identical sets of direct hypernyms and hyponyms in the transitive reduction.

While NOCYC itself does support finding synonyms within the graph implicitly, we also experiment with an explicit synonym-clustering version, NOCYC+CLUS. We modify NOCYC by collapsing into a single node all subsets of nodes predicted to be synonym clusters, using a method described in Section 4.2.2, prior to executing the cycle breaking algorithm.

3.2 DMST: Organizing a Tree

Our second method selects hypernym edges for the taxonomy by using the Chu-Liu-Edmonds optimum branching algorithm (Chu and Liu, 1965; Edmonds, 1967) to solve the directed analog of the maximum spanning tree problem (DMST). It constrains the final graph to be a **tree** and is **not transitive**.

[2]In the *transitive closure* of a graph, each node e_i is directly connected by a single edge to every node e_j to which it has a path. The *transitive reduction* can be obtained for a graph G by removing all edges from G that do not change its transitive closure. The transitive reduction of a DAG is unique (Aho et al., 1972).



(a) Selected edges in $\hat{R}$. (b) SCC from 3a collapsed (c) Transitive reduction of 3b

Figure 3: An example transitive taxonomy graph as output by MAXTRANSGRAPH or MAXTRANSFOREST is given in 3a. Its strongly-connected component (SCC) is collapsed into a single node of synonyms to create the DAG in 3b. Finally, its transitive reduction is in 3c. Because flipping edges in the result produces a tree rooted at *organism*, the graph in 3a is called forest-reducible.

The algorithm works by adding a dummy root node e_{ROOT} to E, and an edge from e_{ROOT} to every other node e_i in the graph. We then use Chu-Liu-Edmonds to find the directed tree rooted at e_{ROOT} that spans all nodes in E and has the maximal sum of scores. Note that until now we have considered edges in taxonomy graphs to point from hyponyms to hypernyms; in this case we must switch the order, so that the spanning tree starts at the most general level of the hierarchy and reaches down to the leaves. Chu-Liu-Edmonds finds the DMST efficiently in polynomial time (Tarjan, 1977).

Because DMST requires the final graph to be a tree, there is no implicit way to find synonyms within the taxonomy graphs it generates. As with NOCYC, we test a modification called DMST+CLUS that collapses predicted synonym clusters into a single graph node prior to running the DMST algorithm (see Section 4.2.2).

3.3 MAXTRANSGRAPH: Organizing a Transitive DAG

The first **transitive** algorithm we evaluate is MAXTRANSGRAPH (Berant et al., 2012, 2015), which constrains the graph structure to be a **DAG**. MAXTRANSGRAPH was originally designed for building taxonomies of entailment relations (which can be subclassified as either synonyms or hypernyms) and is solved using integer linear programming (ILP). Rather than using classifier scores directly as input, MAXTRANSGRAPH first computes a weight between each term pair (e_i, e_j) that is equal to the classifier score minus a tunable parameter: $w_{ij} = s(r_{ij}) - \lambda$. The purpose of modifying scores this way is efficiency; MAXTRANSGRAPH solves its optimization on each connected component of the graph independently, where components are constructed by considering only positively-weighted edges in the graph. Increasing λ increases sparsity and decreases runtime.

The objective of the ILP is to maximize the weights of selected relations, while requiring that the graph respects transitivity. Berant et al. (2012) proved this problem is NP-hard and provided an ILP formulation for it as follows. Let x_{ij} be a binary variable that indicates whether edge (e_i, e_j) is in the subset of selected edges, $\hat{R}$.

$$\begin{aligned} \max_{x} \quad & \sum_{i \neq j} w_{ij} x_{ij} \\ \text{s.t.} \quad & \forall e_i, e_j, e_k \in E, \; x_{ij} + x_{jk} - x_{ik} \leq 1 \\ & \forall e_i, e_j \in E, \; x_{ij} \in \{0, 1\} \end{aligned} \tag{1}$$

The objective maximizes the sum of edge weights where the edge is 'turned on' (i.e. $x_{ij} = 1$). The first constraint enforces transitivity, i.e. for every triple of nodes (e_i, e_j, e_k), if edge $(e_i, e_j) \in \hat{R}$ and edge $(e_j, e_k) \in \hat{R}$, then edge $(e_i, e_k) \in \hat{R}$. The second constraint specifies that all x_{ij} are binary. The number of variables is $O(|E|^2)$ and number of constraints is $O(|E|^3)$.

MAXTRANSGRAPH assumes that cycles of entailment relations in the resulting graph $G(E, \hat{R})$ comprise cycles of synonyms, and that the remaining edges which are not part of a cycle are hypernym edges. Because the resulting graph must be transitive, all cycles of three or more nodes are

cliques, in which each node is directly connected to every other. Once every SCC is collapsed into a single synonym cluster node, the transitive reduction of the resulting graph is a DAG (Figure 3b).

3.4 MAXTRANSFOREST: Organizing a Transitive Forest

The final algorithm we evaluate is MAXTRANSFOREST (Berant et al., 2012, 2015), which like MAXTRANSGRAPH is **transitive**, but produces a **forest/tree** structure.

MAXTRANSFOREST is nearly identical to MAXTRANSGRAPH, with the addition of one constraint that imposes its forest structure. More specifically, the graphs produced by MAXTRANSFOREST are *forest reducible*. A forest reducible graph is one where, after collapsing every SCC into a single node, the transitive reduction of the result is a forest (see Figure 3).

In practice, the forest reducibility constraint is enforced by applying one additional constraint to the ILP in Equation 1:

$$\forall e_i, e_j, e_k \in E \;\; x_{ij} + x_{ik} - x_{jk} - x_{kj} \leq 1 \quad (2)$$

This constraint says that each node e_i can have only a single parent. If relations r_{ij} and r_{ik} are in $\hat{R}$, then either e_j is the parent of e_k or vice versa; e_i may not have two parents that are not related via a hypernym relationship. Like MAXTRANSGRAPH, the number of variables is $O(|E|^2)$ and number of constraints is $O(|E|^3)$. Also like MAXTRANSGRAPH, cycles in the resulting graph are assumed to constitute clusters of synonymous terms.

4 Experimental Setup

In order to directly compare the organization algorithms described, we organize our experiments as follows. We first run entity extraction (Section 4.1) and relation prediction (Section 4.2) as a common initialization for all algorithms. Then, we take the edge scores output by the relation prediction step and feed them to each taxonomic organization algorithm (Section 4.3). Finally, we compare the output from each algorithm. Here we describe the initialization steps in more detail.

4.1 Entity Extraction

We extract sets of entities from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013; Pavlick et al., 2015). Our goal is to construct *local taxonomies*, where each entity set E consists of terms sharing a common target paraphrase. For example, a local taxonomy centered around the target *coach* might contain entities *bus*, *vehicle*, *trainer*, *person*, *car*, and *railcar*. The local taxonomy for a target word does not contain the target word itself.

We build a dataset for constructing local taxonomies centered around 50 target nouns drawn from the 2010 SemEval word sense induction dataset (Manandhar et al., 2010). For each target noun, we extract as taxonomy terms the set of PPDB paraphrases having a PPDB2.0SCORE of at least 2.0 with the target.[3] The number of entities in each local taxonomy ranges from 13 to 126, with a median of 40 entities per set. We hold out 5 local taxonomies to tune parameters for NOCYC, MAXTRANSGRAPH, and MAXTRANSFOREST, and use the remaining 45 as our test set.

Because they consist of related terms centered around a common paraphrase, there are several semantic relations present among these entity sets in addition to hypernymy and synonymy. We analyze the overlap between all pairs of terms appearing in our local taxonomies and in WordNet, and find that the distribution of relation types among the overlapping pairs is 6.0% hypernym/hyponym, 1.3% synonym, 0.1% meronym/holonym, 3.1% coordinate terms (sharing a common direct hypernym), and 89.5% none of these.

4.2 Relation Prediction

Having extracted a set of entities, the next step in our initialization process is to make pairwise relation predictions for each pair of terms (e_i, e_j) that exist within an entity set E. The different organization algorithms we compare take predicted synonym and/or hypernym edge scores as input. Here we describe the methods we use to generate these scores.

4.2.1 Hypernym Prediction

For hypernym prediction, we adopt the state-of-the-art HypeNET method of Shwartz et al. (2016). HypeNET integrates distributional (Lin and Pantel, 2002; Roller et al., 2014; Levy et al., 2015; Benotto, 2015) and path-based (Hearst, 1992; Snow et al., 2004; Nakashole et al., 2012) ap-

[3] The PPDB2.0SCORE is a supervised metric designed to correlate with human judgements of paraphrase quality (Pavlick et al., 2015).

proaches to hypernym prediction. It uses a recurrent neural network to represent the set of observed dependency paths connecting an input word pair, and concatenates this representation with distributional word embeddings to produce a set of features for predicting hypernymy.

We create a dataset of noun pairs for training and evaluating the HypeNET model. It combines noun pairs from four benchmark relation prediction datasets (BLESS (Baroni and Lenci, 2011), ROOT09 (Santus et al., 2016), EVALution (Santus et al., 2015), and K&H+N (Necsulescu et al., 2015)) with a set of related and unrelated noun pairs extracted from PPDB. Since each of these is a multi-class dataset, we binarize the data by labeling noun pairs with a hypernym relation as positive instances, and all others as negative. The combined benchmark+PPDB training set contains 76,152 noun pairs with a 1:4 hypernym:non-hypernym ratio, and the evaluation set contains 29,051 pairs. We ensure lexical separation from our taxonomy induction dataset; no terms in the classifier training set appear in any of the local taxonomies. We train HypeNET using our 76K-pair test set, and provide the results of evaluation on the 29K-pair test set in Table 1. The trained model achieves an overall average F1-score of 0.93 on the entire benchmark+PPDB test set. The full details of our dataset creation and classifier training are provided in the supplementary material.

Finally, we use the trained model to predict hypernym likelihoods for each potential edge r_{ij} in one of our local taxonomies, corresponding to an ordered pair of terms (e_i, e_j) that appear together in one of the 50 entity sets. We assign a hypernym score $s_h(r_{ij})$ to each potential directed edge that equals the HypeNET predicted likelihood for that pair of terms.

4.2.2 Synonym Prediction and Cluster Formation

We predict synonymy between noun pairs using distributional similarity, operationalized as the cosine similarity of PARAGRAM (Wieting et al., 2015) word embeddings.[4] We use PARAGRAM vectors because they perform well in semantic similarity tasks, and because they were originally extracted from PPDB and thus have 100% coverage of our entity sets. The synonym score $s_s(r_{ij})$ for a potential edge r_{ij} between entities (e_i, e_j) is simply the cosine similarity of their PARAGRAM embeddings.

[4]We also tried using HypeNET to predict synonym relations, but results were significantly worse.

Dataset	# Test Inst.	% Hyp.	Avg F1 (hyp.)	% Syn.	Avg F1 (syn.)
PPDB	3,000	20.1	.777	24.7	.707
BLESS	6,637	5.3	.978	0	–
EVALution	1,846	24.5	.763	15.1	.797
K&H+N	14,377	7.3	.988	0	–
ROOT09	3,191	26.3	.808	0	–

Table 1: Evaluation of the HypeNET hypernym classifier and the PARAGRAM synonym classifier on the PPDB test set and four benchmark test sets. We report micro-averaged F1-scores for positive and negative instances in the test sets.

We also tune a synonymy threshold for the purpose of consolidating clusters of synonymous terms into a single node for DMST+CLUS and NOCYC+CLUS (see Section 4.3). We tune threshold $\tau = 0.76$ over the benchmark+PPDB training set (binarized for synonymy) such that we predict a term pair (e_i, e_j) to be synonymous if $s_s(r_{ij}) \geq \tau$. When evaluated over the test sets, this method achieves weighted average F1-scores of 0.707 and 0.797 for predicting synonyms in the PPDB and EVALution test sets respectively (Table 1).

Target word	Clustered Entities
field	[(topic, issue, subject matter), (respect, regard), (battlefield, battleground), (outside, exterior), (territory, land), (domain, purview, sphere, ambit, realm, area, fields)]
address	[(directorate, direction), (administration, management), (answer, response), (discourse, speech), (treat, handling), (domicile, residence)]
innovation	[(novelty, imagination, creativity, newness), (modernization, modernisation), (regeneration, renewal, renovation, rejuvenation)]

Table 2: Examples of clustered entities produced using the PARAGRAM vector cosine similarity threshold of 0.76.

4.3 Input to organization algorithms

Finally, we use the calculated hypernym and synonym scores $s_h(r_{ij})$ and $s_s(r_{ij})$ to initialize each organization algorithm as follows.

NOCYC and DMST: We use the hypernym scores as input, setting $s(r_{ij}) = s_h(r_{ij})$ for all

	Algorithm	Constraint	Hypernyms			Synonyms			Combined		
			P	R	F	P	R	F	P	R	F
Baseline Methods											
	RANDOM	(none)	.036	.235	.061	.013	.034	.018	.033	.173	.054

Table 3: Precision, recall, and F1 of hypernym, synonym, and all (relation-specific) edges for each method. Metrics are weighted averages over the 45 local taxonomies in the test set, where each taxonomy's result is weighted by its number of nodes. Starred methods indicate an oracle, where the weight of edges appearing in WordNet is set to 1 at input.

potential edges.

NOCYC+CLUS and DMST+CLUS: Initialization for these algorithms requires two steps. First, we collapse clusters of likely synonyms into a single entity as follows. For each local taxonomy, we create a graph with the extracted terms as nodes, and add an edge between every pair of terms having $s_s(r_{ij}) \geq \tau$ (the threshold tuned on our training set). We take the resulting connected components as the final entity set E. See examples of synonyms clustered by this method in Table 2.

Next, we calculate scores $s(r_{ij})$ for each pair of entities. When e_i and e_j are single-term entities (i.e. not synonym clusters), we simply set $s(r_{ij}) = s_h(r_{ij})$. To obtain an edge score when one or both nodes is a cluster, we simply calculate the average hypernym score over every pair of terms (t_m, t_n) such that $t_m \in e_i$ and $t_n \in e_j$:

$$s(r_{ij}) = \frac{\sum_{t_m \in e_i; t_n \in e_j} s_h(r_{mn})}{|e_i| + |e_j|}$$

MAXTRANSGRAPH and MAXTRANSFOREST: Since these algorithms are designed to use entailment relation predictions as input, we set the score of each edge to be the maximum of the synonym and hypernym scores: $s(r_{ij}) = \max(s_h(r_{ij}), s_s(r_{ij}))$. Intuitively, this reflects the idea that entailment can be sub-classified as synonymy *or* hypernymy.

5 Experiments

We conduct experiments aimed at addressing three primary research questions: (1) How does each taxonomic organization algorithm perform? In particular, how do DAG algorithms compare to tree-constrained ones, and how do transitive algorithms compare to their non-transitive counterparts? (2) Are any algorithms, particularly the ILP methods, too slow to use on large sets of terms? (3) Given that hypernym relation prediction is far from perfect, how robust is each algorithm to noise in the predicted relations?

5.1 Head-to-head Algorithm Comparison

In our first experiment, we predict PPDB local taxonomies for the 45 target nouns in our test set using each of the six algorithms after the initialization described in Section 4. In keeping with current work on this topic (Bordea et al., 2015, 2016), we evaluate the taxonomy organization algorithms' performance by calculating precision, recall, and F1-score of WordNet 3.0 hypernym and synonym edges for the 93% of PPDB taxonomy terms that are in WordNet. When evaluating hypernym edges we consider both di-

rect and transitive hypernym edges. We report hypernym-specific scores – where the set of ground-truth edges considers just WordNet hypernyms – synonym-specific scores, and combined scores – where all WordNet hypernym and synonym edges are taken as ground truth, and a predicted edge must have the correct start node, end node, and relation type to be correct. Results are reported in Table 3. We compare the results of the six algorithms to two types of baselines. As a lower bound, we implement a random baseline where edges are selected randomly with likelihood tuned on the benchmark+PPDB training set. As an upper bound, we run 'oracle' versions of MAXTRANSFOREST and DMST where we set the score of any edge appearing in WordNet to 1.

The transitive, tree-constrained MAXTRANSFOREST algorithm achieves the best average combined F-score (0.21) over all the local taxonomies, followed closely by the non-transitive, tree-constrained clustering method DMST+CLUS (0.20). These two methods, which are the only two tree-constrained methods that incorporate synonymy, outperform all DAG-constrained methods on this dataset. While they perform similarly in terms of combined F-score, their results are complementary; MAXTRANSFOREST obtains a relatively high score on hypernym edges and lower score for synonym edges, while for DMST+CLUS the results are reversed.

In general, these results suggest that consolidating synonyms into a single node helps tree-constrained methods by improving recall of both hypernym and synonym edges (DMST vs DMST+CLUS), but the same is not true for DAG-constrained methods. To understand why, we examine the output taxonomies. The average depth of the DAG taxonomies is greater than that of the tree taxonomies. When incorrect hyponym attachments are made in a deep taxonomy, the errors in transitive hypernym links can be magnified, which is evident in the low hypernym precision of NOCYC and NOCYC+CLUS. Synonym clustering prior to NOCYC+CLUS can magnify errors further, as synonyms are dragged into the incorrect hypernym relationships (see the NOCYC+CLUS example in Figure 4, where *telephone* is dragged along with *phone* into incorrect hypernym relations with *battery* and *pile*). For the shallower tree-constrained graph outputs, finding correct synonym relations helps the overall accuracy without inducing as many incorrect hypernym relations.

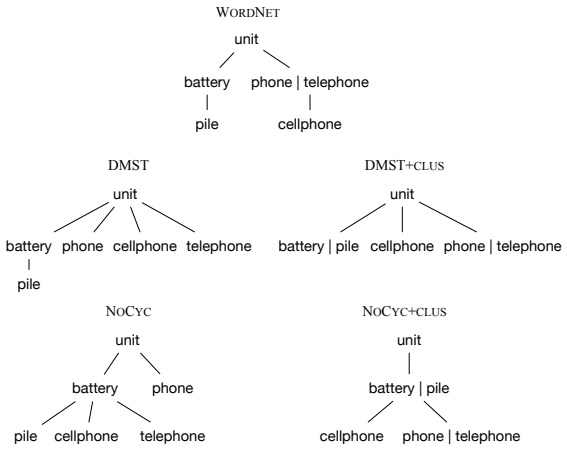

Figure 4: Examples from a portion of the local taxonomy for *cell*, with the WordNet gold standard compared to four of the algorithms' output. The bar notation denotes synonym clusters.

Finally, we note that transitive algorithms consistently out-perform their non-transitive counterparts. For the DAG-constrained algorithms, the transitive version, MAXTRANSGRAPH, improves precision of hypernym and synonym edges over its non-transitive counterparts NOCYC and NOCYC+CLUS. For the tree-constrained algorithms, the transitive MAXTRANSFOREST substantially improves recall of hypernym edges over its non-transitive counterparts DMST and DMST+CLUS.

5.2 Assessing Runtime

Next, we address the question of whether all algorithms are fast enough to be useful in practice. We record the runtime for each algorithm on each local taxonomy, and note the number of runs that timed out at 5 minutes. Results are in Table 4.

Method	Avg Runtime	% Timeout
MAXTRANSGRAPH	0.31	0.0
MAXTRANSFOREST	136.83	24.4
NOCYC	2.04	0.0
DMST	0.04	0.0
NOCYC+CLUS	6.41	0.0
DMST+CLUS	0.02	0.0

Table 4: Average runtime (seconds) over all 45 targets, and percent of targets for which runtime exceeded 5 minutes, by algorithm.

MAXTRANSFOREST, while most accurate on hypernyms and overall, is too slow to be use-

ful on large inputs. The average runtime over all local taxonomies was over two minutes, and the runtime on local taxonomies with as few as 50 nodes reached the five minute limit. Meanwhile, DMST+CLUS, which performed best for synonyms and competitively for hypernyms, has a runtime that is over 6,000 times faster. In practice, this simpler algorithm may be preferable to use.

One surprising result is the speed of MAXTRANSGRAPH, which theoretically has a number of variables and constraints on the same order as that of MAXTRANSFOREST. In practice, we found that the average number of *active* constraints for MAXTRANSGRAPH – those violated at any point in the course of solving the ILP – was less than one percent of the average number of active constraints in MAXTRANSFOREST.

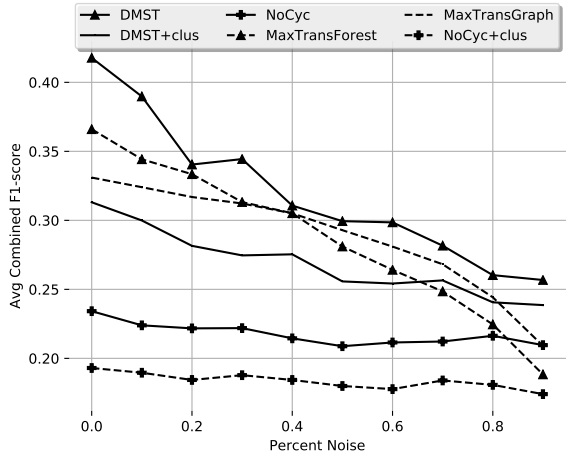

Figure 5: Weighted average combined F1-scores over the test set, where each algorithm is run in an oracle setting with noise percentage (p) settings in the range from 0% to 90%.

5.3 Assessing robustness to noise

Finally, given that hypernym prediction is still an open problem, we are interested in finding out how robust each algorithm is to noise in the input hypernym predictions. To test this, we re-run each taxonomy organization algorithm on the local taxonomies in an oracle setting, where the score of all potential edges that are present as direct or transitive edges in WordNet is set to 1. In each iteration, we set a noise probability p, and randomly perturb edge scores (according to a Gaussian distribution with 0 mean and 0.15 standard deviation) with probability p. We run this experiment with $p \in [0, 90]$. The combined F1-score is plotted against the noise level in Figure 5. We find that the performance of transitive algorithms MAXTRANSGRAPH and MAXTRANSFOREST degrades more quickly than the performance of other algorithms at higher noise levels. DMST performs best in the oracle setting at all levels of noise. The results are shown in Figure 5.

The performance of the top two performing algorithms, MAXTRANSFOREST and DMST+CLUS, in terms of combined F1-score degrades most with the introduction of noise. But even with up to 40% noise, these algorithms still out-perform all others.

6 Conclusion

In this paper we have conducted a direct comparison of six taxonomy organization algorithms that vary in terms of their transitivity and graph structure constraints, and their treatment of synonyms. Evaluating their performance over a dataset of local taxonomies drawn from PPDB, we find that transitive algorithms generally out-perform their non-transitive counterparts. While the best-performing algorithm – an ILP approach that constrains graphs to be transitive and tree-structured – is too slow to use on large inputs, a much simpler maximum spanning tree algorithm that consolidates synonyms into a single taxonomic node has complementary performance, with a small fraction of the runtime. Our results suggest that incorporating synonym detection into tree-constrained taxonomy organization algorithms is a promising area for future research.

Improving Lexical Choice in Neural Machine Translation

Abstract

We explore two solutions to the problem of mistranslating rare words in neural machine translation. First, we argue that the standard output layer, which computes the inner product of a vector representing the context with all possible output word embeddings, rewards frequent words disproportionately, and we propose to fix the norms of both vectors to a constant value. Second, we integrate a simple lexical module which is jointly trained with the rest of the model. We evaluate our approaches on eight language pairs with data sizes ranging from 100k to 8M words, and achieve improvements of up to +4.3 BLEU, surpassing phrase-based translation in nearly all settings.[1]

1 Introduction

Neural network approaches to machine translation (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015a; Gehring et al., 2017) are appealing for their single-model, end-to-end training process, and have demonstrated competitive performance compared to earlier statistical approaches (Koehn et al., 2007; Junczys-Dowmunt et al., 2016). However, there are still many open problems in NMT (Koehn and Knowles, 2017). One particular issue is mistranslation of rare words. For example, consider the Uzbek sentence:

Source: Ammo muammolar hali ko'p, deydi amerikalik olim Entoni Fauchi.

Reference: But still there are many problems, says American scientist Anthony Fauci.

Baseline NMT: But there is still a lot of problems, says James Chan.

At the position where the output should be *Fauci*, the NMT model's top three candidates are *Chan*, *Fauci*, and *Jenner*. All three surnames occur in the training data with reference to immunologists: Fauci is the director of the National Institute of Allergy and Infectious Diseases, Margaret (not James) Chan is the former director of the World Health Organization, and Edward Jenner invented smallpox vaccine. But *Chan* is more frequent in the training data than *Fauci*, and *James* is more frequent than either *Anthony* or *Margaret*.

Because NMT learns word representations in continuous space, it tends to translate words that "seem natural in the context, but do not reflect the content of the source sentence" (Arthur et al., 2016). This coincides with other observations that NMT's translations are often fluent but lack accuracy (Wang et al., 2017b; Wu et al., 2016).

Why does this happen? At each time step, the model's distribution over output words e is

$$p(e) \propto \exp\left(W_e \cdot \tilde{h} + b_e\right)$$

where W_e and b_e are a vector and a scalar depending only on e, and $\tilde{h}$ is a vector depending only on the source sentence and previous output words. We propose two modifications to this layer. First, we argue that the term $W_e \cdot \tilde{h}$, which measures how well e fits into the context $\tilde{h}$, favors common words disproportionately, and show that it helps to fix the norm of both vectors to a constant. Second, we add a new term representing a more direct connection from the source sentence, which allows the model to better memorize translations of rare words.

Below, we describe our models in more detail. Then we evaluate our approaches on eight language pairs, with training data sizes ranging from 100k words to 8M words, and show improvements of up to +4.3 BLEU, surpassing phrase-based translation in nearly all settings. Finally, we provide some analysis to better understand why our modifications work well.

	ha-en	tu-en	hu-en
untied embeddings	17.2	11.5	26.5
tied embeddings	17.4	13.8	26.5
don't normalize $\tilde{h}_t$	18.6	14.2	27.1
normalize $\tilde{h}_t$	20.5	16.1	28.8

Table 1: Preliminary experiments show that tying target embeddings with output layer weights performs as well as or better than the baseline, and that normalizing $\tilde{h}$ is better than not normalizing $\tilde{h}$. All numbers are BLEU scores on development sets, scored against tokenized references.

2 Neural Machine Translation

Given a source sequence $f = f_1 f_2 \cdots f_m$, the goal of NMT is to find the target sequence $e = e_1 e_2 \cdots e_n$ that maximizes the objective function:

$$\log p(e \mid f) = \sum_{t=1}^{n} \log p(e_t \mid e_{<t}, f).$$

We use the *global attentional* model with *general scoring function* and *input feeding* by Luong et al. (2015a). We provide only a very brief overview of this model here. It has an encoder, an attention, and a decoder. The encoder converts the words of the source sentence into *word embeddings*, then into a sequence of *hidden states*. The decoder generates the target sentence word by word with the help of the attention. At each time step t, the attention calculates a set of *attention weights* $a_t(s)$. These attention weights are used to form a weighted average of the encoder hidden states to form a *context vector* c_t. From c_t and the hidden state of the decoder are computed the *attentional hidden state* $\tilde{h}_t$. Finally, the predicted probability distribution of the t'th target word is:

$$p(e_t \mid e_{<t}, f) = \text{softmax}(W^o \tilde{h}_t + b^o). \quad (1)$$

The rows of the output layer's weight matrix W^o can be thought of as embeddings of the output vocabulary, and sometimes are in fact tied to the embeddings in the input layer, reducing model size while often achieving similar performance (Inan et al., 2017; Press and Wolf, 2017). We verified this claim on some language pairs and found out that this approach usually performs better than without tying, as seen in Table 1. For this reason, we always tie the target embeddings and W^o in all of our models.

3 Normalization

The output word distribution (1) can be written as:

$$p(e) \propto \exp\left(\|W_e\| \, \|\tilde{h}\| \cos\theta_{W_e,\tilde{h}} + b_e\right),$$

where W_e is the embedding of e, b_e is the e'th component of the bias b^o, and $\theta_{W_e,\tilde{h}}$ is the angle between W_e and $\tilde{h}$. We can intuitively interpret the terms as follows. The term $\|\tilde{h}\|$ has the effect of sharpening or flattening the distribution, reflecting whether the model is more or less certain in a particular context. The cosine similarity $\cos\theta_{W_e,\tilde{h}}$ measures how well e fits into the context. The bias b_e controls how much the word e is generated; it is analogous to the language model in a log-linear translation model (Och and Ney, 2002).

Finally, $\|W_e\|$ also controls how much e is generated. Figure 1 shows that it generally correlates with frequency. But because it is multiplied by $\cos\theta_{W_e,\tilde{h}}$, it has a stronger effect on words whose embeddings have direction similar to $\tilde{h}$, and less effect or even a negative effect on words in other directions. We hypothesize that the result is that the model learns $\|W_e\|$ that are disproportionately large.

For example, returning to the example from Section 1, these terms are:

e	$\|W_e\|$	$\|\tilde{h}\|$	$\cos\theta_{W_e,\tilde{h}}$	b_e	logit
Chan	5.25	19.5	0.144	−1.53	13.2
Fauci	4.69	19.5	0.154	−1.35	12.8
Jenner	5.23	19.5	0.120	−1.59	10.7

Observe that $\cos\theta_{W_e,\tilde{h}}$ and even b_e both favor the correct output word *Fauci*, whereas $\|W_e\|$ favors the more frequent, but incorrect, word *Chan*. The most frequently-mentioned immunologist trumps other immunologists.

To solve this issue, we propose to fix the norm of all target word embeddings to some value r. Followingthe weight normalization approach of Salimans and Kingma (2016), we reparameterize W_e as $r\frac{v_e}{\|v_e\|}$, but keep r fixed.

A similar argument could be made for $\|\tilde{h}_t\|$: because a large $\|\tilde{h}_t\|$ sharpens the distribution, causing frequent words to more strongly dominate rare words, we might want to limit it as well. We compared both approaches on a development set and found that replacing $\tilde{h}_t$ in equation (1) with $r\frac{\tilde{h}_t}{\|\tilde{h}_t\|}$ indeed performs better, as shown in Table 1.

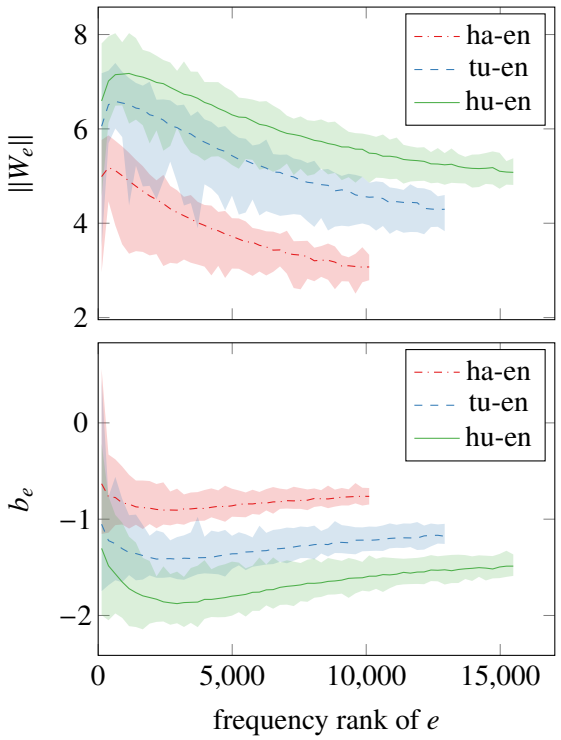

Figure 1: The word embedding norm $\|W_e\|$ generally correlates with the frequency of e, except for the most frequent words. The bias b_e has the opposite behavior. The plots show the median and range of bins of size 256.

4 Lexical Translation

The attentional hidden state $\tilde{h}$ contains information not only about the source word(s) corresponding to the current target word, but also the contexts of those source words and the preceding context of the target word. This could make the model prone to generate a target word that fits the context but doesn't necessarily correspond to the source word(s). Count-based statistical models, by contrast, don't have this problem, because they simply don't model any of this context. Arthur et al. (2016) try to alleviate this issue by integrating a count-based lexicon into an NMT system. However, this lexicon must be trained separately using GIZA++ (Och and Ney, 2003), and its parameters form a large, sparse array, which can be difficult to store in GPU memory.

We propose instead to use a simple feedforward neural network (FFNN) that is trained jointly with the rest of the NMT model to generate a target word based directly on the source word(s). Let f_s ($s = 1, \ldots, m$) be the embeddings of the source words. We use the attention weights to form a weighted average of the embeddings (not the hidden states, as in the main model) to give an average source-word embedding at each decoding time step t:

$$f_t^\ell = \tanh \sum_s a_t(s) f_s.$$

Then we use a one-hidden-layer FFNN with skip connections (He et al., 2016):

$$h_t^\ell = \tanh(W f_t^\ell) + f_t^\ell$$

and combine its output with the decoder output to get the predictive distribution over output words at time step t:

$$p(y_t \mid y_{<t}, x) = \text{softmax}(W^o \tilde{h}_t + b^o + W^\ell h_t^\ell + b^\ell).$$

For the same reasons that were given in Section 3 for normalizing $\tilde{h}_t$ and the rows of W_t^o, we normalize h_t^ℓ and the rows of W^ℓ as well. Note, however, that we do not tie the rows of W^ℓ with the word embeddings; in preliminary experiments, we found this to yield worse results.

5 Experiments

We conducted experiments testing our normalization approach and our lexical model on eight language pairs using training data sets of various sizes. This section describes the systems tested and our results.

5.1 Data

We evaluated our approaches on various language pairs and datasets:

- Tamil (ta), Urdu (ur), Hausa (ha), Turkish (tu), and Hungarian (hu) to English (en), using data from the LORELEI program.
- English to Vietnamese (vi), using data from the IWSLT 2015 shared task.[2]
- To compare our approach with that of Arthur et al. (2016), we also ran on their English to Japanese (ja) KFTT and BTEC datasets.[3]

We tokenized the LORELEI datasets using the default Moses tokenizer, except for Urdu-English, where the Urdu side happened to be tokenized using Morfessor FlatCat ($w = 0.5$). We used the preprocessed English-Vietnamese and English-Japanese datasets as distributed by Luong et al., and Arthur et al., respectively. Statistics about our data sets are shown in Table 2.

5.2 Systems

We compared our approaches against two baseline NMT systems:

untied, which does not tie the rows of W_o to the target word embeddings, and

tied, which does.

In addition, we compared against two other baseline systems:

Moses: The Moses phrase-based translation system (Koehn et al., 2007), trained on the same data as the NMT systems, with the same maximum sentence length of 50. No additional data was used for training the language model. Unlike the NMT systems, Moses used the full vocabulary from the training data; unknown words were copied to the target sentence.

Arthur: Our reimplementation of the discrete lexicon approach of Arthur et al. (2016). We only tried their `auto` lexicon, using GIZA++ (Och and Ney, 2003), integrated using their `bias` approach. Note that we also tied embedding as we found it also helped in this case.

Against these baselines, we compared our new systems:

fixnorm: The normalization approach described in Section 3.

fixnorm+lex: The same, with the addition of the lexical translation module from Section 4.

5.3 Details

Model For all NMT systems, we fed the source sentences to the encoder in reverse order during both training and testing, following Luong et al. (2015a). Information about the number and size of hidden layers is shown in Table 2. The word embedding size is always equal to the hidden layer size.

Following common practice, we only trained on sentences of 50 tokens or less. We limited the vocabulary to word types that appear no less than 5 times in the training data and map the rest to `UNK`. For the English-Japanese and English-Vietnamese datasets, we used the vocabulary sizes reported in their respective papers (Arthur et al., 2016; Luong and Manning, 2015).

For **fixnorm**, we tried $r \in \{3, 5, 7\}$ and selected the best value based on the development set performance, which was $r = 5$ except for English-Japanese (BTEC), where $r = 7$. For **fixnorm+lex**, because $W_s\tilde{h}_t + W^\ell h_t^\ell$ takes on values in $[-2r^2, 2r^2]$, we reduced our candidate r values by roughly a factor of $\sqrt{2}$, to $r \in \{2, 3.5, 5\}$. A radius $r = 3.5$ seemed to work the best for all language pairs.

Training We trained all NMT systems with Adadelta (Zeiler, 2012). All parameters were initialized uniformly from $[-0.01, 0.01]$. When a gradient's norm exceeded 5, we normalized it to 5. We also used dropout on non-recurrent connections only (Zaremba et al., 2014), with probability 0.2. We used minibatches of size 32. We trained for 50 epochs, validating on the development set after every epoch, except on English-Japanese, where we validated twice per epoch. We kept the best checkpoint according to its BLEU on the development set.

Inference We used beam search with a beam size of 12 for translating both the development and test sets. Since NMT often favors short translations (Cho et al., 2014), we followed Wu et al. (2016) in using a modified score $s(e \mid f)$ in place of log-probability:

$$s(e \mid f) = \frac{\log p(e \mid f)}{lp(e)}$$

$$lp(e) = \frac{(5 + |e|)^\alpha}{(5 + 1)^\alpha}$$

We set $\alpha = 0.8$ for all of our experiments.

Finally, we applied a postprocessing step to replace each `UNK` in the target translation with the

source word with the highest attention score (Luong et al., 2015b).

Evaluation For translation into English, we report case-sensitive NIST BLEU against detokenized references. For English-Japanese and English-Vietnamese, we report tokenized, case-sensitive BLEU following Arthur et al. (2016) and Luong and Manning (2015). We measure statistical significance using bootstrap resampling (Koehn, 2004).

6 Results and Analysis

6.1 Overall

Our results are shown in Table 3. First, we observe, as has often been noted in the literature, that NMT tends to perform poorer than PBMT on low resource settings (note that the rows of this table are sorted by training data size).

Our **fixnorm** system alone shows large improvements (shown in parentheses) relative to **tied**. Integrating the lexical module (**fixnorm+lex**) adds in further gains. Our **fixnorm+lex** models surpass Moses on all tasks except Urdu- and Hausa-English, where it is 1.6 and 0.7 BLEU short respectively.

The method of Arthur et al. (2016) does improve over the baseline NMT on most language pairs, but not by as much and as consistently as our models, and often not as well as Moses. Unfortunately, we could not replicate their approach for English-Japanese (KFTT) because the lexical table was too large to fit into the computational graph.

For English-Japanese (BTEC), we note that, due to the small size of the test set, all systems except for Moses are in fact not significantly different from **tied** ($p > 0.01$). On all other tasks, however, our systems significantly improve over **tied** ($p < 0.01$).

6.2 Impact on translation

In Table 4, we show examples of typical translation mistakes made by the baseline NMT systems. In the Uzbek example (top), **untied** and **tied** have confused *34* with *UNK* and *700*, while in the Turkish one (middle), they incorrectly output other proper names, *Afghan* and *Myanmar*, for the proper name *Kenya*. Our systems, on the other hand, translate these words correctly.

The bottom example is the one introduced in Section 1. We can see that our **fixnorm** approach does not completely solve the mistranslation issue, since it translates *Entoni Fauchi* to *UNK UNK* (which is arguably better than *James Chan*). On the other hand, **fixnorm+lex** gets this right. To better understand how the lexical module helps in this case, we look at the top five translations for the word *Fauci* in **fixnorm+lex**:

e	$\cos\theta_{W_e,\tilde{h}}$	$\cos\theta_{W_e^l,h_l}$	$b_e + b_e^l$	logit
Fauci	0.522	0.762	−8.71	7.0
UNK	0.566	−0.009	−1.25	5.6
Anthony	0.263	0.644	−8.70	2.4
Ahmedova	0.555	0.173	−8.66	0.3
Chan	0.546	0.150	−8.73	−0.2

As we can see, while $\cos\theta_{W_e,\tilde{h}}$ might still be confused between similar words, $\cos\theta_{W_e^l,h_l}$ significantly favors *Fauci*.

6.3 Alignment and unknown words

Both our baseline NMT and **fixnorm** models suffer from the problem of shifted alignments noted by Koehn and Knowles (2017). As seen in Figure 2a and 2b, the alignments for those two systems seem to shift by one word to the left (on the source side). For example, *nói* should be aligned to *said* instead of *Telekom*, and so on. Although this is not a problem *per se*, since the decoder can decide to attend to any position in the encoder states as long as the state at that position holds the information the decoder needs, this becomes a real issue when we need to make use of the alignment information, as in unknown word replacement (Luong et al., 2015b). As we can see in Figure 2, because of the alignment shift, both **tied** and **fixnorm** incorrectly replace the two unknown words (in bold) with *But Deutsche* instead of *Deutsche Telekom*. In contrast, under **fixnorm+lex** and the model of Arthur et al. (2016), the alignment is corrected, causing the UNKs to be replaced with the correct source words.

6.4 Impact of r

The single most important hyper-parameter in our models is r. Informally speaking, r controls how much surface area we have on the hypersphere to allocate to word embeddings. To better understand its impact, we look at the training perplexity and dev BLEUs during training with different values of r. Table 6 shows the train perplexity and best tokenized dev BLEU on Turkish-English for **fixnorm** and **fixnorm+lex** with different values of r. As we can see, a smaller r results in

	untied	tied	fixnorm	fixnorm+lex	Moses	Arthur

en-ja (KFTT)	24.1	24.5	26.1 (+1.6)	26.2 (+1.7)	21.7 (−2.8)	—

Table 3: Test BLEU of all models. Differences shown in parentheses are relative to **tied**, with a dagger (†) indicating an *insignificant* difference in BLEU ($p > 0.01$). While the method of Arthur et al. (2016) does not always help, **fixnorm** and **fixnorm+lex** consistently achieve significant improvements over **tied** ($p < 0.01$) except for English-Japanese (BTEC). Our models also outperform the method of Arthur et al. on all tasks and outperform Moses on all tasks but Urdu-English and Hausa-English.

worse training perplexity, indicating underfitting, whereas if r is too large, the model achieves better training perplexity but decrased dev BLEU, indicating overfitting.

6.5 Lexicon

One byproduct of **lex** is the lexicon, which we can extract and examine simply by feeding each source word embedding to the FFNN module and calculating $p^\ell(y) = \text{softmax}(W^\ell h^\ell + b_\ell)$. In Table 5, we show the top translations for some entries in the lexicons extracted from **fixnorm+lex** for Hungarian, Turkish, and Hausa-English. As expected, the lexical distribution is sparse, with a few top translations accounting for the most probability mass.

6.6 Byte Pair Encoding

Byte-Pair-Encoding (BPE) (Sennrich et al., 2016) is commonly used in NMT to break words into word-pieces, improving the translation of rare words. For this reason, we reran our experiments using BPE on the LORELEI and English-Vietnamese datasets. Additionally, to see if our proposed methods work in high-resource scenarios, we run on the WMT 2014 English-German (en-de) dataset,[4] using *newstest2013* as the development set and reporting tokenized, case-sensitive BLEU on *newstest2014* and *newstest2015*.

We validate across different numbers of BPE operations; specifically, we try {1k, 2k, 3k} merge operations for ta-en and ur-en due to their small sizes, {10k, 12k, 15k} for the other LORELEI datasets and en-vi, and 32k for en-de. Using BPE results in much smaller vocabulary sizes, so we do not apply a vocabulary cut-off. Instead, we train on an additional copy of the training data in which all types that appear once are replaced with `UNK`, and halve the number of epochs accordingly. Our models, training, and evaluation processes are largely the same, except that for en-de, we use a 4-layer decoder and 4-layer bidirectional encoder (2 layers for each direction).

Table 7 shows that our proposed methods also significantly improve the translation when used with BPE, for both high and low resource language pairs. With BPE, we are only behind Moses on Urdu-English.

7 Related Work

The closest work to our **lex** model is that of Arthur et al. (2016), which we have discussed already in Section 4. Recent work by Liu et al. (2016) has very similar motivation to that of our **fixnorm** model. They reformulate the output layer in terms of directions and magnitudes, as we do here. Whereas we have focused on the magnitudes, they focus on the directions, modifying the loss function to try to learn a classifier that separates the classes' directions with something like a margin. Wang et al. (2017a) also make the same observation that we do for the **fixnorm** model, but for the task of face verification.

Handling rare words is an important problem for NMT that has been approached in various ways. Some have focused on reducing the number of `UNK`s by enabling NMT to learn from a larger vocabulary (Jean et al., 2015; Mi et al., 2016); others have focused on replacing `UNK`s by copying source words (Gulcehre et al., 2016; Gu et al., 2016; Luong et al., 2015b). However, these methods only help with unknown words, not rare words. An approach that addresses both unknown and rare words is to use subword-level information (Sennrich et al., 2016; Chung et al., 2016; Luong and Manning, 2016). Our approach is different in that we try to identify and address the root of the rare word problem. We expect that our models would benefit from more advanced `UNK`-replacement or subword-level techniques as well.

Recently, Liu and Kirchhoff (2018) have shown that their baseline NMT system with BPE already outperforms Moses for low-resource translation. However, in their work, they use the Transformer network (Vaswani et al., 2017), which is quite different from our baseline model. It would be interesting to see if our methods benefit the Trans-

former network and other models as well.

8 Conclusion

In this paper, we have presented two simple yet effective changes to the output layer of a NMT model. Both of these changes improve translation quality substantially on low-resource language pairs. In many of the language pairs we tested, the baseline NMT system performs poorly relative to phrase-based translation, but our system surpasses it (when both are trained on the same data). We conclude that NMT, equipped with the methods demonstrated here, is a more viable choice for low-resource translation than before, and are optimistic that NMT's repertoire will continue to grow.

Abstract

In this paper, we propose a new universal machine translation approach focusing on languages with a limited amount of parallel data. Our proposed approach utilizes a transfer-learning approach to share lexical and sentence level representations across multiple source languages into one target language. The lexical part is shared through a Universal Lexical Representation to support multi-lingual word-level sharing. The sentence-level sharing is represented by a model of experts from all source languages that share the source encoders with all other languages. This enables the low-resource language to utilize the lexical and sentence representations of the higher resource languages. Our approach is able to achieve 23 BLEU on Romanian-English WMT2016 using a tiny parallel corpus of 6k sentences, compared to the 18 BLEU of strong baseline system which uses multi-lingual training and back-translation. Furthermore, we show that the proposed approach can achieve almost 20 BLEU on the same dataset through fine-tuning a pre-trained multi-lingual system in a zero-shot setting.

1 Introduction

Neural Machine Translation (NMT) (Bahdanau et al., 2015) has achieved remarkable translation quality in various on-line large-scale systems (Wu et al., 2016; Devlin, 2017) as well as achieving state-of-the-art results on Chinese-English translation (Hassan et al., 2018). With such large systems, NMT showed that it can scale up to immense amounts of parallel data in the order of tens of millions of sentences. However, such data is not widely available for all language pairs and domains. In this paper, we propose a novel universal multi-lingual NMT approach focusing mainly on low resource languages to overcome the limitations of NMT and leverage the capabilities of multi-lingual NMT in such scenarios.

Our approach utilizes multi-lingual neural translation system to share lexical and sentence level representations across multiple source languages into one target language. In this setup, some of the source languages may be of extremely limited or even zero data. The lexical sharing is represented by a universal word-level representation where various words from all source languages share the same underlaying representation. The sharing module utilizes monolingual embeddings along with seed parallel data from all languages to build the universal representation. The sentence-level sharing is represented by a model of language experts which enables low-resource languages to utilize the sentence representation of the higher resource languages. This allows the system to translate from any language even with tiny amount of parallel resources.

We evaluate the proposed approach on 3 different languages with tiny or even zero parallel data. We show that for the simulated “zero-resource" settings, our model can consistently outperform a strong multi-lingual NMT baseline with a tiny amount of parallel sentence pairs.

2 Motivation

Neural Machine Translation (NMT) (Bahdanau et al., 2015; Sutskever et al., 2014) is based on Sequence-to-Sequence encoder-decoder model along with an attention mechanism to enable better handling of longer sentences (Bahdanau et al., 2015). Attentional sequence-to-sequence models are modeling the log conditional probability of the

New Orleans, Louisiana, June 1 - 6, 2018.

Figure 1: BLEU scores reported on the test set for Ro-En. The amount of training data effects the translation performance dramatically using a single NMT model.

translation Y given an input sequence X. In general, the NMT system θ consists of two components: an encoder θ_e which transforms the input sequence into an array of continuous representations, and a decoder θ_d that dynamically reads the encoder's output with an attention mechanism and predicts the distribution of each target word. Generally, θ is trained to maximize the likelihood on a training set consisting of N parallel sentences:

$$\begin{aligned}\mathcal{L}(\theta) &= \frac{1}{N}\sum_{n=1}^{N}\log p\left(Y^{(n)}|X^{(n)};\theta\right)\\ &= \frac{1}{N}\sum_{n=1}^{N}\sum_{t=1}^{T}\log p\left(y_t^{(n)}|y_{1:t-1}^{(n)}, f_t^{\text{att}}(h_{1:T_s}^{(n)})\right)\end{aligned} \quad (1)$$

where at each step, f_t^{att} builds the attention mechanism over the encoder's output $h_{1:T_s}$. More precisely, let the vocabulary size of source words as V

$$h_{1:T_s} = f^{\text{ext}}\left[e_{x_1}, ..., e_{x_{T_s}}\right], \quad e_x = E^I(x) \quad (2)$$

where $E^I \in \mathbb{R}^{V\times d}$ is a look-up table of source embeddings, assigning each individual word a unique embedding vector; f^{ext} is a sentence-level feature extractor and is usually implemented by a multi-layer bidirectional RNN (Bahdanau et al., 2015; Wu et al., 2016), recent efforts also achieved the state-of-the-art using non-recurrence f^{ext}, e.g. ConvS2S (Gehring et al., 2017) and Transformer (Vaswani et al., 2017).

Extremely Low-Resource NMT Both θ_e and θ_d should be trained to converge using parallel training examples. However, the performance is highly correlated to the amount of training data. As shown in Figure. 1, the system cannot achieve reasonable translation quality when the number of the parallel examples is extremely small ($N \approx 13k$ sentences, or not available at all $N = 0$).

Multi-lingual NMT Lee et al. (2017) and Johnson et al. (2017) have shown that NMT is quite efficient for multilingual machine translation. Assuming the translation from K source languages into one target language, a system is trained with maximum likelihood on the mixed parallel pairs $\{X^{(n,k)}, Y^{(n,k)}\}_{k=1...K}^{n=1...N_k}$, that is

$$\mathcal{L}(\theta) = \frac{1}{N}\sum_{k=1}^{K}\sum_{n=1}^{N_k}\log p\left(Y^{(n,k)}|X^{(n,k)};\theta\right) \quad (3)$$

where $N = \sum_{k=1}^{K} N_k$. As the input layer, the system assumes a multilingual vocabulary which is usually the union of all source language vocabularies with a total size as $V = \sum_{k=1}^{K} V_k$. In practice, it is essential to shuffle the multilingual sentence pairs into mini-batches so that different languages can be trained equally. Multi-lingual NMT is quite appealing for low-resource languages; several papers highlighted the characteristic that make it a good fit for that such as Lee et al. (2017), Johnson et al. (2017), Zoph et al. (2016) and Firat et al. (2016). Multi-lingual NMT utilizes the training examples of multiple languages to regularize the models avoiding over-fitting to the limited data of the smaller languages. Moreover, the model transfers the translation knowledge from high-resource languages to low-resource ones. Finlay, the decoder part of the model is sufficiently trained since it shares multilingual examples from all languages.

2.1 Challenges

Despite the success of training multi-lingual NMT systems; there are a couple of challenges to leverage them for zero-resource languages:

Lexical-level Sharing Conventionally, a multi-lingual NMT model has a vocabulary that represents the union of the vocabularies of all source languages. Therefore, the multi-lingual words do not practically share the same embedding space since each word has its own representation. This does not pose a problem for languages with sufficiently large amount of data, yet it is a major limitation for extremely low resource languages since most of the vocabulary items will not have enough, if any, training examples to get a reliably trained models.

A possible solution is to share the surface form of all source languages through sharing sub-units

such as subwords (Sennrich et al., 2016b) or characters (Kim et al., 2016; Luong and Manning, 2016; Lee et al., 2017). However, for an arbitrary low-resource language we cannot assume significant overlap in the lexical surface forms compared to the high-resource languages. The low-resource language may not even share the same character set as any high-resource language. It is crucial to create a shared semantic representation across all languages that does not rely on surface form overlap.

Sentence-level Sharing It is also crucial for low-resource languages to share source sentence representation with other similar languages. For example, if a language shares syntactic order with another language it should be feasible for the low-resource language to share such representation with another high recourse language. It is also important to utilize monolingual data to learn such representation since the low or zero resource language may have monolingual resources only.

3 Universal Neural Machine Translation

We propose a Universal NMT system that is focused on the scenario where minimal parallel sentences are available. As shown in Fig. 2, we introduce two components to extend the conventional multi-lingual NMT system (Johnson et al., 2017): Universal Lexical Representation (ULR) and Mixture of Language Experts (MoLE) to enable both word-level and sentence-level sharing, respectively.

3.1 Universal Lexical Representation (ULR)

As we highlighted above, it is not straightforward to have a universal representation for all languages. One potential approach is to use a shared source vocabulary, but this is not adequate since it assumes significant surface-form overlap in order being able to generalize between high-resource and low-resource languages. Alternatively, we could train monolingual embeddings in a shared space and use these as the input to our MT system. However, since these embeddings are trained on a monolingual objective, they will not be optimal for an NMT objective. If we simply allow them to change during NMT training, then this will not generalize to the low-resource language where many of the words are unseen in the parallel data. Therefore, our goal is to create a shared embedding space which (a) is trained towards NMT rather than a monolingual objective, (b) is not based on lexical surface forms, and (c) will generalize from the high-resource languages to the low-resource language.

We propose a novel representation for multilingual embedding where each word from any language is represented as a probabilistic mixture of universal-space word embeddings. In this way, semantically similar words from different languages will naturally have similar representations. Our method achieves this utilizing a discrete (but probabilistic) "universal token space", and then learning the embedding matrix for these universal tokens directly in our NMT training.

Lexicon Mapping to the Universal Token Space We first define a discrete universal token set of size M into which all source languages will be projected. In principle, this could correspond to any human or symbolic language, but all experiments here use English as the basis for the universal token space. As shown in Figure 2, we have multiple embedding representations. E^Q is language-specific embedding trained on monolingual data and E^K is universal tokens embedding. The matrices E^K and E^Q are created beforehand and are not trainable during NMT training. E^U is the embedding matrix for these universal tokens which is learned during our NMT training. It is worth noting that shaded parts in Figure2 are trainable during NMT training process.

Therefore, each source word e_x is represented as a mixture of universal tokens M of E^U.

$$e_x = \sum_{i=1}^{M} E^U(u_i) \cdot q(u_i|x) \tag{4}$$

where E^U is an NMT embedding matrix, which is learned during NMT training.

The mapping q projects the multilingual words into the universal space based on their semantic similarity. That is, $q(u|x)$ is a distribution based on the distance $D_s(u, x)$ between u and x as:

$$q(u_i|x) = \frac{e^{D(u_i,x)/\tau}}{\sum_{u_j} e^{D(u_j,x)/\tau}} \tag{5}$$

where τ is a temperature and $D(u_i, x)$ is a scalar score which represents the similarity between source word x and universal token u_i:

$$D(u, x) = E^K(u) \cdot A \cdot E^Q(x)^T \tag{6}$$

where $E^K(u)$ is the "key" embedding of word u, $E^Q(x)$ is the "query" embedding of source word x.

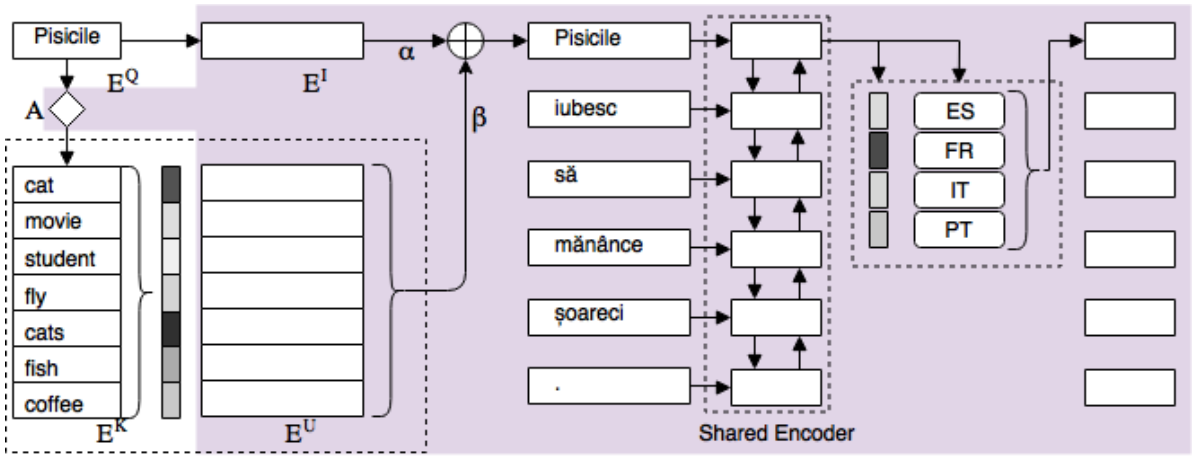

Figure 2: An illustration of the proposed architecture of the ULR and MoLE. Shaded parts are trained within NMT model while unshaded parts are not changed during training.

The transformation matrix A, which is initialized to the identity matrix, is learned during NMT training and shared across all languages.

This is a key-value representation, where the queries are the monolingual language-specific embedding, the keys are the universal tokens embeddings and the values are a probabilistic distribution over the universal NMT embeddings. This can represent unlimited multi-lingual vocabulary that has never been observed in the parallel training data. It is worth noting that the trainable transformation matrix A is added to the query matching mechanism with the main purpose to tune the similarity scores towards the translation task. A is shared across all languages and optimized discriminatively during NMT training such that the system can fine-tune the similarity score $q()$ to be optimal for NMT.

Shared Monolingual Embeddings In general, we create one E^Q matrix per source language, as well as a single E^K matrix in our universal token language. For Equation 6 to make sense and generalize across language pairs, all of these embedding matrices must live in a similar semantic space. To do this, we first train off-the-shelf monolingual word embeddings in each language, and then learn one projection matrix per source language which maps the original monolingual embeddings into E^K space. Typically, we need a list of *source word - universal token* pairs (seeds S_k) to train the projection matrix for language k. Since vectors are normalized, learning the optimal projection is equivalent to finding an orthogonal transformation O_k that makes the projected word vectors as close as to its corresponded universal tokens:

$$\max_{O_k} \sum_{(\tilde{x},\tilde{y})\in S_k} \left(E^{Q_k}(\tilde{x}) \cdot O_k\right) \cdot E^K(\tilde{y})^T \quad \text{s.t. } O_k^T O_k = I, \quad k = 1, ..., K \tag{7}$$

which can be solved by SVD decomposition based on the seeds (Smith et al., 2017). In this paper, we chose to use a short list of seeds from automatic word-alignment of parallel sentences to learn the projection. However, recent efforts (Artetxe et al., 2017; Conneau et al., 2018) also showed that it is possible to learn the transformation without any seeds, which makes it feasible for our proposed method to be utilized in purely zero parallel resource cases.

It is worth noting that O_k is a language-specific matrix which maps the monolingual embeddings of each source language into a similar semantic space as the universal token language.

Interpolated Embeddings Certain lexical categories (e.g. function words) are poorly captured by Equation 4. Luckily, function words often have very high frequency, and can be estimated robustly from even a tiny amount of data. This motivates an interpolated e_x where embeddings for very frequent words are optimized directly and not through the universal tokens:

$$\alpha(x)E^I(x) + \beta(x)\sum_{i=1}^{M} E^U(u_i) \cdot q(u_i|x) \tag{8}$$

Where $E^I(x)$ is a language-specific embedding of word x which is optimized during NMT training. In general, we set $\alpha(x)$ to 1.0 for the top k most frequent words in each language, and 0.0 otherwise,

where k is set to 500 in this work. It is worth noting that we do not use an absolute frequency cutoff because this would cause a mismatch between high-resource and low-resource languages, which we want to avoid. We keep $\beta(x)$ fixed to 1.0.

An Example To give a concrete example, imagine that our target language is English (En), our high-resource auxiliary source languages are Spanish (Es) and French (Fr), and our low-resource source language is Romanian (Ro). En is also used for the universal token set. We assume to have 10M+ parallel Es-En and Fr-En, and a few thousand in Ro-En. We also have millions of monolingual sentences in each language.

We first train word2vec embeddings on monolingual corpora from each of the four languages. We next align the Es-En, Fr-En, and Ro-En parallel corpora and extract a seed dictionary of a few hundred words per language, e.g., `gato` $\rightarrow$ `cat`, `chien` $\rightarrow$ `dog`. We then learn three matrices O_1, O_2, O_3 to project the Es, Fr and Ro embeddings ($E^{Q_1}, E^{Q_2}, E^{Q_3}$), into En ($E^K$) based on these seed dictionaries. At this point, Equation 5 should produce *reasonable* alignments between the source languages and En, e.g., $q(\texttt{horse}|\texttt{magar}) = 0.5$, $q(\texttt{donkey}|\texttt{magar}) = 0.3$, $q(\texttt{cow}|\texttt{magar}) = 0.2$, where `magar` is the Ro word for `donkey`.

3.2 Mixture of Language Experts (MoLE)

As we paved the road for having a universal embedding representation; it is crucial to have a language-sensitive module for the encoder that would help in modeling various language structures which may vary between different languages. We propose a Mixture of Language Experts (MoLE) to model the sentence-level universal encoder. As shown in Fig. 2, an additional module of mixture of experts is used after the last layer of the encoder. Similar to (Shazeer et al., 2017), we have a set of expert networks and a gating network to control the weight of each expert. More precisely, we have a set of expert networks as $f_1(h), ..., f_K(h)$ where for each expert, a two-layer feed-forward network which reads the output hidden states h of the encoder is utilized. The output of the MoLE module h' will be a weighted sum of these experts to replace the encoder's representation:

$$h' = \sum_{k=1}^{K} f_k(h) \cdot \text{softmax}(g(h))_k, \qquad (9)$$

where an one-layer feed-forward network $g(h)$ is used as a gate to compute scores for all the experts.

In our case, we create one expert per auxiliary language. In other words, we train to only use expert f_i when training on a parallel sentence from auxiliary language i. Assume the language $1...K-1$ are the auxiliary languages. That is, we have a multi-task objective as:

$$\mathcal{L}^{\text{gate}} = \sum_{k=1}^{K-1} \sum_{n=1}^{N_k} \log \left[\text{softmax}\left(g(h)\right)_k\right] \qquad (10)$$

We do not update the MoLE module for training on a sentence from the low-resource language. Intuitively, this allows us to represent each token in the low-resource language as a context-dependent mixture of the auxiliary language experts.

4 Experiments

We extensively study the effectiveness of the proposed methods by evaluating on three "almost-zero-resource" language pairs with variant auxiliary languages. The vanilla single-source NMT and the multi-lingual NMT models are used as baselines.

4.1 Settings

Dataset We empirically evaluate the proposed Universal NMT system on 3 languages – Romanian (Ro) / Latvian (Lv) / Korean (Ko) – translating to English (En) in near zero-resource settings. To achieve this, single or multiple auxiliary languages from Czech (Cs), German (De), Greek (El), Spanish (Es), Finnish (Fi), French (Fr), Italian (It), Portuguese (Pt) and Russian (Ru) are jointly trained. The detailed statistics and sources of the available parallel resource can be found in Table 1, where we further down-sample the corpora for the targeted languages to simulate zero-resource.

It also requires additional large amount of monolingual data to obtain the word embeddings for each language, where we use the latest Wikipedia dumps [5] for all the languages. Typically, the monolingual corpora are much larger than the parallel corpora. For validation and testing, the standard validation and testing sets are utilized for each targeted language.

subset	0/6k/60k	10k	6k	/								2.00m

Table 1: Statistics of the available parallel resource in our experiments. All the languages are translated to English.

Preprocessing All the data (parallel and monolingual) have been tokenized and segmented into subword symbols using byte-pair encoding (BPE) (Sennrich et al., 2016b). We use sentences of length up to 50 subword symbols for all languages. For each language, a maximum number of $40,000$ BPE operations are learned and applied to restrict the size of the vocabulary. We concatenate the vocabularies of all source languages in the multilingual setting where special a "language marker " have been appended to each word so that there will be no embedding sharing on the surface form. Thus, we avoid sharing the representation of words that have similar surface forms though with different meaning in various languages.

Architecture We implement an attention-based neural machine translation model which consists of a one-layer bidirectional RNN encoder and a two-layer attention-based RNN decoder. All RNNs have 512 LSTM units (Hochreiter and Schmidhuber, 1997). Both the dimensions of the source and target embedding vectors are set to 512. The dimensionality of universal embeddings is also the same. For a fair comparison, the same architecture is also utilized for training both the vanilla and multilingual NMT systems. For multilingual experiments, $1 \sim 5$ auxiliary languages are used. When training with the universal tokens, the temperature τ (in Eq. 6) is fixed to 0.05 for all the experiments.

Learning All the models are trained to maximize the log-likelihood using Adam (Kingma and Ba, 2014) optimizer for 1 million steps on the mixed dataset with a batch size of 128. The dropout rates for both the encoder and the decoder is set to 0.4. We have open-sourced an implementation of the proposed model. [6]

4.2 Back-Translation

We utilize back-translation (BT) (Sennrich et al., 2016a) to encourage the model to use more information of the zero-resource languages. More concretely, we build the synthetic parallel corpus by translating on monolingual data[7] with a trained translation system and use it to train a backward direction translation model. Once trained, the same operation can be used on the forward direction. Generally, BT is difficult to apply for zero resource setting since it requires a reasonably good translation system to generate good quality synthetic parallel data. Such a system may not be feasible with tiny or zero parallel data. However, it is possible to start with a trained multi-NMT model.

4.3 Preliminary Experiments

Training Monolingual Embeddings We train the monolingual embeddings using `fastText`[8] (Bojanowski et al., 2017) over the Wikipedia corpora of all the languages. The vectors are set to 300 dimensions, trained using the default setting of skip-gram . All the vectors are normalized to norm 1.

Pre-projection In this paper, the pre-projection requires initial word alignments (seeds) between words of each source language and the universal tokens. More precisely, for the experiments of Ro/Ko/Lv-En, we use the target language (En) as the universal tokens; `fast_align`[9] is used to automatically collect the aligned words between the source languages and English.

5 Results

We show our main results of multiple source languages to English with different auxiliary languages in Table 2. To have a fair comparison, we use only 6k sentences corpus for both Ro and Lv with all the settings and 10k for Ko. It is obvious that applying both the universal tokens and mixture of experts modules improve the overall translation quality for all the language pairs and the improvements are additive.

To examine the influence of auxiliary languages, we tested four sets of different combinations of auxiliary languages for Ro-En and two sets for Lv-En.

Table 3: BLEU scores evaluated on test set (6k), compared with ULR and MoLE. "vanilla" is the standard NMT system trained only on Ro-En training set

It shows that Ro performs best when the auxiliary languages are all selected in the same family (Ro, Es, Fr, It and Pt are all from the Romance family of European languages) which makes sense as more knowledge can be shared across the same family. Similarly, for the experiment of Lv-En, improvements are also observed when adding Ru as additional auxiliary language as Lv and Ru share many similarities because of the geo-graphical influence even though they don't share the same alphabet.

We also tested a set of Ko-En experiments to examine the generalization capability of our approach on non-European languages while using languages of Romance family as auxiliary languages. Although the BLEU score is relatively low, the proposed methods can consistently help translating less-related low-resource languages. It is more reasonable to have similar languages as auxiliary languages.

5.1 Ablation Study

We perform thorough experiments to examine effectiveness of the proposed method; we do ablation study on Ro-En where all the models are trained based on the same Ro-En corpus with 6k sentences.

As shown in Table 3, it is obvious that 6k sentences of parallel corpora completely fails to train a vanilla NMT model. Using Multi-NMT with the assistance of 7.8M auxiliary language sentence pairs, Ro-En translation performance gets a substantial improvement which, however, is still limited to be usable. By contrast, the proposed ULR boosts the Multi-NMT significantly with +5.07 BLEU, which is further boosted to +7.98 BLEU when incorporating sentence-level information using both MoLE and BT. Furthermore, it is also shown that ULR works better when a trainable transformation matrix A is used (4th vs 5th row in the table). Note that, although still $5 \sim 6$ BLEU scores lower than the full data ($\times 100$ large) model.

We also measure the translation quality of simply training the vanilla system while replacing each token of the Ro sentence with its closet universal token in the projected embedding space, considering we are using the target languages (En) as

the universal tokens. Although the performance is much worse than the baseline Multi-NMT, it still outperforms the vanilla model which implies the effectiveness of the embedding alignments.

Monolingual Data In Table. 3, we also showed the performance when incorporating the monolingual Ro corpora to help the UniNMT training in both cases with and without ULR. The back-translation improves in both cases, while the ULR still obtains the best score which indicates that the gains achieved are additive.

Corpus Size As shown in Fig. 3, we also evaluated our methods with varied sizes – 0k[10], 6k, 60k and 600k – of the Ro-En corpus. The vanilla NMT and the multi-lingual NMT are used as baselines. It is clear in all cases that the performance gets better when the training corpus is larger. However, the multilingual with ULR works much better with a small amount of training examples. Note that, the usage of ULR universal tokens also enables us to directly work on a "pure zero" resource translation with a shared multilingual NMT model.

Unknown Tokens One explanation on how ULR help the translation for almost zero resource languages is it greatly cancel out the effects of missing tokens that would cause out-of-vocabularies during testing. As in Fig. 4, the translation performance heavily drops when it has more "unknown" which cannot be found in the given 6k training set, especially for the typical multilingual NMT. Instead, these "unknown" tokens will naturally have their embeddings based on ULR projected universal tokens even if we never saw them in the training set. When we apply back-translation over the monolingual data, the performance further improves which can almost catch up with the model trained with 60k data.

5.2 Qualitative Analysis

Examples Figure 5 shows some cherry-picked examples for Ro-En. Example (a) shows how the lexical selection get enriched when introducing ULR (Lex-6K) as well as when adding Back Translation (Lex-6K-BT). Example (b) shows the effect of using romance vs non-romance languages as the supporting languages for Ro. Example (c) shows the importance of having a trainable A as have been discussed; without trainable A the model confuses "india" and "china" as they may have close representation in the mono-lingual embeddings.

Visualization of MoLE Figure 6 shows the activations along with the same source sentence with various auxiliary languages. It is clear that MoLE is effectively switching between the experts when dealing with zero-resource language words. For this particular example of Ro, we can see that the system is utilizing various auxiliary languages based on their relatedness to the source language. We can approximately rank the relatedness based of the influence of each language. For instance, the influence can be approximately ranked as $Es \approx Pt > Fr \approx It > Cs \approx El > De > Fi$, which is interestingly close to the grammatical relatedness of Ro to these languages. On the other hand, Cs has a strong influence although it does not fall in the same language family with Ro, we think this is due to the geo-graphical influence between the two languages since Cs and Ro share similar phrases and expressions. This shows that MoLE learns to utilize resources from similar languages.

5.3 Fine-tuning a Pre-trained Model

All the described experiments above had the low resource languages jointly trained with all the auxiliary high-resource languages, where the training of the large amount of high-resource languages can be seen as a sort of regularization. It is also common to train a model on high-resource languages first, and then fine-tune the model on a small resource language similar to transfer learning approaches (Zoph et al., 2016). However, it is not trivial to effectively fine-tune NMT models on extremely low resource data since the models easily over-fit due to over-parameterization of the neural networks.

In this experiment, we have explored the fine-tuning tasks using our approach. First, we train a Multi-NMT model (with ULR) on {Es, Fr, It, Pt}-En languages only to create a zero-shot setting for Ro-En translation. Then, we start fine-tuning the model with $6k$ parallel corpora of Ro-En, with and without ULR. As shown in Fig. 7, both models improve a lot over the baseline. With the help of ULR, we can achieve a BLEU score of around 10.7 (also shown in Fig. 3) for Ro-En translation with "zero-resource" translation. The BLEU score can further improve to almost 20 BLEU after 3 epochs of training on $6k$ sentences using ULR. This is almost 6 BLEU higher than the best score of the

[10]For 0k experiments, we used the pre-projection learned from 6k data. It is also possible to use unsupervised learned dictionary.

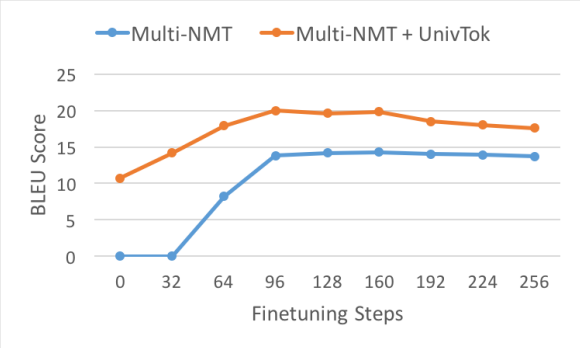

Figure 7: Performance comparison of Fine-tuning on 6K RO sentences.

baseline. It is worth noting that this fine-tuning is a very efficient process since it only takes less than 2 minutes to train for 3 epochs over such tiny amount of data. This is very appealing for practical applications where adapting a per-trained system on-line is a big advantage. As a future work, we will further investigate a better fine-tuning strategy such as meta-learning (Finn et al., 2017) using ULR.

6 Related Work

Multi-lingual NMT has been extensively studied in a number of papers such as Lee et al. (2017), Johnson et al. (2017), Zoph et al. (2016) and Firat et al. (2016). As we discussed, these approaches have significant limitations with zero-resource cases. Johnson et al. (2017) is more closely related to our current approach, our work is extending it to overcome the limitations with very low-resource languages and enable sharing of lexical and sentence representation across multiple languages.

Two recent related works are targeting the same problem of minimally supervised or totally unsupervised NMT. Artetxe et al. (2018) proposed a totally unsupervised approach depending on multi-lingual embedding similar to ours and dual-learning and reconstruction techniques to train the model from mono-lingual data only. Lample et al. (2018) also proposed a quite similar approach while utilizing adversarial learning.

7 Conclusion

In this paper, we propose a new universal machine translation approach that enables sharing resources between high resource languages and extremely low resource languages. Our approach is able to achieve 23 BLEU on Romanian-English WMT2016 using a tiny parallel corpus of 6k sentences, compared to the 18 BLEU of strong multi-lingual baseline system.

Classical Structured Prediction Losses for Sequence to Sequence Learning

Abstract

There has been much recent work on training neural attention models at the sequence-level using either reinforcement learning-style methods or by optimizing the beam. In this paper, we survey a range of classical objective functions that have been widely used to train linear models for structured prediction and apply them to neural sequence to sequence models. Our experiments show that these losses can perform surprisingly well by slightly outperforming beam search optimization in a like for like setup. We also report new state of the art results on both IWSLT'14 German-English translation as well as Gigaword abstractive summarization. On the large WMT'14 English-French task, sequence-level training achieves 41.5 BLEU which is on par with the state of the art.[1]

1 Introduction

Sequence to sequence models are usually trained with a simple token-level likelihood loss (Sutskever et al., 2014; Bahdanau et al., 2014). However, at test time, these models do not produce a single token but a whole sequence. In order to resolve this inconsistency and to potentially improve generation, recent work has focused on training these models at the sequence-level, for instance using REINFORCE (Ranzato et al., 2015), actor-critic (Bahdanau et al., 2016), or with beam search optimization (Wiseman and Rush, 2016).

Before the recent work on sequence level training for neural networks, there has been a large body of research on training linear models at the sequence level. For example, direct loss optimization has been popularized in machine translation with the Minimum Error Rate Training algorithm (MERT; Och 2003) and expected risk minimization has an extensive history in NLP (Smith and Eisner, 2006; Rosti et al., 2010; Green et al., 2014). This paper revisits several objective functions that have been commonly used for structured prediction tasks in NLP (Gimpel and Smith, 2010) and apply them to a neural sequence to sequence model (Gehring et al., 2017b) (§2). Specifically, we consider likelihood training at the sequence-level, a margin loss as well as expected risk training. We also investigate several combinations of global losses with token-level likelihood. This is, to our knowledge, the most comprehensive comparison of structured losses in the context of neural sequence to sequence models (§3).

We experiment on the IWSLT'14 German-English translation task (Cettolo et al., 2014) as well as the Gigaword abstractive summarization task (Rush et al., 2015). We achieve the best reported accuracy to date on both tasks. We find that the sequence level losses we survey perform similarly to one another and outperform beam search optimization (Wiseman and Rush, 2016) on a comparable setup. On WMT'14 English-French, we also illustrate the effectiveness of risk minimization on a larger translation task. Classical losses for structured prediction are still very competitive and effective for neural models (§5, §6).

2 Sequence to Sequence Learning

The general architecture of our sequence to sequence models follows the encoder-decoder approach with soft attention first introduced in (Bahdanau et al., 2014). As a main difference, in most of our experiments we parameterize the encoder and the decoder as convolutional neural

* Equal contribution.

[1] An implementation of the losses is available as part of fairseq at https://github.com/facebookresearch/fairseq-py/tree/classic_seqlevel

Proceedings of NAACL-HLT 2018, pages 355–364
New Orleans, Louisiana, June 1 - 6, 2018.

networks instead of recurrent networks (Gehring et al., 2017a,b). Our use of convolution is motivated by computational and accuracy considerations. However, the objective functions we present are model agnostic and equally applicable to recurrent and convolutional models. We demonstrate the applicability of our objective functions to recurrent models (LSTM) in our comparison to Wiseman and Rush (2016) in §6.6.

Notation. We denote the source sentence as $\mathbf{x}$, an output sentence of our model as $\mathbf{u}$, and the reference or *target* sentence as $\mathbf{t}$. For some objectives, we choose a pseudo reference $\mathbf{u}^*$ instead, such as a model output with the highest BLEU or ROUGE score among a set of candidate outputs, $\mathcal{U}$, generated by our model.

Concretely, the encoder processes a source sentence $\mathbf{x} = (x_1, \ldots, x_m)$ containing m words and outputs a sequence of states $\mathbf{z} = (z_1 \ldots, z_m)$. The decoder takes $\mathbf{z}$ and generates the output sequence $\mathbf{u} = (u_1, \ldots, u_n)$ left to right, one element at a time. For each output u_i, the decoder computes hidden state h_i based on the previous state h_{i-1}, an embedding g_{i-1} of the previous target language word u_{i-1}, as well as a conditional input c_i derived from the encoder output $\mathbf{z}$. The attention context c_i is computed as a weighted sum of $(z_1, \ldots, z_m)$ at each time step. The weights of this sum are referred to as attention scores and allow the network to focus on the most relevant parts of the input at each generation step. Attention scores are computed by comparing each encoder state z_j to a combination of the previous decoder state h_i and the last prediction u_i; the result is normalized to be a distribution over input elements. At each generation step, the model scores for the V possible next target words u_i by transforming the decoder output h_i via a linear layer with weights W_o and bias b_o: $s_i = W_o h_i + b_o$. This is turned into a distribution via a softmax: $p(u_i|u_1, \ldots, u_{i-1}, \mathbf{x}) = \text{softmax}(s_i)$.

Our encoder and decoder use gated convolutional neural networks which enable fast and accurate generation (Gehring et al., 2017b). Fast generation is essential to efficiently train on the model output as is done in this work as sequence-level losses require generating at training time. Both encoder and decoder networks share a simple block structure that computes intermediate states based on a fixed number of input tokens and we stack several blocks on top of each other. Each block contains a 1-D convolution that takes as input k feature vectors and outputs another vector; subsequent layers operate over the k output elements of the previous layer. The output of the convolution is then fed into a gated linear unit (Dauphin et al., 2017). In the decoder network, we rely on causal convolution which rely only on states from the previous time steps. The parameters θ of our model are all the weight matrices in the encoder and decoder networks. Further details can be found in Gehring et al. (2017b).

3 Objective Functions

We compare several objective functions for training the model architecture described in §2. The corresponding loss functions are either computed over individual tokens (§3.1), over entire sequences (§3.2) or over a combination of tokens and sequences (§3.3). An overview of these loss functions is given in Figure 1.

3.1 Token-Level Objectives

Most prior work on sequence to sequence learning has focused on optimizing token-level loss functions, i.e., functions for which the loss is computed additively over individual tokens.

Token Negative Log Likelihood (`TokNLL`)

Token-level likelihood (`TokNLL`, Equation 1) minimizes the negative log likelihood of individual reference tokens $\mathbf{t} = (t_1, \ldots, t_n)$. It is the most common loss function optimized in related work and serves as a baseline for our comparison.

Token NLL with Label Smoothing (`TokLS`)

Likelihood training forces the model to make extreme zero or one predictions to distinguish between the ground truth and alternatives. This may result in a model that is too confident in its training predictions, which may hurt its generalization performance. Label smoothing addresses this by acting as a regularizer that makes the model less confident in its predictions. Specifically, we smooth the target distribution with a prior distribution f that is independent of the current input $\mathbf{x}$ (Szegedy et al., 2015; Pereyra et al., 2017; Vaswani et al., 2017). We use a uniform prior distribution over all words in the vocabulary, $f = \frac{1}{V}$. One may also use a unigram distribution which has been shown to work better on some tasks (Pereyra et al., 2017). Label smoothing is equivalent to adding the KL divergence between f and the model prediction

$$\mathcal{L}_{\texttt{TokNLL}} = -\sum_{i=1}^{n} \log p(t_i|t_1, \ldots, t_{i-1}, \mathbf{x}) \tag{1}$$

$$\mathcal{L}_{\texttt{TokLS}} = -\sum_{i=1}^{n} \log p(t_i|t_1, \ldots, t_{i-1}, \mathbf{x}) - D_{KL}(f \| p(t_i|t_1, \ldots, t_{i-1}, \mathbf{x})) \tag{2}$$

$$\mathcal{L}_{\texttt{SeqNLL}} = -\log p(\mathbf{u}^*|\mathbf{x}) + \log \sum_{\mathbf{u} \in \mathcal{U}(\mathbf{x})} p(\mathbf{u}|\mathbf{x}) \tag{3}$$

$$\mathcal{L}_{\texttt{Risk}} = \sum_{\mathbf{u} \in \mathcal{U}(\mathbf{x})} \text{cost}(\mathbf{t}, \mathbf{u}) \frac{p(\mathbf{u}|\mathbf{x})}{\sum_{\mathbf{u}' \in \mathcal{U}(\mathbf{x})} p(\mathbf{u}'|\mathbf{x})} \tag{4}$$

$$\mathcal{L}_{\texttt{MaxMargin}} = \max\left[0, \text{cost}(\mathbf{t}, \hat{\mathbf{u}}) - \text{cost}(\mathbf{t}, \mathbf{u}^*) - s(\mathbf{u}^*|\mathbf{x}) + s(\hat{\mathbf{u}}|\mathbf{x})\right] \tag{5}$$

$$\mathcal{L}_{\texttt{MultiMargin}} = \sum_{\mathbf{u} \in \mathcal{U}(\mathbf{x})} \max\left[0, \text{cost}(\mathbf{t}, \mathbf{u}) - \text{cost}(\mathbf{t}, \mathbf{u}^*) - s(\mathbf{u}^*|\mathbf{x}) + s(\mathbf{u}|\mathbf{x})\right] \tag{6}$$

$$\mathcal{L}_{\texttt{SoftmaxMargin}} = -\log p(\mathbf{u}^*|\mathbf{x}) + \log \sum_{\mathbf{u} \in \mathcal{U}(\mathbf{x})} \exp\left[s(\mathbf{u}|\mathbf{x}) + \text{cost}(\mathbf{t}, \mathbf{u})\right] \tag{7}$$

Figure 1: Token and sequence negative log-likelihood (Equations 1 and 3), token-level label smoothing (Equation 2), expected risk (Equation 4), max-margin (Equation 5), multi-margin (Equation 6), softmax-margin (Equation 7). We denote the source as $\mathbf{x}$, the reference target as $\mathbf{t}$, the set of candidate outputs as $\mathcal{U}$ and the best candidate (pseudo reference) as $\mathbf{u}^*$. For max-margin we denote the candidate with the highest model score as $\hat{\mathbf{u}}$.

$p(\mathbf{u}|\mathbf{x})$ to the negative log likelihood (TokLS, Equation 2). In practice, we implement label smoothing by modifying the ground truth distribution for word u to be $q(u) = 1 - \epsilon$ and $q(u') = \frac{\epsilon}{V}$ for $u' \neq u$ instead of $q(u) = 1$ and $q(u') = 0$ where ϵ is a smoothing parameter.

3.2 Sequence-Level Objectives

We also consider a class of objective functions that are computed over entire sequences, i.e., sequence-level objectives. Training with these objectives requires generating and scoring multiple candidate output sequences for each input sequence during training, which is computationally expensive but allows us to directly optimize task-specific metrics such as BLEU or ROUGE.

Unfortunately, these objectives are also typically defined over the entire space of possible output sequences, which is intractable to enumerate or score with our models. Instead, we compute our sequence losses over a subset of the output space, $\mathcal{U}(\mathbf{x})$, generated by the model. We discuss approaches for generating this subset in §4.

Sequence Negative Log Likelihood (SeqNLL)

Similar to TokNLL, we can minimize the negative log likelihood of an entire sequence rather than individual tokens (SeqNLL, Equation 3). The log-likelihood of sequence $\mathbf{u}$ is the sum of individual token log probabilities, normalized by the number of tokens to avoid bias towards shorter sequences:

$$p(\mathbf{u}|\mathbf{x}) = \exp \frac{1}{n} \sum_{i=1}^{n} \log p(u_i|u_1, \ldots, u_{i-1}, \mathbf{x})$$

As target we choose a pseudo reference[2] amongst the candidates which maximizes either BLEU or ROUGE with respect to $\mathbf{t}$, the gold reference:

$$\mathbf{u}^*(\mathbf{x}) = \arg\max_{\mathbf{u} \in \mathcal{U}(\mathbf{x})} \text{BLEU}(\mathbf{t}, \mathbf{u})$$

As is common practice when computing BLEU at the sentence-level, we smooth all initial counts to one (except for unigram counts) so that the geometric mean is not dominated by zero-valued n-gram match counts (Lin and Och, 2004).

Expected Risk Minimization (Risk)

This objective minimizes the expected value of a given cost function over the space of candidate sequences (Risk, Equation 4). In this work we use task-specific cost functions designed to maximize BLEU or ROUGE (Lin, 2004), e.g., $\text{cost}(\mathbf{t}, \mathbf{u}) =$

[2] Another option is to use the gold reference target, $\mathbf{t}$, but in practice this can lead to degenerate solutions in which the model assigns low probabilities to nearly all outputs. This is discussed further in §4.

$1 - \text{BLEU}(\mathbf{t}, \mathbf{u})$, for a given a candidate sequence $\mathbf{u}$ and target $\mathbf{t}$. Different to SeqNLL (§3.2), this loss may increase the score of several candidates that have low cost, instead of focusing on a single sequence which may only be marginally better than any alternatives. Optimizing this loss is a particularly good strategy if the reference is not always reachable, although compared to classical phrase-based models, this is less of an issue with neural sequence to sequence models that predict individual words or even sub-word units.

The Risk objective is similar to the REINFORCE objective used in Ranzato et al. (2015), since both objectives optimize an expected cost or reward (Williams, 1992). However, there are a few important differences: (1) whereas REINFORCE typically approximates the expectation with a single sampled sequence, the Risk objective considers multiple sequences; (2) whereas REINFORCE relies on a *baseline reward*[3] to determine the sign of the gradients for the current sequence, for the Risk objective we instead estimate the expected cost over a set of candidate output sequences (see §4); and (3) while the baseline reward is different for every word in REINFORCE, the expected cost is the same for every word in risk minimization since it is computed on the sequence level based on the actual cost.

Max-Margin

MaxMargin (Equation 5) is a classical margin loss for structured prediction (Taskar et al., 2003; Tsochantaridis et al., 2005) which enforces a margin between the model scores of the highest scoring candidate sequence $\hat{\mathbf{u}}$ and a reference sequence. We replace the human reference $\mathbf{t}$ with a pseudo-reference $\mathbf{u}^*$ since this setting performed slightly better in early experiments; $\mathbf{u}^*$ is the candidate sequence with the highest BLEU score. The size of the margin *varies* between samples and is given by the difference between the cost of $\mathbf{u}^*$ and the cost of $\hat{\mathbf{u}}$. In practice, we scale the margin by a hyper-parameter β determined on the validation set: $\beta(\text{cost}(\mathbf{t}, \hat{\mathbf{u}}) - \text{cost}(\mathbf{t}, \mathbf{u}^*))$. For this loss we use the unnormalized scores computed by the model before the final softmax:

$$s(\mathbf{u}|\mathbf{x}) = \frac{1}{n}\sum_{i=1}^{n} s(u_i|u_1, \ldots, u_{i-1}, \mathbf{x})$$

[3]Ranzato et al. (2015) estimate the baseline reward for REINFORCE with a separate linear regressor over the model's current hidden state.

Multi-Margin

MaxMargin only updates two elements in the candidate set. We therefore consider MultiMargin (Equation 6) which enforces a margin between *every* candidate sequence $\mathbf{u}$ and a reference sequence (Herbrich et al., 1999), hence the name Multi-Margin. Similar to MaxMargin, we replace the reference $\mathbf{t}$ with the pseudo-reference $\mathbf{u}^*$.

Softmax-Margin

Finally, SoftmaxMargin (Equation 7) is another classic loss that has been proposed by Gimpel and Smith (2010) as another way to optimize task-specific costs. The loss augments the scores inside the exp of SeqNLL (Equation 3) by a cost. The intuition is that we want to penalize high cost outputs proportional to their cost.

3.3 Combined Objectives

We also experiment with two variants of combining sequence-level objectives (§3.2) with token-level objectives (§3.1). First, we consider a weighted combination (Weighted) of both a sequence-level and token-level objective (Wu et al., 2016), e.g., for TokLS and Risk we have:

$$\mathcal{L}_{\texttt{Weighted}} = \alpha\mathcal{L}_{\texttt{TokLS}} + (1-\alpha)\mathcal{L}_{\texttt{Risk}} \quad (8)$$

where α is a scaling constant that is tuned on a held-out validation set.

Second, we consider a constrained combination (Constrained), where for any given input we use either the token-level or sequence-level loss, but not both. The motivation is to maintain good token-level accuracy while optimizing on the sequence-level. In particular, a sample is processed with the sequence loss if the token loss under the current model is at least as good as the token loss of a baseline model $\mathcal{L}^b_{\texttt{TokLS}}$. Otherwise, we update according to the token loss:

$$\mathcal{L}_{\texttt{Constrained}} = \begin{cases} \mathcal{L}_{\texttt{Risk}} & \mathcal{L}_{\texttt{TokLS}} \leq \mathcal{L}^b_{\texttt{TokLS}} \\ \mathcal{L}_{\texttt{TokLS}} & \text{otherwise} \end{cases} \quad (9)$$

In this work we use a fixed baseline model that was trained with a token-level loss to convergence.

4 Candidate Generation Strategies

The sequence-level objectives we consider (§3.2) are defined over the entire space of possible output sequences, which is intractable to enumerate or

score with our models. We therefore use a subset of K candidate sequences $\mathcal{U}(\mathbf{x}) = \{u_1, \ldots, u_K\}$, which we generate with our models.

We consider two search strategies for generating the set of candidate sequences. The first is *beam search*, a greedy breadth-first search that maintains a "beam" of the top-K scoring candidates at each generation step. Beam search is the *de facto* decoding strategy for achieving state-of-the-art results in machine translation. The second strategy is *sampling* (Chatterjee and Cancedda, 2010), which produces K independent output sequences by sampling from the model's conditional distribution. Whereas beam search focuses on high probability candidates, sampling introduces more diverse candidates (see comparison in §6.5).

We also consider both online and offline candidate generation settings in §6.4. In the online setting, we regenerate the candidate set every time we encounter an input sentence $\mathbf{x}$ during training. In the offline setting, candidates are generated before training and are never regenerated. Offline generation is also embarrassingly parallel because all samples use the same model. The disadvantage is that the candidates become stale. Our model may perfectly be able to discriminate between them after only a single update, hindering the ability of the loss to correct eventual search errors.[4]

Finally, while some past work has added the reference target to the candidate set, i.e., $\mathcal{U}'(\mathbf{x}) = \mathcal{U}(\mathbf{x}) \cup \{\mathbf{t}\}$, we find this can destabilize training since the model learns to assign low probabilities nearly everywhere, ruining the candidates generated by the model, while still assigning a slightly higher score to the reference (cf. Shen et al. (2016)). Accordingly we do not add the reference translation to our candidate sets.

5 Experimental Setup

5.1 Translation

We experiment on the IWSLT'14 German to English (Cettolo et al., 2014) task using a similar setup as Ranzato et al. (2015), which allows us to compare to other recent studies that also adopted this setup, e.g., Wiseman and Rush (2016).[5] The training data consists of 160K sentence pairs and the validation set comprises 7K sentences randomly sampled and held-out from the train data. We test on the concatenation of *tst2010, tst2011, tst2012, tst2013* and *dev2010* which is of similar size to the validation set. All data is lowercased and tokenized with a byte-pair encoding (BPE) of 14,000 types (Sennrich et al., 2016) and we evaluate with case-insensitive BLEU.

We also experiment on the much larger WMT'14 English-French task. We remove sentences longer than 175 words as well as pairs with a source/target length ratio exceeding 1.5 resulting in 35.5M sentence-pairs for training. The source and target vocabulary is based on 40K BPE types. Results are reported on both newstest2014 and a validation set held-out from the training data comprising 26,658 sentence pairs.

We modify the *fairseq-py* toolkit to implement the objectives described in §3.[6] Our translation models have four convolutional encoder layers and three convolutional decoder layers with a kernel width of 3 and 256 dimensional hidden states and word embeddings. We optimize these models using Nesterov's accelerated gradient method (Sutskever et al., 2013) with a learning rate of 0.25 and momentum of 0.99. Gradient vectors are renormalized to norm 0.1 (Pascanu et al., 2013).

We train our baseline token-level models for 200 epochs and then anneal the learning by shrinking it by a factor of 10 after each subsequent epoch until the learning rate falls below 10^{-4}. All sequence-level models are initialized with parameters of a token-level model before annealing. We then train sequence-level models for another 10 to 20 epochs depending on the objective. Our batches contain 8K tokens and we normalize gradients by the number of non-padding tokens per mini-batch. We use weight normalization for all layers except for lookup tables (Salimans and Kingma, 2016). Besides dropout on the embeddings and the decoder output, we also apply dropout to the input of the convolutional blocks at a rate of 0.3 (Srivastava et al., 2014). We tuned the various parameters above and report accuracy on the test set by choosing the best configuration based on the validation set.

We length normalize all scores and probabilities in the sequence-level losses by dividing by the number of tokens in the sequence so that scores are comparable between different lengths. Ad-

[4] We can mitigate this issue by regenerating infrequently, i.e., once every b batches but we leave this to future work.

[5] Different to Ranzato et al. (2015) we train on sentences of up to 175 rather than 50 tokens.

[6] https://github.com/facebookresearch/fairseq-py.

ditionally, when generating candidate output sequences during training we limit the output sequence length to be less than 200 tokens for efficiency. We generally use 16 candidate sequences per training example, except for the ablations where we use 5 for faster experimental turnaround.

5.2 Abstractive Summarization

For summarization we use the Gigaword corpus as training data (Graff et al., 2003) and pre-process it identically to Rush et al. (2015) resulting in 3.8M training and 190K validation examples. We evaluate on a Gigaword test set of 2,000 pairs identical to the one used by Rush et al. (2015) and report F1 ROUGE similar to prior work. Our results are in terms of three variants of ROUGE (Lin, 2004), namely, ROUGE-1 (RG-1, unigrams), ROUGE-2 (RG-2, bigrams), and ROUGE-L (RG-L, longest-common substring). Similar to Ayana et al. (2016) we use a source and target vocabulary of 30k words. Our models for this task have 12 layers in the encoder and decoder each with 256 hidden units and kernel width 3. We train on batches of 8,000 tokens with a learning rate of 0.25 for 20 epochs and then anneal as in §5.1.

6 Results

6.1 Comparison of Sequence Level Losses

First, we compare all objectives based on a weighted combination with token-level label smoothing (Equation 8). We also show the likelihood baseline (MLE) of Wiseman and Rush (2016), their beam search optimization method (BSO), the actor critic result of Bahdanau et al. (2016) as well as the best reported result on this dataset to date by Huang et al. (2017). We show a like-for-like comparison to Wiseman and Rush (2016) with a similar baseline model below (§6.6).

Table 1 shows that all sequence-level losses outperform token-level losses. Our baseline token-level results are several points above other figures in the literature and we further improve these results by up to 0.61 BLEU with `Risk` training.

6.2 Combination with Token-Level Loss

Next, we compare various strategies to combine sequence-level and token-level objectives (cf. §3.3). For these experiments we use 5 candidate sequences per training example for faster experimental turnaround. We consider `Risk` as sequence-level loss and label smoothing as token-level loss. Table 2 shows that combined objectives perform better than pure `Risk`. The weighted combination (Equation 8) with $\alpha = 0.3$ performs best, outperforming constrained combination (Equation 9). We also compare to randomly choosing between token-level and sequence-level updates and find it underperforms the more principled constrained strategy. In the remaining experiments we use the weighted strategy.

	test	std
MLE (W & R, 2016) [T]	24.03

Table 1: Test accuracy in terms of BLEU on IWSLT'14 German-English translation with various loss functions cf. Figure 1. W & R (2016) refers to Wiseman and Rush (2016), B (2016) to Bahdanau et al. (2016), [S] indicates sequence level-training and [T] token-level training. We report averages and standard deviations over five runs with different random initialization.

	valid	test
`TokLS`	33.11	32.21
`Risk` only	33.55	32.45
`Weighted`	33.91	32.85
`Constrained`	33.77	32.79
Random	33.70	32.61

Table 2: Validation and test BLEU for loss combination strategies. We either use token-level `TokLS` and sequence-level `Risk`individually or combine them as a weighted combination, a constrained combination, a random choice for each sample, cf. §3.3.

6.3 Effect of initialization

So far we initialized sequence-level models with parameters from a token-level model trained with label smoothing. Table 3 shows that initializing weighted `Risk` with token-level label smoothing

	valid	test
TokNLL	32.96	31.74
Risk init with TokNLL	33.27	32.07
Δ	+0.31	+0.33
TokLS	33.11	32.21
Risk init with TokLS	33.91	32.85
Δ	+0.8	+0.64

Table 3: Effect of initializing sequence-level training (Risk) with parameters from token-level likelihood (TokNLL) or label smoothing (TokLS).

	valid	test
Online generation	33.91	32.85
Offline generation	33.52	32.44

Table 4: Generating candidates online or offline.

achieves 0.7-0.8 better BLEU compared to initializing with parameters from token-level likelihood. The improvement of initializing with TokNLL is only 0.3 BLEU with respect to the TokNLL baseline, whereas, the improvement from initializing with TokLS is 0.6-0.8 BLEU. We believe that the regularization provided by label smoothing leads to models with less sharp distributions that are a better starting point for sequence-level training.

6.4 Online vs. Offline Candidate Generation

Next, we consider the question if refreshing the candidate subset at every training step (online) results in better accuracy compared to generating candidates before training and keeping the set static throughout training (offline). Table 4 shows that offline generation gives lower accuracy. However the online setting is much slower, since regenerating the candidate set requires incremental (left to right) inference with our model which is very slow compared to efficient forward/backward over large batches of pre-generated hypothesis. In our setting, offline generation has 26 times higher throughput than the online generation setting, despite the high inference speed of fairseq (Gehring et al., 2017b).

6.5 Beam Search vs. Sampling and Candidate Set Size

So far we generated candidates with beam search, however, we may also sample to obtain a more diverse set of candidates (Shen et al., 2016). Figure 2 compares beam search and sampling for various candidate set sizes on the validation set. Beam search performs better for all candidate set sizes considered. In other experiments, we rely on a candidate set size of 16 which strikes a good balance between efficiency and accuracy.

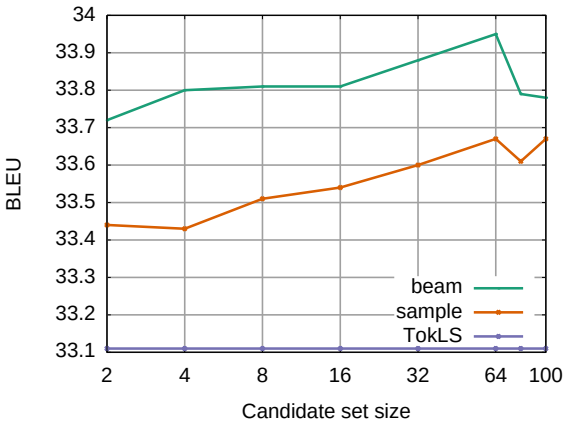

Figure 2: Candidate set generation with beam search and sampling for various candidate set sizes during sequence-level training in terms of validation accuracy. Token-level label smoothing (TokLS) is the baseline.

	BLEU	Δ
MLE	24.03	
+ BSO	26.36	+2.33
MLE Reimplementation	23.93	
+ Risk	26.68	+2.75

Table 5: Comparison to Beam Search Optimization. We report the best likelihood (MLE) and BSO results from Wiseman and Rush (2016), as well as results from our MLE reimplementation and training with Risk. Results based on unnormalized beam search ($k = 5$).

6.6 Comparison to Beam-Search Optimization

Next, we compare classical sequence-level training to the recently proposed Beam Search Optimization (Wiseman and Rush, 2016). To enable a fair comparison, we re-implement their baseline, a single layer LSTM encoder/decoder model with 256-dimensional hidden layers and word embeddings as well as attention and input feeding (Luong et al., 2015). This baseline is trained with Adagrad (Duchi et al., 2011) using a learning rate of 0.05 for five epochs, with batches of 64 sequences. For sequence-level training we initialize weights with the baseline parameters and train

	RG-1	RG-2	RG-L
ABS+ [T]	29.78	11.89	26.97
RNN MLE [T]	32.67	15.23	30.56
RNN MRT [S]	36.54	16.59	33.44
WFE [T]	36.30	17.31	33.88
SEASS [T]	36.15	17.54	33.63

+ Risk RG-1	36.96	17.61	34.18
+ Risk RG-2	36.65	18.32	34.07
+ Risk RG-L	36.70	17.88	34.29

Table 6: Accuracy on Gigaword abstractive summarization in terms of F-measure Rouge-1 (RG-1), Rouge-2 (RG-2), and Rouge-L (RG-L) for token-level label smoothing, and Risk optimization of all three ROUGE F1 metrics. [T] indicates a token-level objective and [S] indicates a sequence level objectives. ABS+ refers to Rush et al. (2015), RNN MLE/MRT (Ayana et al., 2016), WFE (Suzuki and Nagata, 2017), SEASS (Zhou et al., 2017), DRGD (Li et al., 2017).

with Adam (Kingma and Ba, 2014) for another 10 epochs with learning rate 0.00003 and 16 candidate sequences per training example. We conduct experiments with Risk since it performed best in trial experiments.

Different from other sequence-level experiments (§5), we rescale the BLEU scores in each candidate set by the difference between the maximum and minimum scores of each sentence. This avoids short sentences dominating the sequence updates, since candidate sets for short sentences have a wider range of BLEU scores compared to longer sentences; a similar rescaling was used by Bahdanau et al. (2016).

Table 5 shows the results from Wiseman and Rush (2016) for their token-level likelihood baseline (MLE), best beam search optimization results (BSO), as well as our reimplemented baseline. Risk significantly improves BLEU compared to our baseline at +2.75 BLEU, which is slightly better than the +2.33 BLEU improvement reported for Beam Search Optimization (cf. Wiseman and Rush (2016)). This shows that classical objectives for structured prediction are still very competitive.

6.7 WMT'14 English-French results

Next, we experiment on the much larger WMT'14 English-French task using the same model setup as Gehring et al. (2017b). We TokLSfor 15 epochs and then switch to sequence-level training for another epoch. Table 7 shows that sequence-level training can improve an already very strong model by another +0.37 BLEU. Next, we improve the baseline by adding *self-attention* (Paulus et al., 2017; Vaswani et al., 2017) to the decoder network (TokLS + selfatt) which results in a smaller gain of +0.2 BLEU by Risk. If we train Risk only on the news-commentary portion of the training data, then we achieve state of the art accuracy on this dataset of 41.5 BLEU (Xia et al., 2017).

	valid	test
TokLS	34.06	40.58
+ Risk	34.20	40.95
TokLS + selfatt	34.24	41.02
+ in domain	34.51	41.26
+ Risk	34.30	41.22
+ Risk in domain	34.50	41.47

Table 7: Test and valid BLEU on WMT'14 English-French with and without decoder self-attention.

6.8 Abstractive Summarization

Our final experiment evaluates sequence-level training on Gigaword headline summarization. There has been much prior art on this dataset originally introduced by Rush et al. (2015) who experiment with a feed-forward network (ABS+). Ayana et al. (2016) report a likelihood baseline (RNN MLE) and also experiment with risk training (RNN MRT). Different to their setup we did not find a softmax temperature to be beneficial, and we use beam search instead of sampling to obtain the candidate set (cf. §6.5). Suzuki and Nagata (2017) improve over an MLE RNN baseline by limiting generation of repeated phrases. Zhou et al. (2017) also consider an MLE RNN baseline and add an additional gating mechanism for the encoder. Li et al. (2017) equip the decoder of a similar network with additional latent variables to accommodate the uncertainty of this task.

Table 6 shows that our baseline (TokLS) outperforms all prior approaches in terms of ROUGE-2 and ROUGE-L and it is on par to the best previous result for ROUGE-1. We optimize all three ROUGE metrics separately and find that Risk can further improve our strong baseline. We also compared Risk only training to Weighted on this dataset (cf. §6.2) but accuracy was generally lower on the validation set: RG-1

(36.59 `Risk` only vs. 36.67 `Weighted`), RG-2 (17.34 vs. 18.05), and RG-L (33.66 vs. 33.98).

7 Conclusion

We present a comprehensive comparison of classical losses for structured prediction and apply them to a strong neural sequence to sequence model. We found that combining sequence-level and token-level losses is necessary to perform best, and so is training on candidates decoded with the current model.

We show that sequence-level training improves state-of-the-art baselines both for IWSLT'14 German-English translation and Gigaword abstractive sentence summarization. Structured prediction losses are very competitive to recent work on reinforcement or beam optimization. Classical expected risk can slightly outperform beam search optimization (Wiseman and Rush, 2016) in a like-for-like setup. Future work may investigate better use of already generated candidates since invoking generation for each batch slows down training by a large factor, e.g., mixing with fresh and older candidates inspired by MERT (Och, 2003).

Deep Dirichlet Multinomial Regression

Adrian Benton Mark Dredze

Johns Hopkins University
Baltimore, MD 21218, USA
{adrian,mdredze}@cs.jhu.edu

Abstract

Dirichlet Multinomial Regression (*DMR*) and other supervised topic models can incorporate arbitrary document-level features to inform topic priors. However, their ability to model corpora are limited by the representation and selection of these features – a choice the topic modeler must make. Instead, we seek models that can learn the feature representations upon which to condition topic selection. We present *deep Dirichlet Multinomial Regression* (*dDMR*), a generative topic model that simultaneously learns document feature representations and topics. We evaluate *dDMR* on three datasets: New York Times articles with fine-grained tags, Amazon product reviews with product images, and Reddit posts with subreddit identity. *dDMR* learns representations that outperform *DMR* and *LDA* according to heldout perplexity and are more effective at downstream predictive tasks as the number of topics grows. Additionally, human subjects judge *dDMR* topics as being more representative of associated document features. Finally, we find that supervision leads to faster convergence as compared to an *LDA* baseline and that *dDMR*'s model fit is less sensitive to training parameters than *DMR*.

1 Introduction

Fifteen years of research on topic models, starting from Latent Dirichlet Allocation (*LDA*) (Blei et al., 2003), have led to a variety of models for numerous data settings. These models identify sets (distributions) of related words that reflect semantic topics in a large corpus of text data. Topic models are now routinely used in the social sciences and humanities to analyze text collections (Schmidt, 2012).

Document collections are often accompanied by metadata and annotations, such as a book's author, an article's topic descriptor tags, images associated with a product review, or structured patient information associated with clinical records. These document-level annotations can provide additional supervision for guiding topic model learning. Additional information can be integrated into topic models using either *downstream* or *upstream* models. Downstream models, such as supervised *LDA* (Mcauliffe and Blei, 2008), assume that these additional document features are generated from each document's topic distribution. These models are most helpful when you desire topics that are predictive of the output, such as models for predicting the sentiment of product reviews. Upstream models, such as Dirichlet Multinomial Regression (*DMR*), condition each document's topic distribution on document features, such as author (Rosen-Zvi et al., 2004), social network (McCallum et al., 2007), or document labels (Ramage et al., 2009). Previous work has demonstrated that upstream models tend to outperform downstream models in terms of model fit, as well as extracting topics that are useful in prediction of related tasks (Benton et al., 2016).

DMR is an upstream topic model with a particularly attractive method for incorporating arbitrary document features. Rather than defining specific random variables in the graphical model for each new document feature, *DMR* treats the document annotations as features in a log-linear model. The log-linear model parameterizes the Dirichlet prior for the document's topic distribution, making the Dirichlet's hyperparameter (typically α) document-specific. By making no assumptions on model structure of new random variables, *DMR* is flexible to incorporating different types of features.

Despite this flexibility, *DMR* models are typically restricted to a small number of document features. Several reasons account for this restriction: 1) Many text corpora only have a small number of document-level features; 2) Model hyperparameters become less interpretable as the dimensionality grows; and 3) *DMR* is liable to overfit the hyperparameters when the dimensionality of document features is high. In practice, applications of *DMR* are limited to settings with a small number of features, or where the analyst selects a few meaningful features

Proceedings of NAACL-HLT 2018, pages 365–374
New Orleans, Louisiana, June 1 - 6, 2018.

by hand.

A solution to this restriction is to learn low-dimensional representations of document features. Neural networks have shown wide-spread success at learning generalizable representations, often obviating the need for hand designed features (Collobert and Weston, 2008). A prime example is word embedding features in natural language processing, which supplant traditional lexical features (Brown et al., 1992; Mikolov et al., 2013; Pennington et al., 2014). Jointly learning networks that construct feature representations along with the parameters of a standard NLP model has become a common approach. For example, (Yu et al., 2015) used a tensor decomposition to jointly learn features from both word embeddings and traditional NLP features, along with the parameters of a relation extraction model. Additionally, neural networks can handle a variety of data types, including text, images and general metadata features. This makes them appropriate for addressing dimensionality reduction in *DMR*.

We propose **deep** Dirichlet Multinomial Regression (*dDMR*), a model that extends *DMR* by introducing a deep neural network that learns a transformation of the input metadata into features used to form the Dirichlet hyperparameter. Whereas *DMR* parameterizes the document-topic priors as a log-linear function of document features, *dDMR* jointly learns a feature representation for each document along with a log-linear function that best captures the distribution over topics. Since the function mapping document features to topic prior is a neural network, we can jointly optimize the topic model and the neural network parameters by gradient ascent and back-propagation. We show that *dDMR* can use network architectures to better fit text corpora with high-dimensional document features as compared to other supervised topic models. The topics learned by *dDMR* are judged as being more representative of document features by human subjects. We also find that *dDMR* tends to converge in many fewer iterations than *LDA*, and also does not suffer from tuning difficulties that *DMR* encounters when applied to high-dimensional document features.

2 Model

Our model builds on the generative model of *DMR*: an LDA-style topic model that replaces the hyperparameter (vector) of the topic distribution Dirichlet prior with a hyperparameter that is output from a log-linear model given the document features. Our model deep DMR (*dDMR*) replaces this log-linear model with an arbitrary function f that maps a real-valued vector of dimension F to a representation of dimension K. For simplicity we make no assumptions on the choice of this function, only

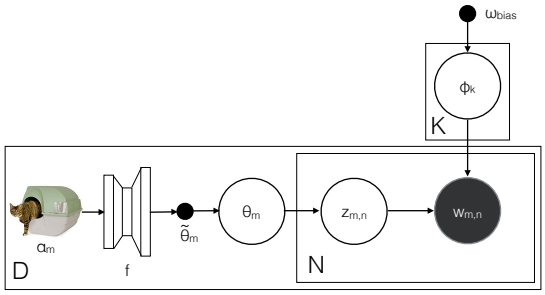

Figure 1: The graphical model for *dDMR*. f is shown as a feedforward fully-connected network, and the document features are given by the image (a cat carrier).

that it can be optimized to minimize a cost on its output by gradient ascent. In practice, we define this function as a neural network, where the architecture of this network is informed by the type of document features, e.g. a convolutional neural network for images. We use neural networks since they are expressive, generalize well to unseen data, and can be jointly trained using straightforward gradient ascent with back-propagation.

The generative story for *dDMR* is as follows:

1. Representation function $f \in \mathbb{R}^F \rightarrow \mathbb{R}^K$
2. Topic-word prior parameters: $\omega^{bias} \in \mathbb{R}^V$
3. For each document m with features $\alpha_m \in \mathbb{R}^F$, generate document prior:
   (a) $\widetilde{\theta}_m = exp(f(\alpha_m))$
   (b) $\theta_m \sim Dirichlet(\widetilde{\theta}_m)$
4. For each topic k, generate word distribution:
   (a) $\widetilde{\phi}_k = exp(\omega^{bias})$
   (b) $\phi_k \sim Dirichlet(\widetilde{\phi}_k)$
5. For each token (m, n), generate data:
   (a) Topic (unobserved): $z_{m,n} \sim \theta_m$
   (b) Word (observed): $w_{m,n} \sim \phi_{z_{m,n}}$

where V is the vocabulary size and K are the number of topics. In practice, the document features need not be restricted to fixed-length feature vectors, e.g. f may be an RNN that maps from a sequence of characters to a fixed length vector in $\mathbb{R}^k$. *DMR* is a special case of *dDMR* with the choice of a linear function for f. Figure 1 displays the graphical model diagram for *dDMR*.

2.1 Inference and Parameter Estimation

We infer the random variables of the topic model using collapsed Gibbs sampling, and estimate the model parameters using gradient ascent with back-propagation. We use alternating optimization: one

iteration of collapsed Gibbs sampling (sample topics for each word) and then an update of the parameters of f by gradient ascent to maximize the log-likelihood of the tokens and topic assignments. Given the parameters, the sampling step remains unchanged from *LDA* (Griffiths and Steyvers, 2004). The network parameters are estimated via back-propagation through the network for a fixed sample. Eq. 1 shows the gradient of the data log-likelihood, $\mathscr{L}$, with respect to $\widetilde{\theta}_{m,k} = exp(f(\alpha_m)_k)$, the prior weight of topic k for document m. ψ is the digamma function (derivative of the log-gamma function), n_m is the number of tokens in document m, and $n_{m,k}$ is the count of how many tokens topic k was assigned to in document m.

$$\frac{\delta \mathscr{L}}{\delta \widetilde{\theta}_{m,k}} = \psi(\sum_{k=1}^{K} \widetilde{\theta}_{m,k}) - \psi(\sum_{k=1}^{K} \widetilde{\theta}_{m,k} + n_m) + \psi(\widetilde{\theta}_{m,k} + n_{m,k}) - \psi(\widetilde{\theta}_{m,k}) \quad (1)$$

3 Data

We explore the flexibility of our model by considering three different datasets that include different types of metadata associated with each document. For each dataset, we describe the documents and metadata.

New York Times The New York Times Annotated Corpus (Sandhaus, 2008) contains articles with extensive metadata used for indexing by the newspaper. For supervision, we used the "descriptor" tags associated with each article assigned by archivists. These tags reflect the topic of an article, as well as organizations or people mentioned in the article. We selected all articles published in 1998, and kept those tags that were associated with at least 3 articles in that year – 2424 unique tags. 20 of the 200 most frequent tags were held out from training for validation purposes: { *"education and schools", "law and legislation", "advertising", "budgets and budgeting", "freedom and human rights", "telephones and telecommunications", "bombs and explosives", "sexual harassment", "reform and reorganization", "teachers and school employees", "tests and testing", "futures and options trading", "boxing", "firearms", "company reports", "embargoes and economic sanctions", "hospitals", "states (us)", "bridge (card game)",* and *"auctions"*}. Articles contained a mean of 2.1 tags, with 738 articles not containing any of these tags. Tags were represented using a one-hot encoding.

Articles were tokenized by non-alphanumeric characters and numerals were replaced by a special token. Words occurring in more than 40% of documents were removed, and only the 15,000 most frequent types were retained. There were a total of 89,397 articles with an average length of 158 tokens per article.

Amazon Reviews The Amazon product reviews corpus(McAuley and Yang, 2016) contains reviews of products as well as images of the product. We sampled 100,000 Amazon product reviews: 20,000 reviews sampled uniformly from the *Musical Instruments*, *Patio, Lawn, & Garden*, *Grocery & Gourmet Food*, *Automotive*, and *Pet Supplies* product categories. We hypothesize that knowing information about the product's appearance will indicate which words appear in the review, especially for product images occurring in these categories. 66 of the reviews we sampled contained only highly infrequent tokens, and were therefore removed from our data, leaving 99,934 product reviews. Articles were preprocessed identically to the New York Times data.

We include images as supervision by using the 4096-dimensional second fully-connected layer of the Caffe convolutional neural network reference model, trained to predict ImageNet object categories[1]. Using these features as supervision to *dDMR* is similar to fine-tuning a pre-trained CNN to predict a new set of labels. Since the Caffe reference model is already trained on a large corpus of images, we chose to fine-tune only the final layers so as to learn a transformation of the already learned representation.

Reddit We selected a sample of Reddit posts made in January 2016. A standard stop list was used to remove frequent function words and we restricted the vocabulary to the 30,000 most frequent types. We restricted posts made to subreddits, collections of topically-related threads, with at least ten comments in this month (26,830 subreddits), and made by users with at least five comments across these subreddits (total of 1,351,283 million users). We then sampled 10,000 users uniformly at random and used all their comments as a corpus, for a total of 389,234 comments over 7,866 subreddits (token length mean: 16.3, median: 9)[2].

This corpus differs from the others in two ways. First, Reddit documents are very short, which is problematic for topic models that rely on detecting correlations in token use. Second, the Reddit metadata that may be useful for topic modeling is necessarily high-dimensional (e.g. subreddit identity, a proxy for topical content). *DMR* may have trouble exploiting high-dimensional supervision.

4 Experiments

Model Estimation We used the same procedure for training topic models on each dataset. Hyperparameter gradient updates were performed after

[1]Features used directly from http://jmcauley.ucsd.edu/data/amazon/

[2]The sampled comment IDs can be found here: https://github.com/abenton/deep-dmr/blob/master/resources/reddit_comment_ids.txt

a burnin period of 100 Gibbs sampling iterations. Hyperparameters were updated with the adaptive learning rate algorithm Adadelta (Zeiler, 2012), with a tuned base learning rate and fixed $\rho = 0.95$[3]. All models were trained for a maximum of 15,000 epochs, with early stopping if heldout perplexity showed no improvements after 200 epochs (evaluated once every 20 epochs). Hyperparameters were fit on every other token in the corpus, and (heldout) log-likelihood/perplexity was calculated on the remaining tokens.

For the architecture of the *dDMR* model we used single-hidden-layer multi-layer perceptrons (MLPs), with rectified linear unit (ReLU) activations on the hidden layer, and linear activation on the output layer. We sampled three architectures for each dataset, by drawing layer widths independently at random from $[10, 500]$, and also included two architectures with $(50, 10)$ and $(100, 50)$, *(hidden, output)* layers [4] . We compare the performance of *dDMR* to *DMR* trained on the same feature set as well as *LDA*.

For the New York Times dataset, we also compare *dDMR* to *DMR* trained on features after applying principal components analysis (PCA) to reduce the dimensionality of descriptor feature supervision, sweeping over PCA projection width in $\{10, 50, 100, 250, 500, 1000\}$. Comparing performance of *dDMR* to PCA-reduced *DMR* tests two modeling choices. First, it tests the hypothesis that explicitly learning a representation for document annotations to maximize data likelihood produces a "better-fit" topic model than learning this annotation representation in unsupervised fashion – a two-step process. It also lets us determine if a linear dimensionality reduction technique is sufficient to learning a good feature representation for topic modeling, as opposed to learning a non-linear transformation of the document supervision. Note that we cannot apply PCA to reduce the dimensionality for subreddit id in Reddit since it is a one-hot feature.

Documents in each dataset were partitioned into ten equally-sized folds. Model training parameters of L1 and L2 regularization penalties on feature weights for *DMR* and *dDMR* and the base learning rate for each model class were tuned to minimize heldout perplexity on the first fold. These were tuned *independently for each model*, with number of topics fixed to 10, and *dDMR* architecture fixed to narrow layer widths (50, 10). Model selection was based on the macro-averaged performance on the next eight folds, and we report performance on the remaining fold. We selected models separately for each evaluation metric. For *dDMR*, model selection amounts to selecting the document prior architecture, and for *DMR* with PCA-reduced feature supervision, model selection involved selecting the PCA projection width.

Evaluation Each model was evaluated according to heldout perplexity, topic coherence by normalized pointwise mutual information (NPMI) (Lau et al., 2014), and a dataset-specific predictive task.

Heldout perplexity was computed by only aggregating document-topic and topic-word counts from every other token in the corpus, and evaluating perplexity on the remaining heldout tokens. This corresponds to the "document completion" evaluation method as described in (Wallach et al., 2009), where instead of holding out the words in the second half of a document, every other word is held out.

NPMI (Lau et al., 2014) computes a an automatic measure of topic quality, the sum of pointwise mutual information between pairs of m most likely words normalized by the negative log of each pair jointly occurring within a document (Eq. 2). We calculated this topic quality metric on the top 20 most probable words in each topic, and averaged over the most coherent 1, 5, 10, and over all learned topics. However, models were selected to only maximize average NPMI over all topics.

$$\texttt{NPMI} = \sum_{i=1}^{m} \sum_{j=i+1}^{m} \frac{\log \frac{P(w_i, w_j))}{P(w_i)P(w_j)}}{-\log P(w_i, w_j)} \quad (2)$$

For prediction tasks, we used the sampled topic distribution associated with a document, averaged over the last 100 iterations, as features to predict a document-level label. For New York Times articles we predicted 10 of the 200 most frequent descriptor tags restricting to articles with exactly one of these descriptors. For Amazon, we predicted the product category a document belonged to (one of five), and for Reddit we predicted a heldout set of document subreddit IDs. In the case of Reddit, these heldout subreddits were 10 out of the 100 most prevalent in our data, and were held out similar to the New York Times evaluation. SVM models were fit on inferred topic distribution features and were then evaluated according to accuracy, F1-score, and area under the ROC curve. The SVM slack parameter was tuned by 4-fold cross-validation on 60% of the documents, and evaluated on the remaining 40%.

We also collected human topic judgments using Amazon Mechanical Turk (Callison-Burch and

[3]We found this adaptive learning rate algorithm improved model fit in many fewer iterations than gradient descent with tuned step size and decay rate for all models.

[4]We included these two very narrow architectures to ensure that some architecture learned a small feature representation, generalizing better when features are very noisy or only provide a weak signal for topic modeling. We restricted ourselves to only train *dDMR* models with single-hidden-layer MLPs in the priors for simplicity and to avoid model fishing.

Table 1: Test fold heldout perplexity for each dataset and model for number of topics Z. Standard error of mean heldout perplexity over all cross-validation folds in parentheses.

Dredze, 2010). Each subject was presented with a human-readable version of the features used for supervision. For New York Times articles we showed the descriptor tags, for Amazon the product image, and for Reddit the name, title, and public description of the subreddit. We showed the top twenty words for the most probable topic sampled for the document with those features, as learned by two different models. One topic was learned by *dDMR* and the other was either learned by *LDA* or *DMR*. The topics presented were from the 200-topic model architecture that maximized NPMI on development folds. Annotators were asked "*to choose which word list best describes a document* ..." with the displayed features. The topic learned by *dDMR* was shuffled to lie on either the right or left for each Human Intelligence Task (HIT). We obtained judgments on 1,000 documents for each dataset and each model evaluation pair – 6,000 documents in all. This task can be difficult for many of the features, which may be unclear (e.g. descriptor tags without context) or difficult to interpret (e.g. images of automotive parts). We excluded the document text since we did not want subjects to evaluate topic quality based on token overlap with the actual document.

5 Results

Model Fitting *dDMR* achieves lower perplexity than *LDA* or *DMR* for most combinations of number of topics and dataset (Table 1). It is striking that *DMR* achieves higher perplexity than *LDA* in many of these conditions. This is particularly true for the Amazon dataset, where *DMR* consistently lags behind *LDA*. *Supervision alone does not improve topic model fit if it is too high-dimensional for learning.* Perplexity is higher on the Reddit data for all models due to both a larger vocabulary size and shorter documents.

It is also worth noting that finding a low-dimensional linear projection of the supervision features with PCA does not improve model fit as well as *dDMR*. *dDMR* benefits both from joint learning to maximize corpus log-likelihood and possibly by the flexibility of learning non-linear projection (through the hidden layer ReLU activations).

Another striking result is the difference in speed of convergence between the supervised models and *LDA* (Figure 2). Even supervision that provides a weak signal for topic modeling, such as Amazon product image features, can speed convergence over *LDA*. In certain cases (Figure 2 left), training *dDMR* for 1,000 iterations results in a lower perplexity model than *LDA* trained for over 10,000 iterations.

In terms of actual run time, parallelization of model training differs between the supervised model and *LDA*. Gradient updates necessary for learning the representation can be trivially distributed across multiple cores using optimized linear algebra libraries (e.g. BLAS), mitigating the additional cost incurred by hyperparameter updates in supervised models. In contrast, the Gibbs sampling iterations can also be parallelized, but not as easily, ultimately making resampling topics the most expensive step in model training. Because of this, the potential difference in runtime for a single iteration between *dDMR* and *LDA* is small, with the former converging in far fewer iterations. In our experiments, per iteration time taken by *DMR* or *dDMR* was at most twice as long as *LDA* across all experiments.

dDMR performance is also insensitive to training parameters relative to *DMR*. While *DMR* requires heavy L1 and L2 regularization and a very small step size to achieve low heldout perplexity, *dDMR* is relatively insensitive to the penalty on regularization and benefits from a higher base learning rate (Figure 3). We found that dDMR *is easier to tune than* DMR, requiring less exploration of the training parameters. This is also corroborated by higher variance in perplexity achieved by *DMR* across different cross-validation folds (Table 1).

Topic Quality Results for the automatic topic quality evaluation, NPMI, are mixed across datasets. In many cases, *LDA* and *DMR* score highly according to NPMI, despite achieving higher heldout perplexity than *dDMR* (Table 2). This may not be surprising as previous work has found that perplexity does not correlate well with human judgments of topic coherence (Lau et al., 2014).

However, in the human evaluation, subjects find that *dDMR*-learned topics are more representative of document annotations than *DMR* (Table 3). While subjects only statistically significantly favored *dDMR* models over *LDA* on the Reddit data, they favored *dDMR* topics over *LDA* across all datasets, and significantly preferred *dDMR* top-

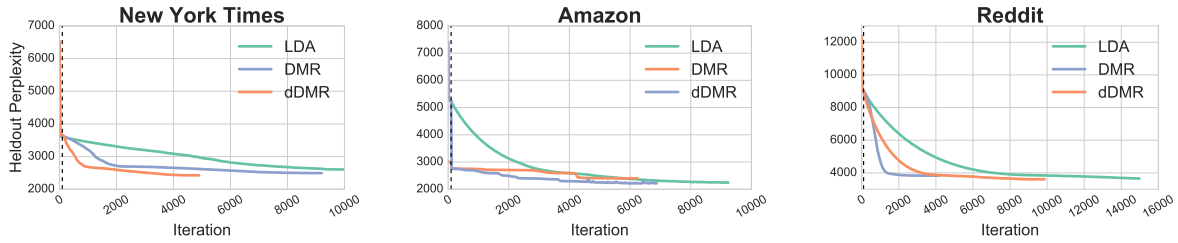

Figure 2: Heldout perplexity as a function of iteration for lowest-perplexity models with $Z = 100$. The vertical dashed line indicates when models are burned in and hyperparameter optimization begins.

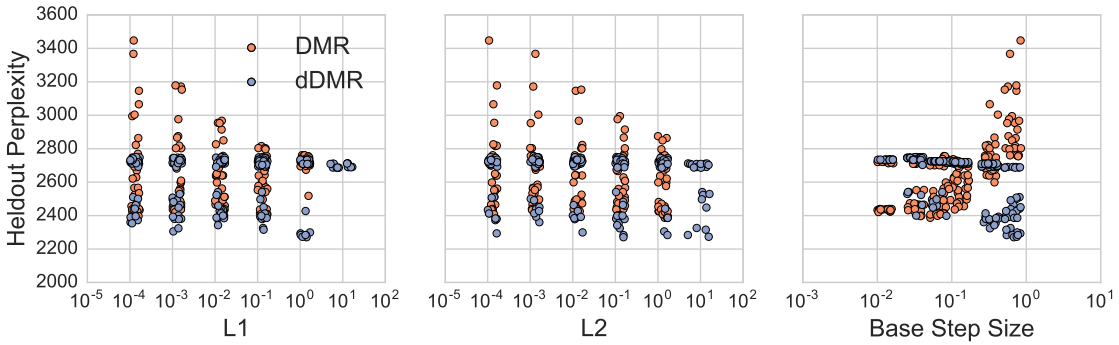

Figure 3: Heldout perplexity on the Amazon data tuning fold for *DMR* (orange) and *dDMR* (purple) with a (50, 10) layer architecture as a function of training parameters: L1, L2 feature weight regularization, and base learning rate. All models were trained for a fixed 5,000 iterations, with horizontal jitter added to each point.

ics over *DMR* on two of the three datasets. This is contrary to themodel rankings according to NPMI, which suggest that *DMR* topics are often higher quality when it comes to human interpretability.

We also qualitatively explored the product image representations *DMR* and *dDMR* learned on the Amazon data. To do so, we computed and normalized the prior document distribution for a sample of documents for lowest perplexity *DMR* and *dDMR* $Z = 200$ topic models: $p(k|m) = \frac{\widetilde{\theta}_m}{\sum_{k=1}^{Z} \widetilde{\theta}_{m,k}}$, the prior probability of sampling topic k, conditioned on the features for document m. We then marginalize over topics to yield the conditional probability of a word w given document m: $p(w|m) = \sum_{k=1}^{Z} p(w|k)p(k|m)$. Table 4 contains a sample of these probable words given document supervision. We find that *dDMR* identifies words likely to appear in a review of the product pictured. However, some images lead *dDMR* down a garden path. For example, a bottle of "Turtle Food" should not be associated with words for human consumables like "coffee" and "chocolate", despite the container resembling some of these products. However, the image-specific document priors *DMR* learned are not as sensitive to the actual product image as those learned by *dDMR*. The prior conditional probabilities $p(w|m)$ for "Turtle Food", "Slushy Magic Cup", and "Rawhide Dog Bones" product images are all ranked identically by *DMR*.

Predictive Performance Finally, we consider the utility of the learned topic distributions for downstream prediction tasks, a common use of topic models. Although token perplexity is a standard measure of topic model fit, it has no direct relationship with how topic models are typically used: to identify consistent themes or reduce the dimensionality of a document corpus. We found that features based on topic distributions from *dDMR* outperform *LDA* and *DMR* on the Amazon and Reddit data when the number of topics fit is large, although they fail to outperform *DMR* on New York Times (Table 5). Heldout perplexity is strongly correlated with predictive performance, with a Pearson correlation coefficient, $\rho = 0.898$ between F1-score and heldout perplexity on the Amazon data. This strong correlation is likely due to the tight relationship between words used in product reviews and product category: a model that assigns high likelihood to a words in a product review corpus should also be informative of the product categories. Prior work showed that upstream supervised topic models, such as *DMR*, learn topic distributions that are effective at downstream prediction tasks (Benton et al., 2016). We find that topic distributions learned by *dDMR* improve over *DMR* in certain cases, particularly as the number of topics increases.

6 Related Work

With the widespread adoption of neural networks, others have sought to combine topic and neural models. One line of work replaces generative, *LDA*-based, topic models with discriminatively-trained models based on neural networks. (Cao et al., 2015) model θ and ϕ using neural networks with softmax output layers and learn network parameters that maximize data likelihood. They also learn n-gram embeddings to identify topics whose elements are not restricted to unigrams. (Chen et al., 2015) similarly expresses the (smoothed) supervised LDA (Mcauliffe and Blei, 2008) generative model as a neural network, and give an algorithm to discriminatively train it. (Wan et al., 2012) take a similar approach to *dDMR* where they use a neural network to extract image representations that maximize the probability of SIFT descriptors extracted from the image. However, this model is used for image classification, not for exploring a corpus of documents as is typical of topic models. These models are computationally attractive in that they avoid approximating the posterior distribution of topic assignments given tokens by dropping the assumption that θ and ϕ are drawn from Dirichlet priors. Model fitting is performed by back-propagation of a max-margin cost. In contrast, we use neural networks to learn feature representations for documents, not as a replacement for the *LDA* generative story. This is similar to variants of SPRITE (Paul and Dredze, 2015), where many document-level factors are combined to generate a document-topic prior. In contrast to several of these models, the core of our topic model remains unchanged, meaning that *dDMR* is agnostic to many other extensions of *LDA*.

There has been extensive work in modeling both textual and visual topics. Models such as Corr-LDA (Blei and Jordan, 2003) suppose that a text document and associated image features are generated by a shared latent topic. This property is shared by other topic models over images, such as STM-TwitterLDA (Cai et al., 2015) and (Zhang et al., 2015). While these models try to model images, we instead use images in the Amazon data to better estimate topic distributions.

Our experiment on using images to model Ama-

Table 4: Top twenty words associated with each of the product images – learned by *dDMR* vs. *DMR* ($Z = 200$). These images were drawn at random from the Amazon corpus (no cherry-picking involved). Word lists were generated by marginalizing over the prior topic distribution associated with that image, and then normalizing each word's probability by subtracting off its mean marginal probability across all images in the corpus. This is done to avoid displaying highly frequent words. Words that differ between each model's ranked list are in bold.

zon product reviews resembles work on image caption generation, yet the similarity is superficial. The relationship between an image and its caption is relatively tight (Fang et al., 2015) – objects in the image will likely be referenced in the caption. For Amazon product reviews, visual features of the product, like color, may be explicitly mentioned in the review, but then again, they may not. Also, the aim of topic models is to extract common themes of co-occurring words, and how those themes are distributed across each document. The similarity between our work and captioning lies only in the fact that we extract image features from a CNN trained as an object recognizer to inform document-topic distributions.

7 Conclusion

We present deep Dirichlet Multinomial Regression, a supervised topic model which both learns a representation of document-level features and how to use that representation for informing a topic distribution. We demonstrate the flexibility of our model on three corpora with different types of metadata: topic descriptor tags, images, and subreddit IDs. *dDMR* is better able to fit text corpora with high-dimensional supervision compared to *LDA* or *DMR*. Furthermore, we find that document supervision greatly reduces the number of Gibbs sampling iterations for a topic model to converge, and that the *dDMR* prior architecture makes it more robust to training parameters than *DMR*. We also find that the topic distributions learned by *dDMR* are more predictive of external

Abstract

Millions of conversations are generated every day on social media platforms. With limited attention, it is challenging for users to select which discussions they would like to participate in. Here we propose a new method for microblog conversation recommendation. While much prior work has focused on post-level recommendation, we exploit both the conversational context, and user content and behavior preferences. We propose a statistical model that jointly captures: (1) *topics* for representing user interests and conversation content, and (2) *discourse modes* for describing user replying behavior and conversation dynamics. Experimental results on two Twitter datasets demonstrate that our system outperforms methods that only model content without considering discourse.

1 Introduction

Online platforms have revolutionized the way individuals collect and share information (O'Connor et al., 2010; Lee and Ma, 2012; Bakshy et al., 2015), but the vast bulk of online content is irrelevant or unpalatable to any given individual. A user interested in political discussion, for instance, might prefer content concerning a specific candidate or issue, and only then if discussed in a positive light without controversy (Adamic and Glance, 2005; Bakshy et al., 2015).

How do individuals facing such large quantities of superfluous material select which conversations to engage in, and how might we better algorithmically recommend conversations suited to individual users? We approach this problem from a *microblog conversation recommendation* framework. Where prior work has focused on the content of individual posts for recommendation (Chen et al., 2012; Yan et al., 2012; Vosecky et al., 2014; He and Tan, 2015), we examine the entire history and context of a conversation, including both topical content and *discourse modes* such as agreement, question-asking, argument and other dialogue acts (Ritter et al., 2010).[1] And where Backstrom et al. (2013) leveraged conversation reply structure (such as previous user engagement), their model is unable to predict first entry into new conversations, while ours is able to predict both new

Conversation 1

[1]In this paper, *discourse mode* refers to a certain type of dialogue act, e.g., agreement or argument. The *discourse structure* of a conversation means some combination (or a probability distribution) of discourse modes.

Proceedings of NAACL-HLT 2018, pages 375–385
New Orleans, Louisiana, June 1 - 6, 2018.

and repeated entry into conversations based on a combination of topical and discourse features.

To illustrate the interplay between topics and discourse, Figure 1 displays two snippets of conversations on Twitter collected during the 2016 United States presidential election. User U_1 participates in both conversations. The first conversation is centered around Clinton, and U_1, who is more typically involved with conversations about candidate Sanders, does not return. In the second conversation, however, U_1 is involved in a heated back-and-forth debate, and thus is drawn back to a conversation that they may otherwise have abandoned but for their enjoyment of adversarial discourse.

Effective conversation prediction and recommendation requires an understanding of both user interests and discourse behaviors, such as agreement, disagreement, inquiry, backchanneling, and emotional reactions. However, acquiring manual labels for both is a time-consuming process and hard to scale for new datasets. We instead propose a unified statistical learning framework for conversation recommendation, which jointly learns (1) hidden factors that reflect *user interests* based on conversation history, and (2) *topics* and *discourse modes* in ongoing conversations, as discovered by a novel probabilistic latent variable model. Our model is built on the success of collaborative filtering (CF) in recommendation systems, where latent dimensions of product ratings or movie reviews are extracted to better capture user preferences (Linden et al., 2003; Salakhutdinov and Mnih, 2008; Wang and Blei, 2011; McAuley and Leskovec, 2013). To the best of our knowledge, we are the first to model *both* topics and discourse modes as part of a CF framework and apply it to microblog conversation recommendation.[2]

Experimental results on two Twitter conversation datasets show that our proposed model yields significantly better performance than state-of-the-art post-level recommendation systems. For example, by leveraging both topical content and discourse structure, our model achieves a mean average precision (MAP) of 0.76 on conversations about the U.S. presidential election, compared with 0.70 by McAuley and Leskovec (2013), which only considers topics. We further conducted detailed analysis on the latent topics and discourse modes and find that our model can discover reasonable topic and discourse representations, which play an important role in characterizing reply behaviors. Finally, we also provide a pilot study on recommendation for first time replies, which shows that our model outperforms comparable recommendation systems.

The rest of this paper is structured as follows. The related work is discussed in Section 2. We then present our microblog conversation recommendation model in Section 3. The experimental setup and results are described in Sections 4 and 5. Finally, we conclude in Section 6.

2 Related Work

Social media has attracted increasing attention in digital communication research (Agichtein et al., 2008; Kwak et al., 2010; Wu et al., 2011). The problem studied here is closely related to work on recommendation and response prediction in microblogs (Artzi et al., 2012; Hong et al., 2013), where the goal is to predict whether a user will share or reply to a given post. Existing methods focus on measuring features that reflect personalized user interests, including topics (Hong et al., 2013) and network structures (Pan et al., 2013; He and Tan, 2015). These features have been investigated under a learning to rank framework (Duan et al., 2010; Artzi et al., 2012), graph ranking models (Yan et al., 2012; Feng and Wang, 2013; Alawad et al., 2016), and neural network-based representation learning methods (Yu et al., 2016).

Distinguishing from prior work that focuses on post-level recommendation, we tackle the challenges of predicting user reply behaviors at the conversation-level. In addition, our model not only captures latent factors such as the topical interests of users, but also leverages the automatically learned discourse structure. Much of the previous work on discourse structure and dialogue acts has relied on labeled data (Jurafsky et al., 1997; Stolcke et al., 2000), while unsupervised approaches have not been applied to the problem of conversation recommendation (Woszczyna and Waibel, 1994; Crook et al., 2009; Ritter et al., 2010; Joty et al., 2011).

Our work is also in line with conversation modeling for social media discussions (Ritter et al., 2010; Budak and Agrawal, 2013; Louis and Cohen, 2015; Cheng et al., 2017). Topic modeling

[2]To ensure the general applicability of our approach to domains lacking such information, we do not utilize external features such as network structure, but it may certainly be added in future, more narrowly targeted applications.

has been employed to identify conversation content on Twitter (Ritter et al., 2010). In this work, we propose a probabilistic model to capture both topics and discourse modes as latent variables. A further line of work studies the reposting and reply structure of conversations (Gómez et al., 2011; Laniado et al., 2011; Backstrom et al., 2013; Budak and Agrawal, 2013). But none of this work distinguishes the rich discourse functions of replies, which is modeled and exploited in our work.

3 The Joint Model of Topic and Discourse for Recommendation

Our proposed microblog conversation recommendation framework is based on collaborative filtering and a novel probabilistic graphical model. Concretely, our objective function takes the form:

$$\min \mathcal{L} + \mu \cdot NLL(\mathcal{C} \mid \mathbf{\Theta}) \tag{1}$$

This function encodes two types of information. First, $\mathcal{L}$ models user reply preference in a similar fashion to collaborative filtering (CF) (Hu et al., 2008; Pan et al., 2008). It captures topics of interests and discourse structures users are commonly involved (e.g., argumentation), and takes the form of mean square error (MSE) based on user reply history. This part is detailed in Section 3.1.

The second term, $NLL(\mathcal{C} \mid \mathbf{\Theta})$, denotes the negative log-likelihood of a set of conversations $\mathcal{C}$, with $\mathbf{\Theta}$ containing all parameters. A probabilistic model is described in Section 3.2 that shows how the topical content and discourse structures of conversations are captured by these latent variables.

The hyperparameter μ controls the trade-off between the two effects. ℓ_2 regularization is also added for parameters to avoid model overfitting.

For the rest of this section, we first present the construction of $\mathcal{L}$ and $NLL(\mathcal{C} \mid \mathbf{\Theta})$ in Sections 3.1 and 3.2. We then discuss how these two components can be mutually informed by each other in Section 3.3. Finally, the generative process and parameter learning are described in Section 3.4.

3.1 Reply Preference ($\mathcal{L}$)

Our user reply preference modeling is built on the success of collaborative filtering (CF) for product ratings. However, classic CF problems, such as product recommendation, generally rely on explicit user feedback. Unlike user ratings on products, our input lacks explicit feedback from users about negative preferences and non-response. Therefore, we follow one-class Collaborative Filtering (Hu et al., 2008; Pan et al., 2008), which weights positive instances higher during training and is thus suited to our data. Formally, for user u and conversation c, we measure reply preference based on the MSE between predicted preference score $p_{u,c}$ and reply history $r_{u,c}$. $r_{u,c}$ equals 1 if u is in the conversation history; otherwise, it is 0. The first term of objective (Eq. 1) takes the following form:

$$\mathcal{L} = \sum_{u=1}^{|\mathcal{U}|} \sum_{c=1}^{|\mathcal{C}|} f_{u,c} \cdot (p_{u,c} - r_{u,c})^2 \tag{2}$$

where $\mathcal{U}$ consists of users $\{u\}$ and $\mathcal{C}$ is a set of conversations $\{c\}$ in a dataset. $f_{u,c}$ is the corresponding weight for a conversation c and a target user u. Intuitively, it has a large value if positive feedback (user replied) is observed. Therefore, we adapt the formulation from Pan et al. (2008):

$$f_{u,c} = \begin{cases} s & \text{if } r_{u,c} = 1 \text{ (i.e., user replied)} \\ 1 & \text{if } r_{u,c} = 0 \end{cases} \tag{3}$$

where $s > 1$, an integer hyperparameter to be tuned.

Inspired by prior models (Koren et al., 2009; McAuley and Leskovec, 2013), we propose the following latent factor model to describe $p_{u,c}$:

$$p_{u,c} = \lambda \cdot \gamma_u^U \cdot \gamma_c^C + (1-\lambda) \cdot \delta_u^U \cdot \delta_c^C + b_u + b_c + a \tag{4}$$

γ_u^U and γ_c^C are K-dimensional latent vectors that encode topic-specific information (where K is the number of latent topics) for users and conversations. Specifically, γ_u^U reflects the topical interests of u, with higher value $\gamma_{u,k}^U$ indicating greater interest by u in topic k. γ_c^C captures the extents that topics are discussed in conversation c.

Similarly, D-dimensional vectors δ_u^U and δ_c^C capture discourse structures in shaping reply behaviors (where D is the number of discourse clusters). δ_u^U reflects the discourse behaviors u prefers, such as u_1 often enjoys arguments as in the second conversation of Figure 1, while δ_c^C captures the discourse modes used throughout conversation c. By multiplying user and conversation factors, we can measure the corresponding similarity. The predicted score $p_{u,c}$ thereby reflects the tendency for a user u to be involved in conversation c.

As pointed out by McAuley and Leskovec (2013), these latent vectors often encode hidden factors that are hard to interpret under a CF framework. Therefore, in Section 3.2, we present a novel probabilistic model which can extract interpretable topics and discourse modes as word

distributions. We then describe how they can be aligned with the latent vectors of γ^C and δ^U.

Parameter a is an offset parameter, b_u and b_c are user and conversation biases, and $\lambda \in [0, 1]$ serves as the weight for trading offs of topic and discourse factors in reply preference modeling.

3.2 Corpus Likelihood $NLL(\mathcal{C} \mid \mathbf{\Theta})$

Here we present a novel probabilistic model that learns coherent word distributions for latent topics and discourse modes of conversations. Formally, we assume that each conversation $c \in \mathcal{C}$ contains M_c messages, and each message m has $N_{c,m}$ words. We distinguish three latent components – *discourse*, *topic*, and *background* – underlying conversations, each with their own type of word distribution. At the corpus level, there are K topics represented by word distribution ϕ_k^T ($k = 1, 2, ..., K$), while ϕ_d^D ($d = 1, 2, ..., D$) represents the D *discourse modes* embedded in corpus. In addition, we add a *background* word distribution ϕ^B to capture general information (e.g., common words), which do not indicate either discourse or topic information. ϕ_d^D, ϕ_k^T, and ϕ^B are all multinomial word distributions over vocabulary size V. Below describes more details.

Message-level Modeling. Our model assigns two types of message-level multinomial variables to each message: $z_{c,m}$ reflects its latent *topic* and $d_{c,m}$ represents its *discourse mode*.

Topic assignments. Due to the short nature of microblog posts, we assume each message m in conversation c contains only one topic, indexed as $z_{c,m}$. This strategy has been proven useful to alleviate data sparsity for topic inference (Quan et al., 2015). We further assume messages in the same conversation would focus on similar topics. We thus draw topic $z_{c,m} \sim \theta_c$, where θ_c denotes the fractions of topics discussed in conversation c.

Discourse assignments. To capture discourse behaviors of u, distribution π_u is used to represent the discourse modes in messages posted by u. The discourse mode $d_{c,m}$ for message m is then generated from $\pi_{u_{c,m}}$, where $u_{c,m}$ is the author of m in c.

Word-level Modeling. We aim to separate *discourse*, *topic*, and *background* information for conversations. Therefore, for each word $w_{c,m,n}$ of message m, a ternary switcher $x_{c,m,n} \in \{\text{DISC}, \text{TOPIC}, \text{BACK}\}$ controls word $w_{c,m,n}$ to fall into one of the three types: *discourse*, *topic*, and *background*.

Discourse words (DISC) are indicative of the discourse modes of messages. When $x_{c,m,n} = \text{DISC}$ (i.e., $w_{c,m,n}$ is assigned as a discourse word), word $w_{c,m,n}$ is generated from the discourse word distribution $\phi_{d_{c,m}}^D$ where $d_{c,m}$ is discourse assignment to message m.

Topic words (TOPIC) describe the topical focus of a conversation. When $x_{c,m,n} = \text{TOPIC}$, $w_{c,m,n}$ is assigned as a topic word and generated from $\phi_{z_{c,m}}^T$ – word distribution given topic of m.

Background words (BACK) capture the general information that is not related to discourse or topic. When word $w_{c,m,n}$ is assigned as a background word ($x_{c,m,n} = \text{BACK}$), it is drawn from background distribution ϕ^B.

Switching among Topic, Discourse, and Background. We further assume the word type switcher $x_{c,m,n}$ is sampled from a multinomial distribution which depends on the current discourse mode $d_{c,m}$. The intuition is that messages of different discourse modes may show different distributions of the three word types. For instance, a statement message may contain more content words than a rhetorical question. Specifically, $x_{c,m,n} \sim Multi(\tau_{d_{c,m}})$, where τ_d is a 3-dimension stochastic vector that expresses the appearing probabilities of three kinds of words (DISC, TOPIC, BACK), when the discourse assignment is d. Stop words and punctuations are forced to be labeled as discourse or background. By explicitly distinguishing different types of words with switcher $x_{c,m,n}$, we can thus separate word distributions that reflect discourse, topic, and background information.

Likelihood. Based on the message-level and the word-level generation process, the probability of observing words in the given corpus is:

$$\begin{aligned} & Pr(\mathcal{C} \mid \boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\phi}, \boldsymbol{\tau}, \mathbf{z}, \mathbf{d}, \mathbf{x}) \\ = & \prod_{c=1}^{C} \prod_{m=1}^{M_c} \theta_{c,z_{c,m}} \pi_{u_{c,m},d_{c,m}} \\ & \times \prod_{x_{c,m,n}=\text{BACK}} \tau_{d_{c,m},\text{BACK}} \phi_{w_{c,m,n}}^B \\ & \times \prod_{x_{c,m,n}=\text{DISC}} \tau_{d_{c,m},\text{DISC}} \phi_{d_{c,m},w_{c,m,n}}^D \\ & \times \prod_{x_{c,m,n}=\text{TOPIC}} \tau_{d_{c,m},\text{TOPIC}} \phi_{z_{c,m},w_{c,m,n}}^T \end{aligned} \tag{5}$$

And we use negative log likelihood to model corpus likelihood effect in Eq. 1, i.e., $NLL(\mathcal{C} \mid \mathbf{\Theta}) =$

$-\log(Pr(\mathcal{C} \mid \mathbf{\Theta})$, where parameters set $\mathbf{\Theta} = \{\boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\phi}, \boldsymbol{\tau}, \mathbf{z}, \mathbf{d}, \mathbf{x}\}$.

3.3 Mutually Informed User Preference and Latent Variables

As mentioned above, the hidden factors discovered in Section 3.1 lack interpretability, which can be boosted by the learned latent topics and discourse modes in Section 3.2. However, it is non-trivial to link the topic-related parameters of γ_c^C to the conversation topic distributions of θ_c, since the former takes real values from $-\infty$ to $+\infty$ while the latter is a stochastic vector. Therefore, we follow the strategy from McAuley and Leskovec (2013) to apply a softmax function over γ_c^C:

$$\theta_{c,k} = \frac{exp(\kappa^T \gamma_{c,k}^C)}{\sum_{k'=1}^{K} exp(\kappa^T \gamma_{c,k'}^C)} \tag{6}$$

We further assume that the discourse mode preference by users, δ_u^U, can also be informed by the discourse mode distribution captured by π_u, i.e., a user who enjoys arguments may be willing to participate another. So similarly, we define:

$$\pi_{u,d} = \frac{exp(\kappa^D \delta_{u,d}^U)}{\sum_{d'=1}^{D} exp(\kappa^D \delta_{u,d'}^U)} \tag{7}$$

where κ^T and κ^D are learnable parameters that control the "peakiness" of the transformation. For example, a larger κ^T indicates a more focused conversation, while a smaller κ^T means users discuss diverse topics.

Finally, softmax transformation is also applied to ϕ_k^T, ϕ_d^D, ϕ^B, and τ_d, as done in McAuley and Leskovec (2013), with additional parameters ψ_k^T, ψ_d^D, ψ^B, and χ_d (as shown in Figure 2). This is to ensure that the distributions ϕ_*^* and τ_d are stochastic vectors. In doing so, these distributions can be learned via optimizing ψ_*^* and χ_d, which take any value and thus ensure that the cost function in Eq. 1 is optimized without considering any parameter constraints.

3.4 Generative Process and Model Learning

Our word generation process is displayed in Figure 2 and described as follows:

- Compute topic distribution θ_c by Eq. 6
- For message $m = 1$ to M_c:
  - Compute discourse distribution $\pi_{u_{c,m}}$ by Eq. 7
  - Draw topic assignment $z_{c,m} \sim Multi(\theta_c)$
  - Draw discourse mode $d_{c,m} \sim Multi(\pi_{u_{c,m}})$
  - For word index $n = 1$ to $N_{c,m}$:
    - Draw word type $x_{c,m,n} \sim Multi(\tau_d)$

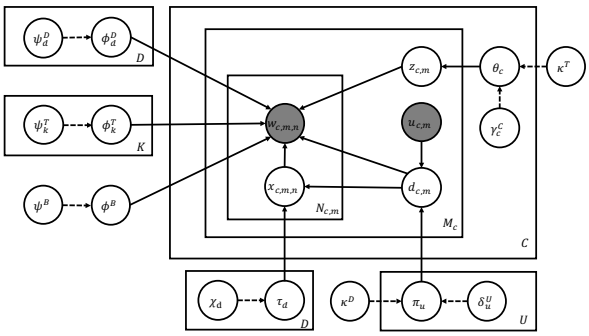

Figure 2: Generative process of our joint model of topic and discourse. u represents users. c represents conversations. Dotted arrows represent the softmax linkings, while solid arrows mean conditional priors.

    - if $x_{c,m,n} == BACK$:
      Draw word $w_{c,m,n} \sim Multi(\phi^B)$
    - if $x_{c,m,n} == DISC$:
      Draw word $w_{c,m,n} \sim Multi(\phi_{d_{c,m}}^D)$
    - if $x_{c,m,n} == TOPIC$:
      Draw word $w_{c,m,n} \sim Multi(\phi_{z_{c,m}}^T)$

Parameter Learning. For learning, we randomly initialize all learnable parameters and then alternate between the following two steps:

Step 1. Fix topic and discourse assignments z and d, and word type switcher x, then optimize the remaining parameters in Eq. 1 by L-BFGS (Nocedal, 1980):

$$\begin{aligned} &\text{Update } a, b, \gamma^*, \delta^*, \kappa^*, \psi^*, \chi = \\ &\qquad argmin\, \mathcal{L} + \mu \cdot NLL(\mathcal{C} \mid \mathbf{\Theta}) \end{aligned} \tag{8}$$

Step 2. Sample topic and discourse assignments z and d at the message level and word type switcher x at the word level, using the distributions, computed according to parameters optimized in step 1:

$$\begin{aligned} &\text{Sample } z_{c,m},\ d_{c,m},\ x_{c,m,n} \text{ with probabilities} \\ &\quad p(z_{c,m} = k) = \theta_{c,k} \\ &\quad p(d_{c,m} = d) = \pi_{u_{c,m},d} \\ &\quad p(x_{c,m,n} = BACK) = \phi_{w_{c,m,n}}^B \tau_{d_{c,m},BACK} \\ &\quad p(x_{c,m,n} = DISC) = \phi_{d_{c,m},w_{c,m,n}}^D \tau_{d_{c,m},DISC} \\ &\quad p(x_{c,m,n} = TOPIC) = \phi_{z_{c,m},w_{c,m,n}}^T \tau_{d_{c,m},TOPIC} \end{aligned} \tag{9}$$

Step 2 is analogous to Gibbs Sampling (Griffiths, 2002) in probabilistic graphical models, such as LDA (Blei et al., 2003). However, distinguishing from previous models, the multinomial distributions in our models are not drawn from a Dirichlet prior. Instead, they are computed based on the parameters learned in Step 1.

Our learning process stops when the change of parameters is small (i.e., below a pre-specified

Dataset	# of user	# of conv	# of msg	Avg msg per user	Avg conv per user
US Election	4,300	2,013	22,092	5.14	1.23
TREC	10,122	7,500	38,999	3.85	1.71

Table 1: Statistics of two datasets.

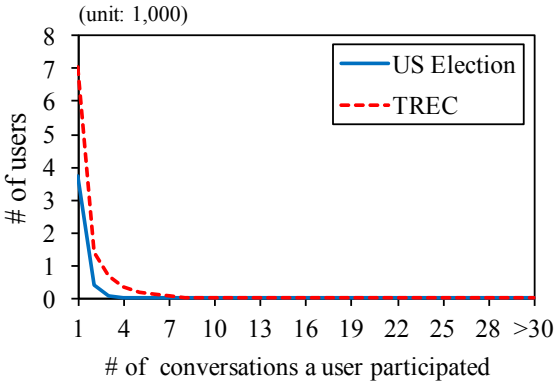

Figure 3: Horizontal axis: number of conversations that a user is involved. Vertical axis: number of users fall in the category (unit: 1,000). Notice that most of users (about 98%) participate in less than 10 conversations.

threshold). Multiple restarts are tried, and similar results are achieved.

4 Experimental Setup

Datasets. We collected two microblog conversation datasets from Twitter for experiments[3]: one contains discussions about the U.S. presidential election (henceforth **US Election**), the other gathers conversations of diverse topics based on the tweets released by TREC 2011 microblog track (henceforth **TREC**)[4]. US Election was collected from January to June of 2016 using Twitter's Streaming API[5] with a small set of political keywords.[6] To recover conversations, Tweet Search API[7] was used to retrieve messages with the "in-reply-to" relations to collect tweets in a recursive way until full conversations were recovered.

Statistics of the datasets are shown in Table 1. Figure 3 displays the number of conversations individual users participated in. As can be seen, most users are involved in only a few conversations. Simply leveraging personal chat history will not produce good performance for conversation recommendation.

In our experiments, we predict whether a user will engage in a conversation given the previous messages in that conversation and past conversations the user is involved. For model training and testing, we divide conversations into three ordered segments, corresponding to training, development, and test sets at 75%, 12.5%, and 12.5%.[8]

Preprocessing and Hyperparameter Tuning. For preprocessing, links, mentions (i.e., @username), and hashtags in tweets were replaced with generic tags of "URL", "MENTION", and "HASHTAG". We then utilized the Twitter NLP tool[9] (Gimpel et al., 2011; Owoputi et al., 2013) for tokenization and non-alphabetic token removal. We removed stop words and punctuations for all comparisons to ensure comparable performance. We maintain a vocabulary with the 5,000 most frequent words.

Our model parameters are tuned on the development set based on grid search, i.e. the parameters that give the lowest value for our objective are selected. Specifically, the number of discourse modes (D) and topics (K) are tuned to be 10. The trade-off parameter μ between user preference and corpus negative log-likelihood takes value of 0.1, and λ, the parameter for balancing topic and discourse, is set to 0.5. Finally, the confidence parameter s takes a value of 200 to give higher weight for positive instances, i.e., a user replied to a conversation.

Evaluation Metrics. Following prior work on social media post recommendation (Chen et al., 2012; Yan et al., 2012), we treat our task on conversation recommendation as a ranking problem. Therefore, popular information retrieval evaluation metrics, including precision at K (P@K), mean average precision (MAP) (Manning et al., 2008), and normalized Discounted Cumulative Gain at K (nDCG@K) (Järvelin and Kekäläinen, 2002) are reported. The metrics are computed per user in the dataset and then averaged over all users. The values range from 0.0 to 1.0, with higher values indicating better performance.

Baselines and Comparisons. For comparison, we first consider three baselines: 1) ranking

[3]The datasets are available at http://www.ccs.neu.edu/home/luwang/

[4] http://trec.nist.gov/data/tweets/

[5]https://developer.twitter.com/en/docs/tweets/filter-realtime/api-reference/post-statuses-filter.html

[6]Keyword list: "trump", "hillary", "clinton", "president", "politics", and "election."

[7]https://developer.twitter.com/en/docs/tweets/search/api-reference/get-saved_searches-show-id

[8]At least one turn per conversation is retained for training. It is possible that one user only replies in either development set or test set, but it is rather infrequent.

Models	US Election			TREC		
	MAP	P@1	nDCG@5	MAP	P@1	nDCG@5
Baselines						
RANDOM	0.018	0.004	0.009	0.006	0.001	0.002
LENGTH	0.025	0.002	0.003	0.013	0.002	0.004
POPULARITY	0.050	0.010	0.025	0.023	0.005	0.010
Comparisons						
OCCF	0.637	0.589	0.649	0.410	0.385	0.425
RSVM	0.687	0.680	0.690	0.554	0.575	0.559
CTR	0.673	0.649	0.678	0.475	0.431	0.495
ADAPTED HFT	0.698	0.652	0.706	0.487	0.447	0.504
Our model	**0.762**	**0.750**	**0.757**	**0.591**	**0.591**	**0.600**

Table 2: Conversation recommendation results on US Election and TREC. The best result for each column is highlighted in **bold**. Our model performs significantly better than all the comparisons ($p < 0.01$, paired t-test).

conversations randomly (RANDOM); 2) longer conversations (i.e., more words) ranked higher (LENGTH); 3) conversations with more distinct users ranked higher (POPULARITY).

We further compare results with three established recommendation models:

• OCCF: one-class Collaborative Filtering (Pan et al., 2008), which only considers users' reply history without modeling content in conversations.

• RSVM: ranking SVM (Joachims, 2002), which ranks conversations for each user with the content and Twitter features as in Duan et al. (2010).

• CTR: messages in one conversation are aggregated into one post and a state-of-the art Collaborative Filtering-based post recommendation model is applied (Chen et al., 2012).

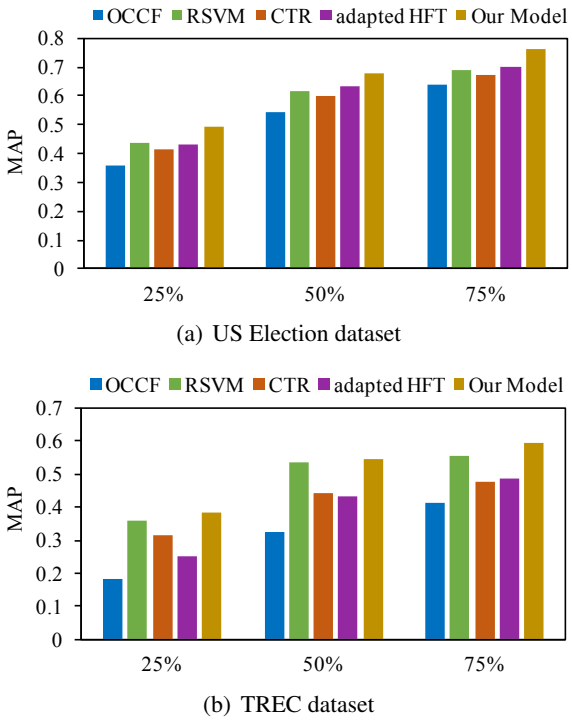
Finally, we also adapt the "hidden factors as topics" (HFT) model proposed in McAuley and Leskovec (2013) (henceforth ADAPTED HFT). Because the original model leverages the ratings for all product reviews and does not handle implicit user feedback well, we replace their user preference objective function with ours (Eq. 2).

5 Experimental Results

In this section, we first discuss our main evaluation in Section 5.1. A case study and corresponding discussion are provided in Section 5.2 to provide further insights, which is followed by an analysis of the topics and discourse modes discovered by our model (Section 5.3). We also examine our performance on first time replies (Section 5.4).

5.1 Conversation Recommendation Results

Experimental results are displayed in Table 2, where our model yields statistically significantly better results than baselines and comparisons



(a) US Election dataset

(b) TREC dataset

Figure 4: MAP scores for models trained on 25%, 50%, and 75% of conversation history. For each quantile, from left to right shows the result of OCCF, RSVM, CTR, ADAPTED HFT, and our model. In general, longer conversation history leads to better performance, and our model outperforms compared systems in all settings.

(paired t-tests, $p < 0.01$). For P@K, we only report P@1, because a significant amount of users participate only in 1 or 2 conversations. For nDCG@K, different K values are experimented, which results in similar trend, so only nDCG@5 is reported.

We find that the baselines that rank conversations with simple features (e.g., length or popularity) perform poorly. This implies that generic algorithms that do not consider conversation content or user preference cannot produce reasonable recommendations.

Although some non-baseline systems capture content in one way or another, only ADAPTED HFT and our model exploit latent topic models to better represent content in tweets, and outperform other methods.

Compared to ADAPTED HFT, which only considers latent topics under a collaborative filtering framework, our model extracts both topics and discourse modes as latent variables, and shows superior performance on both datasets. Our discourse variables go beyond topical content to capture social behaviors that affect user engagement, such as

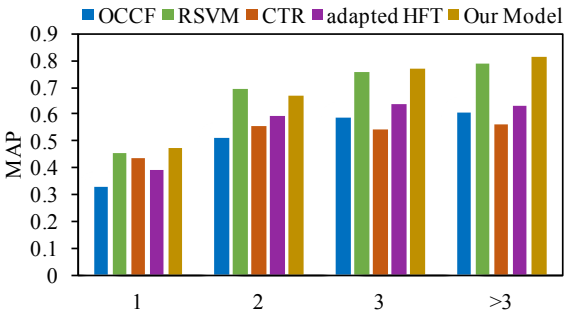


Figure 5: MAP scores of models for users involved in varying number of conversations on TREC dataset. Horizontal axis: degree of data sparsity indicated by the number of conversations a user involved in training data. Vertical axis: MAP scores. For each degree level, from left to right shows the results of OCCF, RSVM, CTR, ADPATED HFT, and our model.

arguments, question-asking, agreement, and other discourse modes.

Training with Varying Conversation History. To test the model performance based different levels of user engagement history, we further experiment with varying the length of conversations for training. Specifically, in addition to using 75% of conversation history, we also extract the first 25% and 50% of history as training. The rest of a conversation is separated equally for development and test. Figure 4 shows the MAP scores for US Election and TREC datasets. The increasing MAP for all methods as the training history increases indicates that generally, conversation history is essential for recommendation. Our model performs consistently better over different lengths of conversation histories.

Results for Varying Degree of Data Sparsity. From Table 1 and Figure 3, we observe that most users in our datasets are involved in only a few conversations. In order to study the effects of data sparsity on recommendation models, we examine in Figure 5 the MAP scores for users engaged in a varying number of conversations, as measured on the TREC dataset. The results on the US Election dataset have similar distributions. As we see, the prediction results become worse for users involved in fewer conversations. This indicates that data sparsity serves as a challenge for all recommendation models. We also observe that our model performs consistently better than other models over different degrees of sparsity. This implies that effectively capturing discourse structure in conversation context is useful to mitigating the effects of data sparsity on conversation recommendation.

Models	*Conv 1 (c_1)*	*Conv 2 (c_2)*
OCCF	0.941	0.922
ADAPTED HFT	0.923	0.954
Our model	0.924	0.961

Table 3: Predicted recommendation scores by different models of U_1 for conversations c_1 and c_2 in Figure 1. U_1 later replies to c_2 but not c_1, where our model predicts scores of 0.961 for c_2 (higher than 0.924 for c_1).

Latent Dim.	*User U_1*	*Conv 1 (c_1)*	*Conv 2 (c_2)*
Topic 1 (Sanders)	0.92 ($\gamma^U_{u_1,1}$)	0.10 ($\gamma^C_{c_1,1}$)	0.63 ($\gamma^C_{c_2,1}$)
Topic 2 (Clinton)	0.14 ($\gamma^U_{u_1,2}$)	0.84 ($\gamma^C_{c_1,2}$)	0.12 ($\gamma^C_{c_2,2}$)
Disc 1 (argument)	0.46 ($\delta^U_{u_1,1}$)	0.28 ($\delta^C_{c_1,1}$)	0.38 ($\delta^C_{c_2,1}$)
Disc 2 (statement)	-0.24 ($\delta^U_{u_1,2}$)	0.98 ($\delta^C_{c_1,2}$)	-0.09 ($\delta^C_{c_2,2}$)

Table 4: Sample latent dimensions of topics ($\gamma^U_{u_1}$ for user, and $\gamma^C_{c_*}$ for conversations) and discourse modes ($\delta^U_{u_1}$ for user, and $\delta^C_{c_*}$ for conversations). User U_1 shows interest in topic 1 (about Sanders), which is also a dominating topic in conversation c_2, but is not interested in topic 2 (about Clinton). U_1 shows a preference for discourse mode 1 (argument) over mode 2 (statement).

5.2 Case Study and Discussion

Here we present a case study based on the sample conversations in Figure 1. Recall that user U_1 is interested in conversations about Sanders, and also prefers more argumentative discourse, and thus returns in conversation c_2 but not c_1.

Table 3 shows the predicted scores for the two conversations from OCCF, ADAPTED HFT, and our model (as in Eq. 2). Both ADAPTED HFT and our model more accurately recommend c_2 over c_1, with our model producing a slightly higher recommendation score for c_2.

Table 4 shows the latent dimension values for the learned topics and discourse modes for this user and these two conversations. Based on human inspection, topic 1 appears to contain words about Sanders, which is the main topic in conversation c_2. Topic 2 is about Clinton, which is a dominating topic in conversation c_1. Our model also picks up user interest in topic 1 (Sanders), and thus assigns $\gamma^U_{u_1,1}$ a high value. For discourse modes, our model also generates a high score for "argument" discourse (labeled via human inspection) for both the user and c_2.

5.3 Further Analysis of Topic and Discourse

Ablation Study. We have shown that joint modeling of topical content and discourse modes produces the superior performance for our model.

Here we provide an ablation study to examine the relative contributions of those two aspects by setting the trade-off parameter λ to 1.0 (topic only) or 0.0 (discourse only). Table 5 shows that topics or discourse individually improve slightly upon the comparison ADAPTED HFT, but only jointly do they improve significantly upon it.

Models	US Election	TREC
ADAPTED HFT	0.698	0.487
Our model (topic only)	0.711	0.491
Our model (discourse only)	0.705	0.483
Our model (full)	**0.762**	**0.591**

Table 5: MAP of different variants of our model. Best results in each column is in **bold**.

Topic Coherence. To examine the quality of topics found by our model, we use the C_V topic coherence score measured via the open-source toolkit Palmetto[10], which has been shown to produce evaluation performance comparable to human judgment (Röder et al., 2015). Our model achieves topic coherence scores of 0.343 and 0.376 on TREC and US Election datasets, compared to 0.338 and 0.371 for the topics from ADAPTED HFT.

Discourse	Top 10 Terms	
	US Election	TREC
Question	? it if ... so all how because when any	? : HASHTAG or too with MENTION and ... what
Reaction	you like any good ! please no ~ lol what	all EMOTICON & !!! right ok u ;) thank haha
Statement	's do think the . should they from and have	i , a what all you be how then ...
Argument	but that all fuck without against out though ! anything	do would up that too even always never anything much
Reference	be i about that MENTION it " you -lrb- ?	MENTION ... ! : what rt it you URL :)

Table 6: Top 10 representative terms for sample discourse modes discovered by our model in two datasets. Names of discourse modes are our interpretations according to the word distributions generated by our model.

Sample Discourse Modes. While our topic word distributions are relatively unsurprising, of greater interest are the discourse mode word distributions. Table 6 shows a sample of discourse modes as labeled by human. Although this is merely a qualitative human judgment at this point, there does appear to be a notable overlap in discourse modes between the two datasets even though they were learned separately.

[10] https://github.com/AKSW/Palmetto/

5.4 First Time Reply Results

From a recommendation perspective, users may be interested in joining new conversations. We thus compare each recommendation system for first time replies. For each user, we only evaluate for conversations where they are newcomers. Table 7 shows that, unsurprisingly, all systems perform poorly on this task, though our model performs slightly better. This suggests that other features, e.g., network structures or other discussion thread features, could usefully be included in future studies that target new conversations.

Models	US Election	TREC
OCCF	0.035	0.033
RSVM	0.023	0.002
CTR	0.029	0.016
ADAPTED HFT	0.054	0.058
Our model	**0.083**	**0.090**

Table 7: MAP of models considering only first time replies. Best results in each column is in **bold**.

6 Conclusion

This paper has presented a framework for microblog conversation recommendation via jointly modeling topics and discourse modes. Experimental results show that our method can outperform competitive approaches that omit user discourse behaviors. Qualitative analysis shows that our joint model yields meaningful topics and discourse representations.

Abstract

Arguing without committing a fallacy is one of the main requirements of an ideal debate. But even when debating rules are strictly enforced and fallacious arguments punished, arguers often lapse into attacking the opponent by an *ad hominem* argument. As existing research lacks solid empirical investigation of the typology of ad hominem arguments as well as their potential causes, this paper fills this gap by (1) performing several large-scale annotation studies, (2) experimenting with various neural architectures and validating our working hypotheses, such as controversy or reasonableness, and (3) providing linguistic insights into triggers of ad hominem using explainable neural network architectures.

1 Introduction

Human reasoning is lazy and biased but it perfectly serves its purpose in the argumentative context (Mercier and Sperber, 2017). When challenged by genuine back-and-forth argumentation, humans do better in both generating and evaluating arguments (Mercier and Sperber, 2011). The dialogical perspective on argumentation has been reflected in argumentation theory prominently by the pragma-dialectic model of argumentation (van Eemeren and Grootendorst, 1992). Not only sketches this theory an ideal normative model of argumentation but also distinguishes the wrong argumentative moves, *fallacies* (van Eemeren and Grootendorst, 1987). Among the plethora of prototypical fallacies, notwithstanding the controversy of most taxonomies (Boudry et al., 2015), *ad hominem* argument is perhaps the most famous one. Arguing *against the person* is considered faulty, yet is prevalent in online and offline discourse.[1]

Although the ad hominem fallacy has been known since Aristotle, surprisingly there are very few empirical works investigating its properties. While Sahlane (2012) analyzed ad hominem and other fallacies in several hundred newspaper editorials, others usually only rely on few examples, as observed by de Wijze (2002). As Macagno (2013) concludes, ad hominem arguments should be considered as multifaceted and complex strategies, involving not a simple argument, but several combined tactics. However, such research, to the best of our knowledge, does not exist. Very little is known not only about the feasibility of ad hominem theories in practical applications (the NLP perspective) but also about the dynamics and triggers of ad hominem (the theoretical counterpart).

This paper investigates the research gap at three levels of increasing discourse complexity: ad hominem in isolation, direct ad hominem without dialogical exchange, and ad hominem in large inter-personal discourse context. We asked the following research questions. First, what qualitative and quantative properties do ad hominem arguments have in Web debates and how does that reflect the common theoretical view (RQ1)? Second, how much of the debate context do we need for recognizing ad hominem by humans and machine learning systems (RQ2)? And finally, what are the actual triggers of ad hominem arguments and can we predict whether the discussion is going to end up with one (RQ3)?

We tackle these questions by leveraging Web-based argumentation data (*Change my View* on Reddit), performing several large-scale annotation studies, and creating a new dataset. We experiment with various neural architectures and ex-

[1] According to 'Godwin's law' known from the internet pop-culture (https://en.wikipedia.org/wiki/Godwin's_law), if a discussion goes on long enough, sooner or later someone will compare someone or something to Adolf Hitler.

Proceedings of NAACL-HLT 2018, pages 386–396
New Orleans, Louisiana, June 1 - 6, 2018.

trapolate the trained models to validate our working hypotheses. Furthermore, we propose a list of potential linguistic and rhetorical triggers of ad hominem based on interpreting parameters of trained neural models.[2] This article thus presents the first NLP work on multi-faceted ad hominem fallacies in genuine dialogical argumentation. We also release the data and the source code to the research community.[3]

2 Theoretical background and related work

The prevalent view on argumentation emphasizes its pragmatic goals, such as persuasion and group-based deliberation (van Eemeren et al., 2014), although numerous works have dealt with argument as product, that is, treating a single argument and its properties in isolation (Toulmin, 1958; Habernal and Gurevych, 2017). Yet the social role of argumentation and its alleged responsibility for the very skill of human reasoning explained from the evolutionary perspective (Mercier and Sperber, 2017) provide convincing reasons to treat argumentation as an inherently dialogical tool.

The observation that some arguments are in fact 'deceptions in disguise' was made already by Aristotle (Aristotle and Kennedy (translator), 1991), for which the term *fallacy* has been adopted. Leaving the controversial typology of fallacies aside (Hamblin, 1970; van Eemeren and Grootendorst, 1987; Boudry et al., 2015), the *ad hominem* argument is addressed in most theories. Ad hominem argumentation relies on the strategy of attacking the opponent and some feature of the opponent's character instead of the counter-arguments (Tindale, 2007). With few exceptions, the following five sub-types of ad hominem are prevalent in the literature: **abusive ad hominem** (a pure attack on the character of the opponent), **tu quoque ad hominem** (essentially analogous to the "He did it first" defense of a three-year-old in a sandbox), **circumstantial ad hominem** (the "practice what you preach" attack and accusation of hypocrisy), **bias ad hominem** (the attacked opponent has a hidden agenda), and **guilt by association** (associating the opponent with somebody with a low credibility) (Schiappa and Nordin, 2013; Macagno, 2013; Walton, 2007; Hansen, 2017; Woods, 2008). We omit examples here as these provided in theoretical works or textbooks are usually artificial, as already criticized by (de Wijze, 2002) or (Boudry et al., 2015).

The topic of fallacies, which might be considered as sub-topic of argumentation quality, has recently been investigated also in the NLP field. Existing works are, however, limited to the monological view (Wachsmuth et al., 2017; Habernal and Gurevych, 2016b,a; Stab and Gurevych, 2017) or they focus primarily on learning fallacy recognition by humans (Habernal et al., 2017, 2018a). Another related NLP sub-field includes abusive language and personal attacks in general. Wulczyn et al. (2017) investigated whether or not Wikipedia talk page comments are personal attacks and annotated 38k instances resulting in a highly skewed distribution (only 0.9% were actual attacks). Regarding the participants' perspective, Jain et al. (2014) examined principal roles in 80 discussions from the *Wikipedia: Article for Deletion* pages (focusing on stubbornness or ignoredness, among others) and found several typical roles, including 'rebels', 'voices', or 'idiots'. In contrast to our data under investigation (Change My View debates), Wikipedia talk pages do not adhere to strict argumentation rules with manual moderation and have a different pragmatic purpose.

Reddit as a source platform has also been used in other relevant works. Saleem et al. (2016) detected hateful speech on Reddit by exploiting particular sub-communities to automatically obtain training data. Wang et al. (2016) experimented with an unsupervised neural model to cluster social roles on sub-reddits dedicated to computer games. Zhang et al. (2017) proposed a set of nine comment-level dialogue act categories and annotated 9k threads with 100k comments and built a CRF classifier for dialogue act labeling. Unlike these works which were not related to argumentation, Tan et al. (2016) examined persuasion strategies on Change My View using word overlap features. In contrast to our work, they focused solely on the successful strategies with delta-awarded posts. Using the same dataset, Musi (2017) recently studied concession in argumentation.

3 Data

Change My View (CMV) is an online 'place to post an opinion you accept [...] in an effort to un-

[2] An attempt to address the plea for thinking about problems, cognitive science, and the details of human language (Manning, 2015).

[3] https://github.com/UKPLab/naacl2018-before-name-calling-habernal-et-al

derstand other perspectives on the issue', in other words an online platform for 'good-faith' argumentation hosted on Reddit.[4] A user posts a **submission** (also called **original post(er); OP**) and other participants provide arguments to change the OP's view, forming a typical tree-form Web discussion. A special feature of CMV is that the OP acknowledges convincing arguments by giving a **delta** point (Δ). Unlike the vast majority of internet discussion forums, CMV enforces obeying strict rules (such as no 'low effort' posts, or accusing of being unwilling to change view) whose violation results into deleting the comment by moderators. These formal requirements of an ideal debate with the notion of violating rules correspond to incorrect moves in critical discussion in the normative pragma-dialectic theory (van Eemeren and Grootendorst, 1987). *Thus, violating the rule of 'not being rude or hostile' is equivalent to committing ad hominem fallacy.* For our experiments, we scraped, in cooperation with Reddit, the complete CMV including the content of the deleted comments so we could fully reconstruct the fallacious discussions, relying on the rule violation labels provided by the moderators. The dataset contains ≈ 2M posts in 32k submissions, forming 780k unique threads.

We will set up the stage for further experiments by providing several quantitative statistics we performed on the dataset. Only 0.2% posts in CMV are ad hominem arguments. This contrasts with a typical online discussion: Coe et al. (2014) found 19.5% of comments under online news articles to be incivil. Most threads contain only a single ad hominem argument (3,396 threads; there are 3,866 ad hominem arguments in total in CMV); only 35 threads contain more than three ad hominem arguments. In 48.6% of threads containing a single ad hominem, the ad hominem argument is the very last comment. This corresponds to the popular belief that if one is out of arguments, they start attacking and the discussion is over. This trend is also shown in Figure 1 which displays the relative position of the first ad hominem argument in a thread. Replying to ad hominem with another ad hominem happens only in 15% of the cases; this speaks for the attempts of CMV participants to keep up with the standards of a rather rational discussion.

Regarding ad hominem authors, about 66% of them start attacking 'out of blue', without any previous interaction in the thread. On the other hand, 11% ad hominem authors write at least one 'normal' argument in the thread (we found one outlier who committed ad hominem after writing 57 normal arguments in the thread). Only in 20% cases, the ad hominem thread is an interplay between the original poster and another participant. It means that there are usually more people involved in an ad hominem thread. Unfortunately, sometimes the OP herself also commits ad hominem (12%).

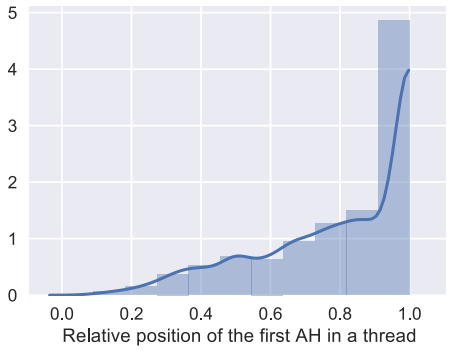

Figure 1: 'No discussion after ad hominem.' Distribution of the number of comments before the first ad hominem is committed proportional to the thread length.

We also investigated the relation between the presence of ad hominem arguments and the submission topic. While most submissions are accompanied by only one or two ad hominem arguments (75% of submissions), there are also extremes with over 50 ad hominem arguments. Manual analysis revealed that these extremes deal with religion, sexuality/gender, U.S. politics (mostly Trump), racism in the U.S., and veganism. We will elaborate on that later in Section 4.2.

4 Experiments

The experimental part is divided into three parts according to the increasing level of discourse complexity. We first experiment with ad hominem in isolation in section 4.1, then with direct ad hominem replies to original posts without dialogical exchange in section 4.2, and finally with ad hominem in a larger inter-personal discourse context in section 4.3.

4.1 Ad hominem without context in CMV

The first experimental set-up examines ad hominem arguments in *Change my view* regardless of its dialogical context.

[4] https://www.reddit.com/r/changemyview/

4.1.1 Data verification

Ad hominem arguments labeled by the CMV moderators come with no warranty. To verify their reliability, we conducted the following annotation studies. First, we needed to estimate parameters of crowdsourcing and its reliability. We sampled 100 random arguments from CMV without context: positive candidates were the reported ad hominem arguments, whereas negative candidates were sampled from comments that either violate other argumentation rules or have a delta label. To ensure the maximal content similarity of these two groups, for each positive instance the semantically closest negative instance was selected.[5] We then experimented with different numbers of Amazon Mechanical Turk workers and various thresholds of the MACE gold label estimator (Hovy et al., 2013); comparing two groups of six workers each and 0.9 threshold yielded almost perfect inter-annotator agreement (0.79 Cohen's κ). We then used this setting (six workers, 0.9 MACE threshold) to annotate another 452 random arguments sampled in the same way as above.

Crowdsourced 'gold' labels were then compared to the original CMV labels (balanced binary task: positive instances (ad hominem) and negative instances) reaching accuracy of 0.878. This means that the ad hominem labels from CMV moderators are quite reliable. Manual error analysis of disagreements revealed 11 missing ad hominem labels. These were not spotted by the moderators but were annotated as such by crowd workers.

4.1.2 Recognizing ad hominem arguments

We sampled a larger balanced set of positive instances (ad hominem) and negative instances using the same methodology as in section 4.1.1, resulting in 7,242 instances, and casted the task of recognition of ad hominem arguments as a binary supervised task. We trained two neural classifiers, namely a 2-stacked bi-directional LSTM network (Graves and Schmidhuber, 2005), and a convolutional network (Kim, 2014), and evaluated them using 10-fold cross validation. Throughout the paper we use pre-trained `word2vec` word embeddings (Mikolov et al., 2013). Detailed hyperparameters are described in the source codes (link provided in section 1). As results in Table 1 show, the task of recognizing ad hominem arguments is feasible and almost achieves the human upper bound performance.

Model	Accuracy
Human upper bound estimate	0.878
2 Stacked Bi-LSTM	0.782
CNN	**0.810**

Table 1: Prediction of ad hominem arguments

4.1.3 Typology of ad hominem

While binary classification of ad hominem as presented above might be sufficient for the purpose of red-flagging arguments, theories provide us with a much finer granularity (recall the typology in section 2). To validate whether this typology is empirically relevant, we executed an annotation experiment to classify ad hominem arguments into the provided five types (plus 'other' if none applies). We sampled 200 ad hominem arguments from threads in which interlocution happens only between two persons and which end up with ad hominem. The Mechanical Turk workers were shown this last ad hominem argument as well as the preceding one. Each instance was annotated by 16 workers to achieve a stable distribution of labels as suggested by Aroyo and Welty (2015). While 41% arguments were categorized as *abusive*, other categories (*tu quoque*, *circumstantial*, and *guilt by association*) were found to be rather ambiguous with very subtle differences. In particular, we observed a very low percentage agreement on these categories and a label distribution spiked around two or more categories. After a manual inspection we concluded that (1) the theoretical typology does not account for longer ad hominem arguments that mix up different attacks and that (2) there are actual phenomena in ad hominem arguments not covered by theoretical categories. These observations reflect those of Macagno (2013, p. 399) about ad hominem moves as multifaceted strategies.

We thus propose a list of phenomena typical to ad hominem arguments in CMV based on our empirical study. For this purpose, we follow up with another annotation experiment on 400 arguments, with seven workers per instance.[6] The goal was

[5] Similarity was computed using a cosine similarity of average embedding vectors multiplied by the argument length difference to minimize length-related artifacts. The sample was balanced with roughly 50% positive and 50% negative instances.

[6] Here we decided on seven workers per item by relying on other span annotation experiments done in a similar setup (Habernal et al., 2018b).

to annotate a text span which made the argument an ad hominem; a single argument could contain several spans. We estimated the gold spans using MACE and performed a manual post-analysis by designing a typology of causes of ad hominem together with their frequency of occurrence. The results and examples are summarized in Table 2.

4.1.4 Results and interpretation

The data verification annotation study (section 4.1.1) has two direct consequences. First, the high κ score (0.79) answers RQ2: for recognizing ad hominem argument, no previous context is necessary. Second, we still found 5% overlooked ad hominem arguments in CMV thus a moderation-facilitating tool might come handy; this can be served by the well-performing CNN model (0.810 accuracy; section 4.1.2).

The existing theoretical typology of ad hominem arguments, as presented for example in most textbooks, provides only a very simplified view. On the one hand, some of the categories which we found in the empirical labeling study (section 4.1.3) do map to their corresponding counterparts (such as the vulgar insults). On the other hand, some ad hominem insults typical to online argumentation (illiteracy insults, condescension) are not present in studies on ad hominem. Hence, we claim that any potential typology of ad hominem arguments should be multinomial rather than categorical, as we found multiple different spans in a single argument.

4.2 Triggers of first level ad hominem

In the following section, we increase the complexity of the studied discourse by taking the original post into account.

4.2.1 Annotation study

We already showed that ad hominem arguments are usually preceded by a discussion between the interlocutors. However, 897 submissions (original posts; OPs) have at least one intermediate ad hominem (in other words, the original post is directly attacked). We were thus interested in what triggers these first-level ad hominem arguments. We hypothesize two causes: (1) the *controversy* of the OP, similarly to some related works on news comments (Coe et al., 2014) and (2) the *reasonableness* of the OP (whether the topic is reasonable to argue about). We model both features on a three-point scale, namely *controversy*: 1 = 'not really controversial', 2 = 'somehow controversial', 3 = 'very controversial' and *reasonableness*: 1 = 'quite stupid', 2 = 'neutral', 3 = 'quite reasonable'.[7]

We sampled two groups of OPs: those which had some ad hominem arguments in any of its threads but no delta (ad hominem group) and those without ad hominem but some deltas (Delta group). In total, 1,800 balanced instances were annotated by five workers and the resulting value was averaged for each item.[8]

Statistical analysis of the annotated 1,800 OPs revealed that ad hominem arguments are associated with more controversial OPs (mean controversy 1.23) while delta-awarded arguments with less controversial OPs (mean controversy 1.06; K-S test;[9] statistics 0.13, P-value: 7.97×10^{-7}). On the other hand, reasonableness does not seem to play such a role. The difference between ad hominem in reasonable OPs (mean 1.20) and delta in reasonable OPs (mean 1.11) is not that statistically strong; (K-S test statistics: 0.07, P-value: 0.02).

4.2.2 Regression model for predicting controversy and reasonableness

We further built a regression model for predicting controversy and reasonableness of the OPs. Along with Bi-LSTM and CNN networks (same models as in 4.1.2) we also developed a neural model that integrates CNN with topic distribution (CNN+LDA). The motivation for a topic-incorporating model was based on our earlier observations presented in section 3. In particular, we trained an LDA topic model (k = 50) (Blei et al., 2003) on the heldout OPs and during training/testing, we merged the estimated topic distribution vector with the output layer after convolution and pooling. We performed 10-fold cross validation on the 1,800 annotated OPs and got reasonable performance for controversy prediction (ρ

[7] Examples of not really controversial: *"I Don't Think Monty Python is Funny"*, very controversial: *"Blacks are generally intellectual inferior to the other major races"*, quite stupid: *"Burritos are better than sandwiches"*, and quite reasonable: *"Nations whose leadership is based upon religion are fundamentally backwards"*.

[8] A pilot crowd sourcing annotation with 5 + 5 workers showed a fair reliability for controversy (Spearman's ρ 0.804) and medium reliability for reasonableness (Spearman's ρ 0.646).

[9] Kolmogorov-Smirnov (K-S) test is a non-parametric test without any assumptions about the underlying probability distribution.

Type	(%)	Example spans
Vulgar insult	31.3	"Your just an asshole", "you dumb fuck", etc.
Illiteracy insult	13.0	"Reading comprehension is your friend", "If you can't grasp the concept, I can't help you"
Condescension	6.5	"little buddy", "sir", "boy", "Again, how old are you?"
Ridiculing and sarcasm	6.5	"Thank you so much for all your pretentious explanations", "Can you also use Google?"
'Idiot'-insults	6.5	"Ever have discussions with narcissistic idiots on the internet? They are so tiring"
Accusation of stupidity	4.3	"You have no capability to understand why", "You're obviously just Nobody with enough brains to operate a computer could possibly believe something this stupid"
Lack of argumentation skills	4.3	"You're making the claims, it's your job to prove it. Don't you know how debating works?", "You're trash at debating."
Accusation of trolling	3.9	"You're just a dishonest troll", "You're using troll tactics"
Accusation of ignorance	3.5	"Please dont waste peoples time pretending to know what you're talking about", "Do you even know what you're saying?"
"You didn't read what I wrote"	3.0	"Read what I posted before acting like a pompous ass", "Did you even read this?"
"What you say is idiotic"	2.6	"To say that people intrinsically understand portion size is idiotic.", "Your second paragraph is fairly idiotic"
Accusation of lying	2.6	"Possible lie any harder?", "You are just a liar."
"You don't face the facts and ignore the obvious"	1.7	"Willful ignorance is not something I can combat", "How can you explain that? You can't because it will hurt your feelings to face reality"
Accusation of ad hominem or other fallacies	1.7	"You started with a fallacy and then deflected.", "You still refuse to acknowledge that you used a strawman argument against me"
Other	8.3	"Wow. Someone sounds like a bit of an anti-semite", "You're too dishonest to actually quote the verse because you know it's bullshit"

Table 2: What makes an argument ad hominem: results of the empirical study of labeling spans in 400 ad hominem arguments.

Controversy (Spearman's ρ)	
Human upper bounds	0.804
Bi-LSTM	0.539
CNN	0.559
CNN-LDA	**0.569**
Reasonableness (Spearman's ρ)	
Human upper bounds	0.646
Bi-LSTM	0.332
CNN	0.320
CNN-LDA	**0.385**

Table 3: Results of predicting controversy and reasonableness of the original post.

0.569) and medium performance for reasonableness prediction (ρ 0.385), respectively; both using the CNN+LDA model (see Table 3).

We then used the trained model and extrapolated on all held-out OPs (1,267 ad hominem and 10,861 delta OPs, respectively). The analysis again showed that ad hominem arguments tend to be found under more controversial OPs whereas delta arguments in the less controversial ones (K-S test statistics: 0.14, P-value: 1×10^{-18}). For reasonableness, the rather low performance of the predictor does not allow us draw any conclusions on the extrapolated data.

4.2.3 Results and interpretation

Controversy of the original post is immediately heating up the debate participants and correlates with a higher number of direct ad hominem responses. This corresponds to observations made in comments in newswire where 'weightier' topics tended to stir incivility (Coe et al., 2014). On the other hand, 'stupidity' (or 'reasonableness') does not seem to play any significant role. The CNN+LDA model for predicting controversy (ρ 0.569) might come handy for signaling potentially 'heated' discussions.

4.3 Before calling names

In this section, we focus on the dialogical aspect of CMV debates and dynamics of ad hominem fallacies. Although ad hominem arguments appear in many forms (Section 4.1.3), we treat all ad hominem arguments equal in the following experiments.

4.3.1 Data sampling

So far we explored what makes an ad hominem argument and whether debated topic influences the

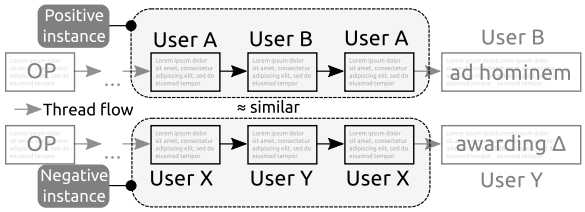

Figure 2: Sampling instances for learning triggers of ad hominem.

number of intermediate attacks. However, possible causes of the argumentative dynamics that ends up with an ad hominem argument remain an open question, which has been addressed in neither argumentation theory nor in cognitive psychology, to the best of our knowledge. We thus cast an explanation of triggers and dynamics of ad hominem discussions as a supervised machine learning problem and draw theoretical insights by a retrospective interpretation of the learned models.

We sample positive instances by taking three contextual arguments preceding the ad hominem argument from threads which are an interplay between two persons. Negative samples are drawn similarly from threads in which the argument is awarded with Δ as shown in Figure 2.[10] Each instance consists of the three concatenated arguments delimited by a special OOV token. This resulted in 2,582 balanced training instances.

4.3.2 Neural models

The alleged lack of interpretability of neural networks has motivated several lines of approaches, such as layer-wise relevance propagation (Arras et al., 2017) or representation erasure (Li et al., 2016), both on sentiment analysis. As our task at hand deals with multi-party discourse that presumably involves temporal relations important for the learned representation, we opted for a state-of-the-art self-attentive LSTM model. In particular, we re-implemented the Structured Self-Attentive Embedding Neural Network (SSAE-NN) (Lin et al., 2017) which learns an embedding matrix representation of the input using attention weights. To make the attention even more interpretable, we replaced the final non-linear MLP layers with a single linear classifier (softmax). By summing over one dimension of the attention embedding matrix, each word from the input sequence gets associated with a single attention weight that gives us insights into the classifier's 'features' (still indirectly, as the true representation is a matrix; see the original paper).[11] The learning objective is to recognize whether the thread ends up in an ad hominem argument or a delta point. We trained the model in 10-fold cross-validation and although our goal is not to achieve the best performance but rather to gain insight, we also tested a CNN model (accuracy 0.7095) which performed slightly worse than the SSAE-NN model (accuracy 0.7208).

4.3.3 Results and interpretation

During testing the model, we projected attention weights to the original texts as heat maps and manually analyzed 191 true positives (ad hominem threads recognized correctly), as well as 77 false positives (ad hominem threads misclassified as delta) and 84 false negatives (delta as ad hominem), in total about 120k tokens. The full output is available in the supplementary materials, we use IDs as a reference in the following text.

In the following analysis, we solely relied on the weights of words or phrases learned by the attention model, see an example in Figure 3. Based on our observations, we summarize several linguistic and argumentative phenomena with examples most likely responsible for ad hominem threads in Table 4.

The identified phenomena have few interesting properties in common. First, they all are topic-independent rhetorical devices (except for the loaded keywords at the bottom). Second, many of them deal with meta-level argumentation, i.e., arguing about argumentation (such as missing support or fallacy accusations). Third, most of them do not contain profanity (in contrast to the actual ad hominem arguments of which a third are vulgar insults; cf. Table 2). And finally, all of them should be easy to avoid.

Misleading 'features' False positives revealed properties that misled the network to classify delta threads as ad hominem threads.

- These include **topic words** (such as *racism, blacks, slave, abortion*) which reflects the implicit bias in the data.
- Actual interest mixed with indifference in

[10] To ensure as much content similarity as possible, we used the same similarity sampling as in section 4.1.1.

[11] We also experimented with regularizing the attention matrix as the authors proposed, but it resulted in worse performance.

587_ah_t1_cm7djx3

(OOV_comment_begin) If only you would n't rely on [fallacious] (http : OOV) [arguments] (http : OOV) to make your point. So no , I do n't realize how stupid and naive I am. All I 've realized is that you are n't actually prepared to have an actual discussion .

(OOV_comment_begin) What god do you believe in ? And it 's not a fallacy when it 's very comparable to the most popular gods .

(OOV_comment_begin) You 're making an assumption on what I believe , then attacking your assumption of what my belief is without me even telling you anything. OOV It is a OOV It 's the comparison itself that is OOV If they were n't comparable at all , then it 'd be impossible to commit the OOV You can compare apples to oranges , but the moment you use your fingernails to peel an apple you look like an idiot .

Figure 3: An example of reconstructed word weight heat map extracted from the attention matrix for a thread which ends up in ad hominem; three previous arguments are shown (see Figure 2 for sampling details).

Phenomena	**Examples**
Introducing vulgar intensifiers or interrogatives	**388(-1)** *"Where the fuck is your idea to ..."*, **712(-2)** *"no shortage of fucking gun"*, **1277(-1)** *"This is fucking CMV"*, **428(-2)** *"I'm fucking trans!"*, **2018(-2)** *"an arrogant fuck"*, **1277(-2)** *"What the fuck are you smoking?"*
Direct imperatives	**1003(-3)** *"You should get more mad about it"*, **857(-2)** *"You need to do a lot better than that."*, **233(-2)** *"So now delete your post"*, **749(-1)** *"google this fact as well"*, **1276(-1)** *"Just look back at the reasons why ..."*
Accusing of believing in or using propaganda	**522(-1)** *"It's right wing propaganda?"*, **1003(-1)** *"If you're not outraged, you're not paying attention to our propaganda that says the opposite of literally thousands of published research articles"*
Accusation of fallacies or bad argumentation practice	**238(-3)** *"your snide remarks and poor argumentation skills"*, **1117(-2)** *"you're circle jerking A vs. B"*, **263(-3)** *"You're grasping at straws"*, **78(-3)** *"You sure like changing words and statements to make your argument appear more cogent, don't you?"*, **210(-1)** *"Your arguments range from ... to ..."*, **1085(-3)** *"It's only a fallacy"*, **144(-1)** *"You haven't presented any evidence or argument that disagrees with anything I've said."*, **587(-3)** *"If only you wouldn't rely on fallacious arguments"*
Reinterpreting opponent's positions	**982(-1)** *"The fact that you obviously think ... reveals ..."*, **982(-2)** *"What makes you think I see myself ... ?"*, **1060(-3)** *"That kind of thinking is ..."*, **760(-1)** *"If I'm understanding you correctly"*, **405(-1)** *"... deluded yourself into believing factually incorrect things"* **587(-1)** *"You're making an assumption on what I believe, then attacking your assumption of what my belief is without me even telling you anything."*
Accusation of not reading the other party's arguments	**586(-1)** *"... me without even reading my ..."*, **240(-1)** *"You are just reading it wrong."*, **310(-1)** *"Oh, you're not actually reading my ..."*
Pointing at missing or unsupported evidence and facts	**1238(-2)** *"unsupported bullshit as before"*, **1121(-3)** *"you can't chose your facts"*, **931(-1)** *"If that's your only argument ..."*, **486(-2)** *"unsubstantiated statement"*, **486(-1)** *"unsupported claims"*, **71(-2)** *"factually correct"*, **915(-1)** *"But for the sake of argument, your points are pitifully .."*, **388(-3)** *"Please provide statistics ... It's silly to debate statistics without actual numbers."*
UPPERCASE	**1238(-3)** *"NO ONE CLAIMED THAT ... ARE NOT ... AGAINST ..."*
Sarcasm	**78(-2)** *"But I'm sure you know best"*, **310(-1)** *"Have a nice day."*, **1276(-1)** *"Good luck with that"*
Mentions of trolling	**701(-2)** *"Then you are giving trolls the victory then?"*
Loaded keywords	*Nazi, rape, racist*

Table 4: Phenomena resulting into ad hominem learned by the SSAE-NN model. The first number is the instance ID (available in the supplementary material), the minus number in parentheses is the position of the argument before the ad hominem.

sarcasm is also problematic (**185(-2)** *"That's a very interesting ..."*).

- Another problematic phenomena is also **expressed disagreement** (**678(-2)** *"overheated rhetoric"*, **203(-2)** *"But I suppose this argument is ..."*, **230(-2)** *"But I don't think it's quite ..."*, **938(-1)** *"I disagree too, however ..."*).

False negatives were caused basically by presence of many 'informative' **content words** (**980** *unemployment, quarterly publication, inflation data*, **474** *actual publications, this experiment, biological ailments, medical doctorate*, **1214** *graduate degree, education, health insurance*) and **misinterpreted sarcasm** (**285(-1)** *"Also this is a cute analogy"*).

5 Conclusion

In this article, we investigated ad hominem argumentation on three levels of discourse complexity. We looked into qualitative and quantative properties of ad hominem arguments, crowdsourced labeled data, experimented with models for prediction (0.810 accuracy; 4.1.2), and proposed an updated typology of ad hominem properties (4.1.3). We then looked into the dynamics of argumentation to examine the relation between the quality of the original post and immediate ad hominem arguments (4.2). Finally, we exploited the learned representation of Self-Attentive Embedding Neural Network to search for features triggering ad hominem in one-to-one discussions. We found several categories of rhetorical devices as well as misleading features (4.3.3).

There are several points that deserve further investigation. First, we have ignored meta-information of the debate participants, such as their overall activity (i.e., whether they are spammers or trolls). Second, the proposed typology of ad hominem causes has not yet been post-verified empirically. Third, we expect that personality traits of the participants (BIG5) may also play a significant role in the argumentative exchange. We leave these points for future work.

We believe that our findings will help gain better understanding of, and hopefully keep restraining from, ad hominem fallacies in good-faith discussions.

Abstract

In this paper, we study the problem of parsing structured knowledge graphs from textual descriptions. In particular, we consider the scene graph representation (Johnson et al., 2015) that considers objects together with their attributes and relations: this representation has been proved useful across a variety of vision and language applications. We begin by introducing an alternative but equivalent edge-centric view of scene graphs that connect to dependency parses. Together with a careful redesign of label and action space, we combine the two-stage pipeline used in prior work (generic dependency parsing followed by simple post-processing) into one, enabling end-to-end training. The scene graphs generated by our learned neural dependency parser achieve an F-score similarity of 49.67% to ground truth graphs on our evaluation set, surpassing best previous approaches by 5%. We further demonstrate the effectiveness of our learned parser on image retrieval applications.[1]

1 Introduction

Recent years have witnessed the rise of interest in many tasks at the intersection of computer vision and natural language processing, including semantic image retrieval (Johnson et al., 2015; Vendrov et al., 2015), image captioning (Mao et al., 2014; Karpathy and Li, 2015; Donahue et al., 2015; Liu et al., 2017b), visual question answering (Antol et al., 2015; Zhu et al., 2016; Andreas et al., 2016), and referring expressions (Hu et al., 2016; Mao et al., 2016; Liu et al., 2017a). The pursuit for these tasks is in line with people's desire for high level understanding of visual content, in particular, using textual descriptions or questions to help understand or express images and scenes.

What is shared among all these tasks is the need for a *common representation* to establish connection between the two different modalities. The majority of recent works handle the vision side with convolutional neural networks, and the language side with recurrent neural networks (Hochreiter and Schmidhuber, 1997; Cho et al., 2014) or word embeddings (Mikolov et al., 2013; Pennington et al., 2014). In either case, neural networks map original sources into a semantically meaningful (Donahue et al., 2014; Mikolov et al., 2013) vector representation that can be aligned through end-to-end training (Frome et al., 2013). This suggests that the vector embedding space is an appropriate choice as the common representation connecting different modalities (see e.g. Kaiser et al. (2017)).

While the dense vector representation yields impressive performance, it has an unfortunate limitation of being less intuitive and hard to interpret. Scene graphs (Johnson et al., 2015), on the other hand, proposed a type of directed graph to encode information in terms of objects, attributes of objects, and relationships between objects (see Figure 1 for visualization). This is a more structured and explainable way of expressing the knowledge from either modality, and is able to serve as an alternative form of common representation. In fact, the value of scene graph representation has already been proven in a wide range of visual tasks, including semantic image retrieval (Johnson et al., 2015), caption quality evaluation (Anderson et al., 2016), etc. In this paper, we focus on scene graph generation from textual descriptions.

Previous attempts at this problem (Schuster et al., 2015; Anderson et al., 2016) follow the same spirit. They first use a dependency parser to obtain the dependency relationship for all words in a sentence, and then use either a rule-based or a learned classifier as post-processing to generate the scene graph. However, the rule-based classifier cannot

[1]Code is available at https://github.com/Yusics/bist-parser/tree/sgparser

Proceedings of NAACL-HLT 2018, pages 397–407
New Orleans, Louisiana, June 1 - 6, 2018.

Figure 1: Each image in the Visual Genome (Krishna et al., 2017) dataset contains tens of region descriptions and the region scene graphs associated with them. In this paper, we study how to generate high quality scene graphs (two such examples are shown in the figure) from textual descriptions, without using image information.

learn from data, and the learned classifier is rather simple with hand-engineered features. In addition, the dependency parser was trained on linguistics data to produce complete dependency trees, some parts of which may be redundant and hence confuse the scene graph generation process.

Therefore, our model abandons the two-stage pipeline, and uses a single, customized dependency parser instead. The customization is necessary for two reasons. First is the difference in label space. Standard dependency parsing has tens of edge labels to represent rich relationships between words in a sentence, but in scene graphs we are only interested in three types, namely objects, attributes, and relations. Second is whether every word needs a head. In some sense, the scene graph represents the "skeleton" of the sentence, which suggests that empty words are unlikely to be included in the scene graph. We argue that in scene graph generation, it is unnecessary to require a parent word for every single word.

We build our model on top of a neural dependency parser implementation (Kiperwasser and Goldberg, 2016) that is among the state-of-the-art. We show that our carefully customized dependency parser is able to generate high quality scene graphs by learning from data. Specifically, we use the Visual Genome dataset (Krishna et al., 2017), which provides rich amounts of region description - region graph pairs. We first align nodes in region graphs with words in the region descriptions using simple rules, and then use this alignment to train our customized dependency parser. We evaluate our parser by computing the F-score between the parsed scene graphs and ground truth scene graphs. We also apply our approach to image retrieval to show its effectiveness.

2 Related Works

2.1 Scene Graphs

The scene graph representation was proposed in Johnson et al. (2015) as a way to represent the rich, structured knowledge within an image. The nodes in a scene graph represent either an object, an attribute for an object, or a relationship between two objects. The edges depict the connection and association between two nodes. This representation is later adopted in the Visual Genome dataset (Krishna et al., 2017), where a large number of scene graphs are annotated through crowd-sourcing.

The scene graph representation has been proved useful in various problems including semantic image retrieval (Johnson et al., 2015), visual question answering (Teney et al., 2016), 3D scene synthesis (Chang et al., 2014), and visual relationship detection (Lu et al., 2016). Excluding Johnson et al. (2015) which used ground truth, scene graphs are obtained either from images (Dai et al., 2017; Xu et al., 2017; Li et al., 2017) or from textual descriptions (Schuster et al., 2015; Anderson et al., 2016). In this paper we focus on the latter.

In particular, parsed scene graphs are used in Schuster et al. (2015) for image retrieval. We show that with our more accurate scene graph parser, performance on this task can be further improved.

2.2 Parsing to Graph Representations

The goal of dependency parsing (Kübler et al., 2009) is to assign a parent word to every word in a sentence, and every such connection is associated with a label. Dependency parsing is particularly suitable for scene graph generation because it directly models the relationship between individual

words without introducing extra nonterminals. In fact, all previous work (Schuster et al., 2015; Anderson et al., 2016) on scene graph generation run dependency parsing on the textual description as a first step, followed by either heuristic rules or simple classifiers. Instead of running two separate stages, our work proposed to use a single dependency parser that is end-to-end. In other words, our customized dependency parser generates the scene graph in an online fashion as it reads the textual description once from left to right.

In recent years, dependency parsing with neural network features (Chen and Manning, 2014; Dyer et al., 2015; Cross and Huang, 2016; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016; Shi et al., 2017) has shown impressive performance. In particular, Kiperwasser and Goldberg (2016) used bidirectional LSTMs to generate features for individual words, which are then used to predict parsing actions. We base our model on Kiperwasser and Goldberg (2016) for both its simplicity and good performance.

Apart from dependency parsing, Abstract Meaning Representation (AMR) parsing (Flanigan et al., 2014; Werling et al., 2015; Wang et al., 2015; Konstas et al., 2017) may also benefit scene graph generation. However, as first pointed out in Anderson et al. (2016), the use of dependency trees still appears to be a common theme in the literature, and we leave the exploration of AMR parsing for scene graph generation as future work.

More broadly, our task also relates to entity and relation extraction, e.g. Katiyar and Cardie (2017), but there object attributes are not handled. Neural module networks (Andreas et al., 2016) also use dependency parses, but they translate questions into a series of actions, whereas we parse descriptions into their graph form. Finally, Krishnamurthy and Kollar (2013) connected parsing and grounding by training the parser in a weakly supervised fashion.

3 Task Description

In this section, we begin by reviewing the scene graph representation, and show how its nodes and edges relate to the words and arcs in dependency parsing. We then describe simple yet reliable rules to align nodes in scene graphs with words in textual descriptions, such that customized dependency parsing, described in the next section, may be trained and applied.

3.1 Scene Graph Definition

There are three types of nodes in a scene graph: object, attribute, and relation. Let $\mathcal{O}$ be the set of object classes, $\mathcal{A}$ be the set of attribute types, and $\mathcal{R}$ be the set of relation types. Given a sentence s, our goal in this paper is to parse s into a scene graph:

$$G(s) = \langle O(s), A(s), R(s) \rangle \tag{1}$$

where $O(s) = \{o_1(s), \ldots, o_m(s)\}, o_i(s) \in \mathcal{O}$ is the set of object instances mentioned in s, $A(s) \subseteq O(s) \times \mathcal{A}$ is the set of attributes associated with object instances, and $R(s) \subseteq O(s) \times \mathcal{R} \times O(s)$ is the set of relations between object instances.

$G(s)$ is a graph because we can first create an object node for every element in $O(s)$; then for every (o, a) pair in $A(s)$, we create an attribute node and add an unlabeled edge $o \rightarrow a$; finally for every (o_1, r, o_2) triplet in $R(s)$, we create a relation node and add two unlabeled edges $o_1 \rightarrow r$ and $r \rightarrow o_2$. The resulting directed graph exactly encodes information in $G(s)$. We call this the **node-centric** graph representation of a scene graph.

We realize that a scene graph can be equivalently represented by no longer distinguishing between the three types of nodes, yet assigning labels to the edges instead. Concretely, this means there is now only one type of node, but we assign a `ATTR` label for every $o \rightarrow a$ edge, a `SUBJ` label for every $o_1 \rightarrow r$ edge, and a `OBJT` label for every $r \rightarrow o_2$ edge. We call this the **edge-centric** graph representation of a scene graph.

We can now establish a connection between scene graphs and dependency trees. Here we only consider scene graphs that are acyclic[2]. The edge-centric view of a scene graph is very similar to a dependency tree: they are both directed acyclic graphs where the edges/arcs have labels. The difference is that in a scene graph, the nodes are the objects/attributes/relations and the edges have label space {`ATTR`, `SUBJ`, `OBJT`}, whereas in a dependency tree, the nodes are individual words in a sentence and the edges have a much larger label space.

3.2 Sentence-Graph Alignment

We have shown the connection between nodes in scene graphs and words in dependency parsing. With alignment between nodes in scene

[2]In Visual Genome, only 4.8% region graphs have cyclic structures.

graphs and words in the textual description, scene graph generation and dependency parsing becomes equivalent: we can construct the generated scene graph from the set of labeled edges returned by the dependency parser. Unfortunately, such alignment is not provided between the region graphs and region descriptions in the Visual Genome (Krishna et al., 2017) dataset. Here we describe how we use simple yet reliable rules to do sentence-graph (word-node) alignment.

There are two strategies that we could use in deciding whether to align a scene graph node d (whose label space is $\mathcal{O} \cup \mathcal{A} \cup \mathcal{R}$) with a word/phrase w in the sentence:

- Word-by-word match (WBW): $d \leftrightarrow w$ only when d's label and w match word-for-word.
- Synonym match (SYN)[3]: $d \leftrightarrow w$ when the wordnet synonyms of d's label contain w.

Obviously WBW is a more conservative strategy than SYN.

We propose to use two cycles and each cycle further consists of three steps, where we try to align objects, attributes, relations in that order. The pseudocode for the first cycle is in Algorithm 1. The second cycle repeats line 4-15 immediately afterwards, except that in line 6 we also allow SYN. Intuitively, in the first cycle we use a conservative strategy to find "safe" objects, and then scan for their attributes and relations. In the second cycle we relax and allow synonyms in aligning object nodes, also followed by the alignment of attribute and relation nodes.

The ablation study of the alignment procedure is reported in the experimental section.

4 Customized Dependency Parsing

In the previous section, we have established the connection between scene graph generation and dependency parsing, which assigns a parent word for every word in a sentence, as well as a label for this directed arc. We start by describing our base dependency parsing model, which is neural network based and performs among the state-of-the-art. We then show why and how we do customization, such that scene graph generation is achieved with a single, end-to-end model.

[3]This strategy is also used in (Denkowski and Lavie, 2014) and (Anderson et al., 2016).

Algorithm 1: First cycle of the alignment procedure.

1 **Input**: Sentence s; Scene graph $G(s)$
2 Initialize aligned nodes N as empty set
3 Initialize aligned words W as empty set
4 **for** o in object nodes of $G(s) \setminus N$ **do**
5 **for** w in $s \setminus W$ **do**
6 **if** $o \leftrightarrow w$ according to WBW **then**
7 Add (o, w); $N = N \cup \{o\}$; $W = W \cup \{w\}$
8 **for** a in attribute nodes of $G(s) \setminus N$ **do**
9 **for** w in $s \setminus W$ **do**

4.1 Neural Dependency Parsing Base Model

We base our model on the transition-based parser of Kiperwasser and Goldberg (2016). Here we describe its key components: the arc-hybrid system that defines the transition actions, the neural architecture for feature extractor and scoring function, and the loss function.

The Arc-Hybrid System In the arc-hybrid system, a configuration consists of a stack σ, a buffer β, and a set T of dependency arcs. Given a sentence $s = w_1, \ldots, w_n$, the system is initialized with an empty stack σ, an empty arc set T, and $\beta = 1, \ldots, n, \texttt{ROOT}$, where ROOT is a special index. The system terminates when σ is empty and β contains only ROOT. The dependency tree is given by the arc set T upon termination.

The arc-hybrid system allows three transition actions, SHIFT, LEFT$_l$, RIGHT$_l$, described in Table 1. The SHIFT transition moves the first element of the buffer to the stack. The LEFT(l) transition yields an arc from the first element of the buffer to the top element of the stack, and then removes the top element from the stack. The

Stack σ_t	Buffer β_t	Arc set T_t	Action	Stack σ_{t+1}	Buffer β_{t+1}	Arc set T_{t+1}
σ	$b_0\|\beta$	T	SHIFT	$\sigma\|b_0$	β	T
$\sigma\|s_1\|s_0$	$b_0\|\beta$	T	LEFT(l)	$\sigma\|s_1$	$b_0\|\beta$	$T \cup \{(b_0, s_0, l)\}$
$\sigma\|s_1\|s_0$	β	T	RIGHT(l)	$\sigma\|s_1$	β	$T \cup \{(s_1, s_0, l)\}$
$\sigma\|s_0$	β	T	REDUCE	σ	β	T

Table 1: Transition actions under the arc-hybrid system. The first three actions are from dependency parsing; the last one is introduced for scene graph parsing.

RIGHT(l) transition yields an arc from the second top element of the stack to the top element of the stack, and then also removes the top element from the stack.

The following paragraphs describe how to select the correct transition action (and label l) in each step in order to generate a correct dependency tree.

BiLSTM Feature Extractor Let the word embeddings of a sentence s be $\mathbf{w}_1, \ldots, \mathbf{w}_n$. An LSTM cell is a parameterized function that takes as input $\mathbf{w}_t$, and updates its hidden states:

$$\text{LSTM cell} : (\mathbf{w}_t, \mathbf{h}_{t-1}) \rightarrow \mathbf{h}_t \quad (2)$$

As a result, an LSTM network, which simply applies the LSTM cell t times, is a parameterized function mapping a sequence of input vectors $\mathbf{w}_{1:t}$ to a sequence of output vectors $\mathbf{h}_{1:t}$. In our notation, we drop the intermediate vectors $\mathbf{h}_{1:t-1}$ and let $\text{LSTM}(\mathbf{w}_{1:t})$ represent $\mathbf{h}_t$.

A bidirectional LSTM, or BiLSTM for short, consists of two LSTMs: LSTM_F which reads the input sequence in the original order, and LSTM_B which reads it in reverse. Then

$$\text{BILSTM}(\mathbf{w}_{1:n}, i) = \text{LSTM}_F(\mathbf{w}_{1:i}) \circ \text{LSTM}_B(\mathbf{w}_{n:i}) \quad (3)$$

where $\circ$ denotes concatenation. Intuitively, the forward LSTM encodes information from the left side of the i-th word and the backward LSTM encodes information to its right, such that the vector $\mathbf{v}_i = \text{BILSTM}(\mathbf{w}_{1:n}, i)$ has the full sentence as context.

When predicting the transition action, the feature function $\phi(c)$ that summarizes the current configuration $c = (\sigma, \beta, T)$ is simply the concatenated BiLSTM vectors of the top three elements in the stack and the first element in the buffer:

$$\phi(c) = \mathbf{v}_{s_2} \circ \mathbf{v}_{s_1} \circ \mathbf{v}_{s_0} \circ \mathbf{v}_{b_0} \quad (4)$$

MLP Scoring Function The score of transition action y under the current configuration c is determined by a multi-layer perceptron with one hidden layer:

$$f(c, y) = MLP(\phi(c))[y] \quad (5)$$

where

$$MLP(x) = W_2 \cdot \tanh(W_1 \cdot x + b_1) + b_2 \quad (6)$$

Hinge Loss Function The training objective is to raise the scores of correct transitions above scores of incorrect ones. Therefore, at each step, we use a hinge loss defined as:

$$\mathcal{L} = \max(0, 1 - \max_{y^+ \in Y^+} f(c, y^+) + \max_{y^- \in Y \setminus Y^+} f(c, y^-)) \quad (7)$$

where Y is the set of possible transitions and Y^+ is the set of correct transitions at the current step. In each training step, the parser scores all possible transitions using Eqn. 5, incurs a loss using Eqn. 7, selects a following transition, and updates the configuration. Losses at individual steps are summed throughout the parsing of a sentence, and then parameters are updated using backpropagation.

In test time, we simply choose the transition action that yields the highest score at each step.

4.2 Customization

In order to generate scene graphs with dependency parsing, modification is necessary for at least two reasons. First, we need to redefine the label space of arcs so as to reflect the edge-centric representation of a scene graph. Second, not every word in the sentence will be (part of) a node in the scene graph (see Figure 2 for an example). In other words, some words in the sentence may not have a parent word, which violates the dependency parsing setting. We tackle these two challenges by redesigning the edge labels and expanding the set of transition actions.

Redesigning Edge Labels We define a total of five edge labels, so as to faithfully bridge the edge-centric view of scene graphs with dependency parsing models:

- CONT: This label is created for nodes whose label is a phrase. For example, the phrase "in front of" is a single relation node in the scene graph. By introducing the CONT label, we expect the parsing result to be either

$$\text{in} \xrightarrow{\text{CONT}} \text{front} \xrightarrow{\text{CONT}} \text{of} \tag{8}$$

  or

$$\text{in} \xleftarrow{\text{CONT}} \text{front} \xleftarrow{\text{CONT}} \text{of} \tag{9}$$

  where the direction of the arcs (left or right) is predefined by hand.

  The leftmost word under the right arc rule or the rightmost word under the left arc rule is called the *head* of the phrase. A single-word node does not need this CONT label, and the head is itself.

- ATTR: The arc label from the head of an object node to the head of an attribute node.

- SUBJ: The arc label from the head of an object node (subject) to the head of a relation node.

- OBJT: The arc label from the head of a relation node to the head of an object node (object).

- BEGN: The arc label from the ROOT index to all heads of object nodes without a parent.

Expanding Transition Actions With the three transition actions SHIFT, LEFT(l), RIGHT(l), we only drop an element (from the top of the stack) after it has already been associated with an arc. This design ensures that an arc is associated with every word. However, in our setting for scene graph generation, there may be no arc for some of the words, especially empty words.

Our solution is to augment the action set with a REDUCE action, that pops the stack *without* adding to the arc set (see Table 1). This action is often used in other transition-based dependency parsing systems (e.g. arc-eager (Nivre, 2004)). More recently, Hershcovich et al. (2017) and Buys and Blunsom (2017) also included this action when parsing sentences to graph structures.

Parser	F-score
Stanford (Schuster et al., 2015)	0.3549
SPICE (Anderson et al., 2016)	0.4469
Ours (left arc rule)	**0.4967**
Ours (right arc rule)	0.4952
Ours (all SYN)	0.4877
Ours (no SYN)	0.4538
Oracle	0.6985

Table 2: The F-scores (i.e. SPICE metric) between scene graphs parsed from region descriptions and ground truth region graphs on the intersection of Visual Genome (Krishna et al., 2017) and MS COCO (Lin et al., 2014) validation set.

We still minimize the loss function defined in Eqn. 7, except that now $|Y|$ increases from 3 to 4. During training, we impose the oracle to select the REDUCE action when it is in Y^+. In terms of loss function, we increment by 1 the loss incurred by the other 3 transition actions if REDUCE incurs zero loss.

5 Experiments

5.1 Implementation Details

We train and evaluate our scene graph parsing model on (a subset of) the Visual Genome (Krishna et al., 2017) dataset. Each image in Visual Genome contains a number of regions, and each region is annotated with both a region description and a region scene graph. Our training set is the intersection of Visual Genome and MS COCO (Lin et al., 2014) train2014 set, which contains a total of 34027 images/ 1070145 regions. We evaluate on the intersection of Visual Genome and MS COCO val2014 set, which contains a total of 17471 images/ 547795 regions.

In our experiments, the number of hidden units in BiLSTM is 256; the number of layers in BiLSTM is 2; the word embedding dimension is 200; the number of hidden units in MLP is 100. We use fixed learning rate 0.001 and Adam optimizer (Kingma and Ba, 2014) with epsilon 0.01. Training usually converges within 4 epochs.

We will release our code and trained model upon acceptance.

5.2 Quality of Parsed Scene Graphs

We use a slightly modified version of SPICE score (Anderson et al., 2016) to evaluate the quality of

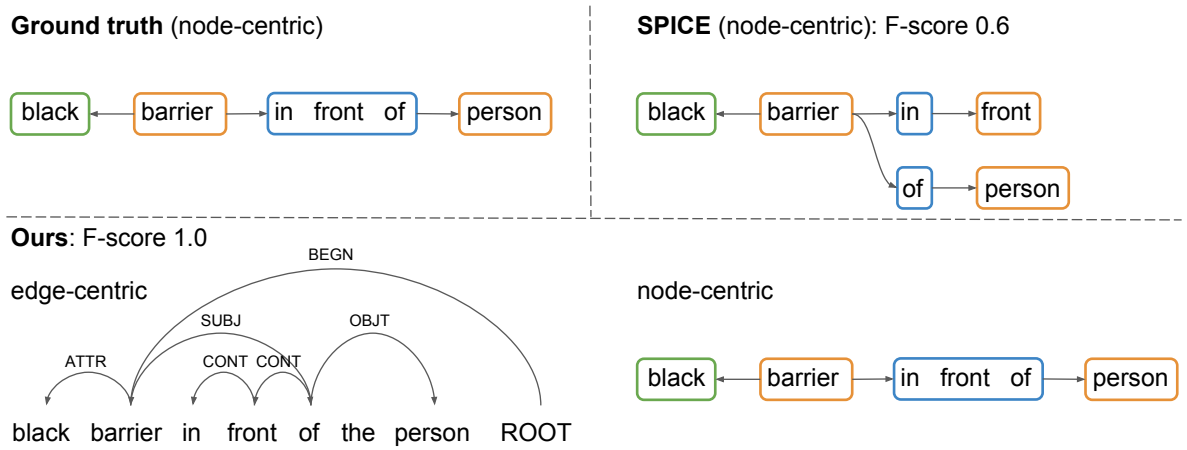

Figure 2: Scene graph parsing result of the sentence "black barrier in front of the person". In the node-centric graphs, orange represents object node, green represents attribute node, blue represents relation node.

	Stack	Buffer	Action
0		black barrier in front of the person ROOT	SHIFT
1	black	barrier in front of the person ROOT	LEFT(ATTR)
2		barrier in front of the person ROOT	SHIFT
3	barrier	in front of the person ROOT	SHIFT
4	barrier in	front of the person ROOT	LEFT(CONT)
5	barrier	front of the person ROOT	SHIFT
6	barrier front	of the person ROOT	LEFT(CONT)
7	barrier	of the person ROOT	SHIFT
8	barrier of	the person ROOT	SHIFT
9	barrier of the	person ROOT	REDUCE
10	barrier of	person ROOT	SHIFT
11	barrier of person	ROOT	RIGHT(OBJT)
12	barrier of	ROOT	RIGHT(SUBJ)
13	barrier	ROOT	LEFT(BEGN)
14		ROOT	

Figure 3: Intermediate actions taken by the trained dependency parser when parsing the sentence "black barrier in front of the person".

scene graph parsing. Specifically, for every region, we parse its description using a parser (e.g. the one used in SPICE or our customized dependency parser), and then calculate the F-score between the parsed graph and the ground truth region graph (see Section 3.2 of Anderson et al. (2016) for more details). Note that when SPICE calculates the F-score, a node in one graph could be matched to several nodes in the other, which is problematic. We fix this and enforce one-to-one matching when calculating the F-score. Finally, we report the average F-score across all regions.

Table 2 summarizes our results. We see that our customized dependency parsing model achieves an average F-score of 49.67%, which significantly outperforms the parser used in SPICE by 5 percent. This result shows that our customized dependency parser is very effective at learning from data, and generates more accurate scene graphs than the best previous approach.

Ablation Studies First, we study how the sentence-graph alignment procedure affects the final performance. Recall that our procedure involves two cycles, each with three steps. Of the six steps, synonym match (SYN) is only not used in the first step. We tried two more settings, where SYN is either used in all six steps or none of the six steps. We can see from Table 2 that the final

	Development set			Test set		
	R@5	**R@10**	**Med. rank**	**R@5**	**R@10**	**Med. rank**
(Schuster et al., 2015)	33.82%	45.58%	6	34.96%	45.68%	**5**
Ours	**36.69%**	**49.41%**	**4**	**36.70%**	**49.37%**	**5**

Table 3: Image retrieval results. We follow the same experiment setup as Schuster et al. (2015), except using a different scoring function when ranking images. Our parser consistently outperforms the Stanford Scene Graph Parser across evaluation metrics.

F-score drops in both cases, hence supporting the procedure that we chose.

Second, we study whether changing the direction of CONT arcs from pointing left to pointing right will make much difference. Table 2 shows that the two choices give very similar performance, suggesting that our dependency parser is robust to this design choice.

Finally, we report the oracle score, which is the similarity between the aligned graphs that we use during training and the ground truth graphs. The F-score is relatively high at 69.85%. This shows that improving the parser (about 20% margin) and improving the sentence-graph alignment (about 30% margin) are both promising directions for future research.

Qualitative Examples We provide one parsing example in Figure 2 and Figure 3. This is a sentence that is relatively simple, and the underlying scene graph includes two object nodes, one attribute node, and one compound word relation node. In parsing this sentence, all four actions listed in Table 1 are used (see Figure 3) to produce the edge-centric scene graph (bottom left of Figure 2), which is then trivially converted to the node-centric scene graph (bottom right of Figure 2).

5.3 Application in Image Retrieval

We test if the advantage of our parser can be propagated to computer vision tasks, such as image retrieval. We directly compare our parser with the Stanford Scene Graph Parser (Schuster et al., 2015) on the development set and test set of the image retrieval dataset used in Schuster et al. (2015) (not Visual Genome).

For every region in an image, there is a human-annotated region description and region scene graph. The queries are the region descriptions. If the region graph corresponding to the query is a subgraph of the complete graph of another image, then that image is added to the ground truth set for this query. All these are strictly following Schuster et al. (2015). However, since we did not obtain nor reproduce the CRF model used in Johnson et al. (2015) and Schuster et al. (2015), we used F-score similarity instead of the likelihood of the maximum a posteriori CRF solution when ranking the images based on the region descriptions. Therefore the numbers we report in Table 3 are not directly comparable with those reported in Schuster et al. (2015).

Our parser delivers better retrieval performance across all three evaluation metrics: recall@5, recall@10, and median rank. We also notice that the numbers in our retrieval setting are higher than those (even with oracle) in Schuster et al. (2015)'s retrieval setting. This strongly suggests that generating accurate scene graphs from images is a very promising research direction in image retrieval, and grounding parsed scene graphs to bounding box proposals without considering visual attributes/relationships (Johnson et al., 2015) is suboptimal.

6 Conclusion

In this paper, we offer a new perspective and solution to the task of parsing scene graphs from textual descriptions. We begin by moving the labels/types from the nodes to the edges and introducing the edge-centric view of scene graphs. We further show that the gap between edge-centric scene graphs and dependency parses can be filled with a careful redesign of label and action space. This motivates us to train a single, customized, end-to-end neural dependency parser for this task, as opposed to prior approaches that used generic dependency parsing followed by heuristics or simple classifier. We directly train our parser on a subset of Visual Genome (Krishna et al., 2017), without transferring any knowledge from Penn Treebank (Marcus et al., 1993) as previous works did.

The quality of our trained parser is validated in terms of both SPICE similarity to the ground truth graphs and recall rate/median rank when performing image retrieval.

We hope our paper can lead to more thoughts on the creative uses and extensions of existing NLP tools to tasks and datasets in other domains. In the future, we plan to tackle more computer vision tasks with this improved scene graph parsing technique in hand, such as image region grounding. We also plan to investigate parsing scene graph with cyclic structures, as well as whether/how the image information can help boost parsing quality.

Acknowledgments

Abstract

We investigate grounded sentence representations, where we train a sentence encoder to predict the image features of a given caption—i.e., we try to "imagine" how a sentence would be depicted visually—and use the resultant features as sentence representations. We examine the quality of the learned representations on a variety of standard sentence representation quality benchmarks, showing improved performance for grounded models over non-grounded ones. In addition, we thoroughly analyze the extent to which grounding contributes to improved performance, and show that the system also learns improved word embeddings.

1 Introduction

Following the word embedding upheaval of the past few years, one of NLP's next big challenges has become the hunt for universal sentence representations: generic representations of sentence meaning that can be "plugged into" any kind of system or pipeline. Examples include Paragraph2Vec (Le and Mikolov, 2014), C-Phrase (Pham et al., 2015), SkipThought (Kiros et al., 2015) and FastSent (Hill et al., 2016a). These representations tend to be learned from large corpora in an unsupervised setting, much like word embeddings, and effectively "transferred" to the task at hand.

Purely text-based semantic models, which represent word meaning as a distribution over other words (Harris, 1954; Turney and Pantel, 2010; Clark, 2015), suffer from the grounding problem (Harnad, 1990). It has been shown that grounding leads to improved performance on a variety of word-level tasks (Baroni, 2016; Kiela, 2017). Unsupervised sentence representation models are often doubly exposed to the grounding problem, especially if they represent sentence meanings as a distribution over other sentences, as in SkipThought (Kiros et al., 2015).

Here, we examine whether grounding also leads to improved sentence representations. In short, the grounding problem is characterized by the lack of an association between symbols and external information. We address this problem by aligning text with paired visual data and hypothesize that sentence representations can be enriched with external information—i.e., grounded—by forcing them to capture visual semantics. We investigate the performance of these representations and the effect of grounding on a variety of semantic benchmarks.

There has been much recent interest in generating actual images from text (Goodfellow et al., 2014; van den Oord et al., 2016; Mansimov et al., 2016). Our method takes a slightly different approach: instead of predicting actual images, we train a deep recurrent neural network to predict the *latent feature representation* of images. That is, we are specifically interested in the semantic content of visual representations and how useful that information is for learning sentence representations. One can think of this as trying to imagine, or form a "mental picture", of a sentence's meaning (Chrupała et al., 2015). Much like a sentence's meaning in classical semantics is given by its model-theoretic ground truth (Tarski, 1944), our ground truth is provided by images.

Grounding is likely to be more useful for concrete words and sentences: a sentence such as "democracy is a political system" does not yield any coherent mental picture. In order to accommodate the fact that much of language is abstract, we take sentence representations obtained using text-only data (which are better for representing abstract meaning) and combine them with the grounded representations that our system learns (which are good for representing concrete meaning), leading to multi-modal sentence representations.

[1]Work done while at Facebook AI Research.

Proceedings of NAACL-HLT 2018, pages 408–418
New Orleans, Louisiana, June 1 - 6, 2018.

In what follows, we introduce a system for grounding sentence representations by learning to predict visual content. Although it is not the primary aim of this work, it is important to first examine how well this system achieves what it is trained to do, by evaluating on the COCO5K image and caption retrieval task. We then analyze the performance of grounded representations on a variety of sentence-level semantic transfer tasks, showing that grounding increases performance over text-only representations. We then investigate an important open question in multi-modal semantics: to what extent are improvements in semantic performance due to grounding, rather than to having more data or data from a different distribution? In the remainder, we analyze the role that concreteness plays in representation quality and show that our system learns grounded word embedding projections that outperform non-grounded ones. To the best of our knowledge, this is the first work to comprehensively study grounding for distributed sentence representations on such a wide set of semantic benchmark tasks.

2 Related work

Sentence representations Although there appears to be a consensus with regard to the methodology for learning word representations, this is much more of an open problem for sentence representations. Recent work has ranged from trying to learn to compose word embeddings (Le and Mikolov, 2014; Pham et al., 2015; Wieting et al., 2016; Arora et al., 2017), to neural architectures for predicting the previous and next sentences (Kiros et al., 2015) or learning representations via large-scale supervised tasks (Conneau et al., 2017). In particular, SkipThought (Kiros et al., 2015) led to an increased interest in learning sentence representations. Hill et al. (2016a) compare a wide selection of unsupervised and supervised methods, including a basic caption prediction system that is similar to ours. That study finds that "different learning methods are preferable for different intended applications", i.e., that the matter of optimal universal sentence representations is as of yet far from decided.

InferSent (Conneau et al., 2017) recently showed that supervised sentence representations can be of very high quality. Here, we learn grounded sentence representations in a supervised setting, combine them with standard unsupervised sentence representations, and show how grounding can help for a variety of sentence-level tasks.

Multi-modal semantics Language grounding in semantics has been motivated by evidence that human meaning representations are grounded in perceptual experience (Jones et al., 1991; Perfetti, 1998; Andrews et al., 2009; Riordan and Jones, 2011). That is, despite ample evidence of humans representing meaning with respect to an external environment and sensorimotor experience (Barsalou, 2008; Louwerse, 2008), standard semantic models rely solely on textual data. This gives rise to an infinite regress in text-only semantic representations, i.e., words are defined in terms of other words, *ad infinitum*.

The field of multi-modal semantics, which aims to address this issue by enriching textual representations with information from other modalities, has mostly been concerned with word representations (Bruni et al., 2014; Baroni, 2016; Kiela, 2017, and references therein). Learning multi-modal representations that ground text-only representations has been shown to improve performance on a variety of core NLP tasks. This work is most closely related to that of Chrupała et al. (2015), who also aim to ground language by relating images to captions: here, we additionally address abstract sentence meaning; have a different architecture, loss function and fusion strategy; and explicitly focus on grounded universal sentence representations.

Bridging vision and language There is a large body of work that involves jointly embedding images and text, at the word level (Frome et al., 2013; Joulin et al., 2016), the phrase level (Karpathy et al., 2014; Li et al., 2016), and the sentence level (Karpathy and Fei-Fei, 2015; Klein et al., 2015; Kiros et al., 2015; Chen and Zitnick, 2015; Reed et al., 2016). Our model similarly learns to map sentence representations to be consistent with a visual semantic space, and we focus on studying how these grounded text representations transfer to NLP tasks.

Moreover, there has been a lot of work in recent years on the task of image caption generation (Bernardi et al., 2016; Vinyals et al., 2015; Mao et al., 2015; Fang et al., 2015). Here, we do the opposite: we predict the correct image (features) from the caption, rather than the caption from the image (features). Similar ideas were recently successfully applied to multi-modal machine translation

(Elliott and Kádár, 2017; Gella et al., 2017; Lee et al., 2017). Recently, Das et al. (2017) trained dialogue agents to communicate about images, trying to predict image features as well.

3 Approach

In the following, let $\mathcal{D} = \{(I_k, C_k)\}_{k=1}^{N}$ be a dataset where each image I_k is associated with one or more captions $C_k = \{C_1, \ldots, C_{|C|_k}\}$. A prominent example of such a dataset is COCO (Lin et al., 2014), which consists of images with up to 5 corresponding captions for each image. The objective of our approach is to encode a given sentence, i.e., a caption C, and learn to ground it in the corresponding image I. To encode the sentence, we train a bidirectional LSTM (BiLSTM) on the caption, where the input is a sequence of projected word embeddings. We combine the final left-to-right and right-to-left hidden states of the LSTM and take the element-wise maximum to obtain a sentence encoding. We then examine three distinct methods for grounding the sentence encoding.

In the first method, we try to predict the image features (Cap2Img). That is, we learn to map the caption to the same space as the image features that represent the correct image. We call this strong perceptual grounding, where we take the visual input directly into account.

An alternative method is to exploit the fact that one image in COCO has multiple captions (Cap2Cap), and to learn to predict which other captions are valid descriptions of the same image. This approach is strictly speaking not perceptually grounded, but exploits the fact that there is an implicit association between the captions and the shared underlying image, and so could be considered a weaker version of grounding.

Finally, we experiment with a model that optimizes both these objectives jointly: that is, we predict both images and alternative captions for the same image (Cap2Both). Thus, Cap2Both incorporates both strong perceptual and weak implicit grounding. Please see Figure 1 for an illustration of the various models. In what follows, we discuss them in more technical detail.

3.1 Bidirectional LSTM

To learn sentence representations, we employ a bidirectional LSTM architecture. In particular, let $x = (x_1, \ldots, x_T)$ be an input sequence where each word is represented via an embedding $\mathbf{x}_t \in \mathbb{R}^n$. Using a standard LSTM (Hochreiter and Schmidhuber, 1997), the hidden state at time t, denoted $\mathbf{h}_t \in \mathbb{R}^m$, is computed via

$$\mathbf{h}_{t+1}, \mathbf{c}_{t+1} = \text{LSTM}(\mathbf{x}_t, \mathbf{h}_t, \mathbf{c}_t \mid \Theta)$$

where $\mathbf{c}_t$ denotes the cell state of the LSTM and where Θ denotes its parameters.

To exploit contextual information in both input directions, we process input sentences using a bidirectional LSTM, that reads an input sequence in both normal and reverse order. In particular, for an input sequence x of length T, we compute the hidden state at time t, $\mathbf{h}_t \in \mathbb{R}^{2m}$ via

$$\mathbf{h}^f_{t+1} = \text{LSTM}(\mathbf{x}_t, \mathbf{h}^f_t, \mathbf{c}^f_t \mid \Theta^f)$$
$$\mathbf{h}^b_{t+1} = \text{LSTM}(\mathbf{x}_{T-t}, \mathbf{h}^b_t, \mathbf{c}^b_t \mid \Theta^b)$$

Here, the two LSTMs process x in a forward and a backward order, respectively. We subsequently use $\max : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ to combine them into their element-wise maximum, yielding the representation of a caption after it has been processed with the BiLSTM:

$$\mathbf{h}_T = \max(\mathbf{h}^f_t, \mathbf{h}^b_t)$$

We use GloVe vectors (Pennington et al., 2014) for our word embeddings. The embeddings are kept fixed during training, which allows a trained sentence encoder to transfer to tasks (and a vocabulary) that it has not yet seen, provided GloVe embeddings are available. Since GloVe representations are not tuned to represent grounded information, we learn a global transformation of GloVe space to grounded word space. Specifically, let $\overline{\mathbf{x}} \in \mathbb{R}^n$ be the original GloVe embeddings. We then learn a linear map $U \in \mathbb{R}^{n \times n}$ such that $\mathbf{x} = U\overline{\mathbf{x}}$ and use $\mathbf{x}$ as input to the BiLSTM. The linear map U and the BiLSTM are trained jointly.

3.2 Cap2Img

Let $\mathbf{v} \in \mathbb{R}^I$ be the latent representation of an image (e.g.the final layer of a ResNet). To ground captions in the images that they describe, we map $\mathbf{h}_T$ into the latent space of image representations such that their similarity is maximized. In other words, we aim to predict the latent features of an image from its caption. The mapping of caption to image space is performed via a series of projections

$$\mathbf{p}_0 = \mathbf{h}_T$$
$$\mathbf{p}_{\ell+1} = \psi(P_\ell \mathbf{p}_\ell)$$

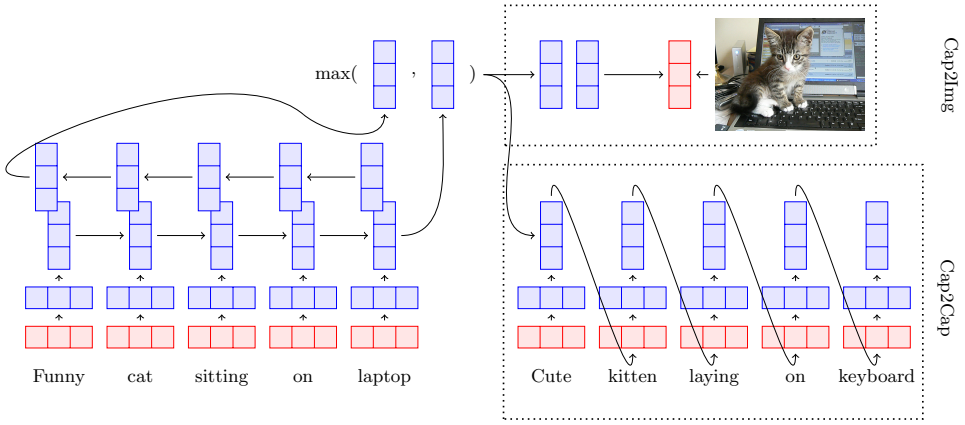

Figure 1: Model architecture: predicting either an image (Cap2Img), an alternative caption (Cap2Cap), or both at the same time (Cap2Both).

where ψ denotes a non-linearity such as ReLUs or tanh.

By jointly training the BiLSTM with these latent projections, we can then ground the language model in its visual counterpart. In particular, let $\Theta = \Theta_{\text{BiLSTM}} \cup \{P_\ell\}_{\ell=1}^{L}$ be the parameters of the BiLSTM as well as the projection layers. We then minimize the following ranking loss:

$$\mathcal{L}_{\text{C2I}}(\Theta) = \sum_{(I,C)\in\mathcal{D}} f_{\text{rank}}(I, C) + f_{\text{rank}}(C, I) \quad (1)$$

where

$$f_{\text{rank}}(a, b) = \sum_{b'\in\mathcal{N}_a} [\gamma - \text{sim}(a, b) + \text{sim}(a, b')]_+$$

where $[x]_+ = \max(0, x)$ denotes the threshold function at zero and γ defines the margin. Furthermore, $\mathcal{N}_a$ denotes the set of negative samples for an image or caption and $\text{sim}(\cdot, \cdot)$ denotes a similarity measure between vectors. In the following, we employ the cosine similarity, i.e.,

$$\text{sim}(a, b) = \frac{\langle \mathbf{a}, \mathbf{b} \rangle}{\|\mathbf{a}\|\|\mathbf{b}\|}.$$

Although this loss is not smooth at zero, it can be trained end-to-end using subgradient methods. Compared to e.g. an l_2 regression loss, Equation (1) is less susceptible to error incurred by subspaces of the visual representation that are irrelevant to the high level visual semantics. Empirically, we found it to be more robust to overfitting.

3.3 Cap2Cap

Let $x = (x_1, \ldots, x_T)$, $y = (y_1, \ldots, y_S)$ be a caption pair that describes the same image. To learn weakly grounded representations, we employ a standard sequence-to-sequence model (Sutskever et al., 2014), whose task is to predict y from x. As in the Cap2Cap model, let $\mathbf{h}_T$ be the representation of the input sentence after it has been processed with a BiLSTM. We then model the joint probability of y given x as

$$p(y \mid x) = \prod_{s=1}^{S} p(y_s \mid \mathbf{h}_T, y_1, \ldots, y_{s-1}, \Theta).$$

To model the conditional probability of y_s we use the usual multiclass classification approach over the vocabulary of the corpus $\mathcal{V}$ such that

$$p(y_s = k \mid \mathbf{h}_T, y_1, \ldots, y_{s-1}, \Theta) = \frac{e^{\langle \mathbf{v}_k, \mathbf{y}_s \rangle}}{\sum_{j=1}^{|\mathcal{V}|} e^{\langle \mathbf{v}_j, \mathbf{y}_s \rangle}}.$$

Here, $\mathbf{y}_s = \psi(W_V \mathbf{g}_s + \mathbf{b})$ and $\mathbf{g}_s$ is hidden state of the decoder LSTM at time s.

To learn the model parameters, we minimize the negative log-likelihood over all caption pairs, i.e.,

$$\mathcal{L}_{\text{C2C}}(\theta) = -\sum_{x,y\in\mathcal{D}} \sum_{s=1}^{|y|} \log p(y_s \mid \mathbf{h}_T, y_1, \ldots, y_{s-1}, \Theta).$$

3.4 Cap2Both

Finally, we also integrate both concepts of grounding into a joint model, where we optimize the following loss function:

$$\mathcal{L}_{\text{C2B}}(\Theta) = \mathcal{L}_{C2I}(\Theta) + \mathcal{L}_{C2C}(\Theta).$$

3.5 Grounded universal representations

On their own, features from this system are likely to suffer from the fact that training on COCO introduces biases: aside from the inherent dataset bias in COCO itself, the system will only have coverage for concrete concepts. COCO is also a much smaller dataset than e.g. the Toronto Books Corpus often used in purely text-based methods (Kiros et al., 2015). As such, grounded representations are potentially less "universal" than text-based alternatives, which also cover abstract concepts.

There is evidence that meaning is dually coded in the human brain: while abstract concepts are processed in linguistic areas, concrete concepts are processed in both linguistic and visual areas (Paivio, 1990). Anderson et al. (2017) recently corroborated this hypothesis using semantic representations and fMRI studies. In our case, we want to be able to accommodate concrete sentence meanings, for which our vision-centric system is likely to help; as well as abstract sentence meanings, where trying to "imagine" what "democracy is a political system" might look like will probably only introduce noise.

Hence, we optionally complement our systems' representations with more abstract universal sentence representations trained on language-only data (specifically, the Toronto Books Corpus). Although it would be interesting to examine multitask scenarios where these representations are jointly learned, we leave this for future work. Here, instead, we combine grounded and language-only representations using simple concatenation, i.e., $r_{gs} = r_{grounded} \mid\mid r_{ling-only}$. Concatenation has been proven to be a strong and straightforward mid-level multi-modal fusion method, previously explored in multi-modal semantics for word representations (Bruni et al., 2014; Kiela and Bottou, 2014). We call the combined system GroundSent (GS), and distinguish between sentences perceptually grounded in images (GroundSent-Img), weakly grounded in captions (GroundSent-Cap) or grounded in both (GroundSent-Both).

3.6 Implementation details

We use 300-dimensional GloVe (Pennington et al., 2014) embeddings, trained on WebCrawl, for the initial word representations and optimize using Adam (Kingma and Ba, 2015). We use ELU (Clevert et al., 2016) for the non-linearity in projection layers, set dropout to 0.5 and use a dimensionality of 1024 for the LSTM. The network was initialized with orthogonal matrices for the recurrent layers (Saxe et al., 2014) and He initialization (He et al., 2015) for all other layers. The learning rate and margin were tuned on the validation set using grid search.

4 Data, evaluation and comparison

We use the same COCO splits as Karpathy and Fei-Fei (2015) for training (113,287 images), validation (5000 images) and testing (5000 images). Image features for COCO were obtained by transferring the final layer from a ResNet-101 (He et al., 2016) trained on ImageNet (ILSVRC 2015).

4.1 Transfer tasks

We are specifically interested in how well (grounded) universal sentence representations transfer to different tasks. To evaluate this, we perform experiments for a variety of tasks. In all cases, we compare against layer-normalized Skip-Thought vectors, a well-known high-performing sentence encoding method (Ba et al., 2016). To ensure that we use the exact same evaluations, with identical hyperparameters and settings, we evaluate all systems with the same evaluation pipeline, namely SentEval (Conneau and Kiela, 2018)[2]. Following previous work in the field, the idea is to take universal sentence representations and to learn a simple classifier on top for each of the transfer tasks—the higher the quality of the sentence representation, the better the performance on these transfer tasks should be.

4.1.1 Semantic classification

We evaluate on the following well-known and widely used evaluations: movie review sentiment (MR) (Pang and Lee, 2005), product reviews (CR) (Hu and Liu, 2004), subjectivity classification (SUBJ) (Pang and Lee, 2004), opinion polarity (MPQA) (Wiebe et al., 2005), paraphrase identification (MSRP) (Dolan et al., 2004) and sentiment classification (SST, binary version) (Socher et al., 2013). Accuracy is measured in all cases, except for MRPC, which measures accuracy and the F1-score.

[2]See https://github.com/facebookresearch/SentEval. The aim of SentEval is to encompass a comprehensive set of benchmarks that has been loosely established in the research community as the standard for evaluating sentence representations.

Table 2: Accuracy results on sentence classification and entailment tasks.

4.1.2 Entailment

Recent years have seen an increased interest in entailment classification as an appropriate evaluation of sentence representation quality. We evaluate representations on two well-known entailment, or natural language inference, datasets: the large-scale SNLI dataset (Bowman et al., 2015) and the SICK dataset (Marelli et al., 2014).

4.2 Implementational details

We implement a simple logistic regression on top of the sentence representation. In the cases of SNLI and SICK, as is the standard for these datasets, the representations for the individual sentences u and v are combined by using $\langle \mathbf{u}, \mathbf{v}, \mathbf{u} * \mathbf{v}, |\mathbf{u} - \mathbf{v}| \rangle$ as the input features. We tune the seed and an l_2 penalty on the validation sets for each, and train using Adam (Kingma and Ba, 2015), with a learning rate of 0.001 and a batch size of 32.

5 Results

Although it is not the primary aim of this work to learn a state-of-the-art image and caption retrieval system, it is important to first establish the capability of our system to do what it is trained to do. Table 1 shows the results on the COCO5K caption and image retrieval tasks for the two models that predict image features. We compare our system against several well-known approaches, namely Deep Visual-Semantic Alignments (DVSA) (Karpathy and Fei-Fei, 2015), Fisher Vectors (FV) (Klein et al., 2015) and Order Embeddings (OE) (Vendrov et al., 2015). As the results show, Cap2Img performs very well on this task, outperforming the compared models on caption retrieval and being very close to order embeddings on image retrieval[3]. The fact that the system outperforms Order Embeddings on caption retrieval suggests that it has a better sentence encoder. Cap2Both does not work as well on this task as the image-only case, probably because interference from the language signal makes the problem harder to optimize. The results indicate that the system has learned to predict image features from captions, and captions from images, at a level exceeding or close to the state-of-the-art on this task.

5.1 Transfer task performance

Having established that we can learn high-quality grounded sentence encodings, the core question we now wish to examine is how well grounded sentence representations transfer. In this section, we combine our grounded features with the

[3]In fact, we found that we can achieve better performance on this task by reducing the dimensionality of the encoder. A lower dimensionality in the encoder also reduces the transferability of the features, unfortunately, so we leave a more thorough investigation of this phenomenon for future work.

Table 3: Thorough investigation of the contribution of grounding, ensuring equal number of components and identical architectures, on the variety of sentence-level semantic benchmark tasks. STb=SkipThought-like model with bidirectional LSTM+max. 2×STb-1024=ensemble of 2 different STb models with different initializations. GroundSent is STb-1024+Cap2Cap/Img/Both. We find that performance improvements are sometimes due to having more parameters, but in most cases due to grounding.

high-quality layer-normalized SkipThought representations of Ba et al. (2016), leading to multi-modal sentence representations as described in Section 3.5. That is, we concatenate Cap2Cap, Cap2Img or Cap2Both and Skip-Thought with Layer Normalization (ST-LN) representations, yielding GroundSent-Cap, GroundSent-Img and GroundSent-Both representations, respectively. We report performance of ST-LN using SentEval, which led to slightly different numbers than what is reported in their paper[4].

Table 2 shows the results for the semantic classification and entailment tasks. Note that all systems use the exact same evaluation pipeline, which makes them directly comparable. We can see that in all cases, grounding increases the performance. The question of which type of grounding works best is more difficult: generally, grounding with Cap2Cap and Cap2Both appears to do slightly better on most tasks, but on e.g. SST, Cap2Img works better. The entailment task results (SNLI and SICK in Table 2) show a similar picture: in all cases grounding improves performance.

It is important to note that, in this work, we are not necessarily concerned with replacing the state-of-the-art on these tasks: there are systems that perform better. We are primarily interested in whether grounding helps relative to text-only baselines. We find that it does.

[4]This is probably due to different seeds, optimization methods and other minor implementational details that differ between the original work and SentEval.

5.2 The contribution of grounding

An important open question is whether the increase in performance in multi-modal semantic models is due to qualitatively different information from *grounding*, or simply due to the fact that we have *more parameters* or *data from a different distribution*. In order to examine this, we implement a SkipThought-like model that also uses a bidirectional LSTM with element-wise max on the final hidden layer (henceforth referred to as STb). This model is architecturally identical to the sentence encoder used before: it can be thought of as Cap2Cap, but where the objective is not to predict an alternative caption, but to predict the previous and next sentence in the Toronto Books Corpus, just like SkipThought (Kiros et al., 2015).

We train a 1024-dimensional and 2048-dimensional STb model (for one full iteration, with all other hyperparameters identical to Cap2Cap) to compare against: if grounding improves results because it introduces qualitatively different information, rather than just from having more parameters (i.e., a higher embedding dimensionality), we should expect the multi-modal GroundSent models to perform better not only than STb-1024, but also than STb-2048, which has the same number of parameters (recall that GroundSent models are combinations of grounded and linguistic-only representations). In addition, we compare against an "ensemble" of two different STb-1024 models (i.e., a concatenation of two separately trained STb-1024), to check that we are not (just) observing an ensemble effect.

Dataset	Concreteness
MR	2.3737 ± 0.965
CR	2.4714 ± 1.025
SUBJ	2.4510 ± 1.007
MPQA	2.3158 ± 0.834
MRPC	2.5086 ± 0.987
SST	2.7471 ± 1.142
SNLI	3.1867 ± 1.309
SICK	3.1282 ± 1.372

Table 4: Mean and variance of dataset concreteness, over all words in the datasets.

As Table 3 shows, a more nuanced picture emerges in this comparison: grounding helps more for some datasets than for others. Grounded models outperform the STb-1024 model (which uses much more data—the Toronto Books Corpus is much larger than COCO) in all cases, often already without concatenating the textual modality. The ensemble of two STb-1024 models performs better than the individual one, and so does the higher-dimensional one. In the cases of CR and MRPC (F1), it appears that improved performance is due to having more data or ensemble effects. For the other datasets, grounding clearly yields better results. These results indicate that grounding does indeed capture qualitatively different information, yielding better universal sentence representations.

6 Discussion

There are a few other important questions to investigate. The average abstractness or concreteness of the evaluation datasets may have a large impact on performance. In addition, word embeddings from the learned projection from GloVe input embeddings, which now provides a generic word-embedding grounding method even for words that are not present in the image-caption training data, can be examined.

6.1 Concreteness

As we have seen, performance across datasets and models can vary substantially. A dataset's concreteness plays an important role in the relative merit of applying grounding: a dataset consisting mostly of abstract words is less likely to benefit from grounding than one that uses mostly concrete words. In order to examine this effect, we calculate the average concreteness of the evaluation datasets used in this study. Table 4 shows the average human-annotated concreteness ratings for all words (where available) in each dataset. The ratings were obtained by Brysbaert et al. (2014) in a large-scale study, yielding scores for 40,000 English words.

We observe that the two entailment datasets are more concrete, which is due to the fact that the premises are derived from caption datasets (Flickr30K in the case of SNLI; Flickr8K and video captions in the case of SICK). This explains why grounding can clearly be seen to help in these cases. For the semantic classification tasks, the more concrete datasets are MRPC and SST. The picture is less clear for the first, but in SST we see that the grounded representations definitely do work better. Concreteness values make it easier to analyze performance, but are apparently not always direct indicators of improvements with grounding.

6.2 Grounded word embeddings

Our models contain a projection layer that maps the GloVe word embeddings that they receive as inputs to a different embedding space. There has been a lot of interest in grounded word representations in recent years, so it is interesting to examine what kind of word representations our models learn. We omit Cap2Cap for reasons of space (it performs similarly to Cap2Both). As shown in Table 5, the grounded word projections that our network learns yield higher-quality word embeddings on four standard lexical semantic similarity benchmarks: MEN (Bruni et al., 2014), SimLex-999 (Hill et al., 2016b), Rare Words (Luong et al., 2013) and WordSim-353 (Finkelstein et al., 2001).

7 Conclusion

We have investigated grounding for universal sentence representations. We achieved good performance on caption and image retrieval tasks on the large-scale COCO dataset. We subsequently showed how the sentence encodings that the sys-

tem learns can be transferred to various NLP tasks, and that grounded universal sentence representations lead to improved performance. We analyzed the source of improvements from grounding, and showed that the increased performance appears to be due to the introduction of qualitatively different information (i.e., grounding), rather than simply having more parameters or applying ensemble methods. Lastly, we showed that our systems learned high-quality grounded word embeddings that outperform non-grounded ones on standard semantic similarity benchmarks. It could well be that our methods are even more suited for more concrete tasks, such as visual question answering, visual storytelling, or image-grounded dialogue—an avenue worth exploring in future work. In addition, it would be interesting to explore multi-task learning for sentence representations where one of the tasks involves grounding.

Abstract

The present work investigates whether different quantification mechanisms (set comparison, vague quantification, and proportional estimation) can be jointly learned from visual scenes by a multi-task computational model. The motivation is that, in humans, these processes underlie the same cognitive, non-symbolic ability, which allows an automatic estimation and comparison of set magnitudes. We show that when information about lower-complexity tasks is available, the higher-level proportional task becomes more accurate than when performed in isolation. Moreover, the multi-task model is able to generalize to unseen combinations of target/non-target objects. Consistently with behavioral evidence showing the interference of absolute number in the proportional task, the multi-task model no longer works when asked to provide the number of target objects in the scene.

1 Introduction

Understanding and producing sentences like 'There are *more* cars than parking lots', '*Most* of the supporters wear blue t-shirts', '*Twenty percent* of the trees have been planted last year', or '*Seven* students passed the exam', is a fundamental competence which allows speakers to communicate information about quantities. Crucially, the type of information conveyed by these expressions, as well as their underlying cognitive mechanisms, are not equivalent, as suggested by evidence from linguistics, language acquisition, and cognition.

First, comparatives ('more', 'less'), quantifiers ('some', 'most', 'all'), and proportions ('20%', 'two thirds') express a comparison or relation *between sets* (e.g., between the set of cars and the set of parking lots). Such relational information is rather coarse when expressed by comparatives and vague quantifiers, more precise when denoted by proportions. In contrast, numbers ('one', 'six', 'twenty-two') denote the exact, absolute cardinality of the items belonging to *one set* (e.g., the set of students who passed the exam).

Second, during language acquisition, these expressions are neither learned at the same time nor governed by the same rules. Recent evidence showed that children can understand comparatives at around 3.3 years (Odic et al., 2013; Bryant, 2017), with quantifiers being learned a few months later, at around 3.4-3.6 years (Hurewitz et al., 2006; Minai, 2006; Halberda et al., 2008). Crucially, knowing the meaning of numbers, an ability that starts not before the age of 3.5 years (Le Corre and Carey, 2007), is not required to understand and use these expressions. As for proportions, they are acquired significantly later, being fully mastered only at the age of 9 or 10 (Hartnett and Gelman, 1998; Moss and Case, 1999; Sophian, 2000).

Third, converging evidence from cognition and neuroscience supports the hypothesis that some important components of these expressions of quantity are grounded on a preverbal, non-symbolic system representing magnitudes (Piazza, 2010). This system, often referred to as Approximate Number System (ANS), is invariant to the sensory modality and almost universal in the animal domain, and consists in the ability of holistically extracting and comparing approximate numerosities (Piazza and Eger, 2016). In humans, it is present since the youngest age, with 6-month-old infants being able to automatically compare sets and combine them by means of proto-arithmetical operations (Xu and Spelke, 2000; McCrink and Wynn, 2004). Since it obeys Weber's law, according to which highly differing sets (e.g. 2:8) are easier to discriminate than highly similar sets (e.g. 7:8), ANS has been recently claimed to be a *ratio-based* mechanism (Sidney et al., 2017; Matthews et al., 2016). In support of this, behavioral findings indicate that, in non-symbolic

Proceedings of NAACL-HLT 2018, pages 419–430
New Orleans, Louisiana, June 1 - 6, 2018.

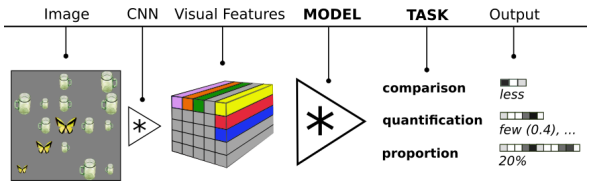

Figure 1: Toy representation of the quantification tasks and corresponding outputs explored in the paper. Note that quantification always refers to animals (target set).

contexts (e.g. visual scenes), proportional values are extracted holistically, i.e. without relying on the pre-computed cardinalities of the sets (Fabbri et al., 2012; Yang et al., 2015). Indeed, people are fairly accurate in providing the proportion of targets in a scene, even in high-speed settings (Healey et al., 1996; Treisman, 2006). Similarly, in briefly-presented scenes, the interpretation of quantifiers is shown to be best described by proportional information (Pezzelle et al., under review).

Altogether, this suggests that performing (1) set comparison, (2) vague quantification, and (3) proportional estimation, which all rely on information regarding relations among sets, underlies increasingly-complex steps of the same mechanism. Notably, such complexity would range from 'more/less' judgements to proportional estimation, as suggested by the increasing precision of ANS through years (Halberda and Feigenson, 2008), the reported boundary role of 'half' in early proportional reasoning (Spinillo and Bryant, 1991), and the different age of acquisition of the corresponding linguistic expressions. Finally, the ratio-based operation underlying these task would be different from (and possibly conflicting with) that of estimating the absolute numerosity of one set. Indeed, absolute numbers are found to interfere with the access to proportions (Fabbri et al., 2012).

Inspired by this converging evidence, the present work proposes a computational framework to explore various quantification tasks in the visual domain (see Figure 1). In particular, we investigate whether ratio-based quantification tasks can be modeled by a single, multi-task learning neural network. Given a synthetic scene depicting animals (in our setting, the 'target' objects) and artifacts ('non-target'), our model is designed to jointly perform all the tasks by means of an architecture that reflects their increasing complexity.[1] To perform proportional estimation (the most complex), the model builds on the representations learned to perform vague quantification and, in turn, set comparison (the least complex). We show that the multi-task model achieves both higher accuracy and higher generalization power compared to the one-task models. In contrast, we prove that introducing the absolute number task in the loop is not beneficial and indeed hurts the performance.

Our main contribution lies in the novel application and evaluation of a multi-task learning architecture on the task of jointly modeling 3 different quantification operations. On the one hand, our results confirm the interdependency of the mechanisms underlying the tasks of set comparison, vague quantification, and proportional estimation. On the other, we provide further evidence on the effectiveness of these computational architectures.

2 Related Work

2.1 Quantities in Language & Vision

In recent years, the task of extracting quantity information from visual scenes has been tackled via Visual Question Answering (VQA). Given a real image and a natural language question, a VQA computational model is asked to understand the image, the linguistic query, and their interaction to provide the correct answer. So-called *count* questions, i.e. 'How many *Xs* have the property *Y*?', are very frequent and have been shown to be particularly challenging for any model (Antol et al., 2015; Malinowski et al., 2015; Ren et al., 2015; Fukui et al., 2016). The difficulty of the task has been further confirmed by the similarly poor performance achieved even on the 'diagnostic' datasets, which include synthetic visual scenes depicting geometric shapes (Johnson et al., 2017; Suhr et al., 2017).

Using Convolutional Neural Networks (CNN), a number of works in Computer Vision (CV) have proposed specific architectures for counting digits (Seguí et al., 2015), people in the crowd (Zhang et al., 2015a), and penguins (Arteta et al., 2016). With a more cognitive flavor, Chattopadhyay et al. (2017) employed a 'divide-and-conquer' strategy to split the image into subparts and count the objects in each subpart by mimicking the 'subitizing' mechanism (i.e. numerosities up to 3-4 can be rapidly and accurately appreciated). Inspired by

[1]The dataset and the code can be downloaded from github.com/sandropezzelle/multitask-quant

the same cognitive ability is Zhang et al. (2015b), who trained a CNN to detect and count the salient objects in the image. Except Suhr et al. (2017), who evaluated models against various types of quantity expressions (including existential quantifiers), these works were just focused on the absolute number.

More akin to our work is Stoianov and Zorzi (2012), who showed that hierarchical generative models learn ANS as a statistical property of (synthetic) images. Their networks were tested on the task of set comparison ('more/less') and obtained 93% accuracy. A few studies specifically focused on the learning of quantifiers. Sorodoc et al. (2016) proposed a model to assign the correct quantifier to synthetic scenes of colored dots, whereas Sorodoc et al. (2018) operationalized the same task in a VQA fashion, using real images and object-property queries (e.g. 'How many *dogs* are *black*?'). Overall, the results of these studies showed that vague quantification can be learned by neural networks, though the performance is much lower when using real images and complex queries. Finally, Pezzelle et al. (2017) investigated the difference between the learning of cardinals and quantifiers from visual scenes, showing that they require two distinct computational operations. To our knowledge, this is the first attempt to jointly investigate the whole range of quantification mechanisms. Moreover, we are the first to exploit a multi-task learning paradigm for exploring the interactions between set comparison, vague quantification, and proportions.

2.2 Multi-Task Learning

Multi-Task Learning (MTL) has been shown to be very effective for a wide range of applications in machine learning (for an overview, see Ruder (2017)). The core idea is that different and yet related tasks can be jointly learned by a multi-purpose model rather than by separate and highly fine-tuned models. Since they share representations between related (or 'auxiliary') tasks, multi-task models are more robust and generalize better than single-task models. Successful applications of MTL have been proposed in CV to improve object classification (Girshick, 2015), face detection and rotation (Zhang et al., 2014; Yim et al., 2015), and to jointly perform a number of tasks as object detection, semantic segmentation, etc. (Misra et al., 2016; Li and Hoiem, 2016). Though, recently, a few studies applied MTL techniques to either count or estimate the number of objects in a scene (Sun et al., 2017; Sindagi and Patel, 2017), to our knowledge none of them were devoted to the learning of various quantification mechanisms.

In the field of natural language processing (NLP), MTL turned out to be beneficial for machine translation (Luong et al., 2016) and for a range of tasks such as chunking, tagging, semantic role labelling, etc. (Collobert et al., 2011; Søgaard and Goldberg, 2016; Bingel and Søgaard, 2017). In particular, Søgaard and Goldberg (2016) showed the benefits of keeping low-level tasks at the lower layers of the network, a setting which enables higher-level tasks to make a better use of the shared representations. Since this finding was also in line with previous evidence suggesting a natural order among different tasks (Shen and Sarkar, 2005), further work proposed MTL models in which several increasingly-complex tasks are hierarchically ordered (Hashimoto et al., 2017). The intuition behind this architecture, referred to as 'joint many-task model' in the source paper (Hashimoto et al., 2017), as well as its technical implementation, constitute the building blocks of the model proposed in the present study.

3 Tasks and Dataset

3.1 Tasks

Given a visual scene depicting a number of animals (targets) and artifacts (non-targets), we explore the following tasks, represented in Figure 1:

(a) set comparison (hence, **setComp**), i.e. judging whether the targets are 'more', 'same', 'less' than non-targets;

(b) vague quantification (hence, **vagueQ**), i.e. predicting the probability to use each of the 9 quantifiers ('none', 'almost none', 'few', 'the smaller part', 'some', 'many', 'most', 'almost all', 'all') to refer to the target set;

(c) proportional estimation (hence, **propTarg**), i.e. predicting the proportion of targets choosing among 17 ratios, ranging from 0 to 100%.

Tasks (a) and (c) are operationalized as classification problems and evaluated through accuracy. That is, only one answer out of 3 and 17, respectively, is considered as correct. Given the vague status of quantifiers, whose meanings are 'fuzzy' and overlapping, task (b) is evaluated by means

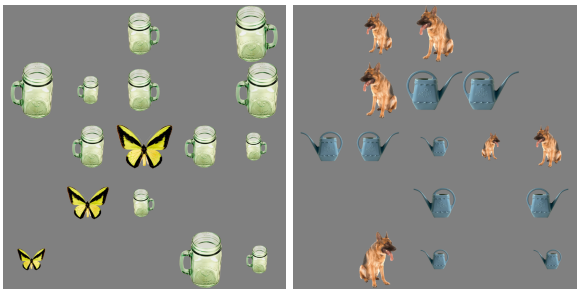

Figure 2: Two scenes included in our dataset. The letfmost one depicts a ratio 1:4 (3 animals, 12 artifacts, 15 total items), the rightmost one a ratio 2:3 (6, 9, 15).

of Pearson's correlation (r) between the predicted and the ground-truth probability vector (cf. § 3.2), for each datapoint.[2] The overall r is obtained by averaging these scores. It is worth mentioning that we could either evaluate (b) in terms of a classification task or operationalize (a) and (c) in terms of a correlation with human responses. The former evaluation is straightforward and can be easily carried out by picking the quantifier with the highest probability. The latter, in contrast, implies relying on behavioral data assessing the degree of overlap between ground-truth classes and speakers' choice. Though interesting, such evaluation is less crucial given the discrete, non-overlapping nature of the classes in tasks (a) and (c).

The tasks are explored by means of a MTL network that jointly performs the three quantification operations (see § 4.2). The intuition is that solving the lower-level tasks would be beneficial for tackling the higher-level ones. In particular, providing a proportional estimation ('80%') after performing vagueQ ('most') and setComp ('more') should lead to a higher accuracy in the highest-level task, which represents a further step in complexity compared to the previous ones. Moreover, lower-level tasks might be boosted in accuracy by the higher-level ones, since the latter include all the operations that are needed to carry out the former. In addition to the MTL model, we test a number of 'one-task' networks specifically designed to solve one task at a time (see § 4.1).

3.2 Dataset

We built a large dataset of synthetic visual scenes depicting a variable number of animals and artifacts on the top of a neutral, grey background

[2]We also experimented with Mean Average Error and dot product and found the same patterns of results (not reported).

	train	val	test	**total**
no. datapoints	11.9K	1.7K	3.4K	**17K**
% datapoints	70%	10%	20%	**100%**

Table 1: Number and partitioning of the datapoints.

(see Figure 2). In doing so, we employed the same methodology and materials used in Pezzelle et al. (under review), where the use of quantifiers in *grounded* contexts was explored by asking participants to select the most suitable quantifier for a given scene. Since the category of animals was always treated as the 'target', and that of artifacts as the 'non-target', we will henceforth use this terminology throughout the paper. The scenes were automatically generated by an in-house script using the following pipeline: (a) Two natural images, one depicting a target object (e.g. a butterfly) and one depicting a non-target (e.g. a mug) were randomly picked up from a sample of the dataset by Kiani et al. (2007). The sample was obtained by Pezzelle et al. (under review), who manually selected pictures depicting whole items (not just parts) and whose color, orientation and shape were not deceptive. In total, 100 unique instances of animals and 145 unique instances of artifacts were included; (b) The proportion of targets in the scene (e.g. 20%) was chosen by selecting one among 17 pre-defined *ratios* between targets:non-targets (e.g. 1:4, 'four non-targets to one target'). Out of 17 ratios, 8 were positive (targets $>$ 50%), 8 negative (targets $<$ 50%), and 1 equal (targets = 50%); (c) The absolute number of targets/non-targets was chosen to equally represent the various combinations available for a given ratio (e.g., for ratio 1:4: 1-4, 2-8, 3-12, 4-16), with the constraint of having a number of total objects in the scene (targets+non-targets) ranging from 3 to 20. In total, 97 combinations were represented in the dataset, with an average of 5.7 combinations/ratio (min 2, max 18); (d) To inject some variability, the instances of target/non-target objects were randomly resized according to one of three possible sizes (i.e. medium, big, and small) and flipped on the vertical axis before being randomly inserted onto a 5*5-cell virtual grid. As reported in Table 1, 17K scenes balanced per ratio (1K scenes/ratio) were generated and further split into train (70%), validation (10%), and test (20%).

Ground-truth classes for the tasks of setComp and propTarg were automatically assigned to each scene while generating the data. For vagueQ,

we took the probability distributions obtained on a dataset of 340 scenes by Pezzelle et al. (under review) and we applied them to our datapoints, which were built in the exact same way. These probability distributions had been collected by asking participants to select, from a list of 9 quantifiers (reported in § 3.1), the most suitable one to describe the target objects in a visual scene presented for 1 second. In particular, they were computed against the proportion of targets in the scene, which in that study was shown to be the overall best predictor for quantifiers. To illustrate, given a scene containing 20% of targets (cf. leftmost panel in Figure 2), the probability of choosing 'few' (ranging from 0 to 1) is 0.38, 'almost none' 0.27, 'the smaller part' 0.25, etc. It is worth mentioning that, for scenes containing either 100% or 0% targets the probability of choosing 'all' and 'none', respectively, is around 1. In all other cases, the distribution of probabilities is fuzzier and reflects the largely overlapping use of quantifiers, as in the example above. On average, the probability of the most-chosen quantifier across ratios is 0.53. Though this number cannot be seen as a genuine inter-annotator agreement score, it suggests that, on average, there is one quantifier which is preferred over the others.

4 Models

In this section, we describe the various models implemented to perform the tasks. For each model, several settings and parameters were evaluated by means of a thorough ablation analysis. Based on a number of factors like performance, speed, and stability of the networks, we opted for using ReLU nonlinear activation at all hidden layers and the simple and effective Stochastic Gradient Descent (SGD) as optimizer (lr = 0.01). We run each model for 100 epochs and saved weights and parameters of the epoch with the lowest validation loss. The best model was then used to obtain the predictions in the test set. All models were implemented using Keras.[3]

4.1 One-Task Models

We implemented separate models to tackle one task at a time. For each task, in particular, both a network using 'frozen' (i.e. pretrained) visual features and one computing the visual features in an 'end-to-end' fashion were tested.

[3] `https://keras.io/`

One-Task-Frozen These models are simple, 2-layer (ReLU) Multi-Layer Perceptron (MLP) networks that take as input a 2048-d frozen representation of the scene and output a vector containing softmax probability values. The frozen representation of the scene had been previously extracted using the state-of-art Inception v3 CNN (Szegedy et al., 2016) pretrained on ImageNet (Deng et al., 2009). In particular, the network is fed with the average of the features computed by the last Convolutional layer, which has size 25*2048.

One-Task-End2end These models are MLP networks that take as input the 203*203-pixel image and compute the visual features by means of the embedded Inception v3 module, which outputs 25*2048-d vectors (the grey and colored box in Figure 1). Subsequently, the 25 feature vectors are reduced twice via ReLU hidden layers, then concatenated, reduced (ReLU), and fed into a softmax layer to obtain the probability values.

4.2 Multi-Task Model

The `multi-task-prop` model performs 3 tasks at the *same time* with an architecture that reproduces in its *order* the conjectured complexity (see Figure 3 and its caption for technical details). The model has a core structure, represented by layers 1-5 in the figure, which is *shared* across tasks and trained with multiple outputs. In particular, (a) layers 1, 2, and 3 are trained using information regarding the output of all 3 tasks. That is, these layers are updated three times by as many back-propagation passes: One on the top of setComp output, the second on the top of vagueQ output, the third on the top of propTarg output; (b) layers 4 and 5 are affected by information regarding the output of vagueQ and propTarg, and thus updated twice; (c) layers 6 and 7 are updated once, on the top of the output of propTarg. Importantly, the three lower layers in Figure 3 (concatenation, ReLU, softmax) are not shared between the tasks, but specialized to output each a specific prediction. As can be noted, the order of the tasks reflects their complexity, since the last task in the pipeline has 2 more layers than the preceding one and 4 more than the first one.

5 Results

Table 2 reports the performance of each model in the various tasks (note that the lowest row and the rightmost column report results described

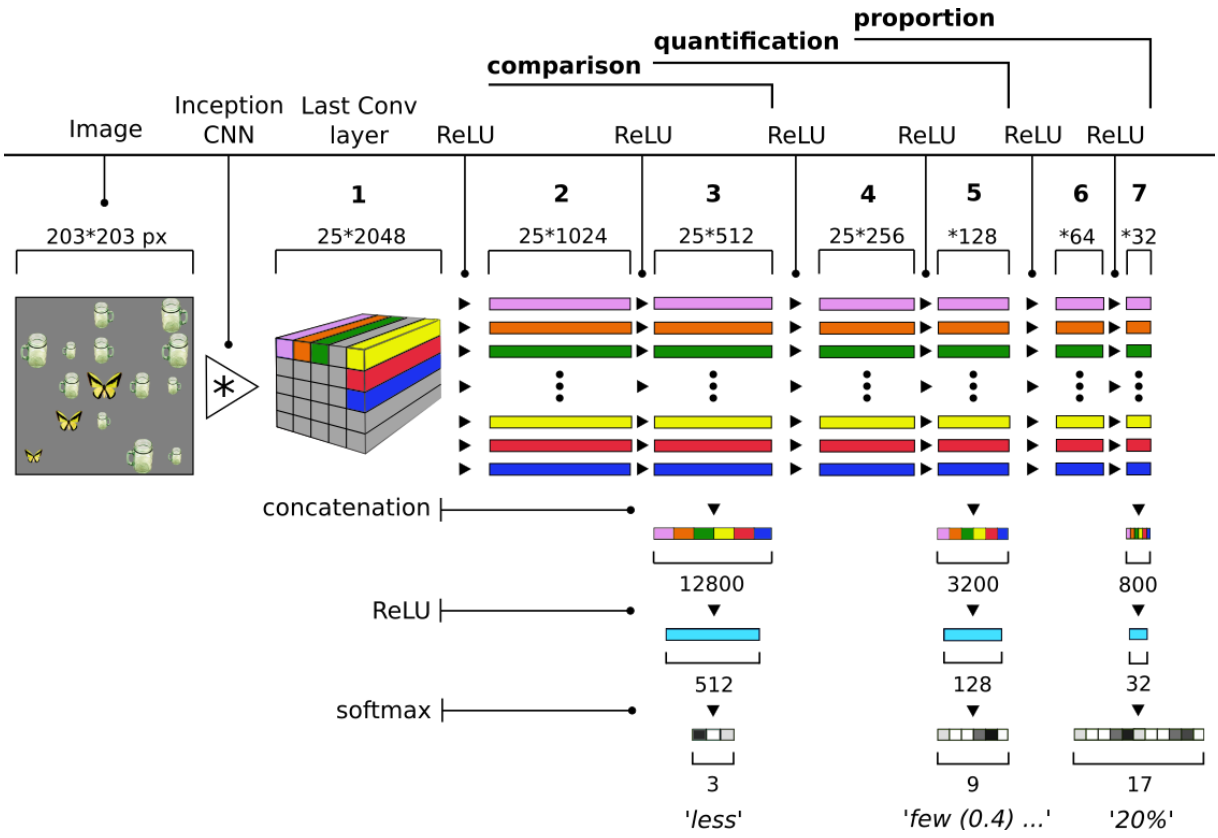

Figure 3: Architecture of the `multi-task-prop` model jointly performing (a) set comparison, (b) vague quantification, and (c) proportional estimation. Given a 203*203-pixel image as input, the model extracts a 25*2048 representation from the last Convolutional layer of the Inception v3. Subsequently, the vectors are reduced twice via ReLU hidden layers to 1024 and 512 dimensions. The 512-d vectors are concatenated and reduced, then a softmax layer is applied to output a 3-d vector with probability distributions for task (a). The same structure (i.e., 2 hidden layers, concatenation, reduction, and softmax) is repeated for tasks (b) and (c). All the tasks are trained with cross-entropy. To evaluate tasks (a) and (c), in testing, we extract the highest-probability class and compute **accuracy**, whereas task (b) is evaluated via **Pearson's correlation** against the 9-d ground-truth probability vector.

in § 6.1). In setComp, all the models are neatly above chance/majority level (0.47). In particular, the `one-task-end2end` model achieves a remarkable 0.90 acc., which is more than 10% better compared to the simple `one-task-frozen` model (0.78). The same pattern of results can be observed for vagueQ, where the Pearson's correlation (r) between the ground-truth and the predicted probability vector is around 0.96, that is more than 30% over the simpler model (0.62). This gap increases even more in propTarg, where the accuracy of the frozen model is more than 40 points below the one achieved by the `one-task-end2end` model (0.21 against 0.66). These results firmly indicate that, on the one hand, the frozen representation of the visual scene encodes little information about the proportion of targets (likely due to the the different task for which they were pretrained, i.e. object classification). On the other hand, computing the visual features in an end-to-end fashion leads to a significant improvement, suggesting that the network learns to pay attention to features that are helpful for specific tasks.

The most interesting results, however, are those achieved by the multi-task model, which turns out to be the best in all the tasks. As reported in Table 2, sharing the weights between the various tasks is especially beneficial for propTarg, where the accuracy reaches 0.92, that is, more than 25 points over the end-to-end, one-task model. An almost perfect performance of the model in this task can be observed in Figure 4, which reports the confusion matrix with the errors made by the model. As can be seen, the few errors are between 'touching' classes, e.g. between ratio 3:4 (43% of targets) and ratio 2:3 (40%). Since these classes

model	setComp	vagueQ	propTarg	nTarg
	accuracy	*Pearson r*	*accuracy*	*accuracy*
chance/majority	0.470	0.320	0.058	0.132
one-task-frozen	0.783	0.622	0.210	0.312
one-task-end2end	0.902	0.964	0.659	**0.966**
multi-task-prop	**0.995**	**0.982**	**0.918**	–
multi-task-number	0.854	0.807	–	0.478

Table 2: Performance of the models in the tasks of set comparison (setComp), vague quantification (vagueQ), proportional estimation (propTarg), and absolute number of targets (nTarg). Values in **bold** are the highest.

differ by a very small percentage, we gain indirect evidence that the model is learning some kind of proportional information rather than trivial associations between scenes and orthogonal classes.

To further explore this point, one way is to inspect the last layer of the proportional task (i.e. the 32-d turquoise vector in Figure 3). If the vectors contain information regarding the proportion of targets, we should expect scenes depicting the same proportion to have a similar representation. Also, scenes with similar proportions (e.g. 40% and 43%) would be closer to each other than are scenes with different proportions (e.g. 25% and 75%). Figure 5 depicts the results of a two-dimensional PCA analysis performed on the vectors of the last layer of the proportional task (the 32-d vectors).[4] As can be noted, scenes depicting the same proportion clearly cluster together, thus indicating that using these representations in a retrieval task would lead to a very high precision. Crucially, the clusters are perfectly ordered with respect to proportion. Starting from the purple cluster on the left side (90%) and proceeding clockwise, we find 83% (green), 80% (turquoise), 75% (brown), and so on, until reaching 10% (light blue). Proportions 0% (blue) and 100% (yellow) are neatly separated from the other clusters, being at the extremes of the 'clock'.

An improvement in the results can be also observed for setComp and vaqueQ, where the model achieves 0.99 acc. and 0.98 *r*, respectively. Figure 6 reports, for each quantifier, the probability values predicted by the model against the ground-truth ones. As can be seen, the red lines (model) approximate very closely the green ones (humans). In the following section, we perform further experiments to provide a deeper evaluation of the results.

6 In-Depth Evaluation

6.1 Absolute Numbers in the Loop

As discussed in § 1, the cognitive operation underlying setComp, vagueQ, and propTarg is different compared to that of estimating the absolute number of objects included in one set. To investigate whether such dissociation emerges at the computational level, we tested a modified version of our proposed multi-task model where propTarg task

[4] We used `https://projector.tensorflow.org/`

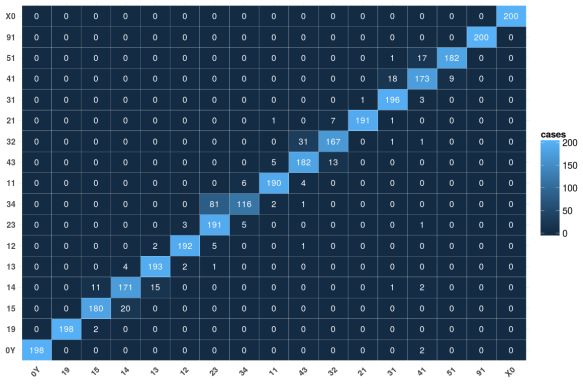

Figure 4: PropTarg. Heatmap reporting the errors made by the `multi-task-prop` model. Note that labels refer to *ratios*, i.e. 14 stands for ratio 1:4 (20% targets).

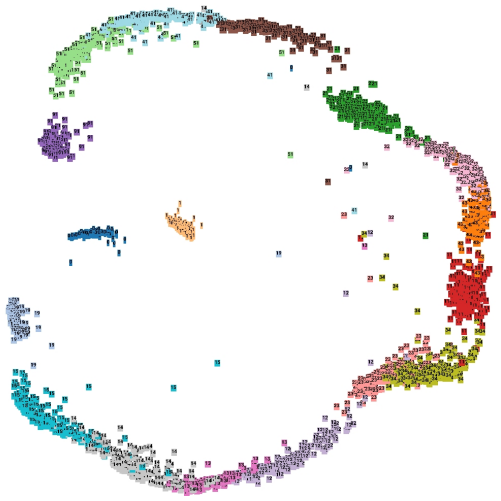

Figure 5: PCA visualization of the last layer (before softmax) of the proportional task in the MTL model.

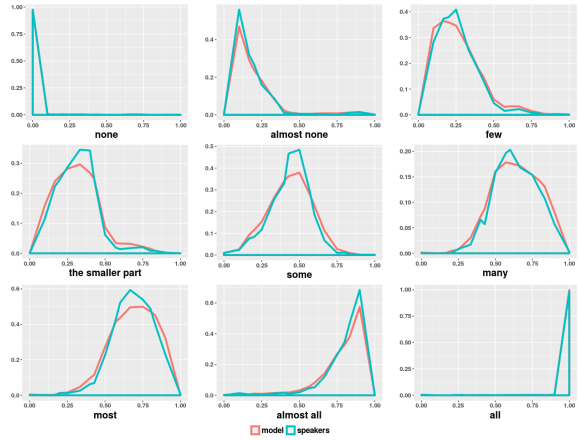

Figure 6: VagueQ. Probability values predicted by the `multi-task-prop` model against ground-truth probability distributions for each quantifier.

has been replaced with nTarg, namely the task of predicting the absolute number of targets. One-task models were also tested to evaluate the difficulty of the task when performed in isolation. Since the number of targets in the scenes ranges from 0 to 20, nTarg is evaluated as a 21-class classification task (majority class 0.13).

As reported in Table 2, the accuracy achieved by the `one-task-end2end` model is extremely high, i.e. around 0.97. This suggests that, when learned in isolation, the task is fairly easy, but only if the features are computed *within* the model. In fact, using frozen features results in a quite low accuracy, namely 0.31. This pattern of results is even more interesting if compared against the results of the `multi-task-number` model. When included in the multi-task pipeline, in fact, nTarg has a huge, 50-point accuracy drop (0.48). Moreover, both setComp and vagueQ turn out to be significantly *hurt* by the highest-level task, and experience a drop of around 14 and 17 points compared to the `one-task-end2end` model, respectively. These findings seem to corroborate the incompatibility of the operations needed for solving the tasks.

6.2 Reversing the Architecture

Previous work exploring MTL suggested that defining a hierarchy of increasingly-complex tasks is beneficial for jointly learning related tasks (see § 2.2). In the present work, the order of the tasks was inspired by cognitive and linguistic abilities (see § 1). Though cognitively implausible, it might still be the case that the model is able to learn even when reversing the order of the tasks, i.e. from the conjectured highest-level to the lowest-level one. To shed light on this issue, we tested the `multi-task-prop` model after reversing its architecture. That is, propTarg is now the first task, followed by vagueQ, and setComp.

model	setComp	vagueQ	propTarg
	accuracy	*Pearson r*	*accuracy*
chance/majority	0.470	0.320	0.058
one-task-frozen	0.763	0.548	0.068
one-task-end2end	0.793	0.922	0.059
multi-task-prop	**0.943**	**0.960**	**0.539**

Table 3: Unseen dataset. Performance of the models in each task. Values in **bold** are the highest.

In contrast with the pattern of results obtained by the original pipeline, no benefits are observed for this version of MTL model compared to one-task networks. In particular, both vagueQ (0.32 *r*) and propTarg (0.08 acc.) performance are around chance level, with setComp reaching just 0.65 acc., i.e. 25 point lower than the `one-task-end2end` model. The pipeline of increasing complexity motivated theoretically is thus confirmed at the computational level.

6.3 Does MTL Generalize?

As discussed in § 2.2, MTL is usually claimed to allow a higher generalization power. To investigate whether our proposed `multi-task-prop` model genuinely learns to quantify from visual scenes, and not just associations between patterns and classes, we tested it with unseen combinations of targets/non-targets. The motivation is that, even in the most challenging propTarg task, the model might learn to match a given combination, e.g. 3:12, to a given proportion, i.e. 20%. If this is the case, the model would solve the task by learning "just" to assign a class to each of the 97 possible combinations included in the dataset. If it learns a more abstract representation of the proportion of targets depicted in the scene, in contrast, it should be able to generalize to unseen combinations.

We built an additional dataset using the exact same pipeline described in § 3.2. This time, however, we randomly selected one combination per ratio (17 combinations in total) to be used only for validation and testing. The remaining 80 combinations were used for training. A balanced number of datapoints for each combination were generated in val/test, whereas datapoints in training set

were balanced with respect to ratios, by randomly selecting scenes among the remaining combinations. The *unseen* dataset included around 14K datapoints (80% train, 10% val, 10% test). Table 3 reports the results of the models on the unseen dataset. Starting from setComp, we note a similar and fairly high accuracy achieved by the two one-task models (0.76 and 0.79, respectively). In vagueQ, in contrast, the `one-task-end2end` model neatly outperforms the simpler model (0.92 vs. 0.55 *r*). Finally, in propTarg both models are at chance level, with an accuracy that is lower than 0.07. Overall, this pattern of results suggests that propTarg is an extremely hard task for the separate models, which are not able to generalize to unseen combinations. The `multi-task-prop` model, in contrast, shows a fairly high generalization power. In particular, it achieves 0.54 acc. in propTarg, that is, almost 10 times chance level. The overall good performance in predicting the correct proportion can be appreciated in Figure 7, where the errors are represented by means of a heatmap. The error analysis reveals that end-of-the-scale proportions (0% and 100%) are the easiest, followed by proportions 75% (3:1), 67% (2:1), 50% (1:1), and 60% (3:2). More in general, negative ratios (targets $< 50\%$) are mispredicted to a much greater extent than are positive ones. Moreover, the model shows a bias toward some proportions, that the model seems 'to see everywhere'. However, the fact that the errors are found among the adjacent ratios (similar proportions) seems to be a convincing evidence that the model learns representations encoding genuine proportional information. Finally, it is worth mentioning that in setComp and vagueQ the model achieves very high results, 0.94 acc. and 0.96 *r*, respectively.

7 Discussion

In the present study, we investigated whether *ratio-based* quantification mechanisms, expressed in language by comparatives, quantifiers, and proportions, can be computationally modeled in vision exploiting MTL. We proved that sharing a common core turned out to boost the performance in all the tasks, supporting evidence from linguistics, language acquisition, and cognition. Moreover, we showed (a) the increasing complexity of the tasks, (b) the interference of absolute number, and (c) the high generalization power of MTL. These results lead to many additional questions.

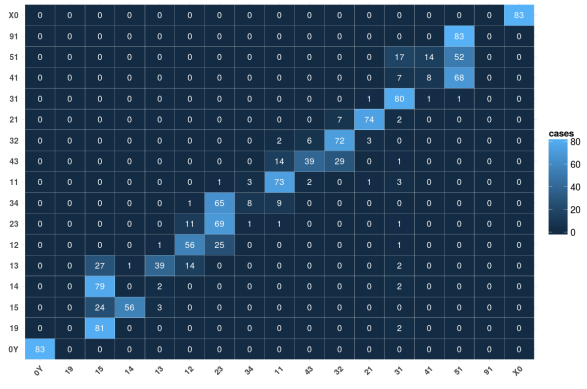

Figure 7: PropTarg. Heatmap with the errors made by the `multi-task-prop` model in the unseen dataset.

For instance, can these methods be successfully applied to datasets of real scenes? We firmly believe this to be the case, though the results might be affected by the natural biases contained in those images. Also, is this pipeline of increasing complexity specific to vision (non-symbolic level), or is it shared across modalities, *in primis* language? Since linguistic expressions of quantity are grounded on a non-symbolic system, we might expect that a model trained on one modality can be applied to another, at least to some extent. Even further, jointly learning representations from both modalities might represent an even more natural, human-like way to learn and refer to quantities. Further work is needed to explore all these issues.

Abstract

Visual question answering (Visual QA) has attracted a lot of attention lately, seen essentially as a form of (visual) Turing test that artificial intelligence should strive to achieve. In this paper, we study a crucial component of this task: how can we design good datasets for the task? We focus on the design of multiple-choice based datasets where the learner has to select the right answer from a set of candidate ones including the target (i.e. the correct one) and the decoys (i.e. the incorrect ones). Through careful analysis of the results attained by state-of-the-art learning models and human annotators on existing datasets, we show that the design of the decoy answers has a significant impact on how and what the learning models learn from the datasets. In particular, the resulting learner can ignore the visual information, the question, or both while still doing well on the task. Inspired by this, we propose automatic procedures to remedy such design deficiencies. We apply the procedures to re-construct decoy answers for two popular Visual QA datasets as well as to create a new Visual QA dataset from the Visual Genome project, resulting in the largest dataset for this task. Extensive empirical studies show that the design deficiencies have been alleviated in the remedied datasets and the performance on them is likely a more faithful indicator of the difference among learning models. The datasets are released and publicly available via http://www.teds.usc.edu/website_vqa/.

1 Introduction

Multimodal information processing tasks such as image captioning (Farhadi et al., 2010; Ordonez et al., 2011; Xu et al., 2015) and visual question answering (Visual QA) (Antol et al., 2015) have gained a lot of attention recently. A number of significant advances in learning algorithms have been made, along with the development of nearly two dozens of datasets in this very active research domain. Among those datasets, popular ones include MSCOCO (Lin et al., 2014; Chen et al., 2015), Visual Genome (Krishna et al., 2017), VQA (Antol et al., 2015), and several others. The overarching objective is that a learning machine needs to go beyond understanding different modalities of information separately (such as image recognition alone) and to learn how to correlate them in order to perform well on those tasks.

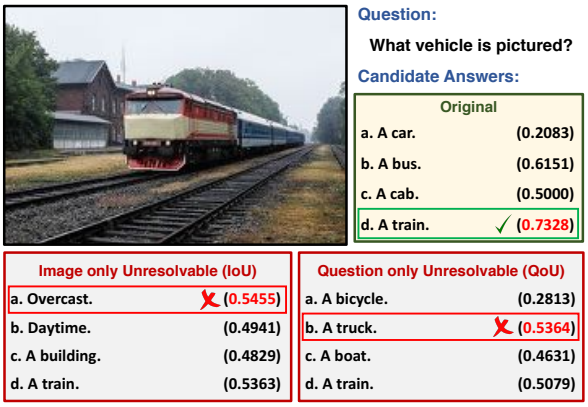

Figure 1: An illustration of how the shortcuts in the Visual7W dataset (Zhu et al., 2016) should be remedied. In the original dataset, the correct answer "A train" is easily selected by a machine as it is far often used as the correct answer than the other decoy (negative) answers. (The numbers in the brackets are probability scores computed using eq. (2)). Our two procedures — QoU and IoU (cf. Sect. 4) — create alternative decoys such that both the correct answer and the decoys are highly likely by examining either the image or the question **alone**. In these cases, machines make mistakes unless they consider all information **together**. Thus, the alternative decoys suggested our procedures are better designed to gauge how well a learning algorithm can understand all information equally well.

*Equal contributions

New Orleans, Louisiana, June 1 - 6, 2018.

To evaluate the progress on those complex and more AI-like tasks is however a challenging topic. For tasks involving language generation, developing an automatic evaluation metric is itself an open problem (Anderson et al., 2016; Kilickaya et al., 2017; Liu et al., 2016; Kafle and Kanan, 2017b). Thus, many efforts have concentrated on tasks such as *multiple-choice* Visual QA (Antol et al., 2015; Zhu et al., 2016; Jabri et al., 2016) or selecting the best caption (Hodosh et al., 2013; Hodosh and Hockenmaier, 2016; Ding et al., 2016; Lin and Parikh, 2016), where the selection accuracy is a natural evaluation metric.

In this paper, we study how to design high-quality multiple choices for the Visual QA task. In this task, the machine (or the human annotator) is presented with an image, a question and a list of candidate answers. The goal is to select the correct answer through a consistent understanding of the image, the question and each of the candidate answers. As in any multiple-choice based tests (such as GRE), designing what should be presented as negative answers — we refer them as *decoys* — is as important as deciding the questions to ask. We all have had the experience of exploiting the elimination strategy: *This question is easy — none of the three answers could be right so the remaining one must be correct!*

While a clever strategy for taking exams, such "shortcuts" prevent us from studying faithfully how different learning algorithms comprehend the meanings in images and languages (e.g., the quality of the embeddings of both images and languages in a semantic space). It has been noted that machines can achieve very high accuracies of selecting the correct answer without the visual input (i.e., the image), the question, or both (Jabri et al., 2016; Antol et al., 2015). Clearly, the learning algorithms have overfit on incidental statistics in the datasets. For instance, if the decoy answers have rarely been used as the correct answers (to any questions), then the machine can rule out a decoy answer with a binary classifier that determines whether the answers are in the set of the correct answers — note that this classifier does not need to examine the image and it just needs to memorize the list of the correct answers in the training dataset. See Fig. 1 for an example, and Sect. 3 for more and detailed analysis.

We focus on minimizing the impacts of exploiting such shortcuts. We suggest a set of principles for creating decoy answers. In light of the amount of human efforts in curating existing datasets for the Visual QA task, we propose two procedures that revise those datasets such that the decoy answers are better designed. In contrast to some earlier works, the procedures are fully automatic and do not incur additional human annotator efforts. We apply the procedures to revise both Visual7W (Zhu et al., 2016) and VQA (Antol et al., 2015). Additionally, we create new multiple-choice based datasets from COCOQA (Ren et al., 2015) and the recently released VQA2 (Goyal et al., 2017) and Visual Genome datasets (Krishna et al., 2017). The one based on Visual Genome becomes the largest multiple-choice dataset for the Visual QA task, with more than one million image-question-candidate answers triplets.

We conduct extensive empirical and human studies to demonstrate the effectiveness of our procedures in creating high-quality datasets for the Visual QA task. In particular, we show that machines need to use all three information (image, questions and answers) to perform well — any missing information induces a large drop in performance. Furthermore, we show that humans dominate machines in the task. However, given the revised datasets are likely reflecting the true gap between the human and the machine understanding of multimodal information, we expect that advances in learning algorithms likely focus more on the task itself instead of overfitting to the idiosyncrasies in the datasets.

The rest of the paper is organized as follows. In Sect. 2, we describe related work. In Sect. 3, we analyze and discuss the design deficiencies in existing datasets. In Sect. 4, we describe our automatic procedures for remedying those deficiencies. In Sect. 5 we conduct experiments and analysis. We conclude the paper in Sect. 6.

2 Related Work

Wu et al. (2017) and Kafle and Kanan (2017b) provide recent overviews of the status quo of the Visual QA task. There are about two dozens of datasets for the task. Most of them use real-world images, while some are based on synthetic ones. Usually, for each image, multiple questions and their corresponding answers are generated. This can be achieved either by human annotators, or with an automatic procedure that uses captions or question templates and detailed image annota-

tions. We concentrate on 3 datasets: VQA (Antol et al., 2015), Visual7W (Zhu et al., 2016), and Visual Genome (Krishna et al., 2017). All of them use images from MSCOCO (Lin et al., 2014).

Besides the pairs of questions and correct answers, VQA, Visual7W, and visual Madlibs (Yu et al., 2015) provide decoy answers for each pair so that the task can be evaluated in multiple-choice selection accuracy. *What decoy answers to use* is the focus of our work.

In VQA, the decoys consist of human-generated plausible answers as well as high-frequency and random answers from the datasets. In Visual7W, the decoys are all human-generated plausible ones. Note that, humans generate those decoys by *only looking at the questions and the correct answers but **not** the images*. Thus, the decoys might be unrelated to the corresponding images. A learning algorithm can potentially examine the image alone and be able to identify the correct answer.

In visual Madlibs, the questions are generated with a limited set of question templates and the detailed annotations (e.g., objects) of the images. Thus, similarly, a learning model can examine the image alone and deduce the correct answer.

We propose automatic procedures to revise VQA and Visual7W (and to create new datasets based on COCOQA (Ren et al., 2015), VQA2 (Goyal et al., 2017), and Visual Genome) such that the decoy generation is carefully orchestrated to prevent learning algorithms from exploiting the shortcuts in the datasets by overfitting on incidental statistics. In particular, our design goal is that a learning machine needs to understand all the 3 components of an image-question-candidate answers triplet in order to make the right choice — ignoring either one or two components will result in drastic degradation in performance.

Our work is inspired by the experiments in (Jabri et al., 2016) where they observe that machines without looking at images or questions can still perform well on the Visual QA task. Others have also reported similar issues (Goyal et al., 2017; Zhang et al., 2016; Johnson et al., 2017; Agrawal et al., 2016; Kafle and Kanan, 2017a; Agrawal et al., 2018), though not in the multiple-choice setting. Our work extends theirs by providing more detailed analysis *as well as automatic procedures* to remedy those design deficiencies.

Besides Visual QA, VisDial (Das et al., 2017) and Ding et al. (2016) also propose automatic ways to generate decoys for the tasks of multiple-choice visual captioning and dialog, respectively.

Recently, Lin and Parikh (2017) study active learning for Visual QA: i.e., how to select informative image-question pairs (for acquiring annotations) or image-question-answer triplets for machines to "learn" from. On the other hand, our work further focuses on designing better datasets for "evaluating" a machine.

3 Analysis of Decoy Answers' Effects

In this section, we examine in detail the dataset Visual7W (Zhu et al., 2016), a popular choice for the Visual QA task. We demonstrate how the deficiencies in designing decoy questions impact the performance of learning algorithms.

In multiple-choice Visual QA datasets, a training or test example is a triplet that consists of an image I, a question Q, and a candidate answer set A. The set A contains a target T (the correct answer) and K decoys (incorrect answers) denoted by D. An IQA triplet is thus $\{\mathrm{I}, \mathrm{Q}, \mathrm{A} = \{\mathrm{T}, \mathrm{D}_1, \cdots, \mathrm{D}_K\}\}$. We use C to denote either the target or a decoy.

3.1 Visual QA models

We investigate how well a learning algorithm can perform when supplied with different modalities of information. We concentrate on the one hidden-layer MLP model proposed in (Jabri et al., 2016), which has achieved state-of-the-art results on the dataset Visual7W. The model computes a scoring function $f(c, i)$

$$f(c, i) = \sigma(\boldsymbol{U} \max(0, \boldsymbol{W} g(c, i)) + b) \qquad (1)$$

over a candidate answer c and the multimodal information i, where g is the joint feature of (c, i) and $\sigma(x) = 1/(1 + \exp(-x))$. The information i can be null, the image (I) alone, the question (Q) alone, or the combination of both (I+Q).

Given an IQA triplet, we use the penultimate layer of ResNet-200 (He et al., 2016) as visual features to represent I and the average WORD2VEC embeddings (Mikolov et al., 2013) as text features to represent Q and C. To form the joint feature $g(c, i)$, we just concatenate the features together. The candidate $c \in$ A that has the highest $f(c, i)$ score in prediction is selected as the model output.

We use the standard training, validation, and test splits of Visual7W, where each contains 69,817, 28,020, and 42,031 examples respectively.

Information used	Machine	Human
random	25.0	25.0
A	52.9	-
I + A	62.4	75.3
Q + A	58.2	36.4
I + Q + A	65.7	88.4

Table 1: Accuracy of selecting the right answers out of 4 choices (%) on the Visual QA task on Visual7W.

Each question has 4 candidate answers. The parameters of $f(c, i)$ are learned by minimizing the binary logistic loss of predicting whether or not a candidate c is the target of an IQA triplet. Details are in Sect. 5 and the Supplementary Material.

3.2 Analysis results

Machines find shortcuts Table 1 summarizes the performance of the learning models, together with the human studies we performed on a subset of 1,000 triplets (c.f. Sect. 5 for details). There are a few interesting observations.

First, in the row of "A" where only the candidate answers (and whether they are right or wrong) are used to train a learning model, the model performs significantly better than random guessing and humans (52.9% vs. 25%) — humans will deem each of the answers equally likely *without* looking at both the image and the question! Note that in this case, the information i in eq. (1) contains nothing. The model learns the specific statistics of the candidate answers in the dataset and exploits those. Adding the information about the image (i.e., the row of "I+A"), the machine improves significantly and gets close to the performance when all information is used (62.4% vs. 65.7%). There is a weaker correlation between the question and the answers as "Q+A" improves over "A" only modestly. This is expected. In the Visual7W dataset, the decoys are generated by human annotators as plausible answers to the questions without being shown the images — thus, many decoy answers do not have visual groundings. For instance, a question of "what animal is running?" elicits equally likely answers such as "dog", "tiger", "lion", or "cat", while an image of a dog running in the park will immediately rule out all 3 but the "dog", see Fig. 1 for a similar example. Thus, the performance of "I+A" implies that many IQA triplets can be solved by object, attribute or concept detection on the image, without understanding the questions. This is indeed the case also for humans — humans can achieve 75.3% by considering "I+A" and not "Q". Note that the difference between machine and human on "I+A" are likely due to their difference in understanding visual information.

Note that human improves significantly from "I+A" to "I+Q+A" with "Q" added, while the machine does so only marginally. The difference can be attributed to the difference in understanding the question and correlating with the answers between the two. Since each image corresponds to multiple questions or have multiple objects, solely relying on the image itself will not work well in principle. Such difference clearly indicates that in the Visual QA model, the language component is weak as the model cannot fully exploit the information in "Q", making a smaller relative improvement 5.3% (from 62.4% to 65.7%) where humans improved relatively 17.4%.

Shortcuts are due to design deficiencies We probe deeper on how the decoy answers have impacted the performance of learning models.

As explained above, the decoys are drawn from all plausible answers to a question, irrespective of whether they are visually grounded or not. We have also discovered that the targets (i.e., correct answers) are infrequently used as decoys.

Specifically, among the 69,817 training samples, there are 19,503 unique correct answers and each one of them is used about 3.6 times as correct answers to a question. However, among all the $69,817 \times 3 \approx 210K$ decoys, each correct answer appears 7.2 times on average, far below a chance level of 10.7 times ($210K \div 19,503 \approx 10.7$). This disparity exists in the test samples too. Consequently, the following rule, computing each answer's likelihood of being correct,

$$P(\text{correct}|\text{C}) = \begin{cases} 0.5, & \text{if C is never seen in training,} \\ \frac{\text{\# times C as target}}{\text{\# times C as target} + (\text{\# times C as decoys})/K}, & \text{otherwise,} \end{cases} \quad (2)$$

should perform well. Essentially, it measures how unbiased C is used as the target and the decoys. Indeed, it attains an accuracy of 48.73% on the test data, far better than the random guess and is close to the learning model using the answers' information only (the "A" row in Table 1).

Good rules for designing decoys Based on our analysis, we summarize the following guidance rules to design decoys: (1) **Question only Unresolvable (QoU)**. The decoys need to be equally

plausible to the question. Otherwise, machines can rely on the correlation between the question and candidate answers to tell the target from decoys, even without the images. Note that this is a principle that is being followed by most datasets. (2) **Neutrality**. The decoys answers should be equally likely used as the correct answers. (3) **Image only Unresolvable (IoU)**. The decoys need to be plausible to the image. That is, they should appear in the image, or there exist questions so that the decoys can be treated as targets to the image. Otherwise, Visual QA can be resolved by objects, attributes, or concepts detection in images, even without the questions.

Ideally, each decoy in an IQA triplet should meet the three principles. **Neutrality** is comparably easier to achieve by *reusing terms in the whole set of targets as decoys.* On the contrary, a decoy may hardly meet **QoU** and **IoU** simultaneously[1]. However, as long as all decoys of an IQA triplet meet **Neutrality** and some meet **QoU** and others meet **IoU**, the triplet as a whole still achieves the three principles — a machine ignoring either images or questions will likely perform poorly.

4 Creating Better Visual QA Datasets

In this section, we describe our approaches of remedying design deficiencies in the existing datasets for the Visual QA task. We introduce two automatic and widely-applicable procedures to create new decoys that can prevent learning models from exploiting incident statistics in the datasets.

4.1 Methods

Main ideas Our procedures operate on a dataset that already contains image-question-target (IQT) triplets, i.e., we do not assume it has decoys already. For instance, we have used our procedures to create a multiple-choice dataset from the Visual Genome dataset which has no decoy. We assume that each image in the dataset is coupled with "multiple" QT pairs, which is the case in nearly all the existing datasets. Given an IQT triplet (I, Q, T), we create two sets of decoy answers.

- **QoU-decoys**. We search among all other triplets that have similar questions to Q. The **targets** of those triplets are then collected as the decoys for T. As the targets to similar questions are likely plausible for the question Q, QoU-decoys likely follow the rules of **Neutrality** and **Question only Unresolvable (QoU)**. We compute the average WORD2VEC (Mikolov et al., 2013) to represent a question, and use the cosine similarity to measure the similarity between questions.
- **IoU-decoys**. We collect the **targets** from other triplets of the *same* image to be the decoys for T. The resulting decoys thus definitely follow the rules of **Neutrality** and **Image only Unresolvable (IoU)**.

We then combine the triplet (I, Q, T) with QoU-decoys and IoU-decoys to form an IQA triplet as a training or test sample.

Resolving ambiguous decoys One potential drawback of automatically selected decoys is that they may be semantically similar, ambiguous, or rephrased terms to the target (Zhu et al., 2016). We utilize two filtering steps to alleviate it. First, we perform string matching between a decoy and the target, deleting those decoys that contain or are covered by the target (e.g., "daytime" vs. "during the daytime" and "ponytail" vs. "pony tail").

Secondly, we utilize the WordNet hierarchy and the Wu-Palmer (WUP) score (Wu and Palmer, 1994) to eliminate semantically similar decoys. The WUP score measures how similar two *word senses* are (in the range of $[0, 1]$), based on the depth of them in the taxonomy and that of their least common subsumer. We compute the similarity of two strings according to the WUP scores in a similar manner to (Malinowski and Fritz, 2014), in which the WUP score is used to evaluate Visual QA performance. We eliminate decoys that have higher WUP-based similarity to the target. We use the NLTK toolkit (Bird et al., 2009) to compute the similarity. See the Supplementary Material for more details.

Other details For QoU-decoys, we sort and keep for each triplet the top N (e.g., 10,000) similar triplets from the entire dataset according to the question similarity. Then for each triplet, we compute the WUP-based similarity of each potential decoy to the target successively, and accept those with similarity below 0.9 until we have K decoys. We choose 0.9 according to (Malinowski and Fritz, 2014). We also perform such a check among selected decoys to ensure they are not very similar to each other. For IoU-decoys, the potential decoys are sorted randomly. The WUP-based

[1]E.g., in Fig 1, for the question "What vehicle is pictured?", the only answer that meets both principles is "train", which is the correct answer instead of being a decoy.

similarity with a threshold of 0.9 is then applied to remove ambiguous decoys.

4.2 Comparison to other datasets

Several authors have noticed the design deficiencies in the existing databases and have proposed "fixes" (Antol et al., 2015; Yu et al., 2015; Zhu et al., 2016; Das et al., 2017). No dataset has used a procedure to generate IoU-decoys. We empirically show that how the IoU-decoys significantly remedy the design deficiencies in the datasets.

Several previous efforts have generated decoys that are similar in spirit to our **QoU**-decoys. Yu et al. (2015), Das et al. (2017), and Ding et al. (2016) automatically find decoys from similar questions or captions based on question templates and annotated objects, tri-grams and GLOVE embeddings (Pennington et al., 2014), and paragraph vectors (Le and Mikolov, 2014) and linguistic surface similarity, respectively. The later two are for different tasks from Visual QA, and only Ding et al. (2016) consider removing semantically ambiguous decoys like ours. Antol et al. (2015) and Zhu et al. (2016) ask humans to create decoys, given the questions and targets. As shown earlier, such decoys may disobey the rule of **Neutrality**.

Goyal et al. (2017) augment the VQA dataset (Antol et al., 2015) (by human efforts) with additional IQT triplets to eliminate the shortcuts (language prior) in the open-ended setting. Their effort is complementary to ours on the multiple-choice setting. Note that an extended task of Visual QA, visual dialog (Das et al., 2017), also adopts the latter setting.

5 Empirical Studies

5.1 Dataset

We examine our automatic procedures for creating decoys on five datasets. Table 2 summarizes the characteristics of the three datasets we focus on.

VQA Real (Antol et al., 2015) The dataset uses images from MSCOCO (Lin et al., 2014) under the same training/validation/testing splits to construct IQA triplets. Totally 614,163 IQA triplets are generated for 204,721 images. Each question has 18 candidate answers: in general 3 decoys are human-generated, 4 are randomly sampled, and 10 are randomly sampled frequent-occurring targets. *As the test set does not indicate the targets, our studies focus on the training and validation sets.*

Dataset Name	# of Images			# of triplets			# of decoys per triplet
	train	val	test	train	val	test	
VQA	83k	41k	81k	248k	121k	244k	17
Visual7W	14k	5k	8k	69k	28k	42k	3
VG	49k	19k	29k	727k	283k	433k	-

Table 2: Summary of Visual QA datasets.

Visual7W Telling (Visual7W) (Zhu et al., 2016) The dataset uses 47,300 images from MSCOCO (Lin et al., 2014) and contains 139,868 IQA triplets. Each has 3 decoys generated by humans.

Visual Genome (VG) (Krishna et al., 2017) The dataset uses 101,174 images from MSCOCO (Lin et al., 2014) and contains 1,445,322 IQT triplets. No decoys are provided. Human annotators are asked to write diverse pairs of questions and answers freely about an image or with respect to some regions of it. On average an image is coupled with 14 question-answer pairs. We divide the dataset into non-overlapping 50%/20%/30% for training/validation/testing. Additionally, we partition such that each portion is a "superset" of the corresponding one in Visual7W, respectively.

VQA2 (Goyal et al., 2017) and COCOQA (Ren et al., 2015) We describe the datasets and experimental results in the Supplementary Material.

Creating decoys We create 3 QoU-decoys and 3 IoU-decoys for every IQT triplet in each dataset, following the steps in Sect. 4.1. In the cases that we cannot find 3 decoys, we include random ones from the original set of decoys for VQA and Visual7W; for other datasets, we randomly include those from the top 10 frequently-occurring targets.

5.2 Setup

Visual QA models We utilize the MLP models mentioned in Sect. 3 for all the experiments. We denote **MLP-A**, **MLP-QA**, **MLP-IA**, **MLP-IQA** as the models using A (Answers only), Q+A (Question plus Answers), I+A (Image plus Answers), and I+Q+A (Image, Question and Answers) for multimodal information, respectively. The hidden-layer has 8,192 neurons. We use a 200-layer ResNet (He et al., 2016) to compute visual features which are 2,048-dimensional. The ResNet is pre-trained on ImageNet (Russakovsky et al., 2015). The WORD2VEC feature (Mikolov et al., 2013) for questions and answers are 300-dimensional, pre-trained on Google News[2]. The

[2]We experiment on using different features in the Supplementary Material.

parameters of the MLP models are learned by minimizing the binary logistic loss of predicting whether or not a candidate answer is the target of the corresponding IQA triplet. Please see the Supplementary Material for details on optimization.

We further experiment with a variant of the spatial memory network (denoted as **Attention**) (Xu and Saenko, 2016) and the **HieCoAtt** model (Lu et al., 2016) adjusted for the multiple-choice setting. Both models utilize the attention mechanism. Details are listed in the Supplementary Material.

Evaluation metric For VQA and VQA2, we follow their protocols by comparing the picked answer to 10 human-generated targets. The accuracy is computed based on the number of exactly matched targets (divided by 3 and clipped at 1). For others, we compute the accuracy of picking the target from multiple choices.

Decoy sets to compare For each dataset, we derive several variants: (1) **Orig**: the original decoys from the datasets, (2) **QoU**: **Orig** replaced with ones selected by our QoU-decoys generating procedure, (3) **IoU**: **Orig** replaced with ones selected by our IoU-decoys generating procedure, (4) **QoU +IoU**: **Orig** replaced with ones combining **QoU** and **IoU**, (5) **All**: combining **Orig**, **QoU**, and **IoU**.

User studies Automatic decoy generation may lead to ambiguous decoys as mentioned in Sect. 4 and (Zhu et al., 2016). We conduct a user study via Amazon Mechanic Turk (AMT) to test humans' performance on the datasets after they are remedied by our automatic procedures. We select 1,000 IQA triplets from each dataset. Each triplet is answered by three workers and in total 169 workers get involved. The total cost is $215 — the rate for every 20 triplets is $0.25. We report the average human performance and compare it to the learning models'. See the Supplementary Material for more details.

5.3 Results

The performances of learning models and humans on the 3 datasets are reported in Table 3, 4, and 5[3].

[3]We note that in Table 3, the 4.3% drop of the human performance on IoU +QoU, compared to Orig, is likely due to that IoU +QoU has more candidates (7 per question). Besides, the human performance on qaVG cannot be directly compared to that on the other datasets, since the questions on qaVG tend to focus on local image regions and are considered harder.

Method	Orig	IoU	QoU	IoU +QoU	All
MLP-A	52.9	27.0	34.1	17.7	15.6
MLP-IA	62.4	27.3	55.0	23.6	22.2
MLP-QA	58.2	84.1	40.7	37.8	31.9
MLP-IQA	65.7	84.1	57.6	52.0	45.1
HieCoAtt∗	63.9	-	-	51.5	-
Attntion∗	65.9	-	-	52.8	-

Random	25.0	25.0	25.0	14.3	10.0

∗: based on our implementation or modification

Table 3: Test accuracy (%) on Visual7W.

Effectiveness of new decoys A better set of decoys will force learning models to integrate all 3 pieces of information — images, questions and answers — to make the correct selection from multiple-choices. In particular, they should prevent learning algorithms from exploiting shortcuts such that partial information is sufficient for performing well on the Visual QA task.

Table 3 clearly indicates that those goals have been achieved. With the Orig decoys, the relatively small gain from MLP-IA to MLP-IQA suggests that the question information can be ignored to attain good performance. However, with the IoU-decoys which require questions to help to resolve (as image itself is inadequate to resolve), the gain is substantial (from 27.3% to 84.1%). Likewise, with the QoU-decoys (question itself is not adequate to resolve), including images information improves from 40.7% (MLP-QA) substantially to 57.6% (MLP-IQA). Note that with the Orig decoys, this gain is smaller (58.2% vs. 65.7%).

It is expected that MLP-IA matches better QoU-decoys but not IoU-decoys, and MLP-QA is the other way around. Thus it is natural to combine these two decoys. What is particularly appealing is that MLP-IQA improves noticeably over models learned with partial information on the combined IoU +QoU-decoys (and "All" decoys[4]). Furthermore, using answer information only (MLP-A) attains about the chance-level accuracy.

On the VQA dataset (Table 4), the same observations hold, though to a lesser degree. On any of the IoU or QoU columns, we observe substan-

[4]We note that the decoys in Orig are not trivial, which can be seen from the gap between All and IoU +QoU. Our main concern on Orig is that for those questions that machines can accurately answer, they mostly rely on only partial information. This will thus hinder designing machines to fully comprehend and reason from multimodal information. We further experiment on random decoys, which can achieve **Neutrality** but not the other two principles, to demonstrate the effectiveness of our methods in the Supplementary Material.

Method	Orig	IoU	QoU	IoU +QoU	All
MLP-A	31.2	39.9	45.7	31.2	27.4
MLP-IA	42.0	39.8	55.1	34.1	28.7

tial gains when the complementary information is added to the model (such as MLP-IA to MLP-IQA). All these improvements are much more visible than those observed on the original decoy sets.

Combining both Table 3 and 4, we notice that the improvements from MLP-QA to MLP-IQA tend to be lower when facing IoU-decoys. This is also expected as it is difficult to have decoys that are simultaneously both IoU and QoU — such answers tend to be the target answers. Nonetheless, we deem this as a future direction to explore.

Differences across datasets Contrasting Visual7W to VQA (on the column IoU +QoU), we notice that Visual7W tends to have bigger improvements in general. This is due to the fact that VQA has many questions with "Yes" or "No" as the targets — the only valid decoy to the target "Yes" is "No", and vice versa. As such decoys are already captured by Orig of VQA ('Yes" and "No" are both top frequently-occurring targets), adding other decoy answers will not make any noticeable improvement. In Supplementary Material, however, we show that once we remove such questions/answers pairs, the degree of improvements increases substantially.

Comparison on Visual QA models As presented in Table 3 and 4, MLP-IQA is on par with or even outperforms **Attention** and **HieCoAtt** on the Orig decoys, showing how the shortcuts make it difficult to compare different models. By eliminating the shortcuts (i.e., on the combined IoU +QoU-decoys), the advantage of using sophisticated models becomes obvious (**Attention** outperforms MLP-IQA by 3% in Table 4), indicating the importance to design advanced models for achieving human-level performance on Visual QA.

Datasets	Decoys	Best w/o using qaVG	qaVG model	
			initial	fine-tuned
Visual7W	Orig	65.7	60.5	**69.1**
	IoU +QoU	52.0	58.1	**58.7**
	All	45.1	48.9	**51.0**
VQA	Orig	64.6	42.2	**65.6**
	IoU +QoU	63.7	47.9	**64.1**
	All	58.9	37.5	**59.4**

Table 6: Using models trained on qaVG to improve Visual7W and VQA (Accuracy in %).

For completeness, we include the results on the Visual Genome dataset in Table 5. This dataset has no "Orig" decoys, and we have created a multiple-choice based dataset **qaVG** from it for the task — it has over 1 million triplets, the largest dataset on this task to our knowledge. On the combined IoU +QoU-decoys, we again clearly see that machines need to use all the information to succeed.

With **qaVG**, we also investigate whether it can help improve the multiple-choice performances on the other two datasets. We use the MLP-IQA trained on qaVG with both IoU and QoU decoys to initialize the models for the Visual7W and VQA datasets. We report the accuracies before and after fine-tuning, together with the best results learned solely on those two datasets. As shown in Table 6, fine-tuning largely improves the performance, justifying the finding by Fukui et al. (2016).

5.4 Qualitative Results

In Fig. 2, we present examples of image-question-target triplets from **V7W**, **VQA**, and **VG**, together with our IoU-decoys (A, B, C) and QoU-decoys (D, E, F). G is the target. The predictions by the corresponding MLP-IQA are also included. Ignoring information from images or questions makes it extremely challenging to answer the triplet correctly, even for humans.

Our automatic procedures do fail at some triplets, resulting in ambiguous decoys to the targets. See Fig. 3 for examples. We categorized those failure cases into two situations.

- Our filtering steps in Sect. 4 fail, as observed in the top example. The WUP-based similarity re-

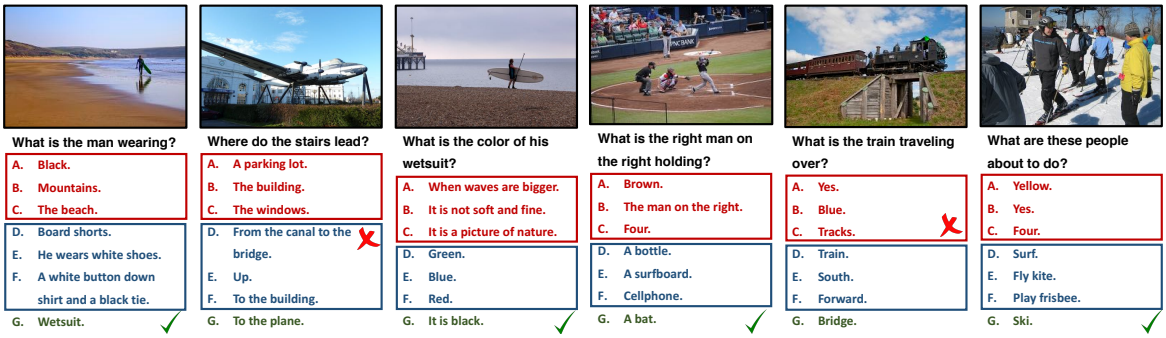

Figure 2: Example image-question-target triplets from Visual7W, VQA, and VG, together with our IoU-decoys (A, B, C.) and QoU-decoys (D, E, F). G is the target. Machine's selections are denoted by green ticks (correct) or red crosses (wrong).

Figure 3: Ambiguous examples by our IoU-decoys (A, B, C) and QoU-decoys (D, E, F). G is the target. Ambiguous decoys F are marked.

lies on the WordNet hierarchy. For some semantically similar words like "lady" and "woman", the similarity is only 0.632, much lower than that of 0.857 between "cat" and "dog". This issue can be alleviated by considering alternative semantic measures by WORD2VEC or by those used in (Das et al., 2017; Ding et al., 2016) for searching similar questions.

- The question is ambiguous to answer. In the bottom example in Fig. 3, both candidates D and F seem valid as a target. Another representative case is when asked about the background of a image. In images that contain sky and mountains in the distance, both terms can be valid.

6 Conclusion

We perform detailed analysis on existing datasets for multiple-choice Visual QA. We found that the design of decoys can inadvertently provide "shortcuts" for machines to exploit to perform well on the task. We describe several principles of constructing good decoys and propose automatic procedures to remedy existing datasets and create new ones. We conduct extensive empirical studies to demonstrate the effectiveness of our methods in creating better Visual QA datasets. The remedied datasets and the newly created ones are released and available at http://www.teds.usc.edu/website_vqa/.

Abstract

Abstract Meaning Representation (AMR) parsing aims at abstracting away from the syntactic realization of a sentence, and denoting only its meaning in a canonical form. As such, it is ideal for paraphrase detection, a problem in which one is required to specify whether two sentences have the same meaning. We show that naïve use of AMR in paraphrase detection is not necessarily useful, and turn to describe a technique based on latent semantic analysis in combination with AMR parsing that significantly advances state-of-the-art results in paraphrase detection for the Microsoft Research Paraphrase Corpus. Our best results in the transductive setting are 86.6% for accuracy and 90.0% for F_1 measure.

1 Introduction

Abstract Meaning Representation (AMR) parsing focuses on the conversion of natural language sentences into AMR graphs, aimed at abstracting away from the surface realizations of the sentences while preserving their meaning.

We make a first step towards showing that AMR can be used in practice for a task that requires identifying the canonicalization of language: paraphrase detection. In a "perfect world" using AMR to test for paraphrasing relation of two sentences should be simple. It would require finding the two AMR parses for each of the sentences, and then checking whether they are identical. Since AMR is aimed at abstracting away from the surface form which is used to express meaning, two sentences should be paraphrases only if they have identical AMRs. For instance, the three sentences:

1. He described her as a curmudgeon,
2. His description of her: curmudgeon,
3. She was a curmudgeon, according to his description.

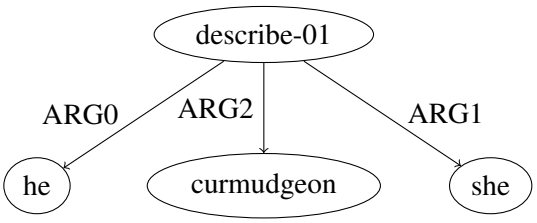

Figure 1: AMR graph for "He described her as a curmudgeon", "His description of her: curmudgeon" and "She was a curmudgeon, according to his description"

should result in the same AMR graph as shown in Figure 1.

However, in practice, things are different. First, there are no known AMR parsers that really distil only the meaning in text. For example, predicates which have interchangeable meaning use different AMR concepts, and there are errors that exist because of the machine learning techniques that are used for learning the parsers from data. Finally, even human annotations do not yield perfect AMRs, as the interannotator agreement reported in the literature for AMR is around 80% (Banarescu et al., 2013).

Second, meaning is often contextual, and it is not fully possible to determine the corresponding AMR parse just by looking at a given sentence. Entity mentions denote different entities in different contexts, and similarly predicates and nouns are ambiguous and depend on context. As such, one cannot expect to use AMR in the transparent way mentioned above to identify paraphrase relations. However, we demonstrate in this paper that AMR can be used in a "softer" way to detect such relations.

Evaluation of AMR parsers is traditionally performed using the Smatch score (Cai and Knight, 2013). However, Damonte et al. (2017) argue that more ad-hoc metrics can be useful for advancing AMR research. Paraphrase detection can be seen

Proceedings of NAACL-HLT 2018, pages 442–452
New Orleans, Louisiana, June 1 - 6, 2018.

as a further benchmark for AMR parsers, highlighting their ability of abstracting away from syntax and representing the core concepts expressed in the sentence. In order to advance research in AMR and its applications, it is important to have metrics that reflect on the ability of AMR graphs to have impact on subsequent tasks. In this work we therefore use two different AMR parsers, comparing them throughout all experiments.

2 Background

AMRs are rooted, edge labeled, node labeled, directed graphs. They are biased towards the English language and rely on PropBank (Kingsbury and Palmer, 2002) for the definition of the main events in the sentence. Nodes in an AMR graph represent events and concepts, while edges represent the relationships between them. Banarescu et al. (2013) state that AMR are aimed at canonicalizing multiple ways of expressing the same idea, which could be of great assistance to solve the problem of paraphrase detection. However, this goal is not entirely achieved in practice, and it will take long for AMR parsers to mature and achieve such canonicalization. At the moment, for example, even a simple pair of sentences such as "the boy desires the cake" and the "the boy wants the cake" would not have the same canonical form by state-of-the-art AMR parsers.

While some researchers (Fodor, 1975) have doubted the practical possibility of canonicalizing language or finding identical paraphrases in English or otherwise, much work in NLP has been devoted to the problem of paraphrase identification (Mitchell and Lapata, 2010; Baroni and Lenci, 2010; Socher et al., 2011; Guo and Diab, 2012; Ji and Eisenstein, 2013) and more weakly, finding entailment between sentences and phrases (Dagan et al., 2006; Bos and Markert, 2005; Harabagiu and Hickl, 2006; Lewis and Steedman, 2013). In this work, we use the AMRs parsed for given sentences as a mean to extract useful information and train paraphrase detection classifiers on top of them.

2.1 Latent Semantic Analysis

Our work falls under the category of distributional methods for paraphrase detection (Turney and Pantel, 2010; Mihalcea et al., 2006; Mitchell and Lapata, 2010; Guo and Diab, 2012; Ji and Eisenstein, 2013) such as with latent semantic analysis (LSA, Landauer et al., 1998). The main principle behind this approach is to detect semantic similarity through distributional representations for a given sentence and its potential paraphrase, where these representations are compared against each other according to some similarity metric or used as features with a discriminative classification method (Mihalcea et al., 2006; Guo and Diab, 2012; Ji and Eisenstein, 2013).

LSA is indeed one of the main tools in obtaining such distributional representations for the problem of paraphrase detection. Most often, TF-IDF weighting has been used for building the sentence-term matrix, but Ji and Eisenstein (2013) have shown that a significant improvement can be achieved in detecting similarity if one re-weights the sentence-term matrix differently. Indeed, this is one of our main contributions: we build on previous work on LSA for paraphrase detection and propose a technique to re-weight a *sentence-concept* matrix based on the AMR graphs for the given sentences. More details on the use of LSA for paraphrase detection appear in Section 4.

2.2 AMR Parsing

AMR parsing is the task of converting natural language sentences into AMR graphs, which are Directed Acyclic Graphs (DAGs) in all cases except a few rare controversial cases. This task embeds several common NLP problems together, such as named entity recognition, sentential-level coreference resolution, semantic role labeling and word-sense disambiguation. Several parsers for AMR have been recently developed (Flanigan et al., 2014; Wang et al., 2015; Peng et al., 2015; Pust et al., 2015; Goodman et al., 2016; Rao et al., 2015; Vanderwende et al., 2015; Artzi et al., 2015; Barzdins and Gosko, 2016a; Zhou et al., 2016; Damonte et al., 2017; Barzdins and Gosko, 2016b; Konstas et al., 2017). Shared tasks were also organized in order to push forward the state-of-the-art (May, 2016; May and Priyadarshi, 2017).

Meaning representations are usually evaluated based on their compositionality (construction of a representation based on parts of the text in a consistent way), verifiability (ability to check whether a meaning representation is true in a given model of the world), unambiguity (ability to full disambiguate text into the representation in a way that does not leave any ambiguity lingering), inference (the existence of a calculus that can be used to

infer whether one meaning representation is logically implied by others) and canonicalization (the ability to map several surface forms, such as paraphrases, into a single unique meaning representation). In this paper, we evaluate AMR on its ability to canonicalize language through its assistance in deciding whether two sentences are paraphrases.

We note that this test is masked by the accuracy of the AMR parsers we use, which indeed do not give always fully correct predictions. These errors in our paraphrase detection due to the accuracy of the AMR parser are different than those which originate in an inherent difficulty of representing paraphrases using AMR because of the limitations of the formalism and the annotation guidelines that AMR follows.

We experiment with two AMR parsers for which a public version is available. The first is JAMR (Flanigan et al., 2014), which is a graph-based approach to AMR parsing. It works by performing two steps on the input sentence: concept identification and relation identification. The former discovers the concept fragments corresponding to span of words in the sentence, while the latter finds the optimal spanning connected subgraph from the concepts identified in the first step. The concept identification step has quadratic complexity and the relation identification step is $O(|V|^2 \log |V|)$, with $|V|$ being the set of nodes in the AMR graph.

The second is AMREager (Damonte et al., 2017), which is a transition-based parser that works by scanning the string left-to-right and building the graph as the scan proceeds. This transition-based system is akin to the dependency parsing transition-system ArcEager of Nivre (2004), only without constraints that ensure that the resulting structure is a tree. In addition, there are operations that make the system create additional non-projective structures by checking after transition step whether siblings should be connected together with an edge. The complexity of AMREager is linear in the length of the sentence. AMREager was extended to other languages (Damonte and Cohen, 2018), and we leave it for future work to test the utility of AMR for paraphrase detection in these languages.

3 Problem Formulation

Let $\mathcal{S}$ be a set of sentences. We are given input data in the form of $(x_1^{(i)}, x_2^{(i)}, b^{(i)})$ for $i \in [n]$ where n is the number of training examples, $x_j^{(i)} \in \mathcal{S}$, $j \in \{1, 2\}$ and $b^{(i)} \in \{0, 1\}$ is a binary indicator that tells whether $x_1^{(i)}$ is a paraphrase of $x_2^{(i)}$.

The goal is to learn a classifier

$$c \colon \mathcal{S} \times \mathcal{S} \rightarrow \{0, 1\}$$

that tells for unseen instances whether the pair of sentences given as input are paraphrases of each other. We denote by $[n]$ the set $\{1, \ldots, n\}$.

4 Latent Semantic Analysis for Paraphrase Detection

The first step in our approach is the construction of lower-dimensional representations for the sentences in the training data. We use latent semantic analysis to get the sentence representations, which are then used to detect paraphrases using a classifier. More specifically, given a set of sentences $S = \{x_j^{(i)} \mid j \in \{1, 2\}, i \in [n]\}$, we build a sentence-term matrix T such that $T_{k\ell}$ indicates the use of the ℓth word in the kth sentence in S. The number of rows is the number of sentences in the dataset and the number of columns is the vocabulary size. This follows previous work with the use of LSA for paraphrasing (Guo and Diab, 2012; Ji and Eisenstein, 2013).

As a baseline, we experiment with two ways of assigning the values to the matrix:

- $T_{k\ell}$ is the count of the ℓth word in the kth sentence:

$$T_{k\ell} = \text{count}(\ell, k)$$

- $T_{k\ell}$ is the term frequency-inverse document frequency (TF-IDF) for the kth sentence with respect to the ℓth word. TF-IDF is commonly used in Information Retrieval to score words in a document and combines the frequency of the words in a document with the rarity of the term across documents. With TF-IDF, in order to have a high score, concepts must appear in this sentence and not in many others. In that case, we define:

$$T_{k\ell} = \text{count}(\ell, k) \times \frac{n}{\text{csent}(\ell, k)}$$

where $\text{count}(\ell, k)$ gives the count of the ℓth word in the kth sentence and csent is the

number of sentences which contain the ℓth word:

$$\text{csent}(\ell, k) = |\{k \in [|S|] : \text{count}(k, \ell) > 0\}|.$$

The AMR-based systems of Section 5 build upon this by re-weighting $T_{k\ell}$ with terms depending on the AMRs of the sentences.

For paraphrasing, previous work (Ji and Eisenstein, 2013) has also considered the *transductive* setting (Gammerman et al., 1998), which we also use in our experiments. In the transductive setting, S also includes the sentences on which we expect to perform the final evaluation for the purpose of learning the latent representations. Note that, in this case, the labels $b^{(i)}$ are not used in the process of constructing word representations. In the inductive setting, on the other hand, the sentences in the testing set are not included in training and we project them instead using the LSA projection matrices onto the latent space learned to find their representations.

Once we constructed the matrix T, we perform truncated singular value decomposition (SVD) on it, such that:

$$T \approx U \Sigma V^\top$$

where $U \in \mathbb{R}^{k \times m}$, $V \in \mathbb{R}^{\ell \times m}$ and $\Sigma \in \mathbb{R}^{m \times m}$ is a diagonal matrix of singular values. The final sentence representations are the rows of the U matrix which range over the sentences and have m dimensions.

The output of this process is a function $f : \mathcal{S} \to \mathbb{R}^m$ which attaches to each sentence a representation. The idea behind LSA is that this matrix decomposition will make semantically similar sentences to appear close in the latent space, hence alleviating the problem of data sparsity and making it easier to detect when two sentences are paraphrases of each other.

Once we construct the sentence representations from the training data (either in the inductive or the transductive setting) we use the function f to map each pair of sentences from the training data $(x_1^{(i)}, x_2^{(i)})$ to two vectors $f(x_1^{(i)}) + f(x_2^{(i)})$ and $|f(x_1^{(i)}) - f(x_2^{(i)})|$ (where the absolute value is taken coordinate-wise) and then concatenate them into a feature vector $\phi(x_1^{(i)}, x_2^{(i)})$, which is then used as input to a support vector machine (SVM) classifier (Ji and Eisenstein, 2013).[1]

5 Abstract Meaning Representation Features

The main hypothesis tested in this work is that AMR can be useful in deciding whether two sentences are paraphrases of each other. We investigate two ways to use AMR information to better inform the classifier: similarity-based and LSA-based.

5.1 Graph Similarity and Bag of AMR Concepts

An obvious way to use AMR information is to just compute the similarity between the two graphs and use the score as an additional feature. As a score we use Smatch, which computes the overlap in terms of recall, precision and F-score between two unaligned graphs by finding the alignments between the graphs that maximizes the overlap. The alignment step is necessary because in AMR multiple nodes can have the same labels and arbitrary variable names are used to distinguish between them. Smatch is the standard metric to evaluate the overlap between AMR graphs. The score returned by Smatch is used as a single additional feature for the SVM.

The amount of overlap in the AMR nodes of the two graphs can be a good indicator of whether the sentences are paraphrases of each other. To test this hypothesis, we extract the unordered sets of AMR nodes and use the Jaccard similarity coefficient as a feature. This is directly related to the concept identification step of the AMR parsing process, which is concerned with generating and labeling the nodes of the AMR graph. Concept identification is arguably one of the most challenging part of AMR parsing as the mapping between word spans and AMR nodes is not trivial (Werling et al., 2015). It is often considered as the first stage in the AMR parsing pipeline and it is therefore reasonable to attempt using its intermediate results. We choose Jaccard as a metric for bag of concepts overlap following previous work in paraphrase detection (Achananuparp et al., 2008; Be-

[1] We note that while the NLP community has largely switched to the use of neural networks for classification problems, in our case support vector machines prove to be a simpler and more efficient solution. They also tend to generalize better than neural networks, as the number of features we use is not large.

rant and Liang, 2014).

We note that while this approach of using AMR to detect paraphrase may sound plausible, it does not perform very well. As such, we compare and contrast this as an AMR baseline with the approach that makes use of PageRank with TF-IDF reweighting for LSA, as described next.

5.2 PageRank and TF-IDF Reweighting for LSA

The main idea is to re-weight the LSA sentence-term matrix T (Section 4) according to a probability distribution over the AMR nodes, which we accomplish by means of PageRank (Page et al., 1999). The utility of re-weighting terms in the sentence-term matrix has been previously proved (Turney and Pantel, 2010). PageRank is a method, originally developed for web pages, for ranking nodes in a graph according to their impact on other nodes. The algorithm works iteratively by adjusting at each iteration the score of each node based on the number and scores of nearby nodes that is connected to it, until convergence. Prior to applying PageRank, we merge the two graphs by collapsing the concepts in the two graphs that have the same labels, similarly to Liu et al. (2015), as shown in Figure 2. We then compute the PageRank score for each node in the merged graph and multiply them by the corresponding frequency count of that concept in the sentence-term matrix. The graph merging step is necessary in order to ensure that overlapping concepts obtain high PageRank scores. The PageRank step applied to the merged graph ensures that this importance propagates to nearby nodes.

For a given graph $G = (V, E)$, PageRank takes as input a list of edges between nodes:

$$E = \{(n_i, m_i)\}, \forall i = 0, \ldots, n$$
$$n = |E|$$

and outputs a PageRank score for each node by solving the following equations with respect to $\mathrm{PG}(\cdot)$:

$$\mathrm{PG}(n) = \sum_{m \in I(n)} \frac{\mathrm{PG}(m)}{l(m)}$$

where $I(n)$ are the input edges to node n and $l(m)$ is the number of edges coming out of m.

For each concept of the merged AMR graph, we compute $T_{k\ell}$, the weight for the LSA matrix introduced in Section 4, as follows:

$$T_{k\ell} = \mathrm{PG}(l, k) \times \mathrm{count}(l, k)$$

where $\mathrm{PG}(l, k)$ is the PageRank of ℓth concept for the kth sentence.

As a baseline for the PageRank system, the TF-IDF re-weighting scheme, as described in Section 4, is also used to re-weight the AMR concepts.

6 Experiments

We now describe the experiments that we devised to discover whether AMR is useful for paraphrase detection. For AMR parsing, we used the JAMR[2] version published for SemEval 2016 (Flanigan et al., 2016), reporting 0.67 Smatch score on LDC2015E86 and the first and only version available for AMREager,[3] obtaining 0.64 Smatch score on the same dataset. First, we discuss experiments where the AMRs are used as a mean to extract additional sparse features for a SVM classifier. Then we turn to LSA to construct a representation of the sentence based on the reweighting on the AMR nodes achieved through either PageRank or TF-IDF. Results show how the latter, which builds on state-of-the-art systems for this task, is a much more promising approach. Finally, we analyze how performance changes as a function of the number of dimensions used in the truncated matrix.

For evaluation, we use the Microsoft Research Paraphrase Corpus (Dolan et al., 2004). We use 70% of the dataset as training data and 30% as a test set. The total number of sentence pairs in the corpus is 5,801.

6.1 Graph Similarity and Bag of AMR Concepts

The Bag of words (BOW) baseline consists of a SVM that takes into account one single feature: the Jaccard score between the BOW representations for the two sentences, i.e., one-hot vectors indicating whether each word in the vocabulary is used or not. The use of the single Jaccard feature means that for the linear kernel we just learn a threshold on the score.

We note that the addition of the similarity-based features does not suffice to outperform the BOW baseline, as described in Table 1. Unlike Smatch, the bag of concepts feature does not need to find a, possibly wrong, alignment between the two graphs

[2]JAMR is available from https://github.com/jflanigan/jamr.

[3]AMREager is available from http://cohort.inf.ed.ac.uk/amreager.html.

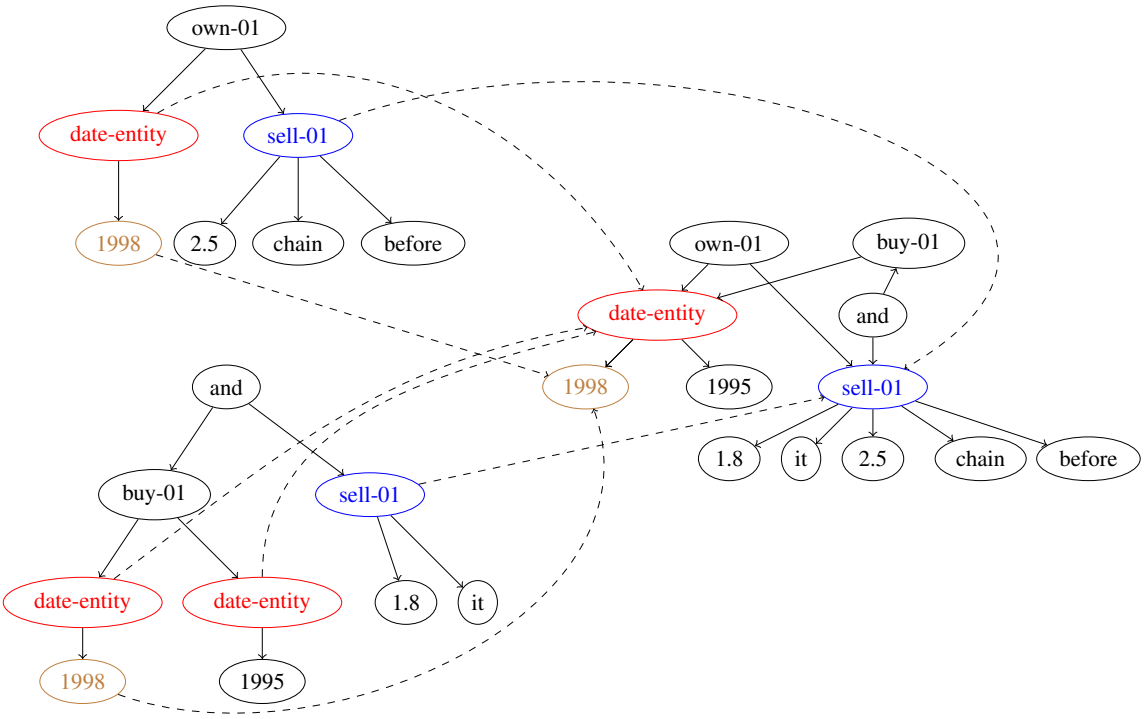

Figure 2: Visualization of the graph merging procedure for the sentence *Yucaipa owned Dominick's before selling the chain to Safeway in 1998 for $2.5 billion.* (above) and *Yucaipa bought Dominick's in 1995 for $693 million and sold it to Safeway for $1.8 billion in 1998.* (below). The "date-entity", "sell-01" and "1998" nodes in the two AMR graphs on the left are merged in the resulting graph on the right.

because it considers the node labels only. Interestingly, the addition of the bag of concepts feature is beneficial only for AMREager. It is indeed worth noting the different behaviors of the two parsers: when using the Smatch score only, JAMR reports slightly higher numbers than AMREager. However, when using the bag of concepts features too, AMREager is considerably better than JAMR, which is unexpected as the concept identification performance of the two parsers is reported to be identical (Damonte et al., 2017).

There is also some variability with the kernel used for the SVM classifier. The polynomial kernel does consistently better than the RBF and linear kernel. This means that a low-level interaction between the sentence representations does exist (when trying to determine whether they are paraphrases), but a higher order interaction, such as implied with RBF, is not necessary to be modeled.

6.2 PageRank and TF-IDF Reweighting for LSA

We now turn to experiments involving LSA as a mean to represent the candidate paraphrases. In this set of experiments, the baseline consists of using TF-IDF to weight the bag of words in the sentence-term matrix.

We first try to replace the bag of words with the bag of concepts from the AMR graphs, also re-weighted by TF-IDF. Then, we also replace the TF-IDF with PageRank as it is more appropriate to re-weight graph structures than TF-IDF. We report experiments for both inductive setting and transductive setting (Table 3). Our first finding is that, regardless of the parser, AMR is very helpful in the tranductive setting while it is harmful in the inductive setting. When using bag of words, it is easy to project sentences of the test set into the latent space learned on the training set only. However, our experiments indicate that this is not as easy with the AMR concepts produced by the two parsers. On the other hand, when the latent space is learned using also the sentences in the test set, the abstractive power of AMRs is helpful for this task. In the inductive setting, PageRank fails to improve over the TF-IDF scheme and neither of them outperform the BOW baseline. AMREager outperforms JAMR in this case. In the transduc-

"Smatch" denotes the use of the additional graph similarity feature and "BOC" the use of the additional Jaccard score on the bag of concept. Best result in each column is in bold.

tive case, the AMRs provided by JAMR are helpful with both TF-IDF and PageRank, while the graphs provided by AMREager give good results only for the PageRank scheme. The best result is achieved with JAMR, PageRank and a linear kernel for the SVM classifier.

We wanted to test in our experiments whether the same gains that are achieved with AMR parsing can also be achieved with just a syntactic parser. To test that, we parsed the paraphrase dataset with a dependency parser and reduced the syntactic parse trees to AMR graphs (meaning, we represented the dependency trees as graphs by representing each word as a node and labeled dependency relations as edges). Figure 3 gives an example of such conversion. As can be see, the AMR-like representation for the dependency trees retains words such as determiners ("the"). It also uses a different set of relations, as reflected by the edge labels that the dependency parser returns.

We chose to do this reduction instead of directly building a classifier that makes use of the dependency trees to ensure we are conducting a controlled experiment in which we precisely compare the use of syntax for paraphrase against the use of semantics. Once the syntactic trees are converted

to AMR graphs, the same code is used to run the experiments as in the case of AMR parsing, with both the PageRank and TF-IDF reweighting settings. We used the dependency parser from the Stanford CoreNLP (Manning et al., 2014). The results are given in Table 3, under "dep." As can be seen, these results lag behind the bag-of-words model in the inductive case and the AMR models in the transductive case. This could be attributed to AMR parsers better abstracting away from the surface form than dependency parsers.

Table 3: LSA experiments in the inductive and transductive settings, with two different reweighting schema: "PageRank" and "TF-IDF". "linear," "poly" and "rbf" denote the kernel for the SVM. "dep." denotes the use of syntactic parsing instead of semantic parsing.

truncated matrix U (Section 4). More specifically, on the x axis of the plots we have m/l, where m is the number of columns in the truncated matrix and l the number of words in the vocabulary. The plot shows that the performance stays stable for inductive inference. With transductive inference, however, performance peaks when m is very close to the vocabulary size. This shows that, in order to achieve good results, it is not necessary to remove a large number of columns from the original sentence-term matrix. The plot gives us more evidence on how the inductive setting is not ideal for the AMR-based approach. For the TF-IDF reweighting, the systems that show a considerably different behavior are JAMR with linear and RBF kernels, where we show clear peaks for the transductive case. For PageRank also the AMREager systems with linear and RBF kernel follow this trend. In general the polynomial kernel is the one less affected by this variable.

Table 2 shows that our best result for the transductive case, which we obtain with JAMR and PageRank, outperforms the current state of the art for paraphrase detection in the transductive setting. This is not true for the inductive case, proving the preference of the AMR-based LSA approach for the former setting.

7 Conclusion

We described an approach to incorporate an AMR parser output into the detection of paraphrases. Our method works by merging two graphs that need to be tested for a paraphrase relation, and then re-weighting a sentence-term matrix by the PageRank values of the nodes in the merged graph. We find that our method gives significant improvements over state of the art in paraphrase detection in the transductive setting, showing that AMR is indeed helpful for this task. We further show that the inductive settings is instead not ideal for this type of approach.

We are encouraged by the results, and believe that paraphrase detection can also be used as a proxy test for the performance of an AMR parser: if an AMR parser is close to canonicalizing language, it should be of significant help in detecting

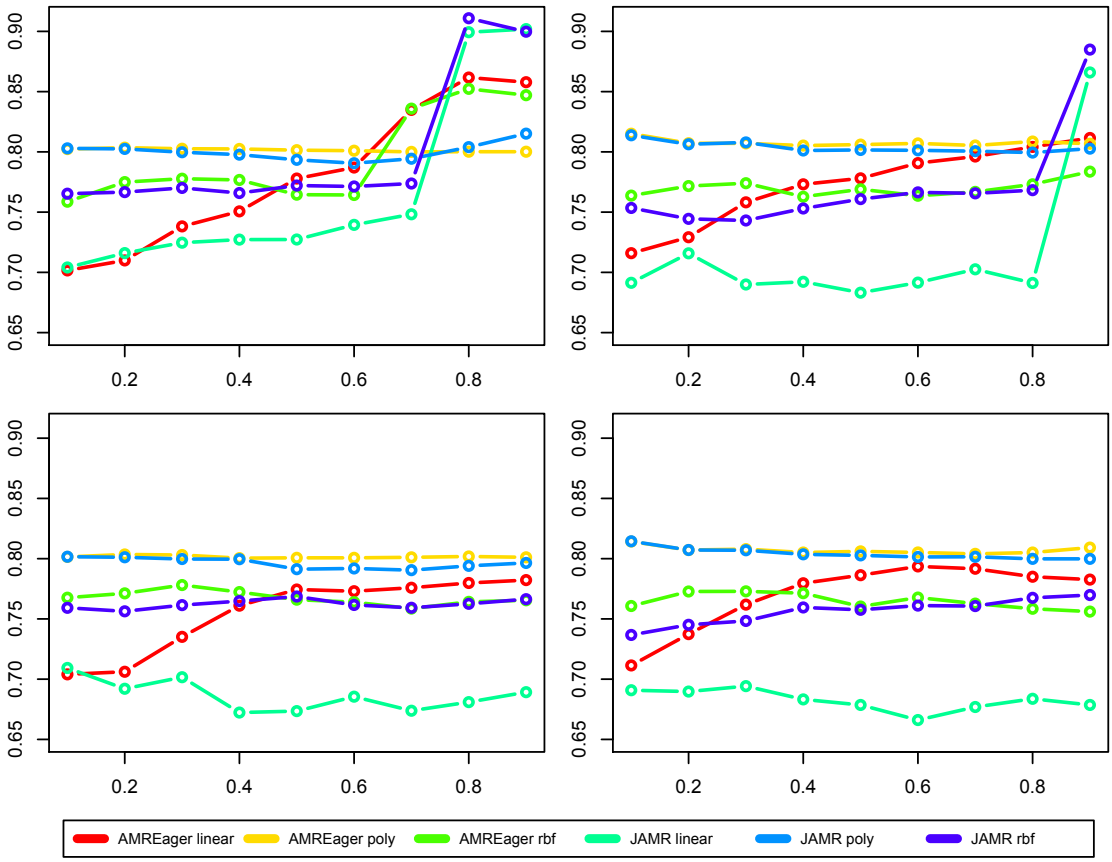

Figure 4: Plots of F_1 measure as a function of m/l, where m is the number of columns in the truncated matrix and l the number of words in the vocabulary. The top plots are in the transductive setting (with the left using PageRank and the right using TF-IDF weighting) while the bottom plots are in the inductive setting.

paraphrase relations. In our experiments, the overall best result was achieved by JAMR. More generally, our results show that JAMR has been more helpful in the transductive setting and in the first set of experiment when using the Smatch score only, while AMREager wins the comparison in the inductive case as well as in the first set of experiments when using both the Smatch score and the bag of concepts score as additional features.

Abstract

The widespread use of word embeddings is associated with the recent successes of many natural language processing (NLP) systems. The key approach of popular models such as word2vec and GloVe is to learn dense vector representations from the context of words. More recently, other approaches have been proposed that incorporate different types of contextual information, including topics, dependency relations, n-grams, and sentiment. However, these models typically integrate only limited additional contextual information, and often in *ad hoc* ways.

In this work, we introduce attr2vec, a novel framework for jointly learning embeddings for words and contextual attributes based on factorization machines. We perform experiments with different types of contextual information. Our experimental results on a text classification task demonstrate that using attr2vec to jointly learn embeddings for words and Part-of-Speech (POS) tags improves results compared to learning the embeddings independently. Moreover, we use attr2vec to train dependency-based embeddings and we show that they exhibit higher similarity between functionally related words compared to traditional approaches.

1 Introduction

Neural network-based methods have been successful in advancing the state-of-the-art in a wide range of NLP tasks, such as dependency parsing (Chen and Manning, 2014), sentence classification (Kim, 2014), machine translation (Sutskever et al., 2014; Luong and Manning, 2016), and information retrieval (Zhang et al., 2017). In all these approaches, vectorial distributed word representations, known as *word embeddings*, have become a fundamental building block. The use of word embeddings is considered a "secret sauce" for contributing to the success of many of these algorithms in recent years (Luong et al., 2013). Popular models for learning such word embeddings include word2vec (Mikolov et al., 2013a,b,c), GloVe (Pennington et al., 2014) and fastText (Bojanowski et al., 2017; Joulin et al., 2017).

The main idea behind these techniques is to represent a word by means of its context. The most popular forms of context are neighboring words in a window of text (Mikolov et al., 2013b; Pennington et al., 2014), though examples of additional contextual information might also include document topics (Li et al., 2016), dependency relations (Levy and Goldberg, 2014), morphemes (Luong et al., 2013), n-grams (Bojanowski et al., 2017), and sentiment (Tang et al., 2014). The embedding idea was originally devised to help overcome problems associated with the high dimensionality of sparse vector representations of words, particularly in the case of neural network modeling, though embeddings have since been used in a variety of machine learning approaches.

However, existing models generally exploit just a small portion of the available contextual information, and they tend to do so in *ad hoc* ways. The main purpose of context in these models is to shape the word vector space (that is, to associate a representation to the word), but contextual information is not usually represented in this space. For instance, Li and Jurafsky (2015) used document topics to derive multiple vectors for the same word, each capturing a different sense, but

*work conducted whilst the author was at Thomson Reuters.

Proceedings of NAACL-HLT 2018, pages 453–462
New Orleans, Louisiana, June 1 - 6, 2018.

their method does not represent topics in the vector space, that is, it does not generate topic vectors. Such contextual representations, jointly learned with the word representations, could potentially be useful for multiple tasks. For instance, pre-trained contextual vectors could be used as additional features, together with pre-trained word vectors, to improve the performance of existing models.

In this paper, we propose attr2vec, a novel framework for learning word embedding models that jointly associate distributed representations with words and with generic contextual attributes. attr2vec is inspired by the GloVe approach of Pennington et al. (2014) and can mimic it when no additional contextual attribute is considered. In contrast with GloVe, attr2vec uses Factorization Machines (FMs) (Rendle et al., 2011; Rendle, 2012). FMs are a generalization of matrix factorization approaches, such as GloVe, and can combine different generic feature types, even when the input data is sparse. Moreover, FMs do not consider input features as independent but model their interaction by factorizing their latent representation in pairwise fashion.

Here, we conduct an experimental study to assess whether the proposed embedding model can lead to better performance for a text classification task on the *Reuters-21578* dataset, using trained vectors as input to a convolutional neural network. The results show that jointly learned word and Part-of-Speech (POS) embeddings with attr2vec can achieve higher F1 and precision scores compared to embeddings learned independently. Moreover, we use attr2vec to train dependency-based word embeddings and show, using the publicly available *WordSim353* dataset, that such embeddings yield more *functional* similarities than embeddings trained using a linear bag-of-word approach (such as GloVe). We also performed a qualitative analysis that provides insights on how contextual attributes affects the distribution of words in the vector space.

Summing up, the main contributions of our work are the following:

- we extend the GloVe model to consider additional contextual information. To the best of our knowledge, this is the first work to present a general model able to jointly train dense vector representations for word and multiple arbitrary contextual attributes;
- we define a novel loss function based on factorization machines to jointly learn word and contextual attribute embeddings;
- we show how to model the input data and compute co-occurrence statistics using either a linear bag-of-word approach or syntactic dependency relations.

We provide the source code for the attr2vec model at `https://github.com/thomsonreuters/attr2vec`.

The remainder of this paper is organized as follows. Section 2 provides an overview of related work and Section 3 introduces the attr2vec model. In Section 4, we present the experimental results, and close this paper with some concluding remarks in Section 5.

2 Related Work

We have already introduced some of the main related approaches including word2vec and GloVe. Essentially, the GloVe model (Pennington et al., 2014) derives word representations by factorizing the word co-occurrence count matrix. The skip-gram and continuous bag-of-words (CBOW) models of Mikolov et al. (2013a), instead, build the vector space by trying to predict a word given its neighbouring words. Mnih and Kavukcuoglu (2013) proposed a closely related model that works in the opposite way, trying to predict neighbouring words given a word. Facebook's fastText model (Bojanowski et al., 2017; Joulin et al., 2017) augments word embeddings with subword-level information using character n-grams. Other examples of word embedding models include the work of Levy et al. (2014), where an explicit word vector space representation is derived using a PPMI metric, and WordRank of Ji et al. (2016), which learns word representations by adopting a ranking-based loss function. However, none of these models includes any contextual information beyond the neighbouring words.

Several forms of contextual information have been successfully integrated into word embedding models. For instance, Luong et al. (2013); Cotterell and Schütze (2015); Bhatia et al. (2016) capture morphological information into word representations; Bojanowski et al. (2017); Wieting et al. (2016) include character n-grams in their embedding model; Tang et al. (2014) learn sentiment-specific word embeddings by integrating sentiment information in the loss function; Li et al.

(2016) combine word embedding and topic modeling to jointly learn a representation for topics and words. In addition, several works in recent years focused on learning separate embeddings for multiple senses of a word (Neelakantan et al., 2015; Iacobacci et al., 2015; Pilehvar and Collier, 2016). However, all these techniques target a particular type of context. Our attr2vec model differs in that it can jointly represent generic contextual attributes and words in the embedding model. To do so, it makes use of factorization machines (Rendle, 2012), which have been successfully used to exploit contextual information in relation extraction tasks (Petroni et al., 2015) and recommender systems (Rendle et al., 2011)

It is well known that contextual information can improve performance of a wide range of NLP tasks, such as machine translation (Koehn and Hoang, 2007; García-Martínez et al., 2017), named entity typing (Corro et al., 2015) or sentiment analysis (Weichselbraun et al., 2013). In addition, (Melamud et al., 2016) observed that different contextual attributes work well for different tasks and that simple concatenation of embeddings, learned independently with different models, can yield further performance gains. Our attr2vec model can jointly learn embeddings for words and contextual attributes, and we show (see Section 4) that using such jointly learned embeddings yields to better performance on a text classification task compared to embeddings learned independently.

3 The attr2vec model

This section presents the attr2vec model. We first describe how we model the input data in terms of a feature matrix and a target vector (Section 3.1) and then how to factorize those using a factorization machines-based formulation (Section 3.3) to obtain word and contextual attribute embeddings.

3.1 Modeling input data

We consider as input a large corpus of text. Let the vocabulary of considered words be denoted by $W = \{w_1, ..., w_{|W|}\}$ and the set of all contextual variables denoted by $C = \{c_1, ..., c_{|C|}\}$. We denote $V = W \cup C$ the set of all considered words and contextual variables. In the rest of the paper we will refer to the elements of V as *variables*. We model the input data in terms of a target vector $Y \in \mathbb{R}^m$ and feature matrix $X \in \mathbb{R}^{m \times n}$, in which each row $x_i \in \mathbb{R}^n$ corresponds to a feature vector and there are as many columns as the number of variables (i.e., $|V| = n$). We group columns according to the type of the variables; e.g., there are word columns and a group of columns for each type of contextual information considered. Each target value $y_i \in Y$ represents the number of times the feature vector x_i has been observed in the input (i.e., the co-occurrence count). We consider a two-fold way to compute the co-occurrence count of a feature vector x_i: (1) *linear bag-of-words* and (2) *dependency-based*.

Linear Bag-of-Words The approach used in Pennington et al. (2014) is to compute the co-occurrence count using a linear bag-of-words assumption. The idea is to use a window of size k around the target word w, and considering the k words before and the k words after w to compute co-occurrence statistics[1]. Note that a small window size may miss some information, while a large window size might result in the algorithm capturing accidental pairs. A decay factor is commonly used to weight the contribution of an observation to the total co-occurrence count according to the distance to the target word. Here we consider a fractional decay, where the importance of a word is assumed to be inversely proportional to its distance from the target word.

To build the feature matrix X we set the values of the variables associated with the words pair and with each contextual variable observed in correspondence with that pair to 1. Note that there could be multiple rows in X referring to the same pair of words but associated with different contextual variables. When contextual variables can assume multiple values for a single observation (e.g., a document with multiple topics) we evenly distribute the unitary weight across all variables (e.g., across all document topics). The target values represent the number of times the corresponding combination of features (i.e., the pair of word and the contextual variables) has been observed in the input corpus, weighting each contribution with the fractional decay factor described above.

An example is shown in Figure 1. The first row in the figure corresponds to the observation of the pair of words *brothers* and *lehman* in a text window, with POS tags *nnp* and *nnps*, respectively, referring to the named entity *Lehman*

[1] In this paper we focus on symmetric windows, however the same model can be extended to asymmetric windows.

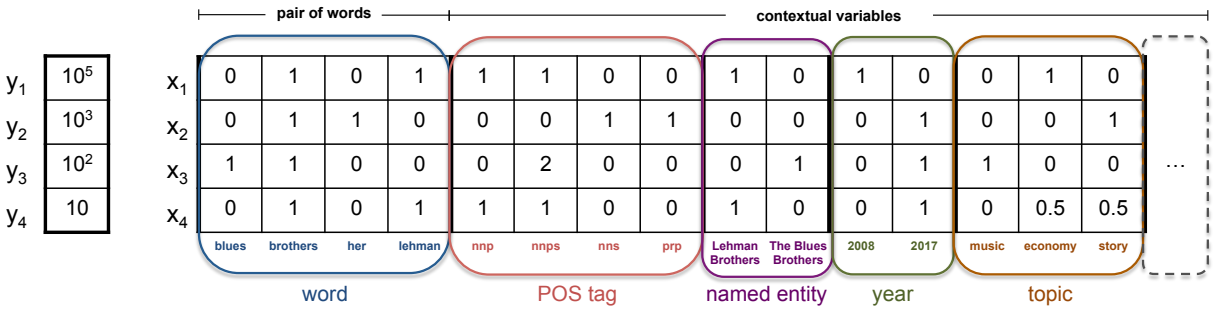

Figure 1: Example for representing input data with attr2vec using a linear window of text approach to compute co-occurrence count. Rows in X and Y are aligned: the row $y_i \in Y$ (a scalar) correspond to the row $x_i \in X$ (a feature vector); y_i represents the frequency of the particular combination of variables described by x_i in the corpus.

Brothers, from documents published in *2008* with topic *economy*. Such a combination of features (i.e., *brothers-lehman-nnp-nnps-Lehman Brothers-2008-economy* has been observed in the input 10^5 times (i.e., $y = 10^5$). The fourth row of Figure 1 conveys the information that the same pair of words (i.e., *brothers-lehman*) has been also observed 10 times in the input associated with different contextual information, in particular in documents published in *2017* with multi-topic *economy* and *story*. When contextual information is not considered (i.e., $c = \emptyset$) y is equal to the co-occurrence count of the pair of words, as in Pennington et al. (2014).

Dependency-Based Our attr2vec model can learn dependency-based embedding as well. In order to do so we adopted a similar strategy of Levy and Goldberg (2014). The main idea is to parse each sentence in the input corpus and to use the dependency tree to derive the co-occurrence count. In particular, for a target word w with modifiers $m_1, ..., m_o$ and a head h, we considered the dependency labels $(m_1, lbl_1), ..., (m_o, lbl_o), (h, lbl_h^{-1})$, where lbl is the type of the dependency relation between the head and the modifier and lbl^{-1} is used to mark the inverse relation. Moreover, edges that include a preposition are "collapsed" by connecting the head and the object of the proposition, and subsuming the preposition itself into the dependency label (see the example in the top part of Figure 2).

The feature matrix X in this case consists of two group of columns, one for the words and one for dependency labels, plus one group of columns for each additional contextual information considered. The co-occurrence count is driven by the dependency tree: each target value represents the number of times the corresponding word and dependency label (and all considered additional contextual information) appear in the dependency trees representing the sentences in the input corpus.

An example is shown in Figure 2. The first row in the matrix corresponds to the observation of the word *ganymede* connected to the word *discovered* through the inverse relation $dobj$ in the dependency tree (i.e., $discovered/dobj^{-1}$). Notice that using this approach it is possible to capture relevant relations between words "far apart" in the text including long-distance dependencies (e.g., *telescope* is not in the window of text around *discovered* for $k = 3$), and also filter out accidental neighbouring words (e.g., *his* is in the window of text of *discovered* for $k = 3$). An additional advantage of this approach with respect to a linear bag-of-words solution is that each observation is typed, indicating, for instance, that *Ganymede* is the object of *discovered* and *Galileo* is the subject.

3.2 GloVe factorization model

Before introducing the attr2vec model we briefly describe the GloVe factorization approach (Pennington et al., 2014). In particular, GloVe employs a matrix factorization model using as input the word-word co-occurrence count. In our example of Figure 1 this corresponds to considering in input just the first group of columns (i.e., the pair of words).

Starting from the observation that the ratio of co-occurrence probabilities is more appropriate for learning word representations as opposed to the probabilities of the words themselves, Pennington et al. propose the following weighted least

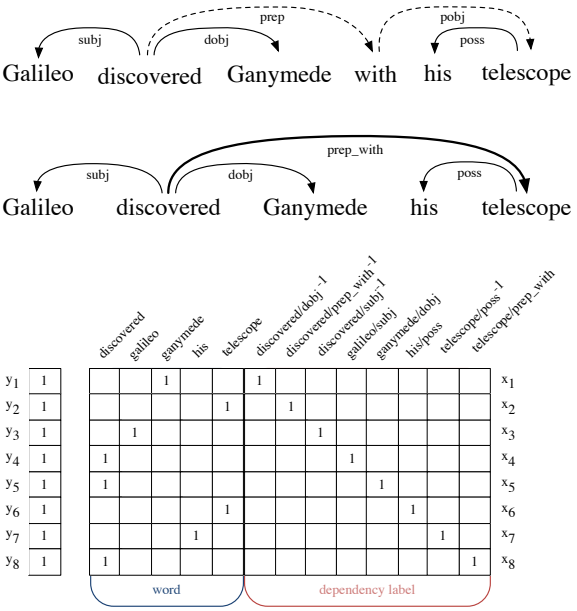

Figure 2: Example for representing input data with attr2vec using a dependency-based approach to compute co-occurrence count. **Top:** preposition relations are collapsed into single arcs, making telescope a direct modifier of discovered. **Bottom:** the attr2vec data matrix. Note that the Y vector contains all 1's since it refer to the modeling of a single sentence; in a real scenario, each row y_i of vector Y will contain a higher value (the frequency count of x_i in the corpus)

squares objective function:

$$J = \sum_{k=1}^{N} f(y_k)\Big(s(x_k) - \log(y_k)\Big)^2 \qquad (1)$$

where $x_k = (w_i, w_j)$ refers to the k-th pair of words in input with co-occurrence count y_k, and $s(x)$ is the score associated with the pair, computed as follows:

$$s(x) = b_{w_i} + b_{w_j} + \boldsymbol{f}_{w_i}^T \boldsymbol{f}_{w_j} \qquad (2)$$

where b_{w_i} and b_{w_j} are the biases, and $\boldsymbol{f}_{w_i}$ and $\boldsymbol{f}_{w_j}$ are the latent factor vectors associated with w_i and w_j, respectively.

The function $f(y)$ is used to reduce the importance of pairs of words that co-occur rarely, and is defined as follows:

$$f(y) = \begin{cases} (y/y_{max})^{\alpha} & \text{if } y < y_{max} \\ 1 & \text{otherwise} \end{cases} \qquad (3)$$

where y_{max} and α are hyperparameters of the model.

3.3 attr2vec factorization model

The model we propose, attr2vec, employs a matrix factorization model based on factorization machines. In particular, we associate with each variable $v \in V$ a *bias term* $b_v \in \mathbb{R}$ and a *latent factor vector* $\boldsymbol{f}_v \in \mathbb{R}^d$, where the *dimensionality* d of the latent factor space is a hyperparameter of the model. For each input feature vector $x \in X$, we denote by x_v the value of variable $v \in V$ in the corresponding row of the features data matrix.

We employ a weighted least squares model that is based of the formulation of Pennington et al. (2014) (Equation 1). In contrast to GloVe, we define a novel score $s(x)$ that takes into account both words and contextual attributes, computed as follows:

$$s(x) = \sum_{v \in V} x_v b_v + \sum_{v_1 \in V} \sum_{v_2 \in V \setminus \{v_1\}} x_{v_1} x_{v_2} \boldsymbol{f}_{v_1}^T \boldsymbol{f}_{v_2} \qquad (4)$$

Here, the bias terms b_v model the contribution of each individual variable to the final score, whereas the latent factor vectors $\boldsymbol{f}_v$ model the contribution of all pairwise interactions between variables. Rendle (2012) has shown that score computation is fast, since $s(x)$ can be computed in time linear to both the number of nonzero entries in x and the dimensionality d. Each latent factor vector can be interpreted as a low-dimensional representation of the corresponding variable, both for variables that refer to words and for variables that refer to contextual information. Note that, when contextual information is not considered the formulation of our factorization model is equivalent to the formulation of Pennington et al. (2014).

The model parameters $\Theta = \{b_v, \boldsymbol{f}_v | v \in V\}$ are estimated by minimizing J, for instance, through stochastic gradient descent. Each $\boldsymbol{f}_v$ can be interpret as a dense vector representation of variable $v \in V$.

4 Experiments

We conducted an experimental study on real-world data to compare our attr2vec model with other state-of-the-art approaches.

4.1 Dataset and Baseline

For a training corpus to learn embeddings, we used the Reuters News Archive, in particular, the collection of all news stories published by the Reuters News Agency from 2003 to 2017. We

embedding	*input*	*logistic regression*	*convolutional neural network*	
			static	*non-static*
random	$\vec{w_r}$	70.5 (69.3)	75.7 (77.5)	74.4 (76.2)
random	$\vec{w_r} \frown \vec{p_r}$	74.0 (73.9)	77.9 (79.7)	77.8 (79.8)
GloVe	$\vec{w_i}$	77.5 (77.5)	79.7 (81.5)	82.7 (84.3)
GloVe	$\vec{w_i} \frown \vec{p_r}$	80.2 (85.4)	82.5 (84.1)	84.5 (86.1)
GloVe	$\vec{w_i} \frown \vec{p_i}$	79.3 (83.3)	84.3 (85.8)	84.9 (86.4)
attr2vec	$\vec{w_j}$	77.5 (77.3)	80.6 (82.3)	82.8 (84.5)
attr2vec	$\vec{w_j} \frown \vec{p_j}$	80.1 (83.1)	84.9 (86.1)	**85.5** (**86.8**)

Table 1: Average F1 score (and precision in parentheses) for topic prediction on the *Reuters-21578* dataset. $\vec{w} \frown \vec{p}$ indicates the concatenation of word and POS tag vectors. $\vec{w_r}$ refer to randomly initialized word vectors and $\vec{p_r}$ to randomly initialized POS tag vector. $\vec{w_i}$ and $\vec{p_i}$ respectively refer to vectors independently trained with the GloVe model for words and POS tags; $\vec{w_j}$ and $\vec{p_j}$ respectively refer to vectors jointly trained with attr2vec for words and POS tags.

first applied a heuristic filtering approach to exclude non-textual documents, resulting in a collection of $\sim 8M$ news articles ($\sim 3B$ tokens). We then performed tokenization, part-of-speech tagging, and syntactic dependency parsing on the corpus using NLP4J[2] (Choi et al., 2015; Choi, 2016). The POS tagger achieves an accuracy score of 97.64% (Choi, 2016), the dependency parser achieve a label accuracy score of 94.94% (Choi et al., 2015). As a baseline we considered 200-dimensional GloVe vectors trained on the corpus using the code and hyperparameters of Pennington et al. (2014). In particular, we used $y_{max} = 100$ and $\alpha = 3/4$ for all our experiments.

4.2 Topic Classification Experiment

Experimental Setup For this experiment we trained 200-dimensional attr2vec vectors using part-of-speech tags as additional contextual information and a linear bag-of-words approach - i.e., each row in the feature matrix consists of a pair of words and the corresponding pair of POS tags (see the first two groups of columns for the example in Figure 1). We used the same hyperparameters as in GloVe. To make a fair comparison we trained two independent GloVe models, one to obtain word vectors ($\vec{w_i}$) and one to obtain POS tag vectors ($\vec{p_i}$). The latter model is trained by substituting each word in the corpus with the corresponding POS tag. Note that our attr2vec model can jointly learn a representation for both words ($\vec{w_j}$) and POS tags ($\vec{p_j}$). As a baseline we also considered randomly initialized vectors for words ($\vec{w_r}$) and POS tags ($\vec{p_r}$). To train attr2vec we used a modified version[3] of tffm (Trofimov and Novikov, 2016), an open-source TensorFlow implementation of Factorization Machines.

To evaluate the performance of the attr2vec model, we used the trained vectors as input for a convolutional neural network (CNN). We used the CNN architecture described by Kim (2014), in particular a modified version of the TensorFlow implementation in Britz (2015), where we add support for pre-trained embeddings. As hyperparameters, we used a batch size of 128 training samples, no dropout, one layer, filter windows of 3, 4, 5 with 100 feature maps each. We trained using the Adam optimizer and a learning rate of 0.001 and let the models train for 100 epochs (an epoch is an iteration over all the training points). We executed three independent runs for each experiment and we report averaged results.

As a benchmark we used the following text classification task: predict all the topic codes associated with an article using the first τ tokens in the article. We used the *Reuters-21578*[4] dataset. This corpus contains 10788 news documents classified into 90 topics. We used the provided training/test split. For each document, we considered the first $\tau = 250$ tokens as input text for the CNN. Note that, in contrast to other previous work (Li et al., 2016), we consider all topics and formulate a multi-label classification problem. For each test article we computed precision, recall and F1 score comparing the actual topic codes and those predicted by the CNN. As evaluation metrics we used the average F1 score and the average preci-

[3] Source code available at https://github.com/thomsonreuters/attr2vec

[4] http://www.nltk.org/book/ch02.html

sion across all test articles.

We trained multiple CNN models, using either word vectors ($\vec{w}$) or the concatenation of word and POS tag vectors ($\vec{w}\frown\vec{p}$) as inputs, and keeping these vectors *static* throughout training or allowing the CNN to update them via backpropagation (*non-static*). We also considered logistic regression as baseline method, using averaged vectors calculated over the input text as features, as in Zhang and Wallace (2015). As this is a multilabel task, we used the one-vs-all formulation of logistic regression, which attempts to fit one classifier per class with each class being fitted against all other classes. L_1 regularization was applied with a weight of 0.005.

Results Table 1 reports the result of our experiments. Each entry shows the average F1 score and the average precision in parentheses.

First note that the CNN model consistently outperforms logistic regression for all considered settings. The CNN performance improves if it receives as input pre-trained vectors as opposed to random ones, consistently with other works (Kim, 2014). The performance is comparable when GloVe or attr2vec word vectors are used as input.

The key advantage of our attr2vec model over GloVe is demonstrated when additional contextual information is considered in the CNN model. The performance of the CNN model improves if POS vectors are considered together with GloVe word vectors in input, both when such POS vectors are randomly initialized ($\vec{w_i}\frown\vec{p_r}$) and independently trained with the GloVe model ($\vec{w_i}\frown\vec{p_i}$). However, the best performance is achieved when word and POS tags vectors are jointly trained with our attr2vec model ($\vec{w_j}\frown\vec{p_j}$).

Note that the aim of the paper was not to show that POS tags help for text classification tasks (to that end, an exhaustive exploration of the parameter space would have been needed); instead, the goal of this work is to introduce a new embedding model that jointly learns a representation for words and POS tags, capturing the interaction between them, and to show that such representation is beneficial for a CNN with respect to embeddings learned in an independent fashion, given the same network settings. Standard embedding models (like GloVe), in fact, can capture either the interactions between words or between POS tags in an independent fashion. Our attr2vec model, in addition, captures the cross-interaction between

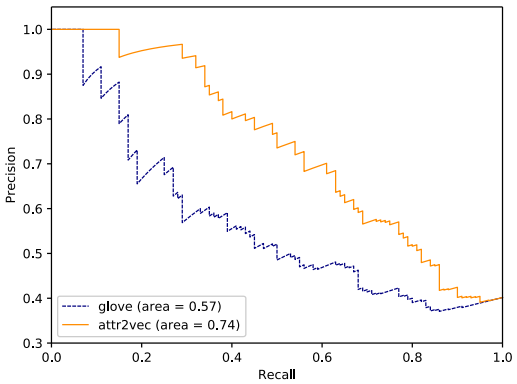

Figure 3: Recall-precision curve when attempting to rank the similar words above the related ones on the *WordSim353* dataset.

words and contextual attributes, jointly learning their representation, and our results suggest that this additional information is beneficial for the performance of the CNN model. Moreover, note that our attr2vec algorithm, unlike GloVe, can handle generic contextual information.

4.3 Word Similarity Experiment

In our second experiment we wanted to address if our attr2vec model was able to produce dependency-based embeddings that exhibit more functional similarity than GloVe embeddings (that usually yield broad topical similarities). To this end, we trained 200-dimensional attr2vec vectors using a dependency-based approach - i.e, each row in the feature matrix consist of a word and a dependency label (see the example in Figure 2).

Our evaluation closely follows the one in Levy and Goldberg (2014). In particular, we used the *WordSim353* dataset (Finkelstein et al., 2001; Agirre et al., 2009) containing pairs of similar words that reflect either *relatedness* (topical similarity) or *similarity* (functional similarity) relations. The pairs are ranked according to the cosine similarity between the corresponding word vectors. The idea is that a model that focuses on functional similarity should rank similar pairs in the dataset above the related ones. For instance, such a model should rank the pair *money-currency* (i.e., functionally similar words) above the pair *money-laundering* (i.e., topically similar words). We drew a recall-precision curve by considering related pair as a miss and similar pair as a hit. In this way we aimed to capture the embeddings affinity towards the *similarity* subset over the *re-*

latedness one.

Figure 3 reports the result of the experiment. The attr2vec curve (orange solid line) is higher than the GloVe one (blue dashed line) and the area under the cuve is larger (0.74 with respect to 0.57), suggesting that attr2vec yields more functional similarities with respect to GloVe. Note that a similar behaviour has been observed in Levy and Goldberg (2014) for context-predictive models (i.e., the skip-gram model with negative sampling). To the best of our knowledge, attr2vec is the first model that incorporates syntactic dependency relations in a co-occurrence counts based model (such as GloVe). Moreover, attr2vec is a general model that can handle additional arbitrary contextual information.

4.4 Qualitative Evaluation

Our final evaluation is qualitative. We trained 200-dimensional attr2vec embeddings using news topics as additional contextual information and a linear bag-of-words approach - i.e., each row in the feature matrix consists of a pair of words and the topic of the news article where such pair has been observed (see the first and the last group of columns for the example in Figure 1). In particular, we used the same collection of $\sim 8M$ news articles presented in Section 4.1 and we considered the following two article topics: general news stories (G) and sport news (SPO).

Figure 4 shows a two-dimensional projection of the 200-dimensional vector space where words and topics representations lie, obtained using the *t-SNE*[5] visualisation technique (Maaten and Hinton, 2008). Here the two topic points (G on the left and SPO on the right of the figure) seem to metaphorically act as "magnets", modifying the space and forming two clusters of words. The left cluster around the representation of topic G includes general words not related to sports such as "mars", "sound", "warranty", "finance", "train", while the right cluster around the representation of topic SPO contains words related to sports such as "football", "coach", "game", "stadium", "cricket". Words that are related with both general news stories and sport news lie somewhere in the middle between these two clusters. Examples of such words include "penalties", "transfer", "medical", "goal", "supporters". Note that there are other attractive and repulsive forces in the vector space driven by word similarity, and that a two-dimensional representation is only able to capture a small portion of all relations that take place in the higher dimensional space.

[5]We used the TensorBoard implementation of *t-SNE*.

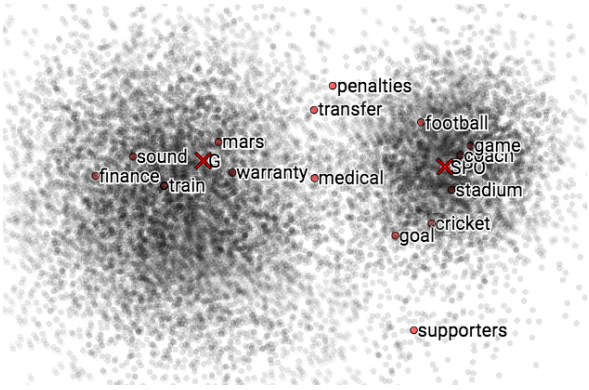

Figure 4: Two-dimensional projection of the 200-dimensional vector space, that contains representations of both words and topics, using *t-SNE*. In particular, we considered two topics: general news stories (G) and sport news (SPO).

5 Conclusions

In this paper, we proposed attr2vec, a novel embedding model that can jointly learn a distributed representation for words and contextual attributes. Our model is general and can handle multiple arbitrary contextual information simultaneously. To do so, we defined a novel loss function based on factorization machines. Moreover, attr2vec can mimic existing word embedding algorithms when no additional contextual information is considered. In particular, GloVe is a special case of our model.

We have presented an experimental study where we considered POS tags as additional contextual information, and fed a convolutional neural network (CNN) with both word and POS tag vectors. The results suggest that the CNN prediction performance improves when word and context vectors are jointly learned by our attr2vec model. In addition, we described how to train dependency-based attr2vec embeddings and showed that they produce different kinds of similarities. We also provided some insights into how the vector space is affected by contextual attributes, which seem to act like "magnets" that attract or repulse words, that are themselves subject to attractive or repulsive forces driven by similarity.

While attr2vec benefits from structural information, it has a price: the number of features is in-

creased, and the computational cost is increased compared to a model that does not use contextual information. Each additional attribute may furthermore introduce its own noise (component-specific errors) into the process. Nevertheless, the overall improvement can help in tasks where quality is of the utmost importance and high-quality annotation components are available.

In future work, we aim to investigate the effect of adding different contextual information, and we plan to test the resulting models in various applications.

Abstract

Distributed representations of words learned from text have proved to be successful in various natural language processing tasks in recent times. While some methods represent words as vectors computed from text using predictive model (Word2vec) or dense count based model (GloVe), others attempt to represent these in a distributional thesaurus network structure where the neighborhood of a word is a set of words having adequate context overlap. Being motivated by recent surge of research in network embedding techniques (DeepWalk, LINE, node2vec etc.), we turn a distributional thesaurus network into dense word vectors and investigate the usefulness of distributional thesaurus embedding in improving overall word representation. This is the first attempt where we show that combining the proposed word representation obtained by distributional thesaurus embedding with the state-of-the-art word representations helps in improving the performance by a significant margin when evaluated against NLP tasks like word similarity and relatedness, synonym detection, analogy detection. Additionally, we show that even without using any handcrafted lexical resources we can come up with representations having comparable performance in the word similarity and relatedness tasks compared to the representations where a lexical resource has been used.

1 Introduction

Natural language understanding has always been a primary challenge in natural language processing (NLP) domain. Learning word representations is one of the basic and primary steps in understanding text and nowadays there are predominantly two views of learning word representations. In one realm of representation, words are vectors of distributions obtained from analyzing their contexts in the text and two words are considered meaningfully similar if the vectors of those words are close in the euclidean space. In recent times, attempts have been made for dense representation of words, be it using predictive model like Word2vec (Mikolov et al., 2013) or count-based model like GloVe (Pennington et al., 2014) which are computationally efficient as well. Another stream of representation talks about network like structure where two words are considered neighbors if they both occur in the same context above a certain number of times. The words are finally represented using these neighbors. Distributional Thesaurus is one such instance of this type, which gets automatically produced from a text corpus and identifies words that occur in similar contexts; the notion of which was used in early work about distributional semantics (Grefenstette, 2012; Lin, 1998; Curran and Moens, 2002). One such representation is JoBimText proposed by Biemann and Riedl (2013) that contains, for each word, a list of words that are similar with respect to their bigram distribution, thus producing a network representation. Later, Riedl and Biemann (2013) introduced a highly scalable approach for computing this network. We mention this representation as a DT network throughout this article. With the emergence of recent trend of embedding large networks into dense low-dimensional vector space efficiently (Perozzi et al., 2014; Tang et al., 2015; Grover and Leskovec, 2016) which are focused on capturing different properties of the network like neighborhood structure, community structure, etc., we explore representing DT network in a dense vector space and evaluate its useful application in various NLP tasks.

There has been attempt (Ferret, 2017) to turn distributional thesauri into word vectors for synonym extraction and expansion but the full utilization of DT embedding has not yet been explored. In this paper, as a main contribution, we

Proceedings of NAACL-HLT 2018, pages 463–473
New Orleans, Louisiana, June 1 - 6, 2018.

investigate the best way of turning a Distributional Thesaurus (DT) network into word embeddings by applying efficient network embedding methods and analyze how these embeddings generated from DT network can improve the representations generated from prediction-based model like Word2vec or dense count based semantic model like GloVe. We experiment with several combination techniques and find that DT network embedding can be combined with Word2vec and GloVe to outperform the performances when used independently. Further, we show that we can use DT network embedding as a proxy of WordNet embedding in order to improve the already existing state-of-the-art word representations as both of them achieve comparable performance as far as word similarity and word relatedness tasks are concerned. Considering the fact that the vocabulary size of WordNet is small and preparing WordNet like lexical resources needs huge human engagement, it would be useful to have a representation which can be generated automatically from corpus. We also attempt to combine both WordNet and DT embeddings to improve the existing word representations and find that DT embedding still has some extra information to bring in leading to better performance when compared to combination of only WordNet embedding and state-of-the-art word embeddings. While most of our experiments are focused on word similarity and relatedness tasks, we show the usefulness of DT embeddings on synonym detection and analogy detection as well. In both the tasks, combined representation of GloVe and DT embeddings shows promising performance gain over state-of-the-art embeddings.

2 Related Work

The core idea behind the construction of distributional thesauri is the distributional hypothesis (Firth, 1957): "You should know a word by the company it keeps". The semantic neighbors of a target word are words whose contexts overlap with the context of a target word above a certain threshold. Some of the initial attempts for preparing distributional thesaurus are made by Lin (1998), Curran and Moens (2002), Grefenstette (2012). The semantic relation between a target word and its neighbors can be of different types, e.g., synonymy, hypernymy, hyponymy or other relations (Adam et al., 2013; Budanitsky and Hirst, 2006) which prove to be very useful in different natural language tasks. Even though computation of sparse count based models used to be inefficient, in this era of high speed processors and storage, attempts are being made to streamline the computation with ease. One such effort is made by Kilgarriff et al. (2004) where they propose Sketch Engine, a corpus tool which takes as input a corpus of any language and corresponding grammar patterns, and generates word sketches for the words of that language and a thesaurus. Recently, Riedl and Biemann (2013) introduce a new highly scalable approach for computing quality distributional thesauri by incorporating pruning techniques and using a distributed computation framework. They prepare distributional thesaurus from Google book corpus in a network structure and make it publicly available.

In another stream of literature, word embeddings represent words as dense unit vectors of real numbers, where vectors that are close together in euclidean space are considered to be semantically related. In this genre of representation, one of the captivating attempt is made by Mikolov et al. (2013), where they propose Word2vec, basically a set of two predictive models for neural embedding whereas Pennington et al. (2014) propose GloVe, which utilizes a dense count based model to come up with word embeddings that approximate this. Comparisons have also been made between count-based and prediction-based distributional models (Baroni et al., 2014) upon various tasks like relatedness, analogy, concept categorization etc., where researchers show that prediction-based word embeddings outperform sparse count-based methods used for computing distributional semantic models. In other study, Levy and Goldberg (2014) show that dense count-based methods, using PPMI weighted co-occurrences and SVD, approximates neural word embeddings. Later, Levy et al. (2015) show the impact of various parameters and the best performing parameters for these methods. All these approaches are completely text based; no external knowledge source has been used.

More recently, a new direction of investigation has been opened up where researchers are trying to combine knowledge extracted from knowledge bases, images with distributed word representations prepared from text with the expectation of getting better representation. Some use

Knowledge bases like WordNet (Miller, 1995), FreeBase (Bollacker et al., 2008), PPDB (Ganitkevitch et al., 2013), ConceptNet (Speer et al., 2017), whereas others use ImageNet (Frome et al., 2013; Kiela and Bottou, 2014; Both et al., 2017; Thoma et al., 2017) for capturing visual representation of lexical items. There are various ways of combining multiple representations. Some of the works extract lists of relations from knowledge bases and use those to either modify the learning algorithms (Halawi et al., 2012; Wang et al., 2014; Tian et al., 2016; Rastogi et al., 2015) or post-process pre-trained word representations (Faruqui et al., 2015). Another line of literature prepares dense vector representation from each of the modes (text, knowledge bases, visual etc.) and tries to combine the vectors using various methods like concatenation, centroid computation, principal component analysis (Jolliffe, 1986), canonical correlation analysis (Faruqui and Dyer, 2014) etc. One such recent attempt is made by Goikoetxea et al. (2016) where they prepare vector representation from WordNet following the method proposed by Goikoetxea et al. (2015), which combines random walks over knowledge bases and neural network language model, and tries to improve the vector representation constructed from text using this. As in lexical knowledge bases, the number of lexical items involved is much less than the raw text and preparing such resources is a cumbersome task, our goal is to see whether we can use DT network instead of some knowledge bases like WordNet and achieve comparable performance on NLP tasks like word similarity and word relatedness. In order to prepare vector representation from DT network, we attempt to use various network embeddings like DeepWalk (Perozzi et al., 2014), LINE (Tang et al., 2015), struc2vec (Ribeiro et al., 2017), node2vec (Grover and Leskovec, 2016) etc. Some of those try to capture the neighbourhood or community structure in the network while others attempt to capture structural similarity between nodes, second order proximity, etc.

3 Proposed Methodology

Our aim is to analyze the effect of integrating the knowledge of Distributional Thesaurus network with the state-of-the-art word representation models to prepare a better word representation. We first prepare vector representations from Distributional Thesaurus (DT) network applying network representation learning model. Next we combine this thesaurus embedding with state-of-the-art vector representations prepared using GloVe and Word2vec model for analysis.

3.1 Distributional Thesaurus (DT) Network

Riedl and Biemann (2013) use the Google books corpus, consisting of texts from over 3.4 million digitized English books published between 1520 and 2008 and construct a distributional thesauri (DT) network using the syntactic n-gram data (Goldberg and Orwant, 2013). The authors first compute the lexicographer's mutual information (LMI) (Kilgarriff et al., 2004) for each bigram, which gives a measure of the collocational strength of a bigram. Each bigram is broken into a word and a feature, where the feature consists of the bigram relation and the related word. Then the top 1000 ranked features for each word are taken and for each word pair, intersection of their corresponding feature set is obtained. The word pairs having number of overlapping features above a threshold are retained in the network. In a nutshell, the DT network contains, for each word, a list of words that are similar with respect to their bigram distribution (Riedl and Biemann, 2013). In the network, each word is a node and there is a weighted edge between a pair of words where the weight corresponds to the number of overlapping features. A sample snapshot of the DT is shown in Figure 1.

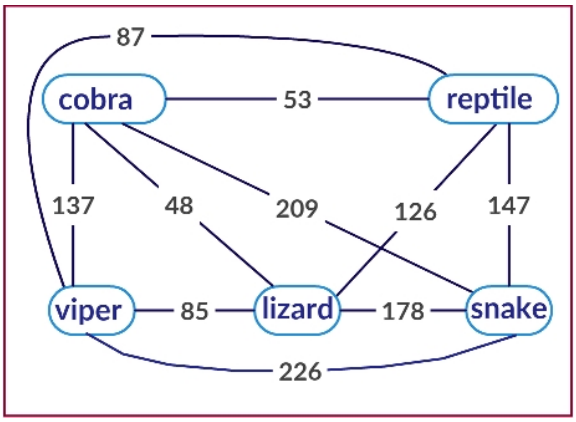

Figure 1: A sample snapshot of Distributional Thesaurus network where each node represents a word and the weight of an edge between two words is defined as the number of context features that these two words share in common.

3.2 Embedding Distributional Thesaurus

Now, from the DT network, we prepare the vector representation for each node using network representation learning models which produce vector representation for each of the node in a network. For this purpose, we use three state-of-the-art network representation learning models as discussed below.

DeepWalk: DeepWalk (Perozzi et al., 2014) learns social representations of a graph's vertices by modeling a stream of short random walks. Social representations signify latent features of the vertices that capture neighborhood similarity and community membership.

LINE: LINE (Tang et al., 2015) is a network embedding model suitable for arbitrary types of networks: undirected, directed and/or weighted. The model optimizes an objective which preserves both the local and global network structures by capturing both first-order and second-order proximity between vertices.

node2vec: node2vec (Grover and Leskovec, 2016) is a semi-supervised algorithm for scalable feature learning in networks which maximizes the likelihood of preserving network neighborhoods of nodes in a d-dimensional feature space. This algorithm can learn representations that organize nodes based on their network roles and/or communities they belong to by developing a family of biased random walks, which efficiently explore diverse neighborhoods of a given node.

Note that, by applying network embedding models on DT network we obtain 128 dimensional vectors for each word in the network. We only consider edges of the DT network having edge weight greater or equal to 50 for network embedding. Henceforth, we will use *D2V-D*, *D2V-L* and *D2V-N* to indicate vector representations obtained from DT network produced by DeepWalk, LINE and node2vec, respectively.

After obtaining vector representations, we also explore whether these can be combined with the pre-trained vector representation of Word2vec and GloVe to come up with a joint vector representation. For that purpose, we directly use very well-known GloVe 1.2 embeddings (Pennington et al., 2014) trained on 840 billion words of the common crawl dataset having vector dimension of 300. As an instance of pre-trained vector of Word2vec, we use prominent pre-trained vector representations prepared by Mikolov et al. (2013) trained on 100 billion words of Google News using skip-grams with negative sampling, having dimension of 300.

3.3 Vector Combination Methods

In order to integrate the word vectors, we apply two strategies inspired by Goikoetxea et al. (2016): concatenation (CC) and principal component analysis (PCA).

Concatenation (CC): This corresponds to the simple vector concatenation operation. Vector representations of both GloVe and Word2vec are of 300 dimensions and word embeddings learnt form DT are of 128 dimensions. The concatenated representation we use are of 428 dimensions.

Principal Component Analysis (PCA): Principal component analysis (Jolliffe, 1986) is a dimensionality reduction statistical procedure that uses an orthogonal transformation to convert a set of observations of possibly correlated variables into a set of values of linearly uncorrelated variables called principal components (linear combinations of the original variables). We apply PCA to the concatenated representations (dimension of 428) reducing these to 300 dimensions. In addition to PCA, we try with truncated singular value decomposition procedure (Hansen, 1987) as well, but as per the experiment set up, it shows negligible improvement in performance compared to simple concatenation; hence we do not continue with the truncated singular value decomposition for dimensionality reduction. After obtaining the combined representations of words, we head towards evaluating the quality of the representation.

4 Experiments and Analysis

In order to evaluate the quality of the word representations, we first conduct qualitative analysis of the joint representation. Next, we follow the most acceptable way of applying on different NLP tasks like word similarity and word relatedness, synonym detection and word analogy as described next.

4.1 Qualitative Analysis:

On qualitative analysis of some of the word pairs from the evaluation dataset, we observe that the joint representation (PCA (GloVe,D2V-N)) captures the notion of similarity much better than GloVe. For example, it gives a higher cosine similarity scores to the pairs (car, cab), (sea, ocean), (cottage,cabin), (vision, perception) etc. in com-

Dataset	GloVe	W2V	D2V-D	D2V-L	D2V-N

Table 1: Comparison of individual performances of different vector representation models w.r.t. word similarity and relatedness tasks. The performance metric is Spearman's rank correlation coefficient (ρ). Best result of each row in bold showing the best vector representation for each dataset.

parison to GloVe. However, in some cases, where words are not similar but are related, e.g., (airport, flight), (food, meat), (peeper, soup), (harbour, shore), the joint representation gives a lower cosine similarity score than GloVe comparatively. In the next set of evaluation experiments, we observe this utility of joint representation towards word similarity task and word relatedness task to some extent.

4.2 Word Similarity and Relatedness

In this genre of tasks, the human judgment score for each word pair is given; we report the Spearman's rank correlation coefficient (ρ) between human judgment score and the predicted score by distributional model. Note that, we take cosine similarity between vector representations of words in a word pair as the predicted score.

Datasets: We use the benchmark datasets for evaluation of word representations. Four word similarity datasets and four word relatedness datasets are used for that purpose. The descriptions of the word similarity datasets are given below.

WordSim353 Similarity (WSSim) : 203 word pairs extracted from WordSim353 dataset (Finkelstein et al., 2001) by manual classification, prepared by Agirre et al. (2009), which deals with only similarity.

SimLex999 (SimL) : 999 word pairs rated by 500 paid native English speakers, recruited via Amazon Mechanical Turk,[1] who were asked to rate the similarity. This dataset is introduced by Hill et al. (2016).

RG-65 : It consists of 65 word pairs collected by Rubenstein and Goodenough (1965). These word pairs are judged by 51 humans in a scale from 0 to 4 according to their similarity, but ignoring any other possible semantic relationships.

MC-30 : 30 words judged by 38 subjects in a scale of 0 and 4 collected by Miller and Charles (1991).

Similarly, a brief overview of word relatedness datasets is given below:

WordSim353 Relatedness (WSR) : 252 word pairs extracted from WordSim353 (Finkelstein et al., 2001) dataset by manual classification, prepared by Agirre et al. (2009) which deals with only relatedness.

MTURK771 (M771) : 771 word pairs evaluated by Amazon Mechanical Turk workers, with an average of 20 ratings for each word pair, where each judgment task consists of a batch of 50 word pairs. Ratings are collected on a 15 scale. This dataset is introduced by Halawi et al. (2012).

MTURK287 (M287) : 287 word pairs evaluated by Amazon Mechanical Turk workers, with an average of 23 ratings for each word pair. This dataset is introduced by Radinsky et al. (2011).

MEN : MEN consists of 3,000 word pairs with [0, 1]-normalized semantic relatedness ratings provided by Amazon Mechanical Turk workers. This dataset was introduced by Bruni et al. (2014).

Along with these datasets we use the full **WordSim353 (WS-353)** dataset (includes both similarity and relatedness pairs) (Finkelstein et al., 2001) which contains 353 word pairs, each associated with an average of 13 to 16 human judgments in a scale of 0 to 10. Being inspired by Baroni et al. (2014), we consider only noun pairs from **SimL** and **MEN** datasets, which will be denoted as **SimL-N** and **MEN-N** whereas other datasets only contain the noun pairs.

We start with experiments to inspect individual performance of each of the vector representations for each of the datasets. Table 1 represents individual performances of GloVe, Word2vec, *D2V-*

Table 5: Performance (ρ) reported for three combined representations: GloVe and DT embedding using node2vec (D2V-N), GloVe and WordNet embedding (WN2V), GloVe, WN2V and D2V-N. Results show that, DT embedding produces comparable performance in comparison to the WordNet embedding. Combining DT embedding along with WordNet embedding helps to boost performance further in many of the cases.

D, *D2V-L* and *D2V-N* for different datasets. In most of the cases, GloVe produces the best results although no model is a clear winner for all the datasets. Interestingly, *D2V-D* and *D2V-N* give results comparable to GloVe and Word2vec for the word similarity datasets, even surpassing GloVe and Word2vec for few of these. *D2V-L* gives very poor performance, indicating that considering second order proximity in the DT network while embedding has an adverse effect on performance in word similarity and word relatedness tasks, whereas random walk based *D2V-D* and *D2V-N* which take care of neighborhood and community, produce decent performance. Hence-

Dataset	GloVe	GloVe with retrofitting	PCA (GloVe,D2V-N)
WSSim	0.799	0.799	**0.832**
SimL-N	0.427	0.423	**0.483**
RG-65	0.791	0.791	**0.857**
MC-30	0.799	0.799	**0.874**
WSR	0.637	**0.69**	0.657
M771	0.707	0.708	**0.719**
M287	0.8	0.795	**0.82**
MEN-N	**0.819**	**0.819**	0.817
WS-353	0.706	0.703	**0.75**

Table 6: Comparison of performances (Spearman's ρ) between GloVe representation and retrofitted (by DT network) GloVe representation. Clearly, DT retrofitting is not helping much to improve the performance of GloVe.

forth, we ignore the *D2V-L* model for the rest of our experiments.

Next, we investigate whether network embeddings applied on Distributional Thesaurus network can be combined with GloVe and Word2vec to improve the performance on the pre-specified tasks. In order to do that, we combine the vector representations using two operations: concatenation (CC), and principal component analysis (PCA). Table 2 represents the performance of combining GloVe with *D2V-D* and *D2V-N* for all the datasets using these combination strategies. In general, PCA turns out to be better technique for vector combination than CC. Clearly, combining DT embeddings and GloVe boosts the performance for all the datasets except for the **MEN-N** dataset, where the combined representation produces comparable performance.

In order to ensure that this observation is consistent, we try combining DT embeddings with Word2vec. The results are presented in Table 3 and we see very similar improvements in the performance except for a few cases, indicating the fact that combining word embeddings prepared form DT network is helpful in enhancing performances. From Tables 1, 2 and 3, we see that GloVe proves to be better than word2Vec for most of the cases, *D2V-N* is the best performing network embedding, and PCA turns out to be the best combination technique. Henceforth, we consider PCA (GloVe, *D2V-N*) as our model for comparison with the baselines for the rest of the experiments.

Further, to scrutinize that the achieved result is not just the effect of combining two different word vectors, we compare PCA (GloVe, D2V-N) against combination of GloVe and Word2vec (W2V). Table 4 shows the performance comparison on different datasets and it is evident that PCA (GloVe, D2V-N) gives better results compared to PCA (GloVe, W2V) in most of the cases.

Now, as we observe that the network embedding from DT network helps to boost the performance of Word2vec and GloVe when combined with them, we further compare the performance against the case when text based embeddings are combined with embeddings from lexical resources. For that purpose, we take **one baseline** (Goikoetxea et al., 2016), where authors combined the text based representation with WordNet based representation. Here we use GloVe as the text based representation and PCA as the combination method as prescribed by the author. Note that, WordNet based representation is made publicly available by Goikoetxea et al. (2016). From the second and third columns of Table 5, we observe that even though we do not use any manually created lexical resources like WordNet our approach achieves comparable performance. Additionally we check whether we gain in terms of performance if we integrate the three embeddings together. Fourth column of Table 5 shows that we gain for some of the datasets and for other cases, it has a negative effect. Looking at the performance, we can conclude that automatically generated DT network from corpus brings in useful additional information as far as word similarity and relatedness tasks are concerned.

So far, we use concatenation and PCA as methods for combining two different representations. However, as per the literature, there are different ways of infusing knowledge from different lexical sources to improve the quality of pre-trained vector embeddings. So we compare our proposed way of combination with a completely different way of integrating information from both dimensions, known as *retrofitting*. Retrofitting is a novel way proposed by Faruqui et al. (2015) for refining vector space representations using relational information from semantic lexicons by encouraging linked words to have similar vector representations. Here instead of using semantic lexicons, we use the DT network to produce the linked words to have similar vector representation. Note that, for a target word, we consider only those words as linked words which are having edge weight greater than a certain threshold. While experimenting with various thresholds, the best results were obtained for a

threshold value of 500. Table 6 shows the performance of GloVe representations when retrofitted with information from DT network. Even though in very few cases it gives little improved performance, compared to other combinations presented in Table2, the correlation is not very good, indicating the fact that retrofitting is probably not the best way of fusing knowledge from a DT network.

Further, we extend our study to investigate the usefulness of DT embedding on other NLP tasks like synonym detection, SAT analogy task as will be discussed next.

4.3 Synonym Detection

We consider two gold standard datasets for the experiment of synonym detection. The descriptions of the used datasets are given below.

TOEFL: It contains 80 multiple-choice synonym questions (4 choices per question) introduced by Landauer and Dumais (1997), as a way of evaluating algorithms for measuring degree of similarity between words. Being consistent with the previous experiments, we consider only nouns for our experiment and prepare **TOEFL-N** which contains 23 synonym questions.

ESL: It contains 50 multiple-choice synonym questions (4 choices per question), along with a sentence for providing context for each of the question, introduced by Turney (2001). Here also we consider only nouns for our experiment and prepare **ESL-N** which contains 22 synonym questions. Note that, in our experimental setup we do not use the context per question provided in the dataset for evaluation.
