While preparing both the datasets, we also keep in mind the availability of word vectors in both downloaded GloVe representation and prepared DT embedding. For evaluation of the word embeddings using **TOEFL-N** and **ESL-N**, we consider the option as the correct answer which is having highest cosine similarity with the question and report accuracy. From the results presented in Table 7, we see that DT embedding leads to boost the performance of GloVe representation.

4.4 Analogy Detection

For analogy detection we experiment with **SAT** analogy dataset. This dataset contains 374 multiple-choice analogy questions (5 choices per question) introduced by Turney and Bigham (2003) as a way of evaluating algorithms for measuring relational similarity. Considering only noun questions, we prepare **SAT-N**, which contains 159 questions.

Dataset	GloVe	D2V-N	PCA (GloVe, D2V-N)
TOEFL-N	0.826	0.739	**0.869**
ESL-N	0.636	0.591	**0.682**
SAT-N	0.465	0.509	**0.515**

Table 7: Comparison of accuracies between GloVe representation, DT embedding using node2vec and combination of both where PCA is the combination technique. Clearly DT embedding is helping to improve the performance of GloVe for synonym detection as well as analogy detection.

In order to find out the correct answer from the 5 options given for each question, we take up a score (s) metric proposed by Speer et al. (2017), where for a question 'a_1 is to b_1', we will consider 'a_2 is to b_2' as the correct answer among the options, whose score (s) is the highest. Score (s) is defined by the author as follows:

$$s = a_1.a_2 + b_1.b_2 + w_1(b_2 - a_2).(b_1 - a_1) + w_2(b_2 - b_1).(a_2 - a_1)$$

As mentioned by the authors, the appropriate values of w_1 and w_2 are optimized separately for each system using grid search, to achieve the best performance. We use accuracy as the evaluation metric. The last row of Table 7 presents the comparison of accuracies (best for each model) obtained using different embeddings portraying the same observation that combination of GloVe and DT embeddings leads to better performance compared to GloVe and DT embeddings when used separately. Note that, the optimized values of (w_1, w_2) are (0.2,0.2), (0.8,0.6), (6,0.6) for GloVe, DT embedding, combined representation of GloVe and DT embeddings, respectively, for the analogy task.

5 Conclusion

In this paper we showed that both dense count based model (GloVe) and predictive model (Word2vec) lead to improved word representation when they are combined with word representation learned using network embedding methods on Distributional Thesaurus (DT) network. We tried with various network embedding models among which *node2vec* proved to be the best in our experimental setup. We also tried with different methodologies to combine vector representations and PCA turned out to be the best among them. The combined vector representation of words yielded the better performance for most

of the similarity and relatedness datasets as compared to the performance of GloVe and Word2vec representation individually. Further we observed that we could use the information from DT as a proxy of WordNet in order to improve the state-of-the-art vector representation as we were getting comparable performances for most of the datasets. Similarly, for synonym detection task and analogy detection task, the same trend of combined vector representation continued, showing the superiority of the combined representation over state-of-the-art embeddings. All the datasets used in our experiments which are not under any copyright protection, along with the DT embeddings are made publicly available[2].

In future we plan to investigate the effectiveness of the joint representation on other NLP tasks like text classification, sentence completion challenge, evaluation of common sense stories etc. The overall aim is to prepare a better generalized representation of words which can be used across languages in different NLP tasks.

Abstract

Diachronic distributional models track changes in word use over time. In this paper, we propose a deep neural network diachronic distributional model. Instead of modeling lexical change via a time series as is done in previous work, we represent time as a continuous variable and model a word's usage as a function of time. Additionally, we have created a novel synthetic task, which quantitatively measures how well a model captures the semantic trajectory of a word over time. Finally, we explore how well the derivatives of our model can be used to measure the speed of lexical change.

1 Introduction

Diachronic distributional models have provided interesting insights into how words change meaning. Generally, they are used to explore how specific words have changed meaning over time (Sagi et al., 2011; Gulordava and Baroni, 2011; Jatowt and Duh, 2014; Kim et al., 2014; Kulkarni et al., 2015; Bamler and Mandt, 2017; Hellrich and Hahn, 2017), but they have also been used to explore historical linguistic theories (Xu and Kemp, 2015; Hamilton et al., 2016a,b), to predict the emergence of novel senses (Bamman and Crane, 2011; Rohrdantz et al., 2011; Cook et al., 2013, 2014), and to predict world events (Kutuzov et al., 2017a,b).

Diachronic distributional models are distributional models where the vector for a word changes over time. Thus, we can calculate the cosine similarity between the vectors for a word at two different time points to measure how much that word has changed over time and we can perform a nearest neighbor analysis to understand in what direction a word is changing. For example, diachronic distributional models can detect that the word *gay* has greatly changed by comparing the word vector for *gay* across different time points. They can also be used to discover that gay has shifted its meaning from *happy* to *homosexual* by analyzing when those words show up as nearest neighbors to *gay*.

Previous research in diachronic distributional semantics has used models where data is partitioned into time bins and a synchronic model is trained on each bin. A synchronic model is a vanilla, time-independent distributional model, such as skip-gram. However, there are several technical issues associated with data binning. For example, if the bins are too large, you can only achieve extremely coarse grained representations of lexical change over time. However, if the bins are too small, the synchronic models get trained on insufficient data.

In this paper, we have built the first diachronic distributional model that represents time as a continuous variable instead of employing data binning. There are several advantages to treating time as continuous. The first advantage is that it is more realistic. Large scale change in the meaning of a word is the result of change happening one person at a time. Thus, semantic change must be a gradual process. By treating time as a continuous variable, we can capture this gradual shift. The second advantage is that it allows a greater representation of the underlying causes behind lexical change. Words change usage in reaction to real world events and multiple words can be affected by the same event. For example, the usage of *gay* and *lesbian* have changed in similar ways due to changing perceptions of homosexuality in society. By associating time with a vector and having word representations be a function of that vector, we can model a single underlying cause affecting multiple words similarly.

Proceedings of NAACL-HLT 2018, pages 474–484
New Orleans, Louisiana, June 1 - 6, 2018.

It is difficult to evaluate diachronic distributional models in their ability to capture semantic shift as it is extremely difficult to acquire gold data. Distributional models are traditionally evaluated with word similarity judgments, which we cannot obtain for word usage in the past. Thus, evaluation of diachronic distributional models is a focus of research, such as work done by Hellrich and Hahn (2016) and Dubossarsky et al. (2017). Our approach is to create a synthetic task to measure how well a model captures gradual semantic shifts.

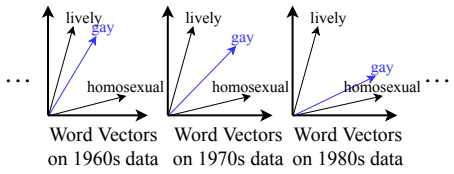
We will also explore how we can use our model to predict the speed at which a word changes. Our model is differentiable with respect to time, which gives us a natural way to measure the velocity, and thus speed, of a word at a given time. We explore the capabilities and limitations of this approach.

In short, our paper provides the following contributions:

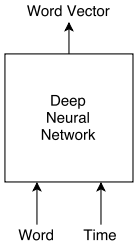
- We have developed the first continuous diachronic distributional model. This is also the first diachronic distributional model using a deep neural network.
- We have designed an evaluation of a model's ability to capture semantic shift that tracks gradual change.
- We have used the derivatives of our model as a natural way to measure the speed of word use change.

2 Related work

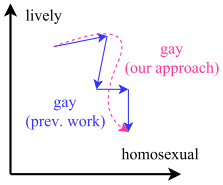
Previous research in diachronic distributional models has applied a binning approach. In this approach, researchers partition the data into bins based on time and train a synchronic distributional model on that bin's data (See Figure 1). Several authors have used large bin models in their research, such as using five year sized bins (Kulkarni et al., 2015), decade sized bins (Gulordava and Baroni, 2011; Xu and Kemp, 2015; Jatowt and Duh, 2014; Hamilton et al., 2016a,b; Hellrich and Hahn, 2016, 2017), and era sized bins (Sagi et al., 2009, 2011). The synchronic model for each time bin was trained independently of the others. In order to get a fine grained representation of semantic shift, several authors have used small bins. Kim et al. (2014) trained a synchronic model for each time bin. To mitigate data issues, Kim et al. preinitialized a time bin's synchronic model with the



(a) Previous work



(b) Our approach



(c) Difference in trajectories

Figure 1: Difference between our approach and previous work. Previous work in diachronic distributional models (a) has trained synchronic distributional models on consecutive time bins. In our work (b), a neural network takes word and time as input and produces a time specific word vector. In (c), we sketch that previous work produces a jagged semantic trajectory (blue, solid curve) whereas our model produces a smooth semantic trajectory (pink, dotted curve).

model from the previous time bin. Bamler and Mandt (2017) developed a small bin probabilistic approach that used transition probabilities to lessen data issues. They have two versions of their method. The first version trains the distribution in each bin iteratively and the second version trains a joint distribution over all bins. In this paper, we only explore the first version as the second version does not scale well to large vocabulary sizes. Following Bamler and Mandt (2017), we compare to models used by Hamilton et al. (2016b), Kim et al. (2014), and the first version of Bamler and Mandt's's model.

There have been other models of lexical change beside distributional ones. Topic modeling has been used to see how topics associated to a word have changed over time (Wijaya and Yeniterzi, 2011; Frermann and Lapata, 2016). Sentiment analysis has been applied to determine how sentiments associated to a word have changed over time (Jatowt and Duh, 2014).

As mentioned in the introduction, it is difficult to quantitatively evaluate diachronic distributional models due to the lack of gold data. Thus, previous research has attempted alternative routes to quantitatively evaluate their models. One route

is to use intrinsic evaluations, such as measuring a trajectory's smoothness (Bamler and Mandt, 2017). However, intrinsic measures do not directly measure semantic shift, which is the main use of diachronic distributional models. Hamilton et al. (2016b) use attested shifts generated by historical linguists. However, outside of first attestations, it is a difficult task for historical linguists themselves to accurately detail semantic shifts (Deo, 2015). Additionally, the task used by Hamilton et al. is unusable for model comparison as all but one model had a 100% accuracy in this task. Kulkarni et al. (2015) used a synthetic task to evaluate how well diachronic distributional models can detect semantic shift. They took 20 copies of wikipedia where each is a synthetic version of a time bin and changed several words in the last 10 copies. Models were then evaluated on their ability to detect when those words changed. Our evaluation improves upon this one by having the test data be from a diachronic corpus and we model lexical change as a gradual process rather than searching for a single change point.

3 Models

In this section, we describe the four diachronic distributional models that we analyze in our current work. Three will be from previous research to be used as benchmarks. Each of the four models we analyze are based on skip-gram with negative sampling (**SGNS**). The difference between the four diachronic distributional models we analyze is how they apply SGNS to changes over time.

Skip-gram with negative sampling (SGNS) is a word embedding model that learns a latent representation of word usage (Mikolov et al., 2013). For target words w and context words c, vector representations $\vec{w}$ and $\vec{c}$ are learned to best predict if c will be in context of w in a corpus. k negative contexts are randomly sampled for each positive context. Vector representations are computed by optimizing the following loss function:

$$\sum_{(w,c)\in D} [log(\sigma(\vec{w}\cdot\vec{c}))+ \sum_{c_1,...c_k\sim P_D} log(1-\sigma(\vec{w}\cdot\vec{c_i}))] \quad (1)$$

where D is a list of target-context pairs extracted from the corpus, P_D is the unigram distribution on the corpus, σ is the sigmoid function, and k is the number of negative samples.

3.1 Binning by Decade

The first diachronic distributional model we will consider is a large time bin model proposed by Hamilton et al. (2016b). Here, time is partitioned into decades and an SGNS model is trained on each decade's worth of data. We label this model **LargeBin**.

3.2 Preinitialization

The second diachronic distributional model we will consider is a small time bin model proposed by Kim et al. (2014). Here, time is partitioned into years and an SGNS model is trained on each year's worth of data. Data issues are mitigated by preinitializing the model[1] for a given time bin with the vectors of the preceding time bin (Kim et al., 2014). We label this model **SmallBinPreInit**.

3.3 Prior and Transition Probabilities

The third diachronic distributional model we will consider comes from Bamler and Mandt (2017). Bamler and Mandt take a probabilistic approach to modeling semantic change over time. The idea is to transform the SGNS loss function into a probability distribution over the target and context vectors. Then, to create a better diachronic distributional model, they apply priors to this distribution.

The first two priors are Gaussian distributions with mean zero on the vector variables to discourage the vectors from growing too large (Barkan, 2017). More formally:

$$\begin{aligned} P_1(\vec{w}) &= \mathcal{N}(0, \alpha_1 I) \\ P_2(\vec{c}) &= \mathcal{N}(0, \alpha_1 I) \end{aligned} \quad (2)$$

where α_1 is a hyperparameter.

The last two priors are also Gaussian distributions on the vector variables. The means are the vector representation from the previous bin. The goal of this prior is to discourage a vector variable from deviating from the previous bin's vectors.

$$\begin{aligned} P_3(\vec{w}) &= \mathcal{N}(\overrightarrow{w_{prev}}, \alpha_2 I) \\ P_4(\vec{c}) &= \mathcal{N}(\overrightarrow{c_{prev}}, \alpha_2 I) \end{aligned} \quad (3)$$

where α_2 is a hyperparameter and $\overrightarrow{w_{prev}}$ and $\overrightarrow{c_{prev}}$ are the vectors from the previous time bin.

We are only exploring point models, thus we take the maximum a posteriori estimate of the

[1] We do not perform preinitialization in LargeBin as large bin models are less susceptible to data issues.

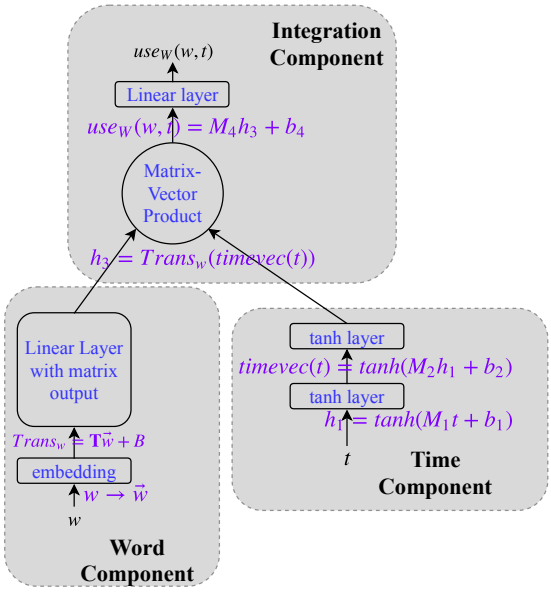


Figure 2: Diagram of DiffTime. $timevec(t)$ encodes temporal information as a vector. M_W encodes lexical information as a matrix. The target vector for w at time t, $use_W(w,t)$, is found by combining $Trans_w$ and $timevec(t)$. Context version $use_C(c,t)$ is the same except that it has its own embedding layer.

joint distribution to recover the vectors for each time bin. We apply a logarithm in constructing the estimate, which transforms the joint probability into the SGNS loss function with four regularizers (each one corresponding to a prior distribution). The prior distribution P_1 becomes $\sum_{w \in W} \frac{\alpha_1}{2}||w||$. The prior distribution P_2 becomes $\sum_{c \in C} \frac{\alpha_1}{2}||c||$. The prior distribution P_3 becomes $\sum_{w \in W} \frac{\alpha_2}{2}||\vec{w} - \overrightarrow{w_{prev}}||$. The prior distribution P_4 becomes $\sum_{c \in C} \frac{\alpha_2}{2}||\vec{c} - \overrightarrow{c_{prev}}||$. W and C are the sets of target and context words. We label this model **SmallBinReg**.

3.4 DiffTime Model

Our model is a modification of the SGNS algorithm to accommodate a continuous time variable. The original SGNS algorithm produces a target embedding $\vec{w}$ for target word w and a context embedding $\vec{c}$ for context word c. Instead, we produce a differentiable function $use_W(w,t)$ that returns a target embedding for target word w at time t and a differentiable function $use_C(c,t)$ that produces a context embedding for context word c at time t.

Our model consists of three components. One component takes time as its input and produces an embedding that characterizes that point in time (lower right). The second component (lower left) takes a word as its input and produces a time-independent word embedding, which is then reshaped into a set of parameters that can modify the time embedding. The third component (top) combines the time embedding and the word embedding.

The first component of our model is a two-layer feed-forward neural network with tanh activation functions. These layers take a time t as input and produces a time embedding $timevec(t)$ as output of those layers:

$$\begin{aligned} h_1 &= tanh(M_1t + b_1) \\ timevec(t) &= tanh(M_2h_1 + b_2) \end{aligned} \tag{4}$$

where M_1 and M_2 are the weights of the first two layers and b_1 and b_2 are the biases. To produce the input value t, a timepoint is scaled to a value between 0 and 1, where 0 corresponds to the year 1900, and 1 corresponds to 2009, the last year for which our corpus has data.

The second component incorporates word-specific information into our model. For $use_W(w,t)$, each target word w has a target vector representation $\vec{w}$. The vector $\vec{w}$ is then transformed into a linear transformation $Trans_w$, which in the third component is applied to the time embedding $timevec(t)$. We do this via a modified linear layer where the weights are a three dimensional tensor, the biases are a matrix and the output is a matrix:

$$Trans_w = \mathbf{T}\vec{w} + B \tag{5}$$

where $\mathbf{T}$ is the tensor acting as the weights and B is the matrix acting as the biases.

The third component combines the word-independent time embedding $timevec(t)$ and the time-independent linear transformation $Trans_w$ together to produce the final result. First, $Trans_w$ is applied to $timevec(t)$:

$$h_3 = Trans_w(timevec(t)) \tag{6}$$

Then, an additional linear layer is used as the output layer, taking h_3 as input:

$$use_W(w,t) = M_4h_3 + b_4 \tag{7}$$

where M_4 and b_4 are the weights and biases of the output layer.

The above details the architecture of $use_W(w,t)$. The corresponding function $use_C(c,t)$ for context words has the same architecture as $use_W(w,t)$ and shares weights with $use_W(w,t)$. The only exception is that $use_C(c,t)$ uses a separate set of vectors $\vec{c}$ in the second component instead of sharing the target vectors $\vec{w}$ with $use_W(w,t)$.

We train our model using a modified version of the SGNS loss function. In particular, our positive samples are now triples (w,c,t) where w is a target word, c is a context word, and t is a time, instead of pairs (w,c) which are typically used in SGNS. For each positive sample (w,c,t), we sample k negative contexts from the unigram distribution, P_D. P_D is trained from all contexts in the entire corpus and is time-independent. Explicitly, the loss function is:

$$\sum_{(w,c,t)\in D} log(\sigma(use_W(w,t)\cdot use_C(c,t)))+ kE_{c_N\sim P_D}[log(\sigma(-use_W(w,t)\cdot use_C(c_N,t)))] \quad (8)$$

3.5 Training

All models are trained on the same training data. We used the English Fiction section of the Google Books ngram corpus (Lin et al., 2012). We use the English fiction specifically, because it is less unbalanced than the full English section and less influenced by technical texts (Pechenick et al., 2015). We only use the years 1900 to 2009 as there is limited data before 1900.

We converted the ngram data for this corpus into a set of (target word, context word, year, frequency) tuples. The frequency is the expected number of times the target word-context word pair is sampled from that year's data using skip-gram. Following Hamilton et al. (2016b), we use subsampling with $t = 10^{-5}$. As the number of texts published since 1900 has increased five fold, we weigh the frequencies so that the sums across each year are equal.

For the binned models, we train each bin's synchronic model using the subset of the training data corresponding to that time bin. For our model, we sample (training word, context word, year) triples from the entire training data as the year is an input to our function.

4 Evaluation

4.1 Synchronic Accuracy

Method	Time	Spearman's ρ
LargeBin	1990s bin	0.615
SmallBinPreInit	1995 bin	0.489
SmallBinReg	1995 bin	0.564
DiffTime	start of 1995	**0.694**

Table 1: Synchronic accuracy of the methods. Time is the point of time we use as our synchronic model.

Before we can evaluate the methods as models of diachronic semantics, we must first ensure that the methods model semantics accurately. To do this, we follow Hamilton et al. (2016b) by performing the MEN word similarity task on vectors extracted from a fixed time point (Bruni et al., 2012). The hope is that the word similarity predictions of a model at that point in time highly correlate with word similarity judgments in the MEN dataset. For the binned models, we used the vectors from the bin best corresponding to 1995 to reflect the 1990s bin chosen by Hamilton et al. (2016b). DiffTime represents time as a continuous variable, so we chose a time t that corresponds to the start of 1995.

The results of MEN word similarity tasks is in Table 1. All of the Spearman's ρ values are comparable to those found in Levy and Goldberg (2014) and Hamilton et al. (2016b). Thus, all of these models reflect human judgments comparable to synchronic models. Thus, the predictions of the models correlate with human judgments.

4.2 Synthetic Task

The goal of creating diachronic distributional models is to help us understand how words change meaning over time. To that end, we have created a synthetic task to compare models by how accurately they track semantic change.

Our task creates synthetic words that change between two senses over time via a sigmoidal path. A sigmoidal path will allow us to emulate a word starting from one sense, shifting gradually to a second sense, then stabilizing on that second sense. By using sigmoidal paths, we can explore how well a model can track words that have switched senses over time such as *gay* (lively to homosexual) and *broadcast* (scattering seeds to televising shows). A similar task is used to evaluate word

sense disambiguation (Gale et al., 1992; Schütze, 1992).

The synthetic words are formed by a combination of two real words, e.g. *banana* and *lobster* are combined together to form $banana{\circ}lobster$. The real words are randomly sampled from two distinct semantic classes from the BLESS dataset (Baroni and Lenci, 2011). We use BLESS classes so that we can capture how semantically similar a synthetic word is to its component words by comparing to other words in the same BLESS classes as the component word. For example, we can capture how similar $banana{\circ}lobster$ is to $banana$ by comparing $banana{\circ}lobster$ to words in the fruit BLESS class. See Appendix B for preprocessing details. We denote the synthetic words with $r_1{\circ}r_2$ where r_1 and r_2 are the component real words.

We also randomly generate the sigmoidal path by which a synthetic word changes from one sense to another. For real words r_1 and r_2, this path will be denoted $\textit{shift}(t; r_1{\circ}r_2)$ and is defined by the following equation:

$$\textit{shift}(t; r_1{\circ}r_2) = \sigma(s(t-m)) \tag{9}$$

The value s is uniformly sampled from $(\frac{1.0}{110}, \frac{10.0}{110})$ and represents the steepness of the sigmoidal path. The value m is uniformly sampled from $\{1930, \ldots, 1980\}$ and represents the point where the synthetic word is equally both senses. For our example synthetic word $banana{\circ}lobster$, $banana{\circ}lobster$ can transition from meaning banana to meaning lobster via the sigmoidal path $\sigma(0.05(t-1957))$ where 1957 is the time where $banana{\circ}lobster$ is equally banana and lobster and 0.05 represents how gradually $banana{\circ}lobster$ shifts senses.

We then use $\textit{shift}(t; r_1{\circ}r_2)$ to integrate $r_1{\circ}r_2$ into the real diachronic corpus data. Our training data is a set of (target word, context word, year, frequency) tuples extracted from a diachronic corpus (see 3.5). For every tuple where r_1 is the target word, we replace the target word with $r_1{\circ}r_2$ and we multiply the frequency by $\textit{shift}(t; r_1{\circ}r_2)$. For every tuple where r_2 is the target word, we replace the target word with $r_1{\circ}r_2$ and we multiply the frequency by $1 - \textit{shift}(t; r_1{\circ}r_2)$. In other words, in the modified corpus, $r_1{\circ}r_2$ has $\textit{shift}(t; r_1{\circ}r_2)$ percent of r_1's contexts at time t and $1 - \textit{shift}(t; r_1{\circ}r_2)$ percent of r_2's contexts at time t.

We train a model mod on this modified training data. This provides a representation for $r_1{\circ}r_2$ over time. We can capture how much a model predicts $r_1{\circ}r_2$ is more semantically similar to r_1 than r_2 by comparing mod's representation of $r_1{\circ}r_2$ to words in the same semantic category as r_1 and r_2. We use BLESS classes as our notion of semantic category. If cls_1 is the BLESS class of r_1 and cls_2 is the BLESS class of r_2, then mod's prediction for how much more similar $r_1{\circ}r_2$ is to r_1 than r_2, $rec(t; r_1{\circ}r_2, mod)$, is defined as follows:

$$\begin{aligned} rec(t; r_1{\circ}r_2, mod) = \\ \frac{1}{|cls_1|} \sum_{r_1' \in cls_1} sim^{mod}(r_1{\circ}r_2, r_1', t) \\ - \frac{1}{|cls_2|} \sum_{r_2' \in cls_2} sim^{mod}(r_1{\circ}r_2, r_2', t) \end{aligned} \tag{10}$$

$sim^{mod}(r_1{\circ}r_2, r_1', t)$ is the cosine similarity between mod's word vector for $r_1{\circ}r_2$ at time t and mod's word vector for r_1' at time t.

Method	AMSE 1900–2009	AMSE 1950–2009
LargeBin	62.52	51.71
SmallBinPreInit	171.43	49.88
SmallBinReg	106.79	42.67
DiffTime	**25.67**	**11.48**

Table 2: Model performance under the synthetic evaluation. The values are the mean sum of squares error (MSSE) for each method. Lower value is better. The first column is MSSE using all times. The second column is MSSE using years 1950 to 2009.

To evaluate a model in its ability to capture semantic shift, we use the mean sum of squares error (MSSE) between $rec(t; r_1{\circ}r_2, mod)$ and $\textit{shift}(t; r_1{\circ}r_2)$ across all synthetic words. The function $rec(t; r_1{\circ}r_2, mod)$ is model mod's prediction of how much more similar $r_1{\circ}r_2$ is to r_1 than r_2. The gold value of $rec(t; r_1{\circ}r_2, mod)$ would then be the sigmoidal path that defines how $r_1{\circ}r_2$ semantically shifts from r_1 to r_2 over time, $\textit{shift}(t; r_1{\circ}r_2)$. To evaluate how accurately mod predicted the semantic trajectory of $r_1{\circ}r_2$, we calculate the mean squared error between $rec(t; r_1{\circ}r_2, mod)$ and $\textit{shift}(t; r_1{\circ}r_2)$ as follows:

$$\sum_{t=1900}^{2009} (rec(t; r_1 \circ r_2, mod) - \textit{shift}(t; r_1 \circ r_2))^2 \quad (11)$$

As $rec(t; r_1 \circ r_2, mod)$ and $\textit{shift}(t; r_1 \circ r_2)$ have different scales, we Z-scale both the $rec(t; r_1 \circ r_2, mod)$ values and the $\textit{shift}(t; r_1 \circ r_2)$ values before calculating the mean squared error.

We use three sets of 15 synthetic words and the average is calculated over all 45 words. The synthetic words and BLESS classes we used are contained in the supplementary material. The results are in Table 2. The column AMSE is MSSE when all years are taken into account. Kim et al. (2014) noted that small bin models require an initialization period, so the column AMSE (1950-) is MSSE when only years 1950 to 2009 are taken into account and the years 1900 to 1949 are used as the initialization period. From the table, we see our model outperforms the three benchmark models in both cases. Using a paired t-test, we found that the reduction in MSSE between our model and the benchmark models are statistically significant.

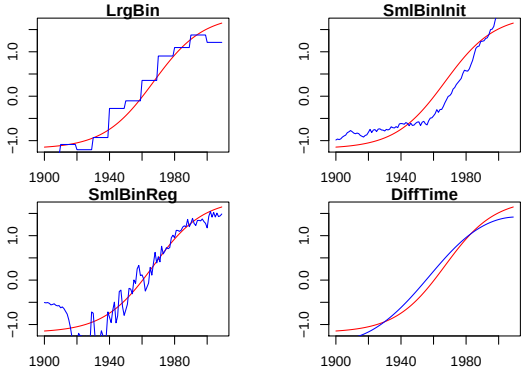

Figure 3: Graph Comparisons between $\textit{shift}(t; r_1 \circ r_2)$ (red) and $rec(t; r_1 \circ r_2,)$ (blue) for the synthetic word $pistol \circ elm$. The x-axis are the years and the y-axis are the values of $\textit{shift}(t; r_1 \circ r_2)$. $rec(t; r_1 \circ r_2, mod)$ and $\textit{shift}(t; r_1 \circ r_2)$ have been Z-scaled.

In Figure 3, we plot $\textit{shift}(t; r_1 \circ r_2)$ and $rec(t; r_1 \circ r_2, mod)$ for the synthetic word $pistol \circ elm$. Each method has a subgraph. The predictions of the large bin model LargeBin appear as a step function with large steps (top left graph). These large steps seem to cause the predicted shift (blue curve) to poorly correlate with the gold shift (red curve). Next, we consider the small bin models SmallBinPreInit (top right graph) and SmallBinReg (bottom left graph). Both predicted shifts have an initial portion that poorly fits the generated shift (between 1900 and 1950). From Kim et al. (2014), it takes several iterations for small bin models to stabilize due to each bin being fed limited data. Additionally, there are fluctuations in the graphs of the predicted shift, which we attribute to the high variance of data per bin. In contrast to the other models, our predicted shift tightly fits the gold shift (bottom right graph).

Although this evaluation provides useful information on the quality of an diachronic distributional model, it has some weaknesses. The first is that it is a synthetic task that operates on synthetic words. Thus, we have limited ability to understand how well a model will perform on real world data. Second, we only generate words that shift from one sense to another. This fails to account for other common changes, such as gaining/losing senses and narrowing/broadening. Finally, by using a sigmoidal function to generate how words change meaning, we may have privileged continuous models that incorporate a sigmoidal function in their architecture. We are working towards improving this evaluation to remove these issues.

4.3 Speed of word use change

In this section, we evaluate our model's ability to measure the speed at which a word is changing. Our model is differentiable with respect to time. Thus, we can get the derivative of $use_W(w, t)$ with respect to t to model how word w is changing usage at time t. We $l2$-normalize $use_W(w, t)$ beforehand to reduce frequency effects. We then get the magnitude of this normalized derivative to model the speed at which a word is changing at a given time.

We explore the connection between speed and the nearest neighbors to a word in Figure 4. First, we use *apple* as a baseline for discussion. We chose *apple*, because the meaning of the word has remained relatively stable throughout the 1900s. With *apple*, we see a low speed over time and a consistency in the cosine similarity to *apple*'s nearest neighbors. While it is true that *apple* has other meanings beyond the fruit, such as referring to Apple Inc., those meanings are much rarer, especially in the fiction corpus we use.

In contrast to *apple*, the word *gay* has a very high speed and a drastic change for *gay*'s nearest

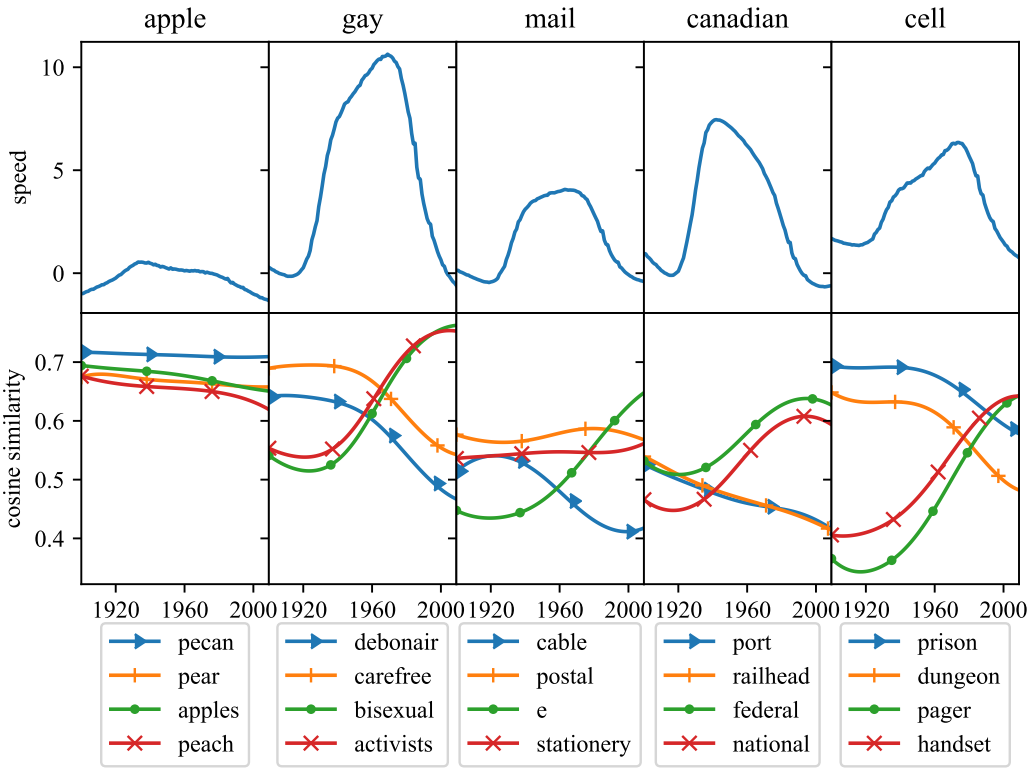

Figure 4: Speed and nearest neighbors over time of selected words. The top graphs as the speed at which a word changes usage according to our model. The bottom graphs are selected nearest neighbors for those words. Each of the chosen nearest neighbors appear as a top 10 nearest neighbor to the word at some year.

neighbors. This makes sense as *gay* is well established to have experienced a drastic sense change in the mid to late 1900s (Harper, 2014).

Next, we explore the word *mail*. The word *mail* has a moderately high speed. This may be reflective of the fact that there have been incredible changes in the medium by which we send mail, e.g. changing from cables to email. A possible reason for the speed only being moderately high is that, even though the medium by which we send mail has changed, many of the same uses of mail, e.g. sending, receiving, opening, etc., remain the same. We see this reflected in the nearest neighbors as well as *mail* shifts from a high similarity to *cable* to a high similarity to *e* (as in email), yet *mail* is consistently similar to *postal* and *stationery*.

The next word we will explore is the word *canadian*. We chose this word as we were surprised to find that *canadian* has one of the fastest speeds in the 1930s to 1940s. The nearest neighbors to *canadian* have shifted from geographic terms like *port* and *railhead* to civil terms like *federal* and *national*. In further analysis, we discovered that this may be reflective of a larger push to form a Canadian identity in the early 1900s (Francis, 1997). The nearest neighbors to *canadian* may reflect the change from being a part of the British Empire to having its own unique national identity.

The final word we will explore is *cell*. The word *cell* also has a high speed over time. However, there is a spike in the speed during the 1980s. Analyzing the nearest neighbors we see a rapid rise in similarity to *pager* and *handset*, which indicates that this spike may be related to the rapid rise of cell phone use. Additionally, this example demonstrates a weakness in our approach. Our graph shows that our model predicts that the word *cell* gradually changed meaning over time and that *cell* started changing meaning much earlier than expected. This prediction error comes from the smoothing out of the output caused by representing time as a continuous variable.

Even though we are able to extract interesting insights from the speed of word use change, Figure 4 also exhibits some limitations. In particu-

lar, most words have a sharp rise in speed in the 1930s and a steep decline in speed in the 1980s. We believe this is an artifact of our representation of word use as a function of time as there is a single time vector that influences all words. In the future, we will explore model variants to address this.

4.4 Automatic extraction of time periods

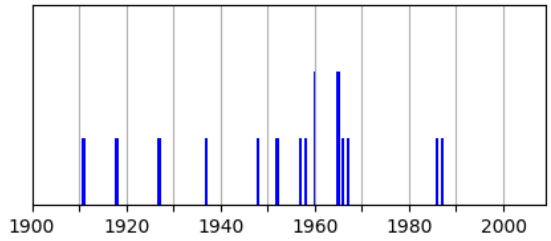

Figure 5: Distribution of time points where a node in h_1 is zero. We could interpret these points as barriers between time periods.

We can inspect h_1, the first layer in the time subnetwork, to gain further understanding of what our model is doing. We do this by analyzing the time points where a node in h_1 is zero.

As the activation function in h_1 is tanh, a node in h_1 switches from positive to negative (or vice versa) at the time points where it is zero. Thus, the time points where a node is zero should indicate barriers between time periods.

We visualize the time points where a node is zero in Figure 5. We see that we have a fairly even distribution of points until the 1940s, a large burst of points in the 1950s-1960s, and two points in the 1980s. Thus, there are many time periods before the 1940s (which may be caused by noisiness of the data in the first half of the century), a big transition between time periods in the 1950s-1960s, and a transition between time periods in the 1980s. Thus, these are time points that the model perceives as having increased semantic change.

However, there is a weakness to this analysis. Only 16% of the 100 nodes in h_1 are zero for time points between 1900 and 2009. Thus, a vast majority of nodes do not correspond to transitions between time periods.

5 Conclusion

Diachronic distributional models are a helpful tool in studying semantic shift. In this paper, we introduced our model of diachronic distributional semantics. Our model incorporates two hypotheses that better help the model capture how words change usage over time. The first hypothesis is that semantic change is gradual and the second hypothesis is that words can change usage due to common causes.

Additionally, we have developed a novel synthetic task to evaluate how accurately a model tracks the semantic shift of a word across time. This task directly measures semantic shift, is quantifiable, allows model comparison, and focuses on the trajectory of a word over time.

We have also used the fact that our model is differentiable to create a measure of the speed at which a word is changing. We then explored this measure's capabilities and limitations.

A Hyperparameters and preprocessing details

We used data from the English Fiction section of the Google Books ngram corpus (Lin et al., 2012). We use the English fiction specifically, because it is less unbalanced than the full English section and less influenced by technical texts (Pechenick et al., 2015). We only use the years 1900 to 2009 as there is limited data before 1900. Both the set of target words and the set of context words are the top 100,000 words by average frequency across the decades as generated by Hamilton et al. (2016b). We take a sampling approach to generating word vectors, so the corpus was converted into a list of (target word, context word, year, frequency) tuples. Frequency is the expected number of times the target word is in context of the context word that year. As the number of texts published since 1900 has increased five fold, we weigh the the frequencies so that the sums across each year are equal.

For every model, the representation of a word's use at time t is a 300 dimensional vector. For $SmallBinReg$, α_1 is set to 1000 and α_2 is set to 1. This choice of hyperparameters comes from Bamler and Mandt (2017). For $DiffTime$, every hidden layer is 100 dimensional, except for $embed_W(w)$ which is 300 dimensional.

We trained each method using random minibatching with 10,000 samples each iteration and 990 epochs total. For LargeBin, since our study spans 11 decades (1900-2009), the synchronic model for each decade is trained for 99 epochs. For SmallBinPreInit and SmallBinReg, since our study spans 110 years, the synchronic model for each year is trained for 9 epochs.

B BLESS class preprocessing

BLESS Class	Size
bird	10
building	7
clothing	10
fruit	7
furniture	8
ground_mammal	17
tool	12
tree	6
vehicle	6
weapon	7

Table 3: BLESS classes with the number of elements in each class after our preprocessing.

In this section, we discuss the BLESS preprocessing details. In the original dataset, there are 200 words categorized into 17 classes. However, we remove words that do not rank in the top 20,000 by frequency in any decade in our training data to ensure that the synthetic words do not lack context words at a given time. We then remove BLESS classes with less than 6 members to ensure that there are a sufficient number of words in each class. See Table 3 for the resulting list of BLESS classes and the number of members of each class.

Distributional Inclusion Vector Embedding for Unsupervised Hypernymy Detection

Abstract

Modeling hypernymy, such as poodle is-a dog, is an important generalization aid to many NLP tasks, such as entailment, coreference, relation extraction, and question answering. Supervised learning from labeled hypernym sources, such as WordNet, limits the coverage of these models, which can be addressed by learning hypernyms from unlabeled text. Existing unsupervised methods either do not scale to large vocabularies or yield unacceptably poor accuracy. This paper introduces *distributional inclusion vector embedding (DIVE)*, a simple-to-implement unsupervised method of hypernym discovery via per-word non-negative vector embeddings which preserve the inclusion property of word contexts in a low-dimensional and interpretable space. In experimental evaluations more comprehensive than any previous literature of which we are aware—evaluating on 11 datasets using multiple existing as well as newly proposed scoring functions—we find that our method provides up to double the precision of previous unsupervised embeddings, and the highest average performance, using a much more compact word representation, and yielding many new state-of-the-art results.

1 Introduction

Numerous applications benefit from compactly representing context distributions, which assign meaning to objects under the rubric of *distributional semantics*. In natural language processing, distributional semantics has long been used to assign meanings to words (that is, to *lexemes* in the dictionary, not individual instances of word tokens). The meaning of a word in the distributional sense is often taken to be the set of textual contexts (nearby tokens) in which that word appears, represented as a large sparse bag of words (SBOW). Without any supervision, Word2Vec (Mikolov et al., 2013), among other approaches based on matrix factorization (Levy et al., 2015a), successfully compress the SBOW into a much lower dimensional embedding space, increasing the scalability and applicability of the embeddings while preserving (or even improving) the correlation of geometric embedding similarities with human word similarity judgments.

While embedding models have achieved impressive results, context distributions capture more semantic information than just word similarity. The *distributional inclusion hypothesis* (DIH) (Weeds and Weir, 2003; Geffet and Dagan, 2005; Cimiano et al., 2005) posits that the context set of a word tends to be a subset of the contexts of its hypernyms. For a concrete example, most adjectives that can be applied to poodle can also be applied to dog, because dog is a hypernym of poodle (e.g. both can be obedient). However, the converse is not necessarily true — a dog can be straight-haired but a poodle cannot. Therefore, dog tends to have a broader context set than poodle. Many asymmetric scoring functions comparing SBOW features based on DIH have been developed for hypernymy detection (Weeds and Weir, 2003; Geffet and Dagan, 2005; Shwartz et al., 2017).

Hypernymy detection plays a key role in many challenging NLP tasks, such as textual entailment (Sammons et al., 2011), coreference (Ponzetto and Strube, 2006), relation extraction (Demeester et al., 2016) and question answering (Huang et al., 2008). Leveraging the variety of contexts and inclusion properties in context distributions can greatly increase the ability to discover taxonomic structure among words (Shwartz et al., 2017). The inability to preserve these features limits the semantic representation power and downstream applicability of some popular unsupervised learning approaches such as Word2Vec.

Several recently proposed methods aim to en-

Proceedings of NAACL-HLT 2018, pages 485–495
New Orleans, Louisiana, June 1 - 6, 2018.

code hypernym relations between words in dense embeddings, such as Gaussian embedding (Vilnis and McCallum, 2015; Athiwaratkun and Wilson, 2017), Boolean Distributional Semantic Model (Kruszewski et al., 2015), order embedding (Vendrov et al., 2016), H-feature detector (Roller and Erk, 2016), HyperVec (Nguyen et al., 2017), dual tensor (Glavaš and Ponzetto, 2017), Poincaré embedding (Nickel and Kiela, 2017), and LEAR (Vulić and Mrkšić, 2017). However, the methods focus on supervised or semi-supervised settings where a massive amount of hypernym annotations are available (Vendrov et al., 2016; Roller and Erk, 2016; Nguyen et al., 2017; Glavaš and Ponzetto, 2017; Vulić and Mrkšić, 2017), do not learn from raw text (Nickel and Kiela, 2017) or lack comprehensive experiments on the hypernym detection task (Vilnis and McCallum, 2015; Athiwaratkun and Wilson, 2017).

Recent studies (Levy et al., 2015b; Shwartz et al., 2017) have underscored the difficulty of generalizing supervised hypernymy annotations to unseen pairs — classifiers often effectively memorize prototypical hypernyms ('general' words) and ignore relations between words. These findings motivate us to develop more accurate and scalable unsupervised embeddings to detect hypernymy and propose several scoring functions to analyze the embeddings from different perspectives.

1.1 Contributions

- A novel unsupervised low-dimensional embedding method via performing non-negative matrix factorization (NMF) on a weighted PMI matrix, which can be efficiently optimized using modified skip-grams.
- Theoretical and qualitative analysis illustrate that the proposed embedding can intuitively and interpretably preserve inclusion relations among word contexts.
- Extensive experiments on 11 hypernym detection datasets demonstrate that the learned embeddings dominate previous low-dimensional unsupervised embedding approaches, achieving similar or better performance than SBOW, on both existing and newly proposed asymmetric scoring functions, while requiring much less memory and compute.

2 Method

The *distributional inclusion hypothesis* (DIH) suggests that the context set of a hypernym tends to contain the context set of its hyponyms. When representing a word as the counts of contextual co-occurrences, the count in every dimension of hypernym y tends to be larger than or equal to the corresponding count of its hyponym x:

$$x \preceq y \iff \forall c \in V,\ \#(x,c) \leq \#(y,c), \quad (1)$$

where $x \preceq y$ means y is a hypernym of x, V is the set of vocabulary, and $\#(x,c)$ indicates the number of times that word x and its context word c co-occur in a small window with size $|W|$ in the corpus of interest D. Notice that the concept of DIH could be applied to different context word representations. For example, Geffet and Dagan (2005) represent each word by the set of its co-occurred context words while discarding their counts. In this study, we define the inclusion property based on counts of context words in (1) because the counts are an effective and noise-robust feature for the hypernymy detection using only the context distribution of words (Clarke, 2009; Vulić et al., 2016; Shwartz et al., 2017).

Our goal is to produce lower-dimensional embeddings preserving the inclusion property that the embedding of hypernym y is larger than or equal to the embedding of its hyponym x in every dimension. Formally, the desired property can be written as

$$x \preceq y \iff \mathbf{x}[i] \leq \mathbf{y}[i]\ , \forall i \in \{1, ..., L\}, \quad (2)$$

where L is number of dimensions in the embedding space. We add additional non-negativity constraints, i.e. $\mathbf{x}[i] \geq 0, \mathbf{y}[i] \geq 0, \forall i$, in order to increase the interpretability of the embeddings (the reason will be explained later in this section).

This is a challenging task. In reality, there are a lot of noise and systematic biases that cause the violation of DIH in Equation (1) (i.e. $\#(x,c) > \#(y,c)$ for some neighboring word c), but the general trend can be discovered by processing thousands of neighboring words in SBOW together (Shwartz et al., 2017). After the compression, the same trend has to be estimated in a much smaller embedding space which discards most of the information in SBOW, so it is not surprising to see most of the unsupervised hypernymy detection studies focus on SBOW (Shwartz et al., 2017)

and the existing unsupervised embedding methods like Gaussian embedding have degraded accuracy (Vulić et al., 2016).

2.1 Inclusion Preserving Matrix Factorization

Popular methods of unsupervised word embedding are usually based on matrix factorization (Levy et al., 2015a). The approaches first compute a co-occurrence statistic between the wth word and the cth context word as the (w, c)th element of the matrix $M[w, c]$. Next, the matrix M is factorized such that $M[w, c] \approx \mathbf{w}^T\mathbf{c}$, where $\mathbf{w}$ is the low dimension embedding of wth word and $\mathbf{c}$ is the cth context embedding.

The statistic in $M[w, c]$ is usually related to pointwise mutual information (Levy et al., 2015a): $PMI(w, c) = \log(\frac{P(w,c)}{P(w)\cdot P(c)})$, where $P(w, c) = \frac{\#(w,c)}{|D|}$, $|D| = \sum_{w\in V}\sum_{c\in V} \#(w, c)$ is number of co-occurrence word pairs in the corpus, $P(w) = \frac{\#(w)}{|D|}$, $\#(w) = \sum_{c\in V} \#(w, c)$ is the frequency of the word w times the window size $|W|$, and similarly for $P(c)$. For example, $M[w, c]$ could be set as positive PMI (PPMI), $\max(PMI(w, c), 0)$, or shifted PMI, $PMI(w, c) - \log(k')$, which (Levy and Goldberg, 2014) demonstrate is connected to skip-grams with negative sampling (SGNS).

Intuitively, since $M[w, c] \approx \mathbf{w}^T\mathbf{c}$, larger embedding values of $\mathbf{w}$ at every dimension seems to imply larger $\mathbf{w}^T\mathbf{c}$, larger $M[w, c]$, larger $PMI(w, c)$, and thus larger co-occurrence count $\#(w, c)$. However, the derivation has two flaws: (1) $\mathbf{c}$ could contain negative values and (2) lower $\#(w, c)$ could still lead to larger $PMI(w, c)$ as long as the $\#(w)$ is small enough.

To preserve DIH, we propose a novel word embedding method, *distributional inclusion vector embedding (DIVE)*, which fixes the two flaws by performing non-negative factorization (NMF) (Lee and Seung, 2001) on the matrix M, where $M[w, c] =$

$$\log(\frac{P(w, c)}{P(w)\cdot P(c)}\cdot\frac{\#(w)}{k_I\cdot Z}) = \log(\frac{\#(w, c)|V|}{\#(c)k_I}), \tag{3}$$

where k_I is a constant which shifts PMI value like SGNS, $Z = \frac{|D|}{|V|}$ is the average word frequency, and $|V|$ is the vocabulary size. We call this weighting term $\frac{\#(w)}{Z}$ *inclusion shift*.

After applying the non-negativity constraint and inclusion shift, the inclusion property in DIVE (i.e. Equation (2)) implies that Equation (1) (DIH) holds if the matrix is reconstructed perfectly. The derivation is simple: If the embedding of hypernym $\mathbf{y}$ is greater than or equal to the embedding of its hyponym $\mathbf{x}$ in every dimension ($\mathbf{x}[i] \leq \mathbf{y}[i]\ , \forall i$), $\mathbf{x}^T\mathbf{c} \leq \mathbf{y}^T\mathbf{c}$ since context vector $\mathbf{c}$ is non-negative. Then, $M[x, c] \leq M[y, c]$ tends to be true because $\mathbf{w}^T\mathbf{c} \approx M[w, c]$. This leads to $\#(x, c) \leq \#(y, c)$ because $M[w, c] = \log(\frac{\#(w,c)|V|}{\#(c)k_I})$ and only $\#(w, c)$ changes with w.

2.2 Optimization

Due to its appealing scalability properties during training time (Levy et al., 2015a), we optimize our embedding based on the skip-gram with negative sampling (SGNS) (Mikolov et al., 2013). The objective function of SGNS is

$$l_{SGNS} = \sum_{w\in V}\sum_{c\in V} \#(w, c)\log\sigma(\mathbf{w}^T\mathbf{c}) + \sum_{w\in V} k'\sum_{c\in V}\#(w, c)\mathop{\mathbb{E}}_{c_N\sim P_D}[\log\sigma(-\mathbf{w}^T\mathbf{c_N})], \tag{4}$$

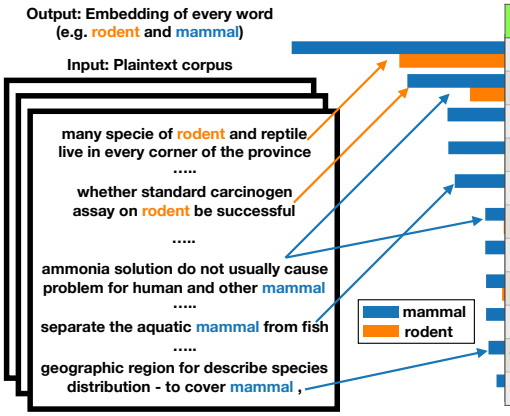
where $\mathbf{w} \in \mathbb{R}$, $\mathbf{c} \in \mathbb{R}$, $\mathbf{c_N} \in \mathbb{R}$, σ is the logistic sigmoid function, and k' is a constant hyper-parameter indicating the ratio between positive and negative samples.

Levy and Goldberg (2014) demonstrate SGNS is equivalent to factorizing a shifted PMI matrix M', where $M'[w, c] = \log(\frac{P(w,c)}{P(w)\cdot P(c)}\cdot\frac{1}{k'})$. By setting $k' = \frac{k_I\cdot Z}{\#(w)}$ and applying non-negativity constraints to the embeddings, DIVE can be optimized using the similar objective function:

$$l_{DIVE} = \sum_{w\in V}\sum_{c\in V} \#(w, c)\log\sigma(\mathbf{w}^T\mathbf{c}) + k_I\sum_{w\in V}\frac{Z}{\#(w)}\sum_{c\in V}\#(w, c)\mathop{\mathbb{E}}_{c_N\sim P_D}[\log\sigma(-\mathbf{w}^T\mathbf{c_N})], \tag{5}$$

where $\mathbf{w} \geq 0, \mathbf{c} \geq 0, \mathbf{c_N} \geq 0$, and k_I is a constant hyper-parameter. P_D is the distribution of negative samples, which we set to be the corpus word frequency distribution (not reducing the probability of drawing frequent words like SGNS) in this paper. Equation (5) is optimized by ADAM (Kingma and Ba, 2015), a variant of stochastic gradient descent (SGD). The non-negativity constraint is implemented by projection (Polyak, 1969) (i.e. clipping any embedding which crosses the zero boundary after an update).

The optimization process provides an alternative angle to explain how DIVE preserves DIH.



id	Top 1-5 words	Top 51-55 words

Figure 1: The embedding of the words rodent and mammal trained by the co-occurrence statistics of context words using DIVE. The index of dimensions is sorted by the embedding values of mammal and values smaller than 0.1 are neglected. The top 5 words (sorted by its embedding value of the dimension) tend to be more general or more representative on the topic than the top 51-105 words.

The gradients for the word embedding $\mathbf{w}$ is

$$\frac{dl_{DIVE}}{d\mathbf{w}} = \sum_{c \in V} \#(w,c)(1-\sigma(\mathbf{w}^T\mathbf{c}))\mathbf{c} - k_I \sum_{c_N \in V} \frac{\#(c_N)}{|V|}\sigma(\mathbf{w}^T\mathbf{c_N})\mathbf{c_N}. \quad (6)$$

Assume hyponym x and hypernym y satisfy DIH in Equation (1) and the embeddings $\mathbf{x}$ and $\mathbf{y}$ are the same at some point during the gradient ascent. At this point, the gradients coming from negative sampling (the second term) decrease the same amount of embedding values for both x and y. However, the embedding of hypernym $\mathbf{y}$ would get higher or equal positive gradients from the first term than $\mathbf{x}$ in every dimension because $\#(x,c) \leq \#(y,c)$. This means Equation (1) tends to imply Equation (2) because the hypernym has larger gradients everywhere in the embedding space.

Combining the analysis from the matrix factorization viewpoint, DIH in Equation (1) is approximately equivalent to the inclusion property in DIVE (i.e. Equation (2)).

2.3 PMI Filtering

For a frequent target word, there must be many neighboring words that incidentally appear near the target word without being semantically meaningful, especially when a large context window size is used. The unrelated context words cause noise in both the word vector and the context vector of DIVE. We address this issue by filtering out context words c for each target word w when the PMI of the co-occurring words is too small (i.e. $\log(\frac{P(w,c)}{P(w)\cdot P(c)}) < \log(k_f)$). That is, we set $\#(w,c) = 0$ in the objective function. This preprocessing step is similar to computing PPMI in SBOW (Bullinaria and Levy, 2007), where low PMI co-occurrences are removed from SBOW.

2.4 Interpretability

After applying the non-negativity constraint, we observe that each latent factor in the embedding is interpretable as previous findings suggest (Pauca et al., 2004; Murphy et al., 2012) (i.e. each dimension roughly corresponds to a topic). Furthermore, DIH suggests that a general word appears in more diverse contexts/topics. By preserving DIH using inclusion shift, the embedding of a general word (i.e. hypernym of many other words) tends to have larger values in these dimensions (topics). This gives rise to a natural and intuitive interpretation of our word embeddings: the word embeddings can be seen as unnormalized probability distributions over topics. In Figure 1, we visualize the unnormalized topical distribution of two words, rodent and mammal, as an example. Since rodent is a kind of mammal, the embedding (i.e. unnormalized topical distribution) of mammal includes the embedding of rodent when DIH holds. More examples are illustrated in our supplementary materials.

3 Unsupervised Embedding Comparison

In this section, we compare DIVE with other unsupervised hypernym detection methods. In this paper, unsupervised approaches refer to the methods that only train on plaintext corpus without using any hypernymy or lexicon annotation.

Dataset	BLESS	EVALution	LenciBenotto	Weeds	Medical	LEDS
Random	5.3	26.6	41.2	51.4	8.5	50.5

DIVE + C·ΔS	**57.2**	36.6	**32.0**	60.9	**32.7**	**32.8**

Table 1: Comparison with other unsupervised embedding methods. The scores are AP@all (%) for the first 10 datasets and Spearman ρ (%) for HyperLex. Avg (10 datasets) shows the micro-average AP of all datasets except HyperLex. Word2Vec+C scores word pairs using cosine similarity on skip-grams. GE+C and GE+KL compute cosine similarity and negative KL divergence on Gaussian embedding, respectively.

3.1 Experiment Setup

The embeddings are tested on 11 datasets. The first 4 datasets come from the recent review of Shwartz et al. (2017)[1]: BLESS (Baroni and Lenci, 2011), EVALution (Santus et al., 2015), Lenci/Benotto (Benotto, 2015), and Weeds (Weeds et al., 2014). The next 4 datasets are downloaded from the code repository of the H-feature detector (Roller and Erk, 2016)[2]: Medical (i.e., Levy 2014) (Levy et al., 2014), LEDS (also referred to as ENTAILMENT or Baroni 2012) (Baroni et al., 2012), TM14 (i.e., Turney 2014) (Turney and Mohammad, 2015), and Kotlerman 2010 (Kotlerman et al., 2010). In addition, the performance on the test set of HypeNet (Shwartz et al., 2016) (using the random train/test split), the test set of WordNet (Vendrov et al., 2016), and all pairs in HyperLex (Vulić et al., 2016) are also evaluated.

The F1 and accuracy measurements are sometimes very similar even though the quality of prediction varies, so we adopted average precision, AP@all (Zhu, 2004) (equivalent to the area under the precision-recall curve when the constant interpolation is used), as the main evaluation metric. The HyperLex dataset has a continuous score on each candidate word pair, so we adopt Spearman rank coefficient ρ (Fieller et al., 1957) as suggested by the review study of Vulić et al. (2016). Any OOV (out-of-vocabulary) word encountered in the testing data is pushed to the bottom of the prediction list (effectively assuming the word pair does not have hypernym relation).

[1] https://github.com/vered1986/UnsupervisedHypernymy

[2] https://github.com/stephenroller/emnlp2016/

We trained all methods on the first 51.2 million tokens of WaCkypedia corpus (Baroni et al., 2009) because DIH holds more often in this subset (i.e. SBOW works better) compared with that in the whole WaCkypedia corpus. The window size $|W|$ of DIVE and Gaussian embedding are set as 20 (left 10 words and right 10 words). The number of embedding dimensions in DIVE L is set to be 100. The other hyper-parameters of DIVE and Gaussian embedding are determined by the training set of HypeNet. Other experimental details are described in our supplementary materials.

3.2 Results

If a pair of words has hypernym relation, the words tend to be similar (sharing some context words) and the hypernym should be more general than the hyponym. Section 2.4 has shown that the embedding could be viewed as an unnormalized topic distribution of its context, so the embedding of hypernym should be similar to the embedding of its hyponym but having larger magnitude. As in HyperVec (Nguyen et al., 2017), we score the hypernym candidates by multiplying two factors corresponding to these properties. The C·ΔS (i.e. the cosine similarity multiply the difference of summation) scoring function is defined as

$$C \cdot \Delta S(\mathbf{w}_q \rightarrow \mathbf{w}_p) = \frac{\mathbf{w}_q^T \mathbf{w}_p}{||\mathbf{w}_q||_2 \cdot ||\mathbf{w}_p||_2} \cdot (\|\mathbf{w}_p\|_1 - \|\mathbf{w}_q\|_1), \quad (7)$$

where $\mathbf{w}_p$ is the embedding of hypernym and $\mathbf{w}_q$ is the embedding of hyponym.

As far as we know, Gaussian embedding (GE) (Vilnis and McCallum, 2015) is the state-of-the-art unsupervised embedding method which can capture the asymmetric relations between a hypernym and its hyponyms. Gaussian embedding

encodes the context distribution of each word as a multivariate Gaussian distribution, where the embeddings of hypernyms tend to have higher variance and overlap with the embedding of their hyponyms. In Table 1, we compare DIVE with Gaussian embedding[3] using the code implemented by Athiwaratkun and Wilson (2017)[4] and with word cosine similarity using skip-grams. The performances of random scores are also presented for reference. As we can see, DIVE is usually significantly better than other unsupervised embedding.

4 SBOW Comparison

Unlike Word2Vec, which only tries to preserve the similarity signal, the goals of DIVE cover preserving the capability of measuring not only the similarity but also whether one context distribution includes the other (inclusion signal) or being more general than the other (generality signal).

In this experiment, we perform a comprehensive comparison between SBOW and DIVE using multiple scoring functions to detect the hypernym relation between words based on different types of signal. The window size $|W|$ of SBOW is also set as 20, and experiment setups are the same as that described in Section 3.1. Notice that the comparison is inherently unfair because most of the information would be lost during the aggressive compression process of DIVE, and we would like to evaluate how well DIVE can preserve signals of interest using the number of dimensions which is several orders of magnitude less than that of SBOW.

4.1 Unsupervised Scoring Functions

After trying many existing and newly proposed functions which score a pair of words to detect hypernym relation between them, we find that good scoring functions for SBOW are also good scoring functions for DIVE. Thus, in addition to C·ΔS used in Section 3.2, we also present 4 other best performing or representative scoring functions in the experiment (see our supplementary materials for more details):

- **Inclusion**: CDE (Clarke, 2009) computes the summation of element-wise minimum over the magnitude of hyponym embedding (i.e. $\frac{||\min(\mathbf{w}_p, \mathbf{w}_q)||_1}{||\mathbf{w}_q||_1}$). CDE measures the degree of violation of equation (1). Equation (1) holds if and only if CDE is 1. Due to noise in SBOW, CDE is rarely exactly 1, but hypernym pairs usually have higher CDE. Despite its effectiveness, the good performance could mostly come from the magnitude of embeddings/features instead of inclusion properties among context distributions. To measure the inclusion properties between context distributions $\mathbf{d}_p$ and $\mathbf{d}_q$ ($\mathbf{w}_p$ and $\mathbf{w}_q$ after normalization, respectively), we use negative asymmetric L1 distance ($-AL_1$)[5] as one of our scoring function, where

$$AL_1 = \min_a \sum_c w_0 \cdot \max(a\mathbf{d}_q[c] - \mathbf{d}_p[c], 0) + \max(\mathbf{d}_p[c] - a\mathbf{d}_q[c], 0), \quad (8)$$

  and w_0 is a constant hyper-parameter.

- **Generality**: When the inclusion property in (2) holds, $||\mathbf{y}||_1 = \sum_i \mathbf{y}[i] \geq \sum_i \mathbf{x}[i] = ||\mathbf{x}||_1$. Thus, we use summation difference ($||\mathbf{w}_p||_1 - ||\mathbf{w}_q||_1$) as our score to measure generality signal (ΔS).

- **Similarity plus generality**: Computing cosine similarity on skip-grams (i.e. Word2Vec + C in Table 1) is a popular way to measure the similarity of two words, so we multiply the Word2Vec similarity with summation difference of DIVE or SBOW (W·ΔS) as an alternative of C·ΔS.

4.2 Baselines

- SBOW Freq: A word is represented by the frequency of its neighboring words. Applying PMI filter (set context feature to be 0 if its value is lower than $\log(k_f)$) to SBOW Freq only makes its performances closer to (but still much worse than) SBOW PPMI, so we omit the baseline.

- SBOW PPMI: SBOW which uses PPMI of its neighboring words as the features (Bullinaria and Levy, 2007). Applying PMI filter to SBOW PPMI usually makes the performances worse, especially when k_f is large. Similarly, a constant $\log(k')$ shifting to SBOW PPMI (i.e. $\max(PMI - \log(k'), 0)$) is not helpful, so we set both k_f and k' to be 1.

[3] Note that higher AP is reported for some models in previous literature: 80 (Vilnis and McCallum, 2015) in LEDS, 74.2 (Athiwaratkun and Wilson, 2017) in LEDS, and 20.6 (Vulić et al., 2016) in HyperLex. The difference could be caused by different train/test setup (e.g. How the hyperparameters are tuned, different training corpus, etc.). However, DIVE beats even these results.

Table 2: AP@all (%) of 10 datasets. The box at lower right corner compares the micro average AP across all 10 datasets. Numbers in different rows come from different feature or embedding spaces. Numbers in different columns come from different datasets and unsupervised scoring functions. We also present the micro average AP across the first 4 datasets (BLESS, EVALution, Lenci/Benotto and Weeds), which are used as a benchmark for unsupervised hypernym detection (Shwartz et al., 2017). IS refers to inclusion shift on the shifted PMI matrix.

5799	3808	**20**

Table 4: The average number of non-zero dimensions across all testing words in 10 datasets.

- SBOW PPMI w/ IS (with additional inclusion shift): The matrix reconstructed by DIVE when $k_I = 1$. Specifically, $\mathbf{w}[c] = \max(\log(\frac{P(w,c)}{P(w)*P(c)*\frac{Z}{\#(w)}}), 0)$.
- SBOW all wiki: SBOW using PPMI features trained on the whole WaCkypedia.
- DIVE without the PMI filter (DIVE w/o PMI)
- NMF on shifted PMI: Non-negative matrix factorization (NMF) on the shifted PMI without inclusion shift for DIVE (DIVE w/o IS). This is the same as applying the non-negative constraint on the skip-gram model.

- K-means (Freq NMF): The method first uses Mini-batch k-means (Sculley, 2010) to cluster words in skip-gram embedding space into 100 topics, and hashes each frequency count in SBOW into the corresponding topic. If running k-means on skip-grams is viewed as an approximation of clustering the SBOW context vectors, the method can be viewed as a kind of NMF (Ding et al., 2005).

DIVE performs non-negative matrix factorization on PMI matrix after applying inclusion shift and PMI filtering. To demonstrate the effectiveness of each step, we show the performances of DIVE after removing PMI filtering (DIVE w/o PMI), removing inclusion shift (DIVE w/o IS), and removing matrix factorization (SBOW PPMI w/ IS, SBOW PPMI, and SBOW all wiki). The methods based on frequency matrix are also tested (SBOW Freq and Freq NMF).

4.3 Results and Discussions

In Table 2, we first confirm the finding of the previous review study of Shwartz et al. (2017): there is no single hypernymy scoring function which always outperforms others. One of the main reasons is that different datasets collect negative samples differently. For example, if negative samples come from random word pairs (e.g. WordNet dataset), a symmetric similarity measure is a good scoring function. On the other hand, negative samples come from related or similar words in HypeNet, EVALution, Lenci/Benotto, and Weeds, so only estimating generality difference leads to the best (or close to the best) performance. The negative samples in many datasets are composed of both random samples and similar words (such as BLESS), so the combination of similarity and generality difference yields the most stable results.

DIVE performs similar or better on most of the scoring functions compared with SBOW consistently across all datasets in Table 2 and Table 3, while using many fewer dimensions (see Table 4). This leads to 2-3 order of magnitude savings on both memory consumption and testing time. Furthermore, the low dimensional embedding makes the computational complexity independent of the vocabulary size, which drastically boosts the scalability of unsupervised hypernym detection especially with the help of GPU. It is surprising that we can achieve such aggressive compression while preserving the similarity, generality, and inclusion signal in various datasets with different types of negative samples. Its results on C·ΔS and W·ΔS outperform SBOW Freq. Meanwhile, its results on AL_1 outperform SBOW PPMI. The fact that W·ΔS or C·ΔS usually outperform generality functions suggests that only memorizing general words is not sufficient. The best average performance on 4 and 10 datasets are both produced by W·ΔS on DIVE.

SBOW PPMI improves the W·ΔS and C·ΔS from SBOW Freq but sacrifices AP on the inclusion functions. It generally hurts performance to directly include inclusion shift in PPMI (PPMI w/ IS) or compute SBOW PPMI on the whole WaCkypedia (all wiki) instead of the first 51.2 million tokens. The similar trend can also be seen in Table 3. Note that AL_1 completely fails in the HyperLex dataset using SBOW PPMI, which suggests that PPMI might not necessarily preserve the distributional inclusion property, even though it can have good performance on scoring functions combining similarity and generality signals.

Removing the PMI filter from DIVE slightly drops the overall precision while removing inclusion shift on shifted PMI (w/o IS) leads to poor performances. K-means (Freq NMF) produces similar AP compared with SBOW Freq but has worse AL_1 scores. Its best AP scores on different datasets are also significantly worse than the best AP of DIVE. This means that only making Word2Vec (skip-grams) non-negative or naively accumulating topic distribution in contexts cannot lead to satisfactory embeddings.

5 Related Work

Most previous unsupervised approaches focus on designing better hypernymy scoring functions for sparse bag of word (SBOW) features. They are well summarized in the recent study (Shwartz et al., 2017). Shwartz et al. (2017) also evaluate the influence of different contexts, such as changing the window size of contexts or incorporating dependency parsing information, but neglect scalability issues inherent to SBOW methods.

A notable exception is the Gaussian embedding model (Vilnis and McCallum, 2015), which represents each word as a Gaussian distribution. However, since a Gaussian distribution is normalized, it is difficult to retain frequency information during the embedding process, and experiments on HyperLex (Vulić et al., 2016) demonstrate that a sim-

ple baseline only relying on word frequency can achieve good results. Follow-up work models contexts by a mixture of Gaussians (Athiwaratkun and Wilson, 2017) relaxing the unimodality assumption but achieves little improvement on hypernym detection tasks.

Kiela et al. (2015) show that images retrieved by a search engine can be a useful source of information to determine the generality of lexicons, but the resources (e.g. pre-trained image classifier for the words of interest) might not be available in many domains.

Order embedding (Vendrov et al., 2016) is a supervised approach to encode many annotated hypernym pairs (e.g. all of the whole WordNet (Miller, 1995)) into a compact embedding space, where the embedding of a hypernym should be smaller than the embedding of its hyponym in every dimension. Our method learns embedding from raw text, where a hypernym embedding should be larger than the embedding of its hyponym in every dimension. Thus, DIVE can be viewed as an unsupervised and reversed form of order embedding.

Non-negative matrix factorization (NMF) has a long history in NLP, for example in the construction of topic models (Pauca et al., 2004). Non-negative sparse embedding (NNSE) (Murphy et al., 2012) and Faruqui et al. (2015) indicate that non-negativity can make embeddings more interpretable and improve word similarity evaluations. The sparse NMF is also shown to be effective in cross-lingual lexical entailment tasks but does not necessarily improve monolingual hypernymy detection (Vyas and Carpuat, 2016). In our study, we show that performing NMF on PMI matrix with inclusion shift can preserve DIH in SBOW, and the comprehensive experimental analysis demonstrates its state-of-the-art performances on unsupervised hypernymy detection.

6 Conclusions

Although large SBOW vectors consistently show the best all-around performance in unsupervised hypernym detection, it is challenging to compress them into a compact representation which preserves inclusion, generality, and similarity signals for this task. Our experiments suggest that the existing approaches and simple baselines such as Gaussian embedding, accumulating K-mean clusters, and non-negative skip-grams do not lead to satisfactory performance.

To achieve this goal, we propose an interpretable and scalable embedding method called *distributional inclusion vector embedding (DIVE)* by performing non-negative matrix factorization (NMF) on a weighted PMI matrix. We demonstrate that scoring functions which measure inclusion and generality properties in SBOW can also be applied to DIVE to detect hypernymy, and DIVE performs the best on average, slightly better than SBOW while using many fewer dimensions.

Our experiments also indicate that unsupervised scoring functions which combine similarity and generality measurements work the best in general, but no one scoring function dominates across all datasets. A combination of unsupervised DIVE with the proposed scoring functions produces new state-of-the-art performances on many datasets in the unsupervised regime.

Mining Possessions: Existence, Type and Temporal Anchors

Dhivya Chinnappa and **Eduardo Blanco**

Abstract

This paper presents a corpus and experiments to mine possession relations from text. Specifically, we target alienable and control possessions, and assign temporal anchors indicating when the possession holds between possessor and possessee. We present new annotations for this task, and experimental results using both traditional classifiers and neural networks. Results show that the three subtasks (predicting possession existence, possession type and temporal anchors) can be automated.

1 Introduction

Every language has a way of expressing possessive relationships (Aikhenvald and Dixon, 2012). Possession is an asymmetric semantic relation between two entities, where one entity (the possessee) *belongs* to the other entity (the possessor) (Stassen, 2009). When it comes to defining possession, *belongs* includes a wide range of relationships, including (hereafter, we use x to refer to the possessor, and y to refer to the possessee) kinship (e.g., *[my]$_x$ oldest [son]$_y$*), part-whole (e.g., *the [car]$_x$'s [dashboard]$_y$*), physical and temporary possession (e.g., *[I]$_x$ have John's [book]$_y$*), possession of something intangible (e.g., *[John]$_x$ got the [flu]$_y$ last year*) and proximity (e.g., *The [shelf]$_x$ has a [glass sculpture]$_y$*).

Possession relations can be divided into alienable (also referred to as acquired, transferable, non-intimate, etc.) and inalienable (also referred to as inherent, inseparable, intimate, etc.). Possessees that can be separated from their possessors are alienable, and possessees that cannot normally be separated from their possessors are inalienable (Heine, 1997). For example, *[John]$_x$'s [condo]$_y$* is alienable, and *[John]$_x$'s [arm]$_y$* is inalienable (some previous works would call the latter a part-whole relation instead). Tham (2004) defines control possession as a relation in which the possessor has temporary control of the possessee, but does not necessarily alienably possess it (e.g., *[John]$_x$ borrowed the [car]$_y$ for the weekend*). Following the aforecited works, possession goes beyond ownership of property.

Possession relations can be expressed in a wide variety of syntactic constructions, including noun phrases (e.g., *[John]$_x$'s [car]$_y$*) and clauses (e.g., *[John]$_x$ bought a [blue car]$_y$*). The subject of a verb can map to either the possessor as exemplified above, or to the possessee (e.g., *The [car]$_y$ belongs to [John]$_x$*) (Aikhenvald and Dixon, 2012).

Within computational linguistics, possession relationships have usually been studied as part of larger studies that target all relations between arguments connected with a syntactic pattern (e.g., possessive constructions, nominals). Additionally, previous efforts have mostly targeted alienable possession—or alternatively, ownership. The work presented here takes a different approach. We start by pairing people (plausible possessors) with physical objects (plausible possesses). Then, we determine whether a possession relationship exists, and if so, (a) determine the type (alienable or control) and (b) assign temporal anchors with respect to the event of which the possessor is the subject. We target all verbs, not only prototypical verbs of possession (e.g., *have*, *get*). Thus, our approach extracts possessions intuitive to humans when there is no specific possession cue (e.g., we extract a control possession from *The [computer]$_y$ at work was slow, [I]$_x$ didn't get anything done*).

The main contributions of this paper are: (a) deterministic procedure to pair plausible possessors and possessees; (b) corpus annotating possession existence, possession type and temporal anchors; (c) detailed corpus analysis per verb and type of possession; and (d) experimental results showing that the task can be automated.

2 Possession Relations

The literature has studied possession relations extensively from theoretical and conceptual points of views. Here, we succinctly present some of the most influential works in the area.

The very definition of possession is not set in stone. Aikhenvald (2013) distinguishes three core meanings for possessive noun phrases that occur across languages: ownership (of property), whole-part (often referred to as part-whole), and kinship. Following a cross-linguistic perspective, she discusses possessions and time (present and former possession relationships, e.g., *my tooth* vs. *my former axe*), temporary and permanent possession (e.g., *borrow* vs. *acquire*) and others. Heine (1997) classifies possession relationships depending on the possessor and possessee. First, he makes a distinction between human (e.g., *[I]$_x$ have a [house]$_y$*) and non-human possessors (e.g. *[This house]$_x$ has [two bedrooms]$_y$*). Second, he differentiates three kinds of possession depending on the possessee: concrete possession (e.g., *[I]$_x$ have [two cats]$_y$*), social possession (e.g., *[I]$_x$ have [two sisters]$_y$*), and abstract possession (e.g., *[I]$_x$ have [an idea]$_y$*). Miller and Johnson-Laird (1976) differentiate between three kinds of possession: inherent, accidental, and physical; and provide the following example: *He owns an umbrella (inherent), but she's borrowed it (accidental), though she doesn't have it with her (physical).*

Possession relationships have also been defined in terms of their parameters. Stassen (2009) consider two parameters: permanent contact and control. These parameters are binary, and four kinds of possessions emerge from combining them: alienable (permanent contact: +, control: +), inalienable (+, -), temporary (-, +), and abstract (-, -). Similarly, Heine (1997) defines five binary parameters: human possessor, concrete possessee, spatial proximity, temporal permanence, and control. Combining these parameters, he defines 7 kinds of possessions: alienable, physical, temporary, inalienable, abstract, inanimate inalienable and inanimate alienable possession.

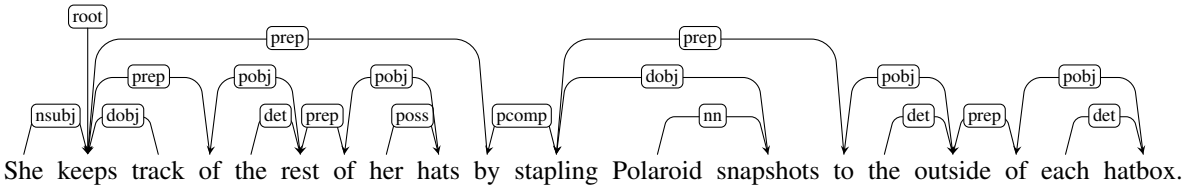
Most influential to the work presented here, Tham (2004) presents four types of possession: (a) inalienable (e.g., *John has a daughter*), (b) alienable (e.g., *John has a car*), (c) control (e.g., *John has the car (for the weekend)*), and (d) focus (e.g., *John has the window (to clean)*). In this paper, we target alienable and control possessions. We discard *inalienable* possessions because automated extraction has been studied before—at least partially, e.g., part-whole (Girju et al., 2006)—and *focus* possessions because they only occurred 5 times in the corpus we work with.

3 Previous Work

Within computational linguistics, possession relations have been mostly studied as one of the many relations encoded in a given syntactic construction. For example, Tratz and Hovy (2013) extract semantic relations within English possessives. They propose a set of 18 relations, e.g. *temporal* (e.g., *[today]$_x$'s [rates]$_y$*), *extent* (e.g., *[6 hours]$_y$' [drive]$_x$*). Their *controller / owner / user* relation (one relation with three aliases) is the closest relation to the alienable and control possessions we target in this paper. Unlike them, we distinguish between alienable and control possessions, and assign temporal anchors to possessions. Additionally, we are not restricted to possessive constructions. Instead, we start by pairing potential possessors and possessees within a sentence.

Extracting semantic relations between noun compounds (Nakov and Hearst, 2013; Tratz and Hovy, 2010) usually includes extracting possession relations, e.g., *[family]$_x$ [estate]$_y$*. Because they target noun compounds, they disregard numerous possessions encoded in text at the clause or sentence level. Although they do extract many relations from noun compounds beyond possessions, they do not distinguish between alienable and control possessions, or temporally anchor relations with respect to events in which the possessor participates.

To the best of our knowledge, the work by Banea et al. (2016) is the only one on extracting possession relations without imposing syntactic constraints. They build a dataset working with blog texts, but do not present results on automatic extraction. Their definition of possession includes alienable and control possessions, but they do not distinguish between them. Additionally, they only consider as possessors the author of a blog, and as possessees concrete nouns in the blog posts by the possessor. Regarding time, they annotate possessions at the time of the utterance. Unlike them, we distinguish between alienable and control possessions, and assign temporal anchors with respect to an event in which the possessor participates.



Pairs generated: (She, hats) and (She, hatbox)

Figure 1: WordNet synsets used to restrict possessees (y) when generating pairs (x, y). *lemma.n.y* indicates the yth synset of *n*oun *lemma*.

4 A Corpus of Possession Relations

We create a corpus[1] following two steps. First, we generate intrasentential pairs (x, y) of potential possessors (x) and possessees (y). Second, we annotate whether a possession exists, and if so, the type and temporal anchors. Generating pairs a priori proved more effective than giving annotators plain text and asking them to annotate possessions.

We add our annotations to OntoNotes (Hovy et al., 2006). Doing so has several advantages. First, OntoNotes contains texts from several domains and genres (e.g., conversational telephone speech, weblogs, broadcast), thus we not only work with newswire. Second, OntoNotes includes part-of-speech tags, named entities and parse trees, three annotation layers that allow us to streamline the corpus creation process.

4.1 Pairing Potential Possessors and Possessees

Our goal is to obtain pairs (x, y) such that it is plausible that x is the possessor of possessee y. To do so, we follow these steps:

1. Collect as potential possessors all PERSON named entities and personal pronouns (part-of-speech tag PRP) *I*, *he*, *she*, *we* and *they*.
2. Discard potential possessors that are not the nominal subject (*nsubj* syntactic dependency) of a verb. Let us name that verb $verb_x$.

[1] Available at http://www.cse.unt.edu/~blanco

possessee (y) is subsumed by	possessor (x) is a		
	pronoun	*person* NE	All
device.n.01	295	74	369

block.n.01	9	2	11
plaything.n.01	3	2	5
fixture.n.01	4	0	4
antiquity.n.01	2	0	2
other	4	0	4
All	774	205	979

Table 1: Counts of pairs (x, y) generated per type of potential possessor (x) and possessee (c).

3. For each possessor, collect as potential possessees all nouns reachable from $verb_x$ in the dependency tree and subsumed in WordNet (Miller, 1995) by the synsets in Figure 1.

Step (1) selects most people (not groups), and is inspired by Aikhenvald (2013, p. 11), who states that possessors are usually animate. Step (2) reduces the number of potential possessors, but note that we do not impose any restriction on $verb_x$, which may or may not be a verb of caused possession (Beavers, 2011). Finally, Step (3) restricts the kind of objects considered as possessees. The list of synsets was defined after analyzing the WordNet noun hierarchy and prior to generating pairs. Most of these synsets are children of *artifact.n.01*, other children of *artifact.n.01* were discarded because intuitively they cannot be possessees. For example, we discard *mystification.n.02: something designed to mystify or bewilder*.

Figure 2 shows a sample sentence and the pairs generated. Note that these pairs include distant possessor-possessee pairs, not only subject-object pairs. Nouns *track*, *rest*, *Polaroid* and *snapshot* are discarded as potential possessees because they are not subsumed by the synsets in Figure 1.

Labels	%	κ
yes, never, unk, inv	86.1	0.79
alienable, control	82.5	0.77
before yes, before no	83.6	0.68
during yes, during no	88.8	0.75
after yes, after no	83.6	0.59

Table 2: Inter-annotator agreements (raw percentage and Cohen's κ). κ values in the 0.60–0.80 range are considered *substantial*, over 0.80 would be *perfect* (Artstein and Poesio, 2008).

The total number of pairs generated after executing Steps (1–3) is 2,025. In order to reduce the annotation effort, we set to annotate 1,000 pairs. After trying several strategies, we reduce the number of pairs as follows. First, we discard pairs with verb$_x$ *see*, *think*, *believe*, *say* and *tell* because pilot annotations revealed that almost no possessions can be extracted from them (1,757 pairs left). Second, we discard pairs (x, y) such that verb$_x$ occurs five or less times (979 pairs left). Table 1 presents basic counts per type of possessor (named entity or personal pronoun) and possessee (WordNet synset) for the 979 pairs.

4.2 Annotating Possession Existence, Types and Temporal Information

After automatically generating pairs of potential possessors and possessees, annotators validate them manually. Annotations were done in-house, and the annotation interface showed the current sentence (with x, y and verb$_x$ highlighted), as well as the previous and next sentences.

The annotation process includes two major steps. First, annotators decide whether a possession relation exists between x and y based on the three sentences provided. More specifically, they choose from the following labels:

- `yes` if a possession exists at some point of time with respect to verb$_x$;
- `never` if a possession does not exist at any point of time with respect to verb$_x$;
- `unk` if it is sound to ask whether x is the possessor of possessee y, but there is not enough information to choose `yes` or `never`; and
- `inv` if either the potential possessor x is not animate, or the potential possessee y is nonsensical in the given context.

Second, annotators make two more decisions if the first label is `yes`:

- Possession type: whether the possession is `alienable` or `control`.

	Before		During		After	
	yes	*no*	*yes*	*no*	*yes*	*no*
Alienable	69.8	30.2	55.9	44.1	92.6	7.4
Control	28.8	71.2	85.3	14.7	33.3	66.7
All	52.0	48.0	68.7	31.3	67.8	32.2

Table 3: Percentage of alienable and control POSSESSION relations annotated *yes* and *no* per temporal anchor (before, during, after) with respect to verb$_x$ (i.e., the verb of which the possessor is the subject).

- Temporal anchors: whether the possession is true at some point of time `before`, `during`, and at some point of time `after` verb$_x$ takes place (three binary decisions).

Following the literature (Tham, 2004), we define *alienable* possession as a possessor owning a possessee, and *control* possession as a possessor having control of the possessee, but not necessarily ownership. Annotators were instructed to use world knowledge and fully interpret the sentences provided beyond what is explicitly stated. We present annotation examples in Section 5.1

Inter-Annotator Agreement. The annotations were done by two graduate students. Both of them annotated 35% of all pairs (possession existence, possession type and temporal anchors). We show inter-annotator agreements in Table 2. Cohen's κ for possession detection (labels `yes`, `never`, `unk` and `inv`) is 0.79, and 0.77 when including possession type (labels `alienable` and `control`). Answering whether the possession is true before, during or after verb$_x$ obtains lower coefficients: 0.68, 0.75 and 0.59 respectively. Not surprisingly, the agreement for `during` is higher. Note that κ coefficients in the range 0.60–0.80 are considered substantial, and coefficients over 0.80 are usually considered perfect (Artstein and Poesio, 2008). Given these high agreement, the rest of pairs (65%) were annotated once.

5 Corpus Analysis

Figure 3 presents percentages per label for all verbs and the top 10 most frequent verbs. Overall, 36.5% of pairs are validated (`alienable`: 20.6%, `control`: 15.9%), and only 5.8% of pairs are annotated `unk`. The relatively high percentage of `inv` label is mostly due to potential possessees that can only be possessed in certain contexts, e.g., compare *[They]$_x$ asked [regulators]$_y$ to suggest new ways to [...]* (`inv`) vs. *[They]$_x$ replaced the [regulators]$_y$ to control the flow of water* (`yes`).

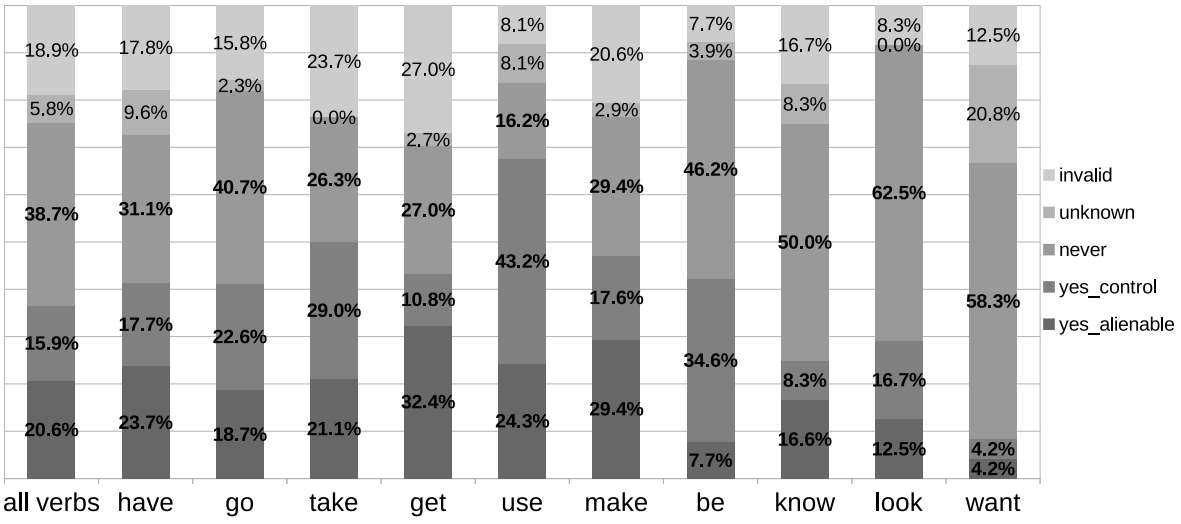

Figure 3: Percentage of labels for all verbs and the top 10 most frequent verbs of which the possessor is the subject. From left to right, they occurred 135, 44, 38, 37, 37, 34, 26, 24, 24, and 24 times respectively.

The percentage distributions depends heavily on the verb at hand. Note that several verbs with high `alienable` and `control` labels are not prototypical verbs of possession (e.g., *go*, *use*, *know*). When a possession holds, the type is most likely `control` for most verbs. The only exceptions are *have* (23.7% vs. 17.7%), *get* (32.4% vs. 10.8%), *make* (29.4% vs. 17.6%) and *know* (16.6% vs. 8.3%). The most productive verb as far as alienable possession is *get* (32.4%), and as far as `control` possessions, *use* (43.2%).

Labels per temporal anchor with respect to verb$_x$ (binary flags for before, during and after) and possession type are presented in Table 3. Alienable and control possessions show opposite trends for *before* and *after*, and substantially different distributions for *during*. The vast majority of control possessions are true during verb$_x$ (85.3% vs. 14.7%), as well as a more modest majority of alienable possessions (55.9% vs. 44.1%). Alienable and control possessions, however, have opposite temporal anchors for *before* and *after*. Specifically, most alienable possessions are true before and after verb$_x$ (69.8% and 92.6% respectively), and most control possessions are not true before and after verb$_x$ (71.2% and 66.7%).

5.1 Examples of Annotations

We present annotation examples using selected pairs of possessors and possessees in Table 4.

In Sentence (1), annotators interpreted that the relationship between *he* and *car* is an alienable possession. While not explicitly stated, annotators interpreted that *he* is an adult, and world knowledge tells us that most adults own the cars they drive unless a modifier indicates otherwise (e.g., *rental* car, my *father*'s car). Regarding temporal anchors, the possession between *he* and *car* is true before and during *died*, but not after.

Sentence (2) is a common example of alienable possession that is true after verb$_x$. The subject of a verb of creation (e.g., *make*, *build*) often becomes an alienable possessor of the direct object after the verb, but not before or during (because the object has not come into being yet).

Sentence (3) and (4) exemplify control possessions. In Sentence (3), *He* is borrowing *my father's car* for a period of time, and thus *He* has control over but does not own it. Regarding temporal anchors, nothing in the sentence indicates that *He* will have control over the car before or after *kept*. Note that our procedure to generate pairs would not generate the pair (*father*, *car*), but previous work has targeted possessives (Section 3).

In Example (4), verb$_x$ is *felt*, yet we extract a valid control possession. *I* is crew member of a warship and is describing his experience while on board. Annotators understood he had control over the ship (at least partially) before, during and after, as *felt* did not last long and there is no indication that *I* left the boat immediately before or after *felt*.

Sentences (5–7) present examples in which annotators did not annotate a possession relation (labels `never`, `unk`, and `inv`). In Sentence (5), the *mask* belongs to *Joseph*. There is no indication that a possession relation exists between *LaToya* and *mask*, although *LaToya* was in close spatial proximity of the *mask* worn by *Joseph*.

	Text (sentence of interest and context if relevant) and pair (x, y)	Label	B	D	A
1	But [he]$_x$ had extreme mood swings and [died]$_{verb_x}$ in a [car]$_y$ crash driving to work when I was five.	`alienable`	✓	✓	✗
2	After moving to the unoccupied zone, [Wang]$_x$ began [carving]$_{verb_x}$ [seals]$_y$ in his spare time to support himself.	`alienable`	✗	✗	✓
3	[He]$_y$ [kept]$_{verb_x}$ my father's [car]$_y$ for a year, without writing a confiscation order for it.	`control`	✗	✓	✗
4	The horror and the heroics of the [...] were relived this evening by one of the crew, Liutenant Ann Chamberlain. [I]$_x$ just [felt]$_{verb_x}$ a large—not so much a bang, but, to me, from where I was, it seemed like something had rammed the [ship]$_y$.	`control`	✓	✓	✓
5	[LaToya]$_x$ also [described]$_{verb_x}$ being awakened in the night by Joseph wearing a "monster [mask]$_y$."	`never`	n/a		
6	[They]$_x$ [asked]$_{verb_x}$ him to come to them immediately because the reported [car]$_y$ had been seized.	`unk`	n/a		
7	Will your political party straighten up and say, damn it, [we]$_x$ [have]$_{verb_x}$ to drop some of our ideological [baggage]$_y$?	`inv`	n/a		

Table 4: Example of annotations for selected pairs (x, y). Recall that temporal anchors (B: before, D: during, A: After) are annotated with respect to verb$_x$ and only if the main label is `yes`, i.e., if there is an alienable or control POSSESSION between x and y (Section 4.2).

In Sentence (6), it is the case that *They* have some knowledge about the *car* that was seized, and it appears that *him*—not *They*—may be the alienable possessor. It is unclear, however, whether *They* and *car* are related by a control possession, thus annotators chose label `unk`.

Finally, Sentence (7) exemplifies label `inv`. While *baggage* is most of the time a concrete object that passes the restrictions on potential possessees (Section 4), in this context, it is part of the metaphor *ideological baggage*. Since we only target concrete possessees, annotators chose `inv`.

6 Experiments and Results

We conduct experiments using Support Vector Machines and neural networks. Each pair (x, y) becomes an instance, and we create stratified train (80%) and test (20%) sets. We report results using the test set after tuning hyper parameters using 10-fold cross validation. More specifically, we train five classifiers and experiment with all instances but the ones annotated `inv`. The first classifier predicts possession existence (`yes`, `never` or `unk`). The second classifier predicts possession types, i.e., classifies pairs between which a possession holds (`yes`) into `alienable` or `control`. The third, fourth and fifth classifiers predict temporal anchors, i.e., classify pairs between which a possession holds—either alienable or control—into `before yes` or `before no`, `during yes` or `during no`, and `after yes` or `after no`.

6.1 Support Vector Machines

We trained the five classifiers using the SVM implementation in scikit-learn (Pedregosa et al., 2011). We tuned hyper-parameters C and γ using 10-fold cross validation, and used the features that are summarized in Table 5.

Verb features include the word and POS tag for the verb, previous and next tokens, as well as information regarding the outgoing and incoming dependencies. We also include a binary flag indicating whether the verb is a possession verb from the list collected by Viberg (2010, Table 1).

Possessor and *Possessee* features are very similar to *Verb* features, but we consider the concatenation of words and POS tags. *Possessee* features also include information derived from the WordNet hypernym paths to the root in the noun hierarchy, i.e., *entity.n.01*. More specifically, *WN synset* captures the synset from Figure 1 the possessee is subsumed by, and *WN path* are features capturing the top 6 synsets in the hypernym path from the possessee to *entity.n.01*. Finally, *Path* features include three syntactic paths (syntactic dependency types and up / down symbols): from the possessor to the verb, from the possessee to the verb, and from the possessor to the possessee. The feature set is heavily inspired in many previous works (e.g, (Gildea and Jurafsky, 2002)).

We experimented with SVMs to establish a strong supervised baseline using linguistic information, and to compare with neural networks that take as input only words along with information

	Feature	Description
Verb	word and tag	word form and part-of-speech tag of verb
	is_possession_verb	flag indicating whether *verb* is in the list of possession verbs
	previous, next tokens	word form and part-of-speech tags of the previous and next tokens
	dependency_out	outgoing syntactic dependency type
	dependencies_in	flags indicating the incoming syntactic dependencies
	left, right children	number of incoming syntactic dependencies to the left and right of *verb*
Possessor	words	concatenation of words
	pos tags	part-of-speech tag (full tag and first character, i.e., pronoun or noun)
	previous, next tokens	word form and part-of-speech tags of the previous and next tokens
	dependency_out	outgoing syntactic dependency type
	dependencies_in	flags indicating the incoming syntactic dependencies
Possessee	same as possessor	same features extracted for the possessor
	WN synset	WordNet synset from Figure 1 the possessee is subsumed by
	WN path	WordNet synsets from entity.n.01 to the possessee
Paths	possessor to verb	syntactic path between possessor and verb
	possessee to verb	syntactic path between possessee and verb
	possessor to possessee	syntactic path between possessor and possessee

Table 5: Feature set used to extract possession relations (existence, type and temporal anchors) with Support Vector Machines.) and possession type (`alienable` or `control`).

regarding who is the potential possessor, possessee and verb$_x$.

6.2 Neural Networks

We experiment with feedforward and Long Short-Term Memory networks, and use the implementations in Keras (Chollet et al., 2015) using TensorFlow backend (Abadi et al., 2015). All networks use GloVe embeddings with 100 dimensions (Pennington et al., 2014) and the Adam optimizer (Kingma and Ba, 2014). Regarding input, we experiment with the potential possessor *x*, possessee *y*, verb$_x$, and the rest of the sentence. The three architectures are depicted in Figure 4.

Feedforward Neural Network. The feedforward neural network takes as input the embeddings of the potential possessor *x*, possessee *y* and verb$_x$. It has a fully connected hidden layer with 50 neurons and uses softmax in the output layer of size 3 for predicting possession existence (`yes`, `never` and `unk`) or size 2 for predicting possession type (`alienable` and `control`) and temporal anchors (`yes` and `never` for before, during and after).

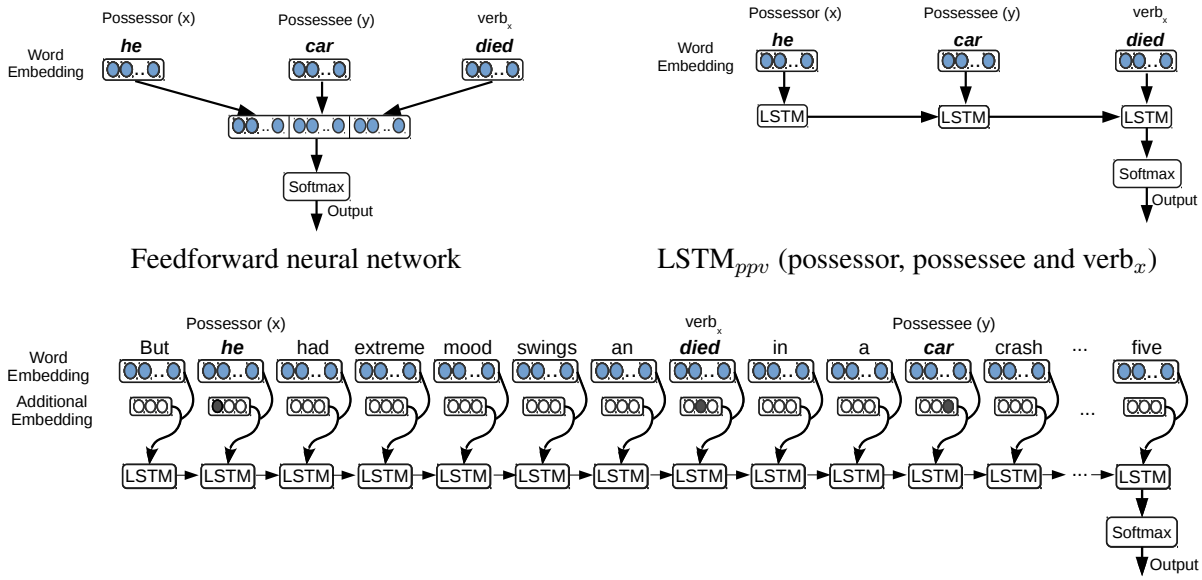
LSTM$_{ppv}$. The first Long Short-Term Memory network takes as input a fixed-length sequence consisting of the potential possessor *x*, possessee *y* and verb$_x$. We used 100 LSTM units (output dimension) and the output layer also uses softmax. While this LSTM has access to the same information than the feedforward network, we expect that the input, output and forget gates will learn to update the cell state to better solve our task.

LSTM$_{sent}$. The architecture of the second Long Short-Term Memory network is the same than LSTM$_{ppv}$, but the input is different. LSTM$_{sent}$ takes as input the sequence of words from which the potential possessor *x*, possessee *y* and verb$_x$ were extracted. Each element in the input is represented by the concatenation of its word embedding and an additional embedding indicating if the token is the potential possessor *x*, possessee *y*, verb$_x$, or none of them. Unlike the other two networks, LSTM$_{sent}$ has access to the full sentence, and we expect that the memory update mechanism (i.e., the input, output and forget gates) will learn the context most relevant for our task.

6.3 Results

Possession Existence and Type. Table 6 presents results obtained with the majority baseline (possession existence: always `never`, possession type: always `alienable`), SVMs and the three neural networks. All models outperform the majority baseline in both tasks (possession existence F1: 0.24, possession type F1: 0.40), and the three neural architectures outperform SVM (existence: 0.57–0.74 vs. 0.56, type: 0.61–0.67 vs. 0.58).

Regarding possession existence, the vanilla feedforward neural network alone performs similar to the SVM (F1: 0.57 vs. 0.56), indicating that word embeddings capture the kind of verbs and (potential) possessors and possessees more likely to have a possession relationship. Despite the small dataset (total: 979 pairs), the LSTMs out-



Feedforward neural network

LSTM$_{ppv}$ (possessor, possessee and verb$_x$)

LSTM$_{sent}$ (full sentence + additional embeddings for posessor, possessee and verb$_x$)

Figure 4: Neural network architectures: feedforward neural network (top left), LSTM$_{ppv}$ (top right), and LSTM$_{sent}$ (bottom). We exemplify the architectures with Example 1 from Table 4, *But [he]$_x$ had extreme mood swings and [died]$_{\text{verb}_x}$ in a [car]$_y$ crash driving to work when I was five* (only partially shown with LSTM$_{sent}$).

Table 6: Results obtained using the majority baseline (possession existence: `never`, possession type: `alienable`), SVMs with the best feature combination (all features), and neural networks. Note that we report results for the possession existence (`yes`, `never` or `unk`) and possession type (`alienable` or `control`).

perform the feedforward neural network (0.74 vs. 0.57). LSTM$_{ppv}$ performs surprisingly well (F1: 0.69) even though it only has access to the possessor, possessee and verb$_x$. LSTM$_{sent}$ highly benefits from having access to the full sentence (F1: 0.74). This shows that context plays a vital role in deciding the existence of possession.

Regarding possession type, the feedforward neural network is comparable to LSTM$_{ppv}$. Intuitively, distinguishing between alienable and control possessions can be done mostly based on the possessor, possessee and verb$_x$, and the embeddings capture this kind of information. For example, verbs such as *use* and *rent* indicate a control possession, while *acquire* indicates alienable possession.

Temporal Anchors. Table 7 presents results obtained with SVMs and the best neural network architecture in this subtask. LSTM$_{ppv}$ performs similar to the SVM (before: 0.71 vs. 0.76, during: 0.75 vs. 0.72, after: 0.70 vs. 0.73). As expected, F1 scores are higher with the labels that occur more often: `yes` is more frequent than `never` with all temporal anchors, especially *during* and *after* (Table 3), and F1 scores for `yes` are higher than for `never` (before: 0.73 vs. 0.68, during: 0.82 vs. 0.59, after: 0.77 vs. 0.54).

7 Conclusions

Possession relations are present in all languages, and they can reflect relationships, values, concepts and cultural changes (Aikhenvald, 2013). In this

		Before			During			After		
		P	R	F1	P	R	F1	P	R	F1

Table 7: Results obtained using SVMs with the best feature combination (all features) and the best neural network architecture when predicting temporal anchors with respect to verb_y for a POSSESSION (both alienable and control).

paper, we mine possessions from text. Specifically, we extract alienable and control possessions, and specify temporal anchors with respect to the verb of which the possessor is the subject.

We have created the first corpus annotating types of possessions following two steps. First, we automatically pair potential possessors and possessees, resulting in 979 pairs. Second, we manually validate pairs by annotating possession existence (`yes`, `never`, `unk` and `inv`), types (`alienable` or `control`) and temporal anchors (`before yes` / `no`, `during yes` / `no`, `after yes` / `no`). Inter-annotator Cohen's κ coefficients show that the annotation task can be done reliably (Table 2). Experimental results show that the task can be automated, and that neural networks outperform SVMs trained with features extracted from linguistic structure although we experiment with a relatively small dataset.

Beyond fundamental research, we believe that mining possession types has several applications. For example, marketers may target people who do not alienably possess something, and certain skills may be inferred from the kind of objects people have control possessions over (e.g., an individual having a control possession of an 18-wheeler most likely knows how to drive large trucks and has a commercial driver's license).

Abstract

Although neural tensor networks (NTNs) have been successful in many natural language processing tasks, they require a large number of parameters to be estimated, which often results in overfitting and long training times. We address these issues by applying eigendecomposition to each slice matrix of a tensor to reduce the number of parameters. We evaluate our proposed NTN models in two tasks. First, the proposed models are evaluated in a knowledge graph completion task. Second, a recursive NTN (RNTN) extension of the proposed models is evaluated on a logical reasoning task. The experimental results show that our proposed models learn better and faster than the original (R)NTNs.

1 Introduction

Alongside the nonlinear activation functions, linear mapping by matrix multiplication is an essential component of neural network (NN) models, as it determines the feature interaction and thus the expressiveness of models. In addition to the matrix-based mapping, neural tensor networks (NTNs) (Socher et al., 2013a) employ a 3-dimensional tensor to capture direct interactions among input features. Due to the large expressive capacity of 3D tensors, NTNs have been successful in an array of natural language processing (NLP) and machine learning tasks, including knowledge graph completion (KGC) (Socher et al., 2013a), sentiment analysis (Socher et al., 2013b), and reasoning with logical semantics (Bowman et al., 2015). However, since a 3D tensor has a large number of parameters, NTNs need longer time to train than other NN models. Moreover, the millions of parameters often make the model suffer from overfitting (Yang et al., 2015).

To solve these problems, we propose two new parameter reduction techniques for NTNs. These techniques drastically decrease the number of parameters in an NTN without diminishing its expressiveness. We use the matrix decomposition techniques that are utilized for KGC in Yang et al. (2015) and Trouillon et al. (2016). Yang et al. (2015) imposed a constraint that a matrix in the bilinear term in their model had to be diagonal. As mentioned in a subsequent section, this is essentially equal to assuming that the matrix be symmetric and performing eigendecomposition. Trouillon et al. (2016) also applied eigendecomposition to a matrix by regarding it as the real part of a normal matrix. Following these studies, we perform simultaneous diagonalization on all slice matrices of a NTN tensor. As a result, mapping by a 3D ($n \times n \times k$) tensor is replaced with an array of k "triple inner products" of two input vectors and a weight vector. Thus, we obtain two new NTN models where the number of parameters is reduced from $O(n^2k)$ to $O(nk)$.

On a KGC task, these parameter-reduced NTNs (NTN-Diag and NTN-Comp) alleviate overfitting and outperform the original NTN. Moreover, our proposed NTNs can learn faster than the original NTN. We also show that our proposed models perform better and learn faster in a recursive setting by examining a logical reasoning task.

2 Background

We consider mapping in a neural network (NN) layer that takes two vectors as input, such as recursive neural networks. Recurrent neural networks also has this structure, with one input vector being the hidden state from the previous time step. As a mapping before activation in the NN layer, linear mapping (matrix multiplication) is commonly used:

$$\boldsymbol{W}_1\boldsymbol{x}_1 + \boldsymbol{W}_2\boldsymbol{x}_2 = [\boldsymbol{W}_1, \boldsymbol{W}_2] \begin{bmatrix} \boldsymbol{x}_1 \\ \boldsymbol{x}_2 \end{bmatrix} = \boldsymbol{W}\boldsymbol{x}.$$

Proceedings of NAACL-HLT 2018, pages 506–515
New Orleans, Louisiana, June 1 - 6, 2018.

Here, since $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathbb{R}^n, \boldsymbol{W}_1, \boldsymbol{W}_2 \in \mathbb{R}^{k \times n}$, this linear mapping is a transformation from $\mathbb{R}^{2n}$ to $\mathbb{R}^k$. Linear mapping, which is a standard component of NNs, has been applied successfully in many tasks. However, it cannot consider the interaction between different components of two input vectors, which renders it not ideal for modeling complex compositional structures such as trees and graphs.

To alleviate this problem, some models such as NTNs (Socher et al., 2013a) have explored 3D tensors to yield more expressive mapping:

$$\begin{aligned} \boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[1:k]} \boldsymbol{x}_2 &= \begin{bmatrix} \boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[1]} \boldsymbol{x}_2 \\ \boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[2]} \boldsymbol{x}_2 \\ \vdots \\ \boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[k]} \boldsymbol{x}_2 \end{bmatrix} \\ &= \begin{bmatrix} \mathrm{sum}\left(\boldsymbol{W}^{[1]} \odot (\boldsymbol{x}_1 \otimes \boldsymbol{x}_2)\right) \\ \mathrm{sum}\left(\boldsymbol{W}^{[2]} \odot (\boldsymbol{x}_1 \otimes \boldsymbol{x}_2)\right) \\ \vdots \\ \mathrm{sum}\left(\boldsymbol{W}^{[k]} \odot (\boldsymbol{x}_1 \otimes \boldsymbol{x}_2)\right) \end{bmatrix} \end{aligned}$$

where $\boldsymbol{W}^{[1:k]} \in \mathbb{R}^{n \times n \times k}$. The output of this mapping is an array of k bilinear products in the form of $\boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[i]} \boldsymbol{x}_2$. Thus, this is also a transformation from $\mathbb{R}^{2n}$ to $\mathbb{R}^k$. Each element of the output of this mapping equals the sum of $\boldsymbol{W}^{[i]} \odot (\boldsymbol{x}_1 \otimes \boldsymbol{x}_2)$, where $\odot$ and $\otimes$ represent, respectively, the Hadamard and the outer products. Hence this mapping captures the direct interaction between different components (or "features") in two input vectors. Thanks to this expressiveness, NTNs are effective in tasks such as knowledge graph completion (Socher et al., 2013a), sentiment analysis (Socher et al., 2013b), and logical reasoning (Bowman et al., 2015).

Although mapping by a 3D tensor provides expressiveness, it has a large number ($O(n^2k)$) of parameters. Due to this, NTNs often suffer from overfitting and long training times.

3 Matrix Decomposition

3.1 Simple Matrix Decomposition (SMD)

To reduce the number of parameters of a slice matrix $\boldsymbol{W}^{[i]} \in \mathbb{R}^{n \times n}$ in a tensor, simple matrix decomposition (SMD) is commonly used (Bai et al., 2009). SMD factorizes $\boldsymbol{W}^{[i]}$ into a product of two low rank matrices $\boldsymbol{S}^{[i]} \in \mathbb{R}^{n \times m}$ and $\boldsymbol{T}^{[i]} \in \mathbb{R}^{m \times n}$ ($m \ll n$):

$$\boldsymbol{W}^{[i]} \simeq \boldsymbol{S}^{[i]} \boldsymbol{T}^{[i]}. \tag{1}$$

By plugging (1) into bilinear term $\boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[i]} \boldsymbol{x}_2$, we obtain the approximation $\boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{S}^{[i]} \boldsymbol{T}^{[i]} \boldsymbol{x}_2$. SMD reduces the number of parameters of $\boldsymbol{W}^{[i]}$ from n^2 to $2nm$. However, the dimension m for $\boldsymbol{S}$ and $\boldsymbol{T}$ is a hyperparameter and must be determined prior to training.

3.2 Simultaneous Diagonalization

This section introduces two techniques that can simultaneously diagonalize all slice matrices $\boldsymbol{W}^{[1]}, \ldots, \boldsymbol{W}^{[i]}, \ldots, \boldsymbol{W}^{[k]} \in \mathbb{R}^{n \times n}$. As described in (Liu et al., 2017), we make use of the fact that if matrices $\boldsymbol{V}^{[1:k]}$ form a commuting family: i.e., $\boldsymbol{V}^{[i]} \boldsymbol{V}^{[j]} = \boldsymbol{V}^{[j]} \boldsymbol{V}^{[i]}, \forall i, j \in \{1, 2, \ldots, k\}$, they can be diagonalized by a shared orthogonal or unitary matrix. Both of the two techniques reduce the number of parameters of $\boldsymbol{W}^{[i]}$ to $O(n)$ from $O(n^2)$.

3.2.1 Orthogonal Diagonalization

Many NLP datasets contain symmetric patterns. For example, if binary relation *(Bob, is_relative_of, Alice)* holds in a knowledge graph, then *(Alice, is_relative_of, Bob)* should also hold in it. English phrases "dog and cat" and "cat and dog" have identical meaning. For symmetric structures, we can reasonably suppose that each slice matrix $\boldsymbol{W}^{[i]}$ of a 3D tensor is symmetric because $\boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[i]} \boldsymbol{x}_2$ must equal $\boldsymbol{x}_2^{\mathrm{T}} \boldsymbol{W}^{[i]} \boldsymbol{x}_1$.

When $\boldsymbol{W}^{[i]} \in \mathbb{R}^{n \times n}$ is symmetric, it can be diagonalized as:

$$\boldsymbol{W}^{[i]} = \boldsymbol{O}^{[i]} \boldsymbol{W}^{[i]\prime} \boldsymbol{O}^{[i]\mathrm{T}}$$

where $\boldsymbol{O}^{[i]} \in \mathbb{R}^{n \times n}$ is an orthogonal matrix and $\boldsymbol{W}^{[i]\prime} \in \mathbb{R}^{n \times n}$ is a diagonal matrix. Note that an orthogonal matrix $\boldsymbol{O}^{[i]}$ may not be equal to $\boldsymbol{O}^j$ if $i \neq j$. However, if all of the slice matrices $\boldsymbol{W}^{[1]}, \ldots, \boldsymbol{W}^{[i]}, \ldots, \boldsymbol{W}^{[k]} \in \mathbb{R}^{n \times n}$ are commuting, we can diagonalize every slice matrix with the same orthogonal matrix $\boldsymbol{O}$. By substituting $\boldsymbol{W}^{[i]}$ with $\boldsymbol{O} \boldsymbol{W}^{[i]\prime} \boldsymbol{O}^{\mathrm{T}}$ into bilinear term $\boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[i]} \boldsymbol{x}_2$, we can rewrite it as follows:

$$\begin{aligned} \boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{W}^{[i]} \boldsymbol{x}_2 &= \boldsymbol{x}_1^{\mathrm{T}} \boldsymbol{O} \boldsymbol{W}^{[i]\prime} \boldsymbol{O}^{\mathrm{T}} \boldsymbol{x}_2 \\ &= \boldsymbol{y}_1^{\mathrm{T}} \boldsymbol{W}^{[i]\prime} \boldsymbol{y}_2 \\ &= \langle \boldsymbol{y}_1, \boldsymbol{w}^{[i]}, \boldsymbol{y}_2 \rangle \end{aligned} \tag{2}$$

where $\boldsymbol{y}_1 = \boldsymbol{O}^{\mathrm{T}} \boldsymbol{x}_1$, $\boldsymbol{y}_2 = \boldsymbol{O}^{\mathrm{T}} \boldsymbol{x}_2$, $\boldsymbol{w}^{[i]} = \mathrm{diag}(\boldsymbol{W}^{[i]\prime}) \in \mathbb{R}^n$ and $\langle \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c} \rangle$ denotes a "triple inner product" defined by $\langle \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c} \rangle = \sum_{l=1}^{n} a_l b_l c_l$. This reduces the number of parameters in a single slice matrix from n^2 to n.

3.2.2 Unitary Diagonalization

Since most of the structures in the NLP data are not symmetric, the symmetric matrix assumption is usually violated. To obtain more expressive diagonal matrix, we regard each slice matrix $\boldsymbol{W}^{[i]}$ as the real part of a complex matrix and consider its eigendecomposition.

For any real matrix $\boldsymbol{W}^{[i]}$, there exists a complex normal matrix $\boldsymbol{Z}^{[i]}$ whose real part is equal to it: $\boldsymbol{W}^{[i]} = \Re\left(\boldsymbol{Z}^{[i]}\right)$. $\Re(\cdot)$ represents an operation that takes the real part of a complex number, vector or matrix. Further, any complex normal matrix can be diagonalized by a unitary matrix. With these two properties, any real matrix $\boldsymbol{W}^{[i]}$ can be diagonalized as follows (Trouillon et al., 2016):

$$\boldsymbol{W}^{[i]} = \Re\left(\boldsymbol{Z}^{[i]}\right) = \Re\left(\boldsymbol{U}^{[i]}\boldsymbol{Z}^{[i]\prime}\boldsymbol{U}^{[i]*}\right).$$

Here, $\boldsymbol{U}^{[i]} \in \mathbb{C}^{n\times n}$ is a unitary matrix, $\boldsymbol{Z}^{[i]\prime} \in \mathbb{C}^{n\times n}$ is a diagonal matrix, and $\boldsymbol{U}^{[i]*}$ is the conjugate transpose of $\boldsymbol{U}^{[i]}$. To guarantee that every slice matrix can be diagonalized with the same unitary matrix $\boldsymbol{U}$ instead of $\boldsymbol{U}^{[i]}$, we assume all of the normal matrices $\boldsymbol{Z}^{[1]}, \ldots, \boldsymbol{Z}^{[i]}, \ldots, \boldsymbol{Z}^{[k]} \in \mathbb{C}^{n\times n}$ are commuting as in Section 3.2.1.

Substituting $\Re\left(\boldsymbol{U}\boldsymbol{Z}^{[i]\prime}\boldsymbol{U}^{*}\right)$ whose $\boldsymbol{U}$ is the same unitary matrix in all slice matrices, we can rewrite every bilinear term $\boldsymbol{x}_1^{\mathrm{T}}\boldsymbol{W}^{[i]}\boldsymbol{x}_2$ as follows:

$$\begin{aligned}
\boldsymbol{x}_1^{\mathrm{T}}\boldsymbol{W}^{[i]}\boldsymbol{x}_2 &= \Re\left(\langle \boldsymbol{y}_1, \boldsymbol{w}^{[i]}, \overline{\boldsymbol{y}_2}\rangle\right) \\
&= \langle \Re(\boldsymbol{y_1}), \Re(\boldsymbol{w}^{[i]}), \Re(\boldsymbol{y}_2)\rangle \\
&\quad + \langle \Re(\boldsymbol{y_1}), \Im(\boldsymbol{w}^{[i]}), \Im(\boldsymbol{y}_2)\rangle \\
&\quad + \langle \Im(\boldsymbol{y_1}), \Re(\boldsymbol{w}^{[i]}), \Im(\boldsymbol{y}_2)\rangle \\
&\quad - \langle \Im(\boldsymbol{y_1}), \Im(\boldsymbol{w}^{[i]}), \Re(\boldsymbol{y}_2)\rangle, \quad (3)
\end{aligned}$$

where $\boldsymbol{y}_1 = \boldsymbol{U}^{\mathrm{T}}\boldsymbol{x}_1$, $\overline{\boldsymbol{y}_2} = \boldsymbol{U}^{*}\boldsymbol{x}_2$, $\boldsymbol{w}^{[i]} = \mathrm{diag}(\boldsymbol{Z}^{[i]\prime}) \in \mathbb{C}^n$, and $\langle \boldsymbol{y}_1, \boldsymbol{w}^{[i]}, \overline{\boldsymbol{y}_2}\rangle$ is the triple Hermitian inner product of $\boldsymbol{y}_1$, $\boldsymbol{w}^{[i]}$ and $\boldsymbol{y}_2$ defined by $\langle \boldsymbol{a}, \boldsymbol{b}, \overline{\boldsymbol{c}}\rangle = \sum_{l=1}^{n} a_l b_l \overline{c_l}$. This technique reduces the number of parameters of the matrices from n^2 to $2n$. As shown in the right-hand side of Eq. (3), $\Re\left(\langle \boldsymbol{y}_1, \boldsymbol{w}^{[i]}, \overline{\boldsymbol{y}_2}\rangle\right)$ can be replaced with three additions and a subtraction of the triple inner product of real vectors.

4 Neural Network Models

This section introduces the baseline and our proposed models. After describing them, we explain how to extend them for handling compositional structures like binary trees.

Model	# of Parameters
NN	$(2n+1)k$
NTN	$(n^2+2n+1)k$
NTN-SMD	$(2mn+2n+1)k$
NTN-Diag	$(3n+1)k$
NTN-Comp	$(6n+1)k$

Table 1: Comparison of the number of parameters among the models

4.1 Baseline Models

Neural Network (NN)

First, we describe a standard single layer neural network (NN) model for two vectors $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathbb{R}^n$. The model uses linear mapping $\boldsymbol{V} \in \mathbb{R}^{k\times 2n}$ to combine two input vectors:

$$f(\boldsymbol{V}\begin{bmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{bmatrix} + \boldsymbol{b})$$

where $\boldsymbol{b} \in \mathbb{R}^k$ is a bias term and f is a non-linear activation function. The NN model has only $(2n+1)k$ parameters, and does not consider the direct interactions between $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$.

Neural Tensor Network (NTN)

Socher et al. (2013a) proposed a neural tensor network (NTN) model that uses a 3D tensor $\boldsymbol{W}^{[1:k]} \in \mathbb{R}^{n\times n\times k}$ to combine two input vectors:

$$f(\boldsymbol{x}_1^{\mathrm{T}}\boldsymbol{W}^{[1:k]}\boldsymbol{x}_2 + \boldsymbol{V}\begin{bmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{bmatrix} + \boldsymbol{b}).$$

Unlike the standard NN model, NTN can directly relate two input vectors using a tensor. However, it has too many parameters; $(n^2+2n+1)k$.

NTN-SMD

Although the NTN model has tremendous expressive power, it is extremely time-consuming to compute, since a naive 3D tensor product incur $O(n^2k)$ computation time. To overcome this weakness, Zhao et al. (2015) and Liu et al. (2015) independently introduced simple matrix decomposition (SMD) to the NTN model by replacing each slice matrix $\boldsymbol{W}^{[i]}$ with its factorized approximation given by Eq. (1):

$$f(\boldsymbol{x}_1^{\mathrm{T}}\boldsymbol{S}^{[1:k]}\boldsymbol{T}^{[1:k]}\boldsymbol{x}_2 + \boldsymbol{V}\begin{bmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{bmatrix} + \boldsymbol{b})$$

where $\boldsymbol{S}^{[1:k]} \in \mathbb{R}^{n\times m\times k}, \boldsymbol{T}^{[1:k]} \in \mathbb{R}^{m\times n\times k}$. When $m \ll n$, the NTN-SMD model drastically reduces the number of parameters compared to the original NTN model; i.e., from $(n^2+2n+1)k$ to $(2mn+2n+1)k$.

4.2 NTNs with Diagonal Slice Matrices

In this paper, we introduce two new NTN models: NTN-Diag and NTN-Comp, both of which reduce the number of parameters in a 3D tensor more than NTN-SMD with little loss in the model's generalization performance. Table 1 summarizes the number of parameters in each model.

NTN-Diag

We replace all slice matrices $\boldsymbol{W}^{[i]}$ of $\boldsymbol{W}^{[1:k]}$ with the triple inner product formulation of Eq. (2) by assuming that they are symmetric and commuting. As a result, we derive the following new NTN formulation:

$$f\left(\begin{bmatrix} \langle \boldsymbol{x}_1, \boldsymbol{w}^{[1]}, \boldsymbol{x}_2 \rangle \\ \vdots \\ \langle \boldsymbol{x}_1, \boldsymbol{w}^{[k]}, \boldsymbol{x}_2 \rangle \end{bmatrix} + \boldsymbol{V} \begin{bmatrix} \boldsymbol{x}_1 \\ \boldsymbol{x}_2 \end{bmatrix} + \boldsymbol{b}\right)$$

where $\boldsymbol{w}^{[i]} \in \mathbb{R}^n, \forall i \in \{1, 2, \ldots, k\}$. Thus, under the symmetric and commuting matrix constraints, we regard mapping by a 3D tensor as an array of k triple inner products. The total number of parameters is just $(3n + 1)k$.

NTN-Comp

By assuming that $\boldsymbol{W}^{[1]}, \ldots, \boldsymbol{W}^{[i]}, \ldots, \boldsymbol{W}^{[k]}$ are real parts of normal matrices forming a commuting family, we can replace each slice matrix of a tensor term in NTN with the triple Hermitian inner product shown in Eq. (3):

$$f\left(\begin{bmatrix} \Re\left(\langle \boldsymbol{x}_1, \boldsymbol{w}^{[1]}, \overline{\boldsymbol{x}_2} \rangle\right) \\ \vdots \\ \Re\left(\langle \boldsymbol{x}_1, \boldsymbol{w}^{[k]}, \overline{\boldsymbol{x}_2} \rangle\right) \end{bmatrix} + \Re\left(\boldsymbol{V} \begin{bmatrix} \boldsymbol{x}_1 \\ \boldsymbol{x}_2 \end{bmatrix}\right) + \boldsymbol{b}\right)$$

where $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathbb{C}^n$, $\boldsymbol{V} \in \mathbb{C}^{n \times n}$ and $\boldsymbol{w}^{[i]} \in \mathbb{C}^n$, $\forall i \in \{1, 2, \ldots, k\}$. Similar to NTN-Diag, we regard mapping by a 3D tensor as an array of k triple Hermitian inner products. The total number of parameters is just $(6n + 1)k$. As is clear of its form, NTN-Diag is a special case of NTN-Comp whose vectors $\boldsymbol{x}_1$, $\boldsymbol{x}_2$ and $\boldsymbol{w}^{[i]}$ are constrained to be real.

4.3 Recursive Neural Tensor Networks

We extend the above NTN models to handle compositional structures. As a representative of compositional structures, we consider a binary tree where each NTN layer computes a vector representation for a node by combining two vectors from its child nodes in the lower layer. Except for NTN-Comp, the models implement mappings $\mathbb{R}^n \to \mathbb{R}^k$ so that each of their layers can receive its lower layer's output directly, if k equals to n. Thus, the models do not have to be modified for them. However, NTN-Comp cannot receive its lower layer's output as it is because NTN-Comp is a mapping from $\mathbb{C}^n$ to $\mathbb{R}^k$. To solve this problem, we set k to $2n$ and treat the output $\boldsymbol{y}' \in \mathbb{R}^{2n}$ as the concatenation of vectors representing the real and imaginary parts of $\boldsymbol{y} \in \mathbb{C}^n$:

$$\Re(\boldsymbol{y}) = (y'_1, \cdots, y'_n),\ \Im(\boldsymbol{y}) = (y'_{n+1}, \cdots, y'_{2n}).$$

Note that this approach is valid since Eq. (3) can actually be defined in real vector space by transforming the complex vectors in $\mathbb{C}^n$ into real vectors in $\mathbb{R}^{2n}$.

5 Related Work

Knowledge Graph Completion

In KGC, researchers usually design scoring function Φ for the given triplet (s, r, o) to judge whether it is a fact or not. Here (s, r, o) denotes that entity s is linked to entity o by relation r. RESCAL (Nickel et al., 2011) uses $\boldsymbol{e}_s^{\mathrm{T}} \boldsymbol{W}_r \boldsymbol{e}_o$ as Φ, where $\boldsymbol{e}_s, \boldsymbol{e}_o$ are entity embedding vectors and $\boldsymbol{W}_r$ is an embedding matrix of relation r. This bilinear operation is effective for the task, but its computational cost is high and it suffers from overfitting. To overcome these problems, DistMult (Yang et al., 2015) adopts the triple inner product $\langle \boldsymbol{e}_s, \boldsymbol{w}_r, \boldsymbol{e}_o \rangle$ as Φ, where $\boldsymbol{w}_r$ is an embedding vector of relation r. This solves those problems, but it degrades the model's ability to capture directionality of relations, because the scoring function of DistMult is symmetric with respect to s and o; i.e., $\langle \boldsymbol{e}_s, \boldsymbol{w}_r, \boldsymbol{e}_o \rangle = \langle \boldsymbol{e}_o, \boldsymbol{w}_r, \boldsymbol{e}_s \rangle$. To reconcile the complexity and expressiveness of a model, ComplEx (Trouillon et al., 2016) uses complex vectors for entity and relation embeddings. As scoring function Φ, they adopted the triple Hermitian inner product $\Re\left(\langle \boldsymbol{e}_s, \boldsymbol{w}_r, \overline{\boldsymbol{e}_o} \rangle\right)$, where $\overline{\boldsymbol{e}_o}$ denotes the complex conjugate of $\boldsymbol{e}_o$. Since $\Re\left(\langle \boldsymbol{e}_s, \boldsymbol{w}_r, \overline{\boldsymbol{e}_o} \rangle\right) \neq \Re\left(\langle \boldsymbol{e}_o, \boldsymbol{w}_r, \overline{\boldsymbol{e}_s} \rangle\right)$, ComplEx solves the expressiveness problem of DistMult without full matrices as relation embeddings. We can regard DistMult as a special case of RESCAL with a symmetric matrix constraint on $\boldsymbol{W}_r$. ComplEx is also a RESCAL variant with $\boldsymbol{W}_r$ as the real part of a normal matrix. Our research is based on these works, but to the best of our knowledge, no previous work applied this ap-

proach to reduce the number of parameters in a tensor.

NN Architectures

To give additional expressiveness power to standard (R)NNs, many architectures have been proposed, such as LSTM (Hochreiter and Schmidhuber, 1997), GRU (Cho et al., 2014), and CNN (LeCun et al., 1998). NTN (Socher et al., 2013a) and RNTN (Socher et al., 2013b) are other such architectures. However, (R)NTNs differ in that they only add 3D tensor mapping to standard neural networks. Thus, they can also be regarded as a powerful basic component of NNs because 3D tensor mapping can be applied to more complicated architectures such as those examples.

Parameter Reduction in NN

Several researchers reduced the number of parameters of NNs by using specific parameter sharing mechanisms. Cheng et al. (2015) used circulant matrix mapping instead of conventional linear mapping and improved the time complexity of the matrix-vector product by using Fast Fourier Transformation (FFT). Circulant matrix

$$C(\boldsymbol{w}) = \begin{bmatrix} w_1 & w_n & \dots & w_3 & w_2 \\ w_2 & w_1 & \dots & w_4 & w_3 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ w_{n-1} & w_{n-2} & \dots & w_1 & w_n \\ w_n & w_{n-1} & \dots & w_2 & w_1 \end{bmatrix}$$

for $\boldsymbol{w}^{\mathrm{T}} = (w_1, \dots, w_n)$ can be factorized into $\mathfrak{F}^{-1}\,\mathrm{diag}(\mathfrak{F}\,\boldsymbol{w})\,\mathfrak{F}$ with the Fourier matrix $\mathfrak{F}$. By assuming each slice matrix $\boldsymbol{W}^{[i]}$ of $\boldsymbol{W}^{[1:k]}$ is circulant, we get the same scoring function as that in Eq. (3); $\boldsymbol{x}_1^{\mathrm{T}}\boldsymbol{W}^{[i]}\boldsymbol{x}_2 = \boldsymbol{x}_1^{\mathrm{T}}\,\mathfrak{F}^{-1}\,\mathrm{diag}(\mathfrak{F}\,\boldsymbol{w}^{[i]})\,\mathfrak{F}\,\boldsymbol{x}_2 = \Re(\langle \boldsymbol{x}_1', \boldsymbol{w}^{[i]\prime}, \overline{\boldsymbol{x}_2}' \rangle)$ where $\boldsymbol{x}_1' = \overline{\mathfrak{F}\,\boldsymbol{x}_1}$, $\boldsymbol{x}_2' = \overline{\mathfrak{F}\,\boldsymbol{x}_2}$, and $\boldsymbol{w}^{[i]\prime} = \frac{1}{n}\,\mathrm{diag}(\mathfrak{F}\,\boldsymbol{w}^{[i]})$ are complex vectors in $\mathbb{C}^n$. In this sense, NTN-Comp is equivalent to NTN where slice matrices of the 3D tensor are restricted to be circulant. Hayashi and Shimbo (2017) established a more detailed proof of the equivalence. Lu et al. (2016) employed a Toeplitz-like structured matrix, reducing parameters of LSTM. Chen et al. (2015) used a feature hashing technique to reduce parameters in RNN. Although these techniques can also be extended to reduce the number of tensor-related parameters in NTN, the former needs FFT operations; i.e., $O(n \log n)$ computation time, and the latter's contribution is only a reduction in memory consumption.

6 Experiment

6.1 Knowledge Graph Completion

To evaluate their performance for link prediction on knowledge graphs, we compared our proposed methods (NTN-Diag and NTN-Comp) to baseline methods (NTN (Socher et al., 2013a) and NTN-SMD).

Task

Let $\mathcal{E}$ and $\mathcal{R}$ denote entities and relations, respectively. A *relational triplet*, or simply a *triplet*, (s, r, o) is a triple with $s, o \in \mathcal{E}$ and $r \in \mathcal{R}$. It represents a proposition that relation r holds between subject entity s and object entity o. A triplet is called a fact if the proposition it denote is true. A *knowledge graph* is a collection of knowledge triplets, with the understanding that all its member triplets are facts. It is called a graph because each triplet can be regarded as an edge in a directed graph; the vertices in this graph represent entities in $\mathcal{E}$, and each edge is labeled by a relation in $\mathcal{R}$. Let $\mathcal{G}$ be a knowledge graph, viewed as a collection of facts. *Knowledge graph completion* (KGC) is the task of predicting whether unknown triplet $(s', r', o') \notin \mathcal{G}$ such that $s', o' \in \mathcal{E}, r' \in \mathcal{R}$ is a fact or not.

Models and Loss Function

The standard approach to KGC is to design a score function $\Phi : \mathcal{E} \times \mathcal{R} \times \mathcal{E} \to \mathbb{R}$ that assigns a large value when a triplet seems to be a fact. Socher et al. (2013a) defined it as follows.

$$\boldsymbol{u}_r^{\mathrm{T}} f\left(\boldsymbol{e}_s^{\mathrm{T}}\boldsymbol{W}_r^{[1:k]}\boldsymbol{e}_o + \boldsymbol{V}_r \begin{bmatrix} \boldsymbol{e}_s \\ \boldsymbol{e}_o \end{bmatrix} + \boldsymbol{b}_r\right)$$

Here, $\boldsymbol{e}_s, \boldsymbol{e}_o \in \mathbb{R}^n$ are entity embeddings and $\boldsymbol{W}_r, \boldsymbol{V}_r, \boldsymbol{b}_r, \boldsymbol{u}_r$ are parameters for each relation r. $\boldsymbol{u}_r$ is a k-dimensional vector to map f's output $\mathbb{R}^k$ to $\mathbb{R}$ which indicates a score. f is the hyperbolic tangent. To compare the performances of the baselines and proposed models, we change the mapping before an activation. For NTN-SMD, we change term $\boldsymbol{e}_s^{\mathrm{T}}\boldsymbol{W}_r^{[1:k]}\boldsymbol{e}_o$ to $\boldsymbol{e}_s^{\mathrm{T}}\boldsymbol{S}_r^{[1:k]}\boldsymbol{T}_r^{[1:k]}\boldsymbol{e}_o$. To apply NTN-Diag and NTN-Comp in this model,

Table 3: Mean Reciprocal Rank (MRR) and Hits@n for the models tested on WN18 and FB15k. MRR is reported in the raw and filtered settings. Hits@n metrics are percentages of test examples that lie in the top n ranked results. We report Hits@n in the filtered setting. *Results are those in (Trouillon et al., 2016)

we assume all slice matrices of tensors among relations form a commuting family. The loss function used to train the models is shown below:

$$\sum_{i=1}^{N}\sum_{c=1}^{C}\max\left(0, 1-\Phi\left(T^{(i)}\right)+\Phi\left(T_c^{(i)}\right)\right) + \lambda\|\mathbf{\Omega}\|_2^2,$$

where $\lambda\|\mathbf{\Omega}\|_2^2$ is an L2 regularization term, $T^{(i)}$ denotes the i-th example of training data of size N, and $T_c^{(i)}$ is one of C randomly sampled negative examples for the i-th training example. We generated negative samples of a triplet (s, r, o) by corrupting its subject or object entity.

Experimental Setup

We used the Wordnet (WN18) and Freebase (FB15k) datasets to verify the benefits of our proposed methods. The dataset statistics are given in Table 2. We selected hyper-parameters based on Socher et al. (2013a) and Yang et al. (2015): For all of the models, the size of mini-batches was set to 1000, the dimensionality of the entity vector to $d = 100$, and the regularization parameter to 0.0001; the tensor slice size was set to $k = 4$ for all models, except NTN for which we also tested with $k = 1$ to see the influence of the slice size on the performance. We performed 300 epochs of training for Wordnet and 100 on Freebase using Adagrad (Duchi et al., 2011) with the initial learning rate set to 0.1.

For evaluation, we removed the subject or object entity of each test example and then replaced it with all the entities in $\mathcal{E}$. We computed the scores of these corrupted triplets and ranked them in descending order of scores. We here report the results collected in filtered and raw settings. In the filtered setting, given test example (s, r, o), we remove from the ranking all the other positive triplets that appear in either training, validation, or test dataset, whereas the raw metrics do not remove these triplets.

Result

Experimental results are shown in Table 3. We observe the following:

- The performance of NN and NTNs differs considerably; Apparently, NN is inadequate for this task.
- By comparing the results of NTNs with different slice sizes, we see that $k = 4$ performs better than $k = 1$.
- NTN-SMDs perform better than NN, but are all inferior to NTNs, although their results improved as m (the rank of decomposed matrices) is increased.
- NTN-Diag achieved better results than NTN, although it has far fewer parameters than NTN and the datasets contain many unsymmetrical triplets. This demonstrates that NTN-Diag solves the overfitting problem of NTN without sacrificing the expressiveness power. NTN-Diag also has fewer parameters than the smallest ($m = 1$) NTN-SMD. Thus,

Conjunctive normal form	$\bigwedge_{i=1}^{m} \bigvee_{j=1}^{n_i} A_{ij}$
Disjunctive normal form	$\bigvee_{i=1}^{m} \bigwedge_{j=1}^{n_i} A_{ij}$

Table 4: Conjunctive and disjunctive normal forms in propositional logic. A_{ij} is a *literal*, which is a propositional variable or its negation. For example, p_1 and $\neg p_2$ are literal, but not $\neg\neg p_3$.

Name	Symbol	Set-theoretic definition
Entailment	$A \sqsubset B$	$A \subset B$
Reverse entailment	$A \sqsupset B$	$A \supset B$
Equivalence	$A \equiv B$	$A = B$
Alternation	$A \mid B$	$A \cap B = \emptyset \wedge A \cup B \neq \mathcal{D}$
Negation	$A \wedge B$	$A \cap B = \emptyset \wedge A \cup B = \mathcal{D}$
Cover	$A \smile B$	$A \cap B \neq \emptyset \wedge A \cup B = \mathcal{D}$
Independence	$A \# B$	else

Table 5: Natural logic relations over formula pairs. A and B denote a formula in propositional logic.

$not\ p_3$	$\wedge$	p_3
p_3	$\sqsubset$	$(p_3\ or\ p_2)$
$(p_1\ or (p_2\ or\ p_4)))$	$\sqsupset$	$(p_2\ and\ not\ p_4)$

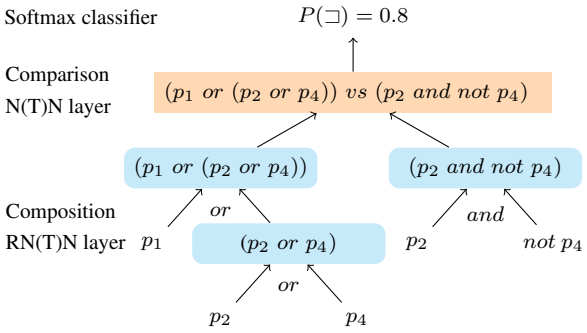

Figure 1: Comparison and composition layers. $not\ p_4$ is treated as an embedding.

we conclude that NTN-Diag is a better alternative of NTN than NTN-SMD is, in terms of both accuracy and computational cost.

- NTN-Comp outperformed NTN-Diag, showing that its flexible constraint on matrices yielded additional expressiveness. However, NTN-Diag and NTN-Comp do not exceed DistMult and ComplEx, respectively, in almost all measures.

Although not shown in the table, in this experiment, NTN-Diag and NTN-Comp was, respectively, 3 and 1.7 times as fast as NTN to train.

6.2 Logical Reasoning

To validate the performance of our proposed models in a recursive neural network setting, we experimentally tested them by having them solve a semantic compositionality problem in logic.

Task

This task definition basically follows Bowman et al. (2015): Given a pair of artificially generated propositional logic formulas, classify the relation between the formulas into one of the seven *basic semantic relations* of natural logic (MacCartney and Manning, 2009). Table 5 shows these seven relation types. The formulas consist of propositional variables, negation, and conjunction and disjunction connectives. Although Bowman et al. (2015) generated formulas with no constraint on its form, we restricted them to disjunctive normal form (DNF) or conjunctive normal form (CNF) (Table 4). Recall that any propositional formula can be transformed into these forms.

Models and Loss Function

Following Bowman et al. (2015), we constructed a model that infers the relations between formula pairs, as described in Table 6.

The model consists of two layers: composition and comparison layers (Figure 1). The composition layer outputs the embeddings of both left and right formulas by recursive neural networks. Subsequently, the comparison layer compares the two embeddings using a single layer neural network, and then a softmax classifier receives its output. In the composition layer, we set different parameters for *and* and *or* operations. As a loss function, we used cross entropy with L2 regularization and apply the NTNs in Section 4 to the comparison layer and uses RNTNs for as the composition layer.

Experimental Setup

In this experiment, an example is a pair of propositional formulas, and its class label is the seven relation types between the pair. We generated examples following the protocol described in Bowman et al. (2015), with the exception that the formulas are restricted to CNF or DNF, as mentioned above. We obtained 62,589 training examples, 13,413 validation examples, and 55,150 test examples. Each formula in the training and validation examples contains up to four logical operators, whereas those in the test examples have

Model	1	2	3	4	5	6	7	8	9	10	11	12	Avg.
Majority class	56.0	53.0	53.4	53.2	55.9	56.5	56.5	57.8	56.5	57.7	56.8	59.9	56.1

RNTN-Comp	99.3	98.1	98.0	96.9	94.3	90.6	86.1	83.5	79.2	76.6	74.5	74.6	87.6

Table 7: Result of logical inference for Tests 1–12. Example in Test n has n logical operators in either or both left and right formulas. Each score is the average accuracy of five trials of the λ that achieved best performance on validation set. "Majority class" denotes the ratio of the majority class (relation "#", i.e., Independence; see Table 5).

Model	Accuracy	(Std. Dev.)
RNN	95.0	(0.8)
RNTN	97.2	(0.4)
RNTN-SMD ($m = 1$)	90.1	(3.4)
RNTN-SMD ($m = 2$)	91.4	(4.6)
RNTN-SMD ($m = 4$)	88.6	(7.1)
RNTN-SMD ($m = 8$)	82.7	(10.2)
RNTN-SMD ($m = 16$)	81.8	(11.7)
RNTN-Diag	98.1	(0.1)
RNTN-Comp	97.5	(0.1)

Table 8: Average accuracy and standard deviation on the validation dataset. The reported values are average over the best-performing model λ in each method.

up to 12 logical operators. Every formula consists of up to four variables taken from six propositional variables that are shared among all the examples. Hyperparameters and optimization are based on Bowman et al. (2015): Embedding size $d = 25$ (for RNN, $d = 45$) and the output size of comparison layer is $k = 75$, and we used AdaDelta (Zeiler, 2012) for an optimizer. We searched for the best coefficient λ of L2 regularization in $\lambda \in \{0.0001, 0.0003, 0.0005, 0.0007, 0.0009, 0.001\}$, whereas Bowman et al. (2015) set λ to 0.001 for RNN and 0.0003 for RNTN.

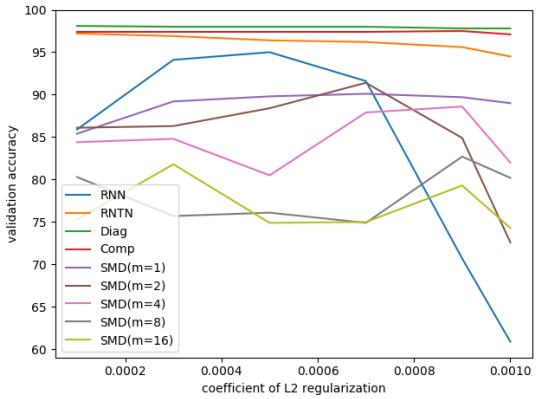
Result

The results are shown in Table 7. From the table, we observe the following:

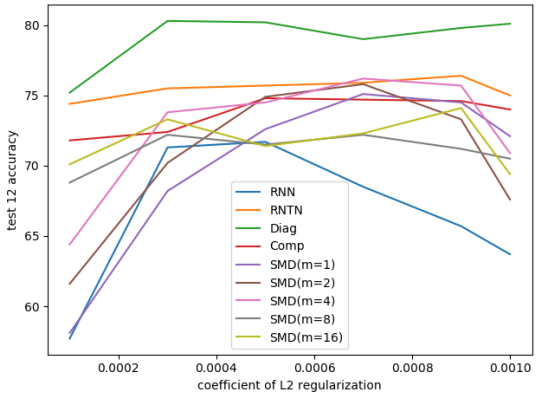
- As with KGC, the large difference in performance between RNN and RNTN suggests that this logical reasoning task requires feature interactions to be captured[1].
- RNTN-Diag achieved the best accuracy except for Tests 2 and 12 and outperformed RNTN except for Test 2. This is not surprising because both *and* and *or* are symmetric: p_1 *and* p_2 equals p_2 *and* p_1. This matches the tensor term in RNTN-Diag which is symmetric with respect to $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$.
- RNTN-Comp was the second best except for Tests 1–3 and 10–12. For all tests, its accuracy was comparable with or superior to that of RNTN.
- RNTN-SMD ($m = 1$) was inferior to RNTN for most test sets, although some good results were observed with $m = 1, 2, 3$ on Tests 11 and 12. Indeed, except for Tests 9–12, RNTN-SMD ($m = 1$) was inferior even to RNN despite the larger number of parameters in RNTN-SMD. RNTN-SMD ($m = 2$) obtained better results than $m = 1$, but it is still worse than RNTN except for Tests 10-12. Further increase in m ($m = 4, 8, 16$) worsened the accuracy despite an increase of the number of parameters.

We also evaluated the stability of the model over different trials and hyperparameters. Table 8 shows the best average accuracy for each compared model (among all the tested λ) on the validation set. The parenthesized figures (on the rightmost column) show the standard deviation over five independent trials used for computing the average, i.e., all five trials used the same λ value that achieved the best average accuracy. We see that RNTN-SMDs have larger standard deviations than

[1] Bowman (2016) also evaluated TreeLSTM, but its advantage over RNN was unclear in their experiment. For that reason, we did not test TreeLSTM in this paper.



(a) Validation set.



(b) Test 12.

Figure 2: Sensitivity of accuracy to λ.

RNTN, RNTN-Diag and RNTN-Comp. This indicates that RNTN-SMD is a less reliable model.

RNTN-SMDs are also unstable, not only within the same λ, but also between different λs. Figure 2 describes how accuracies are impacted by λs. The top graph shows validation accuracies between different λ values. RNTN, RNTN-Diag and RNTN-Comp are stable, whereas RNN and RNTN-SMDs have steep drops. The bottom one describes the accuracies for Test 12. This also shows that RNTN-SMDs are unstable and that RNTN-Diag achieves distinctive performances.

Finally, Figure 3 shows that training times increase quadratically with dimension for RNTN that has $O(n^2k)$ parameters, but not for our methods, which have only $O(nk)$ parameters.

7 Conclusion

We proposed two new parameter reduction methods for tensors in NTNs. The first method constrains the slice matrices to be symmetric, and the second assumes them to be normal matrices. In both methods, the number of a 3D tensor parameters is reduced from $O(n^2k)$ to $O(nk)$ after the constrained matrices are eigendecomposed. By removing the tensor's surplus parameters, our methods learn better and faster as was shown in experiments.[2] Future work will test the versatility of our proposals, RNTN-Diag and RNTN-Comp, in other tasks that deal with data sets exhibiting carious structures.

Abstract

Word vector *specialisation* (also known as *retrofitting*) is a portable, light-weight approach to fine-tuning arbitrary distributional word vector spaces by *injecting* external knowledge from rich lexical resources such as WordNet. By design, these *post-processing* methods only update the vectors of words occurring in external lexicons, leaving the representations of all *unseen* words intact. In this paper, we show that constraint-driven vector space specialisation can be extended to unseen words. We propose a novel *post-specialisation* method that: **a)** preserves the useful linguistic knowledge for seen words; while **b)** propagating this external signal to unseen words in order to improve their vector representations as well. Our post-specialisation approach explicits a non-linear specialisation function in the form of a deep neural network by learning to predict specialised vectors from their original distributional counterparts. The learned function is then used to specialise vectors of unseen words. This approach, applicable to any post-processing model, yields considerable gains over the initial specialisation models both in intrinsic word similarity tasks, and in two downstream tasks: *dialogue state tracking* and *lexical text simplification*. The positive effects persist across three languages, demonstrating the importance of specialising the full vocabulary of distributional word vector spaces.

1 Introduction

Word representation learning is a key research area in current Natural Language Processing (NLP), with its usefulness demonstrated across a range of tasks (Collobert et al., 2011; Chen and Manning, 2014; Melamud et al., 2016b). The standard techniques for inducing distributed word representations are grounded in the distributional hypothesis (Harris, 1954): they rely on co-occurrence information in large textual corpora (Mikolov et al., 2013b; Pennington et al., 2014; Levy and Goldberg, 2014; Levy et al., 2015; Bojanowski et al., 2017). As a result, these models tend to coalesce the notions of semantic similarity and (broader) conceptual relatedness, and cannot accurately distinguish antonyms from synonyms (Hill et al., 2015; Schwartz et al., 2015). Recently, we have witnessed a rise of interest in representation models that move beyond stand-alone unsupervised learning: they leverage external knowledge in human- and automatically-constructed lexical resources to enrich the semantic content of distributional word vectors, in a process termed *semantic specialisation*.

This is often done as a post-processing (sometimes referred to as *retrofitting*) step: input word vectors are *fine-tuned* to satisfy linguistic constraints extracted from lexical resources such as WordNet or BabelNet (Faruqui et al., 2015; Mrkšić et al., 2017). The use of external curated knowledge yields improved word vectors for the benefit of downstream applications (Faruqui, 2016). At the same time, this specialisation of the distributional space distinguishes between true similarity and relatedness, and supports language understanding tasks (Kiela et al., 2015; Mrkšić et al., 2017).

While there is consensus regarding their benefits and ease of use, one property of the post-processing specialisation methods slips under the radar: most existing post-processors update word embeddings only for words which are present (i.e., *seen*) in the external constraints, while vectors of all other (i.e., *unseen*) words remain unaffected. In this work, we propose a new approach that extends the specialisation framework to unseen words, relying on the transformation of the vector (sub)space of seen words. Our intuition is that the process of fine-tuning seen words provides implicit information on how to leverage the external knowledge to unseen words. The method should preserve the already injected knowledge for seen words, simultaneously

Proceedings of NAACL-HLT 2018, pages 516–527
New Orleans, Louisiana, June 1 - 6, 2018.

propagating the external signal to unseen words in order to improve their vectors.

The proposed *post-specialisation* method can be seen as a two-step process, illustrated in Fig. 1a: **1)** We use a state-of-the-art specialisation model to transform the subspace of seen words from the input distributional space into the specialised subspace; **2)** We learn a mapping function based on the transformation of the "seen subspace", and then apply it to the distributional subspace of unseen words. We allow the proposed post-specialisation model to learn from large external linguistic resources by implementing the mapping as a deep feed-forward neural network with non-linear activations. This allows the model to learn the generalisation of the fine-tuning steps taken by the initial specialisation model, itself based on a very large number (e.g., hundreds of thousands) of external linguistic constraints.

As indicated by the results on word similarity and two downstream tasks (dialogue state tracking and lexical text simplification) our post-specialisation method consistently outperforms state-of-the-art methods which specialise seen words only. We report improvements using three distinct input vector spaces for English and for three test languages (English, German, Italian), verifying the robustness of our approach.

2 Related Work and Motivation

Vector Space Specialisation A standard approach to incorporating external and background knowledge into word vector spaces is to pull the representations of similar words closer together and to push words in undesirable relations (e.g., antonyms) away from each other. Some models integrate such constraints into the training procedure and *jointly* optimize distributional and non-distributional objectives: they modify the prior or the regularisation (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Kiela et al., 2015), or use a variant of the SGNS-style objective (Liu et al., 2015; Ono et al., 2015; Osborne et al., 2016; Nguyen et al., 2017). In theory, word embeddings obtained by these joint models could be as good as representations produced by models which fine-tune input vector space. However, their performance falls behind that of fine-tuning methods (Wieting et al., 2015). Another disadvantage is that their architecture is tied to a specific underlying model (typically `word2vec` models).

In contrast, fine-tuning models inject external knowledge from available lexical resources (e.g., WordNet, PPDB) into pre-trained word vectors as a *post-processing step* (Faruqui et al., 2015; Rothe and Schütze, 2015; Wieting et al., 2015; Nguyen et al., 2016; Mrkšić et al., 2016; Cotterell et al., 2016; Mrkšić et al., 2017). Such post-processing models are popular because they offer a portable, flexible, and light-weight approach to incorporating external knowledge into *arbitrary* vector spaces, yielding state-of-the-art results on language understanding tasks (Faruqui et al., 2015; Mrkšić et al., 2016; Kim et al., 2016; Vulić et al., 2017b).

Existing post-processing models, however, suffer from a major limitation. Their *modus operandi* is to enrich the distributional information with external knowledge only if such knowledge is present in a lexical resource. This means that they update and improve only representations of words actually seen in external resources. Because such words constitute only a fraction of the whole vocabulary (see Sect. 4), most words, unseen in the constraints, retain their original vectors. The main goal of this work is to address this shortcoming by specialising *all* words from the initial distributional space.

3 Methodology: Post-Specialisation

Our starting point is the state-of-the-art specialisation model ATTRACT-REPEL (AR) (Mrkšić et al., 2017), outlined in Sect. 3.1. We opt for the AR model due to its strong performance and ease of use, but we note that the proposed post-specialisation approach for specialising unseen words, described in Sect. 3.2, is applicable to any post-processor, as empirically validated in Sect. 5.

3.1 Initial Specialisation Model: AR

Let $\mathcal{V}_s$ be the vocabulary, A the set of synonymous ATTRACT word pairs (e.g., *rich* and *wealthy*), and R the set of antonymous REPEL word pairs (e.g., *increase* and *decrease*). The ATTRACT-REPEL procedure operates over mini-batches of such pairs $\mathcal{B}_A$ and $\mathcal{B}_R$. Let each word pair (x_l, x_r) in these sets correspond to a vector pair $(\mathbf{x}_l, \mathbf{x}_r)$. A mini-batch of b_{att} attract word pairs is given by $\mathcal{B}_A = [(\mathbf{x}_l^1, \mathbf{x}_r^1), \ldots, (\mathbf{x}_l^{k_1}, \mathbf{x}_r^{k_1})]$ (analogously for $\mathcal{B}_R$, which consists of b_{rep} pairs).

Next, the sets of negative examples $T_A = [(\mathbf{t}_l^1, \mathbf{t}_r^1), \ldots, (\mathbf{t}_l^{k_1}, \mathbf{t}_r^{k_1})]$ and $T_R = [(\mathbf{t}_l^1, \mathbf{t}_r^1), \ldots, (\mathbf{t}_l^{k_2}, \mathbf{t}_r^{k_2})]$ are defined as pairs of *negative examples* for each A and R

pair in mini-batches $\mathcal{B}_A$ and $\mathcal{B}_R$. These negative examples are chosen from the word vectors present in $\mathcal{B}_A$ or $\mathcal{B}_R$ so that, for each A pair $(\mathbf{x}_l, \mathbf{x}_r)$, the negative example pair $(\mathbf{t}_l, \mathbf{t}_r)$ is chosen so that $\mathbf{t}_l$ is the vector closest (in terms of cosine distance) to $\mathbf{x}_l$ and $\mathbf{t}_r$ is closest to $\mathbf{x}_r$.[1] The negatives are used **1)** to force A pairs to be closer to each other than to their respective negative examples; and **2)** to force R pairs to be further away from each other than from their negative examples. The first term of the cost function pulls A pairs together:

$$Att(\mathcal{B}_A, T_A) = \sum_{i=1}^{b_{att}} [\, \tau\left(\delta_{att} + \mathbf{x}_l^i \mathbf{t}_l^i - \mathbf{x}_l^i \mathbf{x}_r^i\right) + \tau\left(\delta_{att} + \mathbf{x}_r^i \mathbf{t}_r^i - \mathbf{x}_l^i \mathbf{x}_r^i\right)] \quad (1)$$

where $\tau(z) = \max(0, z)$ is the standard rectifier function (Nair and Hinton, 2010) and δ_{att} is the attract margin: it determines how much closer these vectors should be to each other than to their respective negative examples. The second, REPEL term in the cost function is analogous: it pushes R word pairs away from each other by the margin δ_{rep}.

Finally, in addition to the A and R terms, a regularisation term is used to preserve the semantic content originally present in the distributional vector space, as long as this information does not contradict the injected external knowledge. Let $\mathcal{V}(\mathcal{B})$ be the set of all word vectors present in a mini-batch, the distributional regularisation term is then:

$$Reg(\mathcal{B}_A, \mathcal{B}_R) = \sum_{\mathbf{x}_i \in V(\mathcal{B}_A \cup \mathcal{B}_R)} \lambda_{reg} \left\| \widehat{\mathbf{x}}_i - \mathbf{x}_i \right\|_2 \quad (2)$$

where λ_{reg} is the L_2-regularisation constant and $\widehat{\mathbf{x}}_i$ denotes the original (distributional) word vector for word x_i. The full ATTRACT-REPEL cost function is finally constructed as the sum of all three terms.

3.2 Specialisation of Unseen Words

Problem Formulation The goal is to learn a *global transformation function* that generalises the perturbations of the initial vector space made by ATTRACT-REPEL (or any other specialisation procedure), as conditioned on the external constraints. The learned function propagates the signal coded in the input constraints to all the words unseen during the specialisation process. We seek a regression function $f : \mathbb{R}^{dim} \rightarrow \mathbb{R}^{dim}$, where dim is the vector space dimensionality. It maps word vectors from the initial vector space $\mathbf{X}$ to the specialised target space $\mathbf{X}'$. Let $\widehat{\mathbf{X}'} = f(\mathbf{X})$ refer to the predicted mapping of the vector space, while the mapping of a single word vector is denoted $\widehat{\mathbf{x}'_i} = f(\mathbf{x}_i)$.

An input distributional vector space $\mathbf{X}_d$ represents words from a vocabulary $\mathcal{V}_d$. $\mathcal{V}_d$ may be divided into two vocabulary subsets: $\mathcal{V}_d = \mathcal{V}_s \cup \mathcal{V}_u$, $\mathcal{V}_s \cap \mathcal{V}_u = \emptyset$, with the accompanying vector subspaces $\mathbf{X}_d = \mathbf{X}_s \sqcup \mathbf{X}_u$. $\mathcal{V}_s$ refers to the vocabulary of seen words: those that appear in the external linguistic constraints and have their embeddings changed in the specialisation process. $\mathcal{V}_u$ denotes the vocabulary of unseen words: those not present in the constraints and whose embeddings are unaffected by the specialisation procedure.

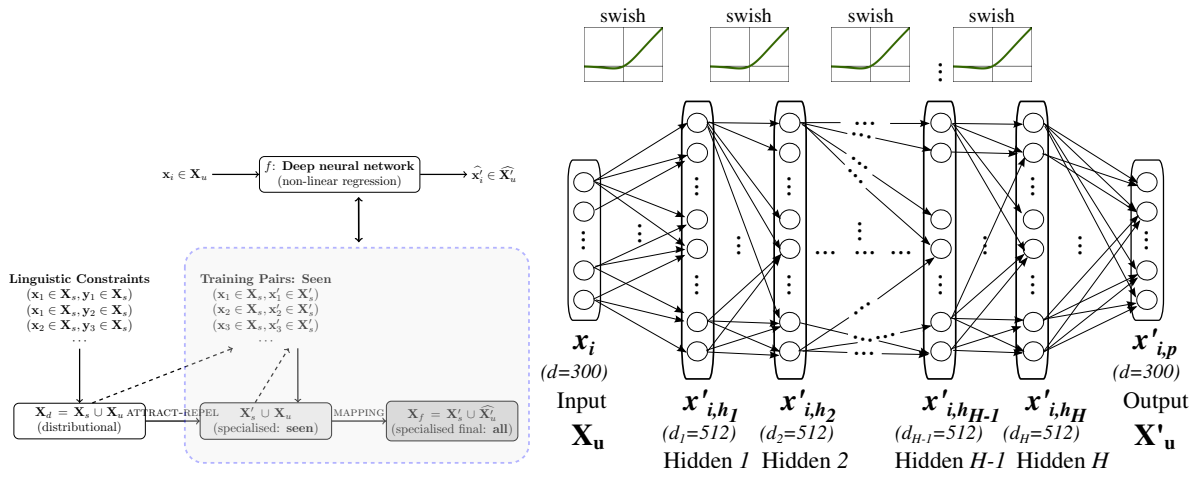
The AR specialisation process transforms only the subspace $\mathbf{X}_s$ into the specialised subspace $\mathbf{X}'_s$. All words $x_i \in \mathcal{V}_s$ may now be used as training examples for learning the explicit mapping function f from $\mathbf{X}_s$ into $\mathbf{X}'_s$. If $N = |\mathcal{V}_s|$, we in fact rely on N training pairs: $(\mathbf{x}_i, \mathbf{x}'_i) = \{\mathbf{x}_i \in \mathbf{X}_s, \mathbf{x}'_i \in \mathbf{X}'_s\}$. Function f can then be applied to unseen words $x \in \mathcal{V}_u$ to yield the specialised subspace $\widehat{\mathbf{X}'_u} = f(\mathbf{X}_u)$. The specialised space containing *all* words is then $\mathbf{X}_f = \mathbf{X}'_s \cup \widehat{\mathbf{X}'_u}$. The complete high-level post-specialisation procedure is outlined in Fig. 1a.

Note that another variant of the approach could obtain $\mathbf{X}_f$ as $\mathbf{X}_f = f(\mathbf{X}_d)$, that is, the entire distributional space is transformed by f. However, this variant seems counter-intuitive as it forgets the actual output of the initial specialisation procedure and replaces word vectors from $\mathbf{X}'_s$ with their approximations, i.e., f-mapped vectors.[2]

Objective Functions As mentioned, the N *seen* words $x_i \in \mathcal{V}_s$ in fact serve as our "pseudo-translation" pairs supporting the learning of a cross-space mapping function. In practice, in its high-level formulation, our mapping problem is equivalent to those encountered in the literature on cross-lingual word embeddings where the goal is to learn a shared cross-lingual space given monolingual vector spaces in two languages and N_1 translation pairs (Mikolov et al., 2013a; Lazaridou et al., 2015; Vulić and Korhonen, 2016b; Artetxe et al., 2016, 2017; Conneau et al., 2017; Ruder et al., 2017). In our setup, the standard objective based on L_2-penalised

[1] Similarly, for each R pair $(\mathbf{x}_l, \mathbf{x}_r)$, the negative pair $(\mathbf{t}_l, \mathbf{t}_r)$ is chosen from the in-batch vectors so that $\mathbf{t}_l$ is the vector furthest away from $\mathbf{x}_l$ and $\mathbf{t}_r$ is furthest from $\mathbf{x}_r$. All vectors are unit length (re)normalised after each epoch.

[2] We have empirically confirmed the intuition that the first variant is superior to this alternative. We do not report the actual quantitative comparison for brevity.



(a) High-level **illustration** (b) Low-level **implementation**: deep feed-forward neural network

Figure 1: **(a)** High-level illustration of the post-specialisation approach: the subspace $\mathbf{X}_s$ of the initial distributional vector space $\mathbf{X}_d = \mathbf{X}_s \cup \mathbf{X}_u$ is first specialised/fine-tuned by the ATTRACT-REPEL specialisation model (or any other post-processing model) to obtain the transformed subspace $\mathbf{X}'_s$. The words present (i.e., *seen*) in the input set of linguistic constraints are now assigned different representations in $\mathbf{X}_s$ (the original distributional vector) and $\mathbf{X}'_s$ (the specialised vector): they are therefore used as training examples to learn a non-linear cross-space mapping function. This function is then applied to all word vectors $\mathbf{x}_i \in \mathbf{X}_u$ representing words *unseen* in the constraints to yield a specialised subspace $\widehat{\mathbf{X}'_u}$. The final space is $\mathbf{X}_f = \mathbf{X}'_s \cup \widehat{\mathbf{X}'_u}$, and it contains transformed representations for *all* words from the initial space $\mathbf{X}_d$. **(b)** The actual implementation of the non-linear regression function which maps from $\mathbf{X}_u$ to $\widehat{\mathbf{X}'_u}$: a deep feed-forward fully-connected neural net with non-linearities and H hidden layers.

least squares may be formulated as follows:

$$f_{\text{MSE}} = \arg\min ||f(\mathbf{X}_s) - \mathbf{X}'_s||_F^2 \quad (3)$$

where $||\cdot||_F^2$ denotes the squared Frobenius norm. In the most common form $f(\mathbf{X}_s)$ is simply a linear map/matrix $\mathbf{W}_f \in \mathbb{R}^{dim \times dim}$ (Mikolov et al., 2013a) as follows: $f(\mathbf{X}) = \mathbf{W}_f\mathbf{X}$.

After learning f based on the $\mathbf{X}_s \rightarrow \mathbf{X}'_s$ transformation, one can simply apply f to unseen words: $\widehat{\mathbf{X}'_u} = f(\mathbf{X}_u)$. This linear mapping model, termed LINEAR-MSE, has an analytical solution (Artetxe et al., 2016), and has been proven to work well with cross-lingual embeddings. However, given that the specialisation model injects hundreds of thousands (or even millions) of linguistic constraints into the distributional space (see later in Sect. 4), we suspect that the assumption of linearity is too limiting and does not fully hold in this particular setup.

Using the same L_2-penalized least squares objective, we can thus replace the linear map with a *non-linear* function $f : \mathbb{R}^{dim} \rightarrow \mathbb{R}^{dim}$. The non-linear mapping, illustrated by Fig. 1b, is implemented as a deep feed-forward fully-connected neural network (DFFN) with H hidden layers and non-linear activations. This variant is called NONLINEAR-MSE.

Another variant objective is the contrastive margin-based ranking loss with negative sampling (MM) similar to the original ATTRACT-REPEL objective, used in other applications in prior work (e.g., for cross-modal mapping) (Weston et al., 2011; Frome et al., 2013; Lazaridou et al., 2015; Kummerfeld et al., 2015). Let $\widehat{\mathbf{x}'_i} = f(\mathbf{x_i})$ denote the predicted vector for the word $x_i \in \mathcal{V}_s$, and let $\mathbf{x}'_i$ refer to the "true" vector of x_i in the specialised space $\mathbf{X}'_s$ after the AR specialisation procedure. The MM loss is then defined as follows:

$$J_{\text{MM}} = \sum_{i=1}^{N}\sum_{j\neq i}^{k} \tau\Big(\delta_{mm} - cos\big(\widehat{\mathbf{x}'_i}, \mathbf{x}'_i\big) + cos\big(\widehat{\mathbf{x}'_i}, \mathbf{x}'_j\big)\Big)$$

where cos is the cosine similarity measure, δ_{mm} is the margin, and k is the number of negative samples. The objective tries to learn the mapping f so that each predicted vector $\widehat{\mathbf{x}'_i}$ is by the specified margin δ_{mm} closer to the correct target vector $\mathbf{x}'_i$ than to any other of k target vectors $\mathbf{x}'_j$ serving as negative examples.[3] Function f can again be either a simple linear map (LINEAR-MM), or implemented as a DFFN (NONLINEAR-MM, see Fig. 1b).

[3]We have also experimented with a simpler *hinge loss* function without negative examples, formulated as $J =$

4 Experimental Setup

Starting Word Embeddings ($\mathbf{X}_d = \mathbf{X}_s \cup \mathbf{X}_u$) To test the robustness of our approach, we experiment with three well-known, publicly available collections of English word vectors: **1)** Skip-Gram with Negative Sampling (SGNS-BOW2) (Mikolov et al., 2013b) trained on the Polyglot Wikipedia (Al-Rfou et al., 2013) by Levy and Goldberg (2014) using bag-of-words windows of size 2; **2)** GLOVE Common Crawl (Pennington et al., 2014); and **3)** FASTTEXT (Bojanowski et al., 2017), a SGNS variant which builds word vectors as the sum of their constituent character n-gram vectors. All word embeddings are 300-dimensional.[4]

AR Specialisation and Constraints ($\mathbf{X}_s \rightarrow \mathbf{X}'_s$) We experiment with linguistic constraints used before by (Mrkšić et al., 2017; Vulić et al., 2017a): they extracted monolingual synonymy/ATTRACT pairs from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013; Pavlick et al., 2015) (640,435 synonymy pairs in total), while their antonymy/REPEL constraints came from BabelNet (Navigli and Ponzetto, 2012) (11,939 pairs).[5]

The coverage of $\mathcal{V}_d$ vocabulary words in the constraints illustrates well the problem of unseen words with the fine-tuning specialisation models. For instance, the constraints cover only a small subset of the entire vocabulary $\mathcal{V}_d$ for SGNS-BOW2: 16.6%. They also cover only 15.3% of the top 200K most frequent $\mathcal{V}_d$ words from FASTTEXT.

Network Design and Parameters ($\mathbf{X}_u \rightarrow \widehat{\mathbf{X}'_u}$) The non-linear regression function $f : \mathbb{R}^d \rightarrow \mathbb{R}^d$ is a DFFN with H hidden layers, each of dimensionality $d_1 = d_2 = \ldots = d_H = 512$ (see Fig. 1b). Non-linear activations are used in each layer and omitted only before the final output layer to enable full-range predictions (see Fig. 1b again).

The choices of non-linear activation and initialisation are guided by recent recommendations from the literature. First, we use *swish* (Ramachandran et al., 2017; Elfwing et al., 2017) as non-linearity, defined as $swish(x) = x \cdot \text{sigmoid}(\beta x)$. We fix $\beta = 1$ as suggested by Ramachandran et al. (2017).[6] Second, we use the HE normal initialisation (He et al., 2015), which is preferred over the XAVIER initialisation (Glorot and Bengio, 2010) for deep models (Mishkin and Matas, 2016; Li et al., 2016), although in our experiments we do not observe a significant difference in performance between the two alternatives. We set $H = 5$ in all experiments without any fine-tuning; we also analyse the impact of the network depth in Sect. 5.

Optimisation For the AR specialisation step, we adopt the original suggested model setup. Hyperparameter values are set to: $\delta_{att} = 0.6$, $\delta_{rep} = 0.0$, $\lambda_{reg} = 10^{-9}$ (Mrkšić et al., 2017). The models are trained for 5 epochs with Adagrad (Duchi et al., 2011), with batch sizes set to $b_{att} = b_{rep} = 50$, again as in the original work.

For training the non-linear mapping with DFFN (Fig. 1b), we use the Adam algorithm (Kingma and Ba, 2015) with default settings. The model is trained for 100 epochs with early stopping on a validation set. We reserve 10% of all available seen data (i.e., the words from $\mathcal{V}_s$ represented in $\mathbf{X}_s$ and $\mathbf{X}'_s$) for validation, the rest are used for training. For the MM objective, we set $\delta_{mm} = 0.6$ and $k = 25$ in all experiments without any fine-tuning.

5 Results and Discussion

5.1 Intrinsic Evaluation: Word Similarity

Evaluation Protocol The first set of experiments evaluates vector spaces with different specialisation procedures intrinsically on word similarity benchmarks: we use the SimLex-999 dataset (Hill et al., 2015), and SimVerb-3500 (Gerz et al., 2016), a recent verb pair similarity dataset providing similarity ratings for 3,500 verb pairs.[7] Spearman's ρ

$\sum_{i=1}^{N} \tau\left(\delta_{mm} - cos(\widehat{\mathbf{x}'_i}, \mathbf{x}'_i)\right)$. For instance, with $\delta_{mm} = 1.0$ the idea is to learn a mapping f that, for each x_i enforces the predicted vector and the correct target vector to have a maximum cosine similarity. We do not report the results with this variant as, although it outscores the MSE-style objective, it was consistently outperformed by the MM objective.

[4] For further details regarding the architectures and training setup of the used vector collections, we refer the reader to the original papers. Additional experiments with other word vectors, e.g., with CONTEXT2VEC (Melamud et al., 2016a) (which uses bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) for context modeling), and with dependency-word based embeddings (Bansal et al., 2014; Melamud et al., 2016b) lead to similar results and same conclusions.

[5] We have experimented with another set of constraints used in prior work (Zhang et al., 2014; Ono et al., 2015), reaching similar conclusions: these were extracted from WordNet (Fellbaum, 1998) and Roget (Kipfer, 2009), and comprise 1,023,082 synonymy pairs and 380,873 antonymy pairs.

[6] According to Ramachandran et al. (2017), for deep networks *swish* has a slight edge over the family of LU/ReLU-related activations (Maas et al., 2013; He et al., 2015; Klambauer et al., 2017). We also observe a minor (and insignificant) difference in performance in favour of *swish*.

[7] While other gold standards such as WordSim-353 (Finkelstein et al., 2002) or MEN (Bruni et al., 2014) coalesce the notions of true semantic similarity and (more broad) conceptual relatedness, SimLex and SimVerb provide explicit guidelines

Figure 2: The results of the *hold-out* experiments on SimLex-999 and SimVerb-3500 after applying our non-linear vector space transformation with different depths (hidden layer size H, see Fig. 1b). The results are presented as averages over 20 runs with the NONLINEAR-MM variant, the shaded regions are spanned by the maximum and minimum scores obtained. Thick horizontal lines refer to Spearman's rank correlations achieved in the initial space $\mathbf{X}_d$. $H = 0$ denotes the standard *linear* regression model (Mikolov et al., 2013a; Lazaridou et al., 2015) (LINEAR-MM shown since it outperforms LINEAR-MSE).

rank correlation is used as the evaluation metric.

We evaluate word vectors in two settings. First, in a synthetic *hold-out* setting, we remove all linguistic constraints which contain words from the SimLex *and* SimVerb evaluation data, effectively forcing all SimLex and SimVerb words to be *unseen* by the AR specialisation model. The specialised vectors for these words are estimated by the learned non-linear DFFN mapping model. Second, the *all* setting is a standard "real-life" scenario where some test (SimLex/SimVerb) words do occur in the constraints, while the mapping is learned for the remaining words.

Results and Analysis The results with the three word vector collections are provided in Tab. 1. In addition, Fig. 2 plots the influence of the network depth H on the model's performance.

The results suggest that the mapping of unseen words is universally useful, as the highest correlation scores are obtained with the final fully specialised vector space $\mathbf{X}_f$ for all three input spaces. The results in the *hold-out* setup are particularly indicative of the improvement achieved by our post-specialisation method. For instance, it achieves a +0.2 correlation gain with GLOVE on both SimLex and SimVerb by specialising vector representations for words present in these datasets *without* seeing a single external constraint which contains any of these words. This suggests that the perturbation of the seen subspace $\mathbf{X}_s$ by ATTRACT-REPEL contains implicit knowledge that can be propagated to $\mathbf{X}_u$, learning better representations for unseen words. We observe small but consistent improvements across the board in the *all* setup. The smaller gains can be explained by the fact that a majority of

to discern between the two, so that related but non-similar words (e.g. *tiger* and *jungle*) have a low rating.

SimLex and SimVerb words are present in the external constraints (93.7% and 87.2%, respectively).

The scores also indicate that *both* non-linearity and the chosen objective function contribute to the quality of the learned mapping: largest gains are reported with the NONLINEAR-MM variant which **a)** employs non-linear activations and **b)** replaces the basic mean-squared-error objective with max-margin. The usefulness of the latter has been established in prior work on cross-space mapping learning (Lazaridou et al., 2015). The former indicates that the initial AR transformation is non-linear. It is guided by a large number of constraints; their effect cannot be captured by a simple linear map as in prior work on, e.g., cross-lingual word embeddings (Mikolov et al., 2013a; Ruder et al., 2017).

Finally, the analysis of the network depth H indicates that going deeper helps only to a certain extent. Adding more layers allows for a richer parametrisation of the network (which is beneficial given the number of linguistic constraints used by AR). This makes the model more expressive, but it seems to saturate with larger H values.

Post-Specialisation with Other Post-Processors We also verify that our post-specialisation approach is not tied to the ATTRACT-REPEL method, and is indeed applicable on top of any post-processing specialisation method. We analyse the impact of post-specialisation in the *hold-out* setting using the original *retrofitting* (*RFit*) model (Faruqui et al., 2015) and *counter-fitting* (*CFit*) (Mrkšić et al., 2016) in lieu of attract-repel. The results on word similarity with the best-performing NONLINEAR-MM variant are summarised in Tab. 2.

The scores again indicate the usefulness of post-specialisation. As expected, the gains are lower

Figure 3: DST labels (user goals given by slot-value pairs) in a multi-turn dialogue (Mrkšić et al., 2015).

than with ATTRACT-REPEL. *RFit* falls short of *CFit* as by design it can leverage only synonymy (i.e., ATTRACT) external constraints.

5.2 Downstream Task I: DST

Next, we evaluate the usefulness of post-specialisation for two downstream tasks – dialogue state tracking and lexical text simplification – in which discerning semantic similarity from other types of semantic relatedness is crucial. We first evaluate the importance of post-specialisation for a downstream language understanding task of *dialogue state tracking* (DST) (Henderson et al., 2014; Williams et al., 2016), adopting the evaluation protocol and data of Mrkšić et al. (2017).

DST: Model and Evaluation The DST model is the first component of modern dialogue pipelines (Young, 2010), which captures the users' goals at each dialogue turn and then updates the dialogue state. Goals are represented as sets of constraints expressed as slot-value pairs (e.g., food=*Chinese*). The set of slots and the set of values for each slot constitute the ontology of a dialogue domain. The probability distribution over the possible states is the system's estimate of the user's goals, and it is used by the dialogue manager module to select the subsequent system response (Su et al., 2016). An example in Fig. 3 illustrates the DST pipeline.

For evaluation, we use the Neural Belief Tracker (NBT), a state-of-the-art DST model which was the first to reason purely over pre-trained word vectors (Mrkšić et al., 2017).[8] The NBT uses no hand-crafted semantic lexicons, instead composing word vectors into intermediate utterance and context representations.[9] For full model details, we refer the reader to the original paper. The importance of word vector specialisation for the DST task (e.g., distinguishing between synonyms and antonyms by pulling *northern* and *north* closer in

[8] https://github.com/nmrksic/neural-belief-tracker

[9] The NBT keeps word vectors *fixed* during training to enable generalisation for words unseen in DST training data.

++Mapping: $\mathbf{X}_f = \mathbf{X}'_s \cup \widehat{\mathbf{X}'_u}$		
LINEAR-MM	.815	.818
NONLINEAR-MM	**.827**	**.835**

Table 3: DST results in two evaluation settings (*hold-out* and *all*) with different GLOVE variants.

the vector space while pushing *north* and *south* away) has been established (Mrkšić et al., 2017).

Again, as in prior work the DST evaluation is based on the Wizard-of-Oz (WOZ) v2.0 dataset (Wen et al., 2017; Mrkšić et al., 2017), comprising 1,200 dialogues split into training (600 dialogues), development (200), and test data (400). In all experiments, we report the standard DST performance measure: *joint goal accuracy*, and report scores as averages over 5 NBT training runs.

Results and Analysis We again evaluate word vectors in two settings: **1)** *hold-out*, where linguistic constraints with words appearing in the WOZ data are removed, making all WOZ words unseen by ATTRACT-REPEL; and **2)** *all*. The results for the English DST task with different GLOVE word vector variants are summarised in Tab. 3; similar trends in results are observed with two other word vector collections. The scores maintain conclusions established in the word similarity task. First, semantic specialisation with ATTRACT-REPEL is again beneficial, and discerning between synonyms and antonyms improves DST performance. However, specialising unseen words (the final $\mathbf{X}_u$ vector space) yields further improvements in both evaluation settings, supporting our claim that the specialisation signal can be propagated to unseen words.

This downstream evaluation again demonstrates the importance of non-linearity, as the peak scores are reported with the NONLINEAR-MM variant. More substantial gains in the *all* setup are observed in the DST task compared to the word similarity task. This stems from a lower coverage of the WOZ data in the AR constraints: 36.3% of all WOZ words are unseen words. Finally, the scores are higher on average in the *all* setup, since this setup uses more external constraints for AR, and consequently uses more training examples to learn the mapping.

Other Languages We test the portability of our framework to two other languages for which we have similar evaluation data: German (DE) and Italian (IT). SimLex-999 has been translated and rescored in the two languages by Leviant and Reichart (2015), and the WOZ data were translated and adapted by Mrkšić et al. (2017). Exactly the same setup is used as in our English experiments, without any additional language-specific fine-tuning. Linguistic constraints were extracted from the same sources: synonyms from the PPDB (135,868 in DE, 362,452 in IT), antonyms from BabelNet (4,124 in DE, and 16,854 in IT). Our starting distributional vector spaces are taken from prior work: IT vectors are from (Dinu et al., 2015), DE vectors are from (Vulić and Korhonen, 2016a). The results are summarised in Tab. 4.

Our post-specialisation approach yields consistent improvements over the initial distributional space and the AR specialisation model in both tasks and for both languages. We do not observe any gain on IT SimLex in the *all* setup since IT constraints have almost complete coverage of all IT SimLex words (99.3%; the coverage is 64.8% in German). As expected, the DST scores in the *all* setup are higher than in the *hold-out* setup due to a larger number of constraints and training examples.

Lower absolute scores for Italian and German compared to the ones reported for English are due to multiple factors, as discussed previously by Mrkšić et al. (2017): **1)** the AR model uses less linguistic constraints for DE and IT; **2)** distributional word vectors are induced from smaller corpora; **3)** linguistic phenomena (e.g., cases and compounding in DE) contribute to data sparsity and also make the DST task more challenging. However, it is important to stress the consistent gains over the vector space specialised by the state-of-the-art ATTRACT-REPEL model across all three test languages. This indicates that the proposed approach is language-agnostic and portable to multiple languages.

5.3 Downstream Task II: Lexical Simplification

In our second downstream task, we examine the effects of post-specialisation on lexical simplification (LS) in English. LS aims to substitute complex words (i.e., less commonly used words) with their simpler synonyms in the context. Simplified text must keep the meaning of the original text, which is discerning similarity from relatedness is important (e.g., in *"The automobile was set on fire"* the word *"automobile"* should be replaced with *"car"* or *"vehicle"* but not with *"wheel"* or *"driver"*).

Table 5: Lexical simplification performance with post-specialisation applied on three input spaces.

We employ LIGHT-LS (Glavaš and Štajner, 2015), a lexical simplification algorithm that: 1) makes substitutions based on word similarities in a semantic vector space, and 2) can be provided an arbitrary embedding space as input.[10] For a complex word, LIGHT-LS considers the most similar words from the vector space as simplification candidates. Candidates are ranked according to several features, indicating simplicity and fitness for the context (semantic relatedness to the context of the complex word). The substitution is made if the best candidate is simpler than the original word. By providing vector spaces post-specialised for semantic similarity to LIGHT-LS, we expect to more often replace complex words with their true synonyms.

We evaluate LIGHT-LS performance in the *all* setup on the LS benchmark compiled by Horn et al. (2014), who crowdsourced 50 manual simplifications for each complex word. As in prior work, we evaluate performance with the following metrics: 1) *Accurracy* (Acc.) is the number of correct simplifications made (i.e., the system made the simplification and its substitution is found in the list of crowdsourced substitutions), divided by the total number of indicated complex words; 2) *Changed* (Ch.) is the percentage of indicated complex words that were replaced by the system (whether or not the replacement was correct).

LS results are summarised in Tab. 5. Post-specialised vector spaces consistently yield 5-6% gain in *Accuracy* compared to respective distributional vectors and embeddings specialised with the state-of-the-art ATTRACT-REPEL model. Similar to DST evaluation, improvements over ATTRACT-REPEL demonstrate the importance of specialising the vectors of the entire vocabulary and not only the vectors of words from the external constraints.

6 Conclusion and Future Work

We have presented a novel post-processing model, termed *post-specialisation*, that specialises word vectors for the full vocabulary of the input vector space. Previous post-processing specialisation models fine-tune word vectors only for words occurring in external lexical resources. In this work, we have demonstrated that the specialisation of the subspace of seen words can be leveraged to learn a mapping function which specialises vectors for all other words, unseen in the external resources. Our results across word similarity and downstream language understanding tasks show consistent improvements over the state-of-the-art specialisation method for all three test languages.

In future work, we plan to extend our approach to specialisation for asymmetric relations such as hypernymy or meronymy (Glavaš and Ponzetto, 2017; Nickel and Kiela, 2017; Vulić and Mrkšić, 2018). We will also investigate more sophisticated non-linear functions. The code is available at: https://github.com/cambridgeltl/post-specialisation/.

Abstract

The recent tremendous success of unsupervised word embeddings in a multitude of applications raises the obvious question if similar methods could be derived to improve embeddings (i.e. semantic representations) of word sequences as well. We present a simple but efficient unsupervised objective to train distributed representations of sentences. Our method outperforms the state-of-the-art unsupervised models on most benchmark tasks, highlighting the robustness of the produced general-purpose sentence embeddings.

1 Introduction

Improving unsupervised learning is of key importance for advancing machine learning methods, as to unlock access to almost unlimited amounts of data to be used as training resources. The majority of recent success stories of deep learning does not fall into this category but instead relied on supervised training (in particular in the vision domain). A very notable exception comes from the text and natural language processing domain, in the form of semantic word embeddings trained unsupervised (Mikolov et al., 2013b,a; Pennington et al., 2014). Within only a few years from their invention, such word representations – which are based on a simple matrix factorization model as we formalize below – are now routinely trained on very large amounts of raw text data, and have become ubiquitous building blocks of a majority of current state-of-the-art NLP applications.

While very useful semantic representations are available for words, it remains challenging to produce and learn such semantic embeddings for longer pieces of text, such as sentences, paragraphs or entire documents. Even more so, it remains a key goal to learn such general-purpose representations in an unsupervised way.

Currently, two contrary research trends have emerged in text representation learning: On one hand, a strong trend in deep-learning for NLP leads towards increasingly powerful and complex models, such as recurrent neural networks (RNNs), LSTMs, attention models and even Neural Turing Machine architectures. While extremely strong in expressiveness, the increased model complexity makes such models much slower to train on larger datasets. On the other end of the spectrum, simpler "shallow" models such as matrix factorizations (or bilinear models) can benefit from training on much larger sets of data, which can be a key advantage, especially in the unsupervised setting.

Surprisingly, for constructing sentence embeddings, naively using averaged word vectors was shown to outperform LSTMs (see Wieting et al. (2016b) for plain averaging, and Arora et al. (2017) for weighted averaging). This example shows potential in exploiting the trade-off between model complexity and ability to process huge amounts of text using scalable algorithms, towards the simpler side. In view of this trade-off, our work here further advances unsupervised learning of sentence embeddings. Our proposed model can be seen as an extension of the C-BOW (Mikolov et al., 2013b,a) training objective to train sentence instead of word embeddings. We demonstrate that the empirical performance of our resulting general-purpose sentence embeddings very significantly exceeds the state of the art, while keeping the model simplicity as well as training and inference complexity exactly as low as in averaging methods (Wieting et al., 2016b; Arora et al., 2017), thereby also putting the work by (Arora et al., 2017) in perspective.

Proceedings of NAACL-HLT 2018, pages 528–540
New Orleans, Louisiana, June 1 - 6, 2018.

Contributions. The main contributions in this work can be summarized as follows:

- **Model.** We propose **Sent2Vec**[1], a simple unsupervised model allowing to compose sentence embeddings using word vectors along with n-gram embeddings, simultaneously training composition and the embedding vectors themselves.

- **Efficiency & Scalability.** The computational complexity of our embeddings is only $\mathcal{O}(1)$ vector operations per word processed, both during training and inference of the sentence embeddings. This strongly contrasts all neural network based approaches, and allows our model to learn from extremely large datasets, in a streaming fashion, which is a crucial advantage in the unsupervised setting. Fast inference is a key benefit in downstream tasks and industry applications.

- **Performance.** Our method shows significant performance improvements compared to the current state-of-the-art unsupervised and even semi-supervised models. The resulting general-purpose embeddings show strong robustness when transferred to a wide range of prediction benchmarks.

2 Model

Our model is inspired by simple matrix factor models (bilinear models) such as recently very successfully used in unsupervised learning of word embeddings (Mikolov et al., 2013b,a; Pennington et al., 2014; Bojanowski et al., 2017) as well as supervised of sentence classification (Joulin et al., 2017). More precisely, these models can all be formalized as an optimization problem of the form

$$\min_{\boldsymbol{U},\boldsymbol{V}} \sum_{S \in \mathcal{C}} f_S(\boldsymbol{U}\boldsymbol{V}\boldsymbol{\iota}_S) \qquad (1)$$

for two parameter matrices $\boldsymbol{U} \in \mathbb{R}^{k \times h}$ and $\boldsymbol{V} \in \mathbb{R}^{h \times |\mathcal{V}|}$, where $\mathcal{V}$ denotes the vocabulary. Here, the columns of the matrix $\boldsymbol{V}$ represent the learnt source word vectors whereas those of $\boldsymbol{U}$ represent the target word vectors. For a given sentence S, which can be of arbitrary length, the indicator vector $\boldsymbol{\iota}_S \in \{0,1\}^{|\mathcal{V}|}$ is a binary vector encoding S (bag of words encoding).

Fixed-length context windows S running over the corpus are used in word embedding methods as in C-BOW (Mikolov et al., 2013b,a) and GloVe (Pennington et al., 2014). Here we have $k = |\mathcal{V}|$ and each cost function $f_S : \mathbb{R}^k \to \mathbb{R}$ only depends on a single row of its input, describing the observed target word for the given fixed-length context S. In contrast, for sentence embeddings which are the focus of our paper here, S will be entire sentences or documents (therefore variable length). This property is shared with the supervised FastText classifier (Joulin et al., 2017), which however uses soft-max with $k \ll |\mathcal{V}|$ being the number of class labels.

2.1 Proposed Unsupervised Model

We propose a new unsupervised model, **Sent2Vec**, for learning universal sentence embeddings. Conceptually, the model can be interpreted as a natural extension of the word-contexts from C-BOW (Mikolov et al., 2013b,a) to a larger sentence context, with the sentence words being specifically optimized towards additive combination over the sentence, by means of the unsupervised objective function.

Formally, we learn a source (or context) embedding $\boldsymbol{v}_w$ and target embedding $\boldsymbol{u}_w$ for each word w in the vocabulary, with embedding dimension h and $k = |\mathcal{V}|$ as in (1). The sentence embedding is defined as the average of the source word embeddings of its constituent words, as in (2). We augment this model furthermore by also learning source embeddings for not only unigrams but also n-grams present in each sentence, and averaging the n-gram embeddings along with the words, i.e., the sentence embedding $\boldsymbol{v}_S$ for S is modeled as

$$\boldsymbol{v}_S := \frac{1}{|R(S)|}\boldsymbol{V}\boldsymbol{\iota}_{R(S)} = \frac{1}{|R(S)|}\sum_{w \in R(S)} \boldsymbol{v}_w \qquad (2)$$

where $R(S)$ is the list of n-grams (including unigrams) present in sentence S. In order to predict a missing word from the context, our objective models the softmax output approximated by negative sampling following (Mikolov et al., 2013b). For the large number of output classes $|\mathcal{V}|$ to be predicted, negative sampling is known to significantly improve training efficiency, see also (Goldberg and Levy, 2014). Given the binary logistic

[1] All our code and pre-trained models will be made publicly available on http://github.com/epfml/sent2vec

loss function $\ell : x \mapsto \log\left(1 + e^{-x}\right)$ coupled with negative sampling, our unsupervised training objective is formulated as follows:

$$\min_{\boldsymbol{U},\boldsymbol{V}} \sum_{S\in\mathcal{C}} \sum_{w_t\in S} \Bigg(\ell\big(\boldsymbol{u}_{w_t}^\top \boldsymbol{v}_{S\setminus\{w_t\}}\big) + \sum_{w'\in N_{w_t}} \ell\big(-\boldsymbol{u}_{w'}^\top \boldsymbol{v}_{S\setminus\{w_t\}}\big)\Bigg)$$

where S corresponds to the current sentence and N_{w_t} is the set of words sampled negatively for the word $w_t \in S$. The negatives are sampled[2] following a multinomial distribution where each word w is associated with a probability $q_n(w) := \sqrt{f_w} \,/\, \big(\sum_{w_i\in\mathcal{V}} \sqrt{f_{w_i}}\big)$, where f_w is the normalized frequency of w in the corpus.

To select the possible target unigrams (positives), we use subsampling as in (Joulin et al., 2017; Bojanowski et al., 2017), each word w being discarded with probability $1 - q_p(w)$ where $q_p(w) := \min\big\{1, \sqrt{t/f_w} + t/f_w\big\}$. Where t is the subsampling hyper-parameter. Subsampling prevents very frequent words of having too much influence in the learning as they would introduce strong biases in the prediction task. With positives subsampling and respecting the negative sampling distribution, the precise training objective function becomes

$$\min_{\boldsymbol{U},\boldsymbol{V}} \sum_{S\in\mathcal{C}} \sum_{w_t\in S} \Bigg(q_p(w_t)\ell\big(\boldsymbol{u}_{w_t}^\top \boldsymbol{v}_{S\setminus\{w_t\}}\big) + |N_{w_t}| \sum_{w'\in\mathcal{V}} q_n(w')\ell\big(-\boldsymbol{u}_{w'}^\top \boldsymbol{v}_{S\setminus\{w_t\}}\big)\Bigg) \tag{3}$$

2.2 Computational Efficiency

In contrast to more complex neural network based models, one of the core advantages of the proposed technique is the low computational cost for both inference and training. Given a sentence S and a trained model, computing the sentence representation $\boldsymbol{v}_S$ only requires $|S| \cdot h$ floating point operations (or $|R(S)| \cdot h$ to be precise for the n-gram case, see (2)), where h is the embedding dimension. The same holds for the cost of training with SGD on the objective (3), per sentence seen in the training corpus. Due to the simplicity of the model, parallel training is straight-forward using parallelized or distributed SGD.

Also, in order to store higher-order n-grams efficiently, we use the standard hashing trick, see e.g. (Weinberger et al., 2009), with the same hashing function as used in FastText (Joulin et al., 2017; Bojanowski et al., 2017).

2.3 Comparison to C-BOW

C-BOW (Mikolov et al., 2013b,a) aims to predict a chosen target word given its fixed-size context window, the context being defined by the average of the vectors associated with the words at a distance less than the window size hyper-parameter ws. If our system, when restricted to unigram features, can be seen as an extension of C-BOW where the context window includes the entire sentence, in practice there are few important differences as C-BOW uses important tricks to facilitate the learning of word embeddings. C-BOW first uses frequent word subsampling on the sentences, deciding to discard each token w with probability $q_p(w)$ or alike (small variations exist across implementations). Subsampling prevents the generation of n-grams features, and deprives the sentence of an important part of its syntactical features. It also shortens the distance between subsampled words, implicitly increasing the span of the context window. A second trick consists of using dynamic context windows: for each subsampled word w, the size of its associated context window is sampled uniformly between 1 and ws. Using dynamic context windows is equivalent to weighing by the distance from the focus word w divided by the window size (Levy et al., 2015). This makes the prediction task local, and go against our objective of creating sentence embeddings as we want to learn how to compose all n-gram features present in a sentence. In the results section, we report a significant improvement of our method over C-BOW.

2.4 Model Training

Three different datasets have been used to train our models: the Toronto book corpus[3], Wikipedia sentences and tweets. The Wikipedia and Toronto books sentences have been tokenized using the Stanford NLP library (Manning et al., 2014), while for tweets we used the NLTK tweets tokenizer (Bird et al., 2009). For training, we select a

[2] To efficiently sample negatives, a pre-processing table is constructed, containing the words corresponding to the square root of their corpora frequency. Then, the negatives N_{w_t} are sampled uniformly at random from the negatives table except the target w_t itself, following (Joulin et al., 2017; Bojanowski et al., 2017).

[3] http://www.cs.toronto.edu/~mbweb/

sentence randomly from the dataset and then proceed to select all the possible target unigrams using subsampling. We update the weights using SGD with a linearly decaying learning rate.

Also, to prevent overfitting, for each sentence we use dropout on its list of n-grams $R(S) \setminus \{U(S)\}$, where $U(S)$ is the set of all unigrams contained in sentence S. After empirically trying multiple dropout schemes, we find that dropping K n-grams ($n > 1$) for each sentence is giving superior results compared to dropping each token with some fixed probability. This dropout mechanism would negatively impact shorter sentences. The regularization can be pushed further by applying L1 regularization to the word vectors. Encouraging sparsity in the embedding vectors is particularly beneficial for high dimension h. The additional soft thresholding in every SGD step adds negligible computational cost. See also Appendix B. We train two models on each dataset, one with unigrams only and one with unigrams and bigrams. All training parameters for the models are provided in Table 5 in the appendix. Our C++ implementation builds upon the FastText library (Joulin et al., 2017; Bojanowski et al., 2017). We will make our code and pre-trained models available open-source.

3 Related Work

We discuss existing models which have been proposed to construct sentence embeddings. While there is a large body of works in this direction – several among these using e.g. labelled datasets of paraphrase pairs to obtain sentence embeddings in a supervised manner (Wieting et al., 2016a,b; Conneau et al., 2017) to learn sentence embeddings – we here focus on unsupervised, task-independent models. While some methods require ordered raw text i.e., a coherent corpus where the next sentence is a logical continuation of the previous sentence, others rely only on raw text i.e., an unordered collection of sentences. Finally, we also discuss alternative models built from structured data sources.

3.1 Unsupervised Models Independent of Sentence Ordering

The **ParagraphVector DBOW** model (Le and Mikolov, 2014) is a log-linear model which is trained to learn sentence as well as word embeddings and then use a softmax distribution to predict words contained in the sentence given the sentence vector representation. They also propose a different model **ParagraphVector DM** where they use n-grams of consecutive words along with the sentence vector representation to predict the next word.

(Lev et al., 2015) also presented an early approach to obtain compositional embeddings from word vectors. They use different compositional techniques including static averaging or Fisher vectors of a multivariate Gaussian to obtain sentence embeddings from word2vec models.

Hill et al. (2016a) propose a **Sequential (Denoising) Autoencoder, S(D)AE**. This model first introduces noise in the input data: Firstly each word is deleted with probability p_0, then for each non-overlapping bigram, words are swapped with probability p_x. The model then uses an LSTM-based architecture to retrieve the original sentence from the corrupted version. The model can then be used to encode new sentences into vector representations. In the case of $p_0 = p_x = 0$, the model simply becomes a Sequential Autoencoder. Hill et al. (2016a) also propose a variant **(S(D)AE + embs.)** in which the words are represented by fixed pre-trained word vector embeddings.

Arora et al. (2017) propose a model in which sentences are represented as a weighted average of fixed (pre-trained) word vectors, followed by post-processing step of subtracting the principal component. Using the generative model of (Arora et al., 2016), words are generated conditioned on a sentence "discourse" vector $\boldsymbol{c}_s$:

$$Pr[w \,|\, \boldsymbol{c}_s] = \alpha f_w + (1-\alpha)\frac{\exp(\tilde{\boldsymbol{c}}_s^\top \boldsymbol{v}_w)}{Z_{\tilde{\boldsymbol{c}}_s}},$$

where $Z_{\tilde{\boldsymbol{c}}_s} := \sum_{w \in \mathcal{V}} \exp(\tilde{\boldsymbol{c}}_s^\top \boldsymbol{v}_w)$ and $\tilde{\boldsymbol{c}}_s := \beta \boldsymbol{c}_0 + (1-\beta)\boldsymbol{c}_s$ and α, β are scalars. $\boldsymbol{c}_0$ is the common discourse vector, representing a shared component among all discourses, mainly related to syntax. It allows the model to better generate syntactical features. The αf_w term is here to enable the model to generate some frequent words even if their matching with the discourse vector $\tilde{\boldsymbol{c}}_s$ is low.

Therefore, this model tries to generate sentences as a mixture of three type of words: words matching the sentence discourse vector $\boldsymbol{c}_s$, syntactical words matching $\boldsymbol{c}_0$, and words with high f_w. (Arora et al., 2017) demonstrated that for this model, the MLE of $\tilde{\boldsymbol{c}}_s$ can be approximated by $\sum_{w \in S} \frac{a}{f_w + a} \boldsymbol{v}_w$, where a is a scalar. The sentence

discourse vector can hence be obtained by subtracting $\boldsymbol{c}_0$ estimated by the first principal component of $\tilde{\boldsymbol{c}}_s$'s on a set of sentences. In other words, the sentence embeddings are obtained by a weighted average of the word vectors stripping away the syntax by subtracting the common discourse vector and down-weighting frequent tokens. They generate sentence embeddings from diverse pre-trained word embeddings among which are unsupervised word embeddings such as GloVe (Pennington et al., 2014) as well as supervised word embeddings such as paragram-SL999 (PSL) (Wieting et al., 2015) trained on the Paraphrase Database (Ganitkevitch et al., 2013).

In a very different line of work, **C-PHRASE** (Pham et al., 2015) relies on additional information from the syntactic parse tree of each sentence, which is incorporated into the C-BOW training objective.

Huang and Anandkumar (2016) show that single layer CNNs can be modeled using a tensor decomposition approach. While building on an unsupervised objective, the employed dictionary learning step for obtaining phrase templates is task-specific (for each use-case), not resulting in general-purpose embeddings.

3.2 Unsupervised Models Depending on Sentence Ordering

The **SkipThought** model (Kiros et al., 2015) combines sentence level models with recurrent neural networks. Given a sentence S_i from an ordered corpus, the model is trained to predict S_{i-1} and S_{i+1}.

FastSent (Hill et al., 2016a) is a sentence-level log-linear bag-of-words model. Like SkipThought, it uses adjacent sentences as the prediction target and is trained in an unsupervised fashion. Using word sequences allows the model to improve over the earlier work of paragraph2vec (Le and Mikolov, 2014). (Hill et al., 2016a) augment FastSent further by training it to predict the constituent words of the sentence as well. This model is named **FastSent + AE** in our comparisons.

Compared to our approach, **Siamese C-BOW** (Kenter et al., 2016) shares the idea of learning to average word embeddings over a sentence. However, it relies on a Siamese neural network architecture to predict surrounding sentences, contrasting our simpler unsupervised objective.

Note that on the character sequence level instead of word sequences, FastText (Bojanowski et al., 2017) uses the same conceptual model to obtain better word embeddings. This is most similar to our proposed model, with two key differences: Firstly, we predict from source word sequences to target words, as opposed to character sequences to target words, and secondly, our model is averaging the source embeddings instead of summing them.

3.3 Models requiring structured data

DictRep (Hill et al., 2016b) is trained to map dictionary definitions of the words to the pre-trained word embeddings of these words. They use two different architectures, namely BOW and RNN (LSTM) with the choice of learning the input word embeddings or using them pre-trained. A similar architecture is used by the **CaptionRep** variant, but here the task is the mapping of given image captions to a pre-trained vector representation of these images.

4 Evaluation Tasks

We use a standard set of supervised as well as unsupervised benchmark tasks from the literature to evaluate our trained models, following (Hill et al., 2016a). The breadth of tasks allows to fairly measure generalization to a wide area of different domains, testing the general-purpose quality (universality) of all competing sentence embeddings. For downstream supervised evaluations, sentence embeddings are combined with logistic regression to predict target labels. In the unsupervised evaluation for sentence similarity, correlation of the cosine similarity between two embeddings is compared to human annotators.

Downstream Supervised Evaluation. Sentence embeddings are evaluated for various supervised classification tasks as follows. We evaluate paraphrase identification (MSRP) (Dolan et al., 2004), classification of movie review sentiment (MR) (Pang and Lee, 2005), product reviews (CR) (Hu and Liu, 2004), subjectivity classification (SUBJ) (Pang and Lee, 2004), opinion polarity (MPQA) (Wiebe et al., 2005) and question type classification (TREC) (Voorhees, 2002). To classify, we use the code provided by (Kiros et al., 2015) in the same manner as in (Hill et al., 2016a). For the MSRP dataset, containing pairs of sentences (S_1, S_2) with associated paraphrase label, we generate feature vectors by concatenating

their Sent2Vec representations $|\boldsymbol{v}_{S_1} - \boldsymbol{v}_{S_2}|$ with the component-wise product $\boldsymbol{v}_{S_1} \odot \boldsymbol{v}_{S_2}$. The predefined training split is used to tune the L2 penalty parameter using cross-validation and the accuracy and F1 scores are computed on the test set. For the remaining 5 datasets, Sent2Vec embeddings are inferred from input sentences and directly fed to a logistic regression classifier. Accuracy scores are obtained using 10-fold cross-validation for the MR, CR, SUBJ and MPQA datasets. For those datasets nested cross-validation is used to tune the L2 penalty. For the TREC dataset, as for the MRSP dataset, the L2 penalty is tuned on the predefined train split using 10-fold cross-validation, and the accuracy is computed on the test set.

Unsupervised Similarity Evaluation. We perform unsupervised evaluation of the learnt sentence embeddings using the sentence cosine similarity, on the STS 2014 (Agirre et al., 2014) and SICK 2014 (Marelli et al., 2014) datasets. These similarity scores are compared to the gold-standard human judgements using Pearson's r (Pearson, 1895) and Spearman's ρ (Spearman, 1904) correlation scores. The SICK dataset consists of about 10,000 sentence pairs along with relatedness scores of the pairs. The STS 2014 dataset contains 3,770 pairs, divided into six different categories on the basis of the origin of sentences/phrases, namely Twitter, headlines, news, forum, WordNet and images.

5 Results and Discussion

In Tables 1 and 2, we compare our results with those obtained by (Hill et al., 2016a) on different models. Table 3 in the last column shows the dramatic improvement in training time of our models (and other C-BOW-inspired models) in contrast to neural network based models. All our Sent2Vec models are trained on a machine with 2x Intel Xeon E5−2680v3, 12 cores @2.5GHz. Along with the models discussed in Section 3, this also includes the sentence embedding baselines obtained by simple averaging of word embeddings over the sentence, in both the C-BOW and skip-gram variants. TF-IDF BOW is a representation consisting of the counts of the 200,000 most common feature-words, weighed by their TF-IDF frequencies. To ensure coherence, we only include unsupervised models in the main paper. Performance of supervised and semi-supervised models on these evaluations can be observed in Tables 6 and 7 in the appendix.

Downstream Supervised Evaluation Results. On running supervised evaluations and observing the results in Table 1, we find that on an average our models are second only to SkipThought vectors. Also, both our models achieve state of the art results on the CR task. We also observe that on half of the supervised tasks, our unigrams + bigram model is the best model after SkipThought. Our models are weaker on the MSRP task (which consists of the identification of labelled paraphrases) compared to state-of-the-art methods. However, we observe that the models which perform very strongly on this task end up faring very poorly on the other tasks, indicating a lack of generalizability.

On rest of the tasks, our models perform extremely well. The SkipThought model is able to outperform our models on most of the tasks as it is trained to predict the previous and next sentences and a lot of tasks are able to make use of this contextual information missing in our Sent2Vec models. For example, the TREC task is a poor measure of how one predicts the content of the sentence (the question) but a good measure of how the next sentence in the sequence (the answer) is predicted.

Unsupervised Similarity Evaluation Results. In Table 2, we see that our Sent2Vec models are state-of-the-art on the majority of tasks when comparing to all the unsupervised models trained on the Toronto corpus, and clearly achieve the best averaged performance. Our Sent2Vec models also on average outperform or are at par with the C-PHRASE model, despite significantly lagging behind on the STS 2014 WordNet and News subtasks. This observation can be attributed to the fact that a big chunk of the data that the C-PHRASE model is trained on comes from English Wikipedia, helping it to perform well on datasets involving definition and news items. Also, C-PHRASE uses data three times the size of the Toronto book corpus. Interestingly, our model outperforms C-PHRASE when trained on Wikipedia, as shown in Table 3, despite the fact that we use no parse tree information.

Official STS 2017 benchmark. In the official results of the most recent edition of the STS 2017 benchmark (Cer et al., 2017), our model also significantly outperforms C-PHRASE, and in fact delivers the best unsupervised baseline method.

Table 2: **Unsupervised Evaluation Tasks**: Comparison of the performance of different models on Spearman/Pearson correlation measures. An underline indicates the best performance for the dataset. Top 3 performances in each data category are shown in bold. The average is calculated as the average of entries for each correlation measure.

Macro Average. To summarize our contributions on both supervised and unsupervised tasks, in Table 3 we present the results in terms of the macro average over the averages of both supervised and unsupervised tasks along with the training times of the models[5]. For unsupervised tasks, averages are taken over both Spearman and Pearson scores. The comparison includes the best performing unsupervised and semi-supervised methods described in Section 3. For models trained on the Toronto books dataset, we report a 3.8 % points improvement over the state of the art. Considering all supervised, semi-supervised methods and all datasets compared in (Hill et al., 2016a), we report a 2.2 % points improvement.

We also see a noticeable improvement in accuracy as we use larger datasets like Twitter and Wikipedia. We furthermore see that the Sent2Vec models are faster to train when compared to methods like SkipThought and DictRep, owing to the SGD optimizer allowing a high degree of parallelizability.

We can clearly see Sent2Vec outperforming other unsupervised and even semi-supervised methods. This can be attributed to the superior generalizability of our model across supervised and unsupervised tasks.

Comparison with Arora et al. (2017). We also compare our work with Arora et al. (2017) who also use additive compositionality to obtain sentence embeddings. However, in contrast to our

corpus, supervised evaluation as well as similarity evaluation results on the SICK 2014 dataset are unavailable.

[5]time taken to train C-PHRASE models is unavailable

Table 3: Best unsupervised and semi-supervised methods ranked by macro average along with their training times. ** indicates trained on GPU. * indicates trained on a single node using 30 threads. Training times for non-Sent2Vec models are due to Hill et al. (2016a). For CPU based competing methods, we were able to reproduce all published timings (+-10%) using our same hardware as for training Sent2Vec.

Dataset	Unsupervised GloVe (840B words) + WR	Semi-supervised PSL + WR	Sent2Vec Unigrams (19.7B words) Tweets Model	Sent2Vec Unigrams + Bigrams (19.7B words) Tweets Model
STS 2014	0.685	0.735	0.710	0.701
SICK 2014	0.722	0.729	0.710	0.715
Supervised average	0.815	0.807	0.822	0.835

Table 4: Comparison of the performance of the unsupervised and semi-supervised sentence embeddings by (Arora et al., 2017) with our models. Unsupervised comparisons are in terms of Pearson's correlation, while comparisons on supervised tasks are stating the average described in Table 1.

model, they use fixed, pre-trained word embeddings to build a weighted average of these embeddings using unigram probabilities. While we couldn't find pre-trained state of the art word embeddings trained on the Toronto books corpus, we evaluated their method using GloVe embeddings obtained from the larger Common Crawl Corpus[6], which is 42 times larger than our twitter corpus, greatly favoring their method over ours.

In Table 4, we report an experimental comparison to their model on unsupervised tasks. In the table, the suffix W indicates that their down-weighting scheme has been used, while the suffix R indicates the removal of the first principal component. They report values of $a \in [10^{-4}, 10^{-3}]$ as giving the best results and used $a = 10^{-3}$ for all their experiments. We observe that our results are competitive with the embeddings of Arora et al. (2017) for purely unsupervised methods. It is important to note that the scores obtained from supervised task-specific PSL embeddings trained for the purpose of semantic similarity outperform our method on both SICK and average STS 2014, which is expected as our model is trained purely unsupervised.

In order to facilitate a more detailed comparison, we also evaluated the unsupervised Glove + WR embeddings on downstream supervised tasks and compared them to our twitter models. To use Arora et al. (2017)'s method in a supervised setup, we precomputed and stored the common discourse vector $\boldsymbol{c}_0$ using 2 million random Wikipedia sentences. On an average, our models outperform their unsupervised models by a significant margin, this despite the fact that they used GloVe embeddings trained on larger corpora than ours (42 times larger). Our models also outperform their semi-supervised PSL + WR model. This indicates our model learns a more precise weighing scheme than the static one proposed by Arora et al. (2017).

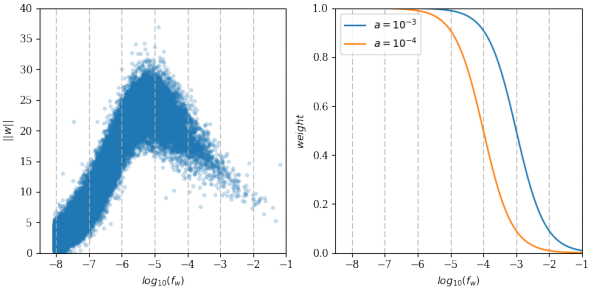

Figure 1: *Left figure:* the profile of the word vector L_2-norms as a function of $\log(f_w)$ for each vocabulary word w, as learnt by our unigram model trained on Toronto books. *Right figure:* down-weighting scheme proposed by Arora et al. (2017): $weight(w) = \frac{a}{a+f_w}$.

The effect of datasets and n-grams. Despite being trained on three very different datasets, all of our models generalize well to sometimes very

[6] http://www.cs.toronto.edu/~mbweb/

specific domains. Models trained on Toronto Corpus are the state-of-the-art on the STS 2014 images dataset even beating the supervised CaptionRep model trained on images. We also see that addition of bigrams to our models doesn't help much when it comes to unsupervised evaluations but gives a significant boost-up in accuracy on supervised tasks. We attribute this phenomenon to the ability of bigrams models to capture some non-compositional features missed by unigrams models. Having a single representation for *"not good"* or *"very bad"* can boost the supervised model's ability to infer relevant features for the corresponding classifier. For semantic similarity tasks however, the relative uniqueness of bigrams results in pushing sentence representations further apart, which can explain the average drop of scores for bigrams models on those tasks.

On learning the importance and the direction of the word vectors. Our model – by learning how to generate and compose word vectors – has to learn both the direction of the word embeddings as well as their norm. Considering the norms of the used word vectors as by our averaging over the sentence, we observe an interesting distribution of the "importance" of each word. In Figure 1 we show the profile of the L_2-norm as a function of $\log(f_w)$ for each $w \in \mathcal{V}$, and compare it to the static down-weighting mechanism of Arora et al. (2017). We can observe that our model is learning to down-weight frequent tokens by itself. It is also down-weighting rare tokens and the $norm$ profile seems to roughly follow Luhn's hypothesis (Luhn, 1958), a well known information retrieval paradigm, stating that mid-rank terms are the most significant to discriminate content.

6 Conclusion

In this paper, we introduce a novel, computationally efficient, unsupervised, C-BOW-inspired method to train and infer sentence embeddings. On supervised evaluations, our method, on an average, achieves better performance than all other unsupervised competitors with the exception of SkipThought. However, SkipThought vectors show a very poor performance on sentence similarity tasks while our model is state-of-the-art for these evaluations on average. Also, our model is generalizable, extremely fast to train, simple to understand and easily interpretable, showing the relevance of simple and well-grounded representation models in contrast to the models using deep architectures. Future work could focus on augmenting the model to exploit data with ordered sentences. Furthermore, we would like to investigate the model's ability to use pre-trained embeddings for downstream transfer learning tasks.

Table 5: Training parameters for the Sent2Vec models

B L1 regularization of models

Optionally, our model can be additionally improved by adding an L1 regularizer term in the objective function, leading to slightly better generalization performance. Additionally, encouraging sparsity in the embedding vectors is beneficial for memory reasons, allowing higher embedding dimensions h.

We propose to apply L1 regularization individually to each word (and n-gram) vector (both source and target vectors). Formally, the training objective function (3) then becomes

$$\min_{\boldsymbol{U},\boldsymbol{V}} \sum_{S \in \mathcal{C}} \sum_{w_t \in S} q_p(w_t) \Bigg(\Big(\ell\big(\boldsymbol{u}_{w_t}^\top \boldsymbol{v}_{S\setminus\{w_t\}}\big) + \tau(\|\boldsymbol{u}_{w_t}\|_1 + \|\boldsymbol{v}_{S\setminus\{w_t\}}\|_1) \Big) + |N_{w_t}| \sum_{w' \in \mathcal{V}} q_n(w') \Big(\ell\big(-\boldsymbol{u}_{w'}^\top \boldsymbol{v}_{S\setminus\{w_t\}}\big) + \tau(\|\boldsymbol{u}_{w'}\|_1) \Big) \Bigg) \tag{4}$$

where τ is the regularization parameter.

Now, in order to minimize a function of the form $f(\mathbf{z}) + g(\mathbf{z})$ where $g(\mathbf{z})$ is not differentiable over the domain, we can use the basic proximal-gradient scheme. In this iterative method, after doing a gradient descent step on $f(\mathbf{z})$ with learning rate α, we update $\mathbf{z}$ as

$$\mathbf{z}_{n+1} = prox_{\alpha,g}(\mathbf{z}_{n+\frac{1}{2}}) \tag{5}$$

where $prox_{\alpha,g}(\mathbf{x}) = \arg\min_{\mathbf{y}} \{g(\mathbf{y}) + \frac{1}{2\alpha}\|\mathbf{y}-\mathbf{x}\|_2^2\}$ is called the proximal function (Rockafellar, 1976) of g with α being the proximal parameter and $\mathbf{z}_{n+\frac{1}{2}}$ is the value of $\mathbf{z}$ after a gradient (or SGD) step on $\mathbf{z}_n$.

In our case, $g(\mathbf{z}) = \|\mathbf{z}\|_1$ and the corresponding proximal operator is given by

$$prox_{\alpha,g}(\mathbf{x}) = sign(\mathbf{x}) \odot \max(|\mathbf{x}_n| - \alpha, 0) \tag{6}$$

where $\odot$ corresponds to element-wise product.

Similar to the proximal-gradient scheme, in our case we can optionally use the thresholding operator on the updated word and n-gram vectors after an SGD step. The soft thresholding parameter used for this update is $\frac{\tau \cdot lr'}{|R(S\setminus\{w_t\})|}$ and $\tau \cdot lr'$ for the source and target vectors respectively where lr' is the current learning rate, τ is the $L1$ regularization parameter and S is the sentence on which SGD is being run.

We observe that $L1$ regularization using the proximal step gives our models a small boost in performance. Also, applying the thresholding operator takes only $|R(S \setminus \{w_t\})| \cdot h$ floating point operations for the updating the word vectors corresponding to the sentence and $(|N|+1) \cdot h$ for updating the target

as well as the negative word vectors, where $|N|$ is the number of negatives sampled and h is the embedding dimension. Thus, performing $L1$ regularization using soft-thresholding operator comes with a small computational overhead.

We set τ to be 0.0005 for both the Wikipedia and the Toronto Book Corpus unigrams + bigrams models.

Abstract

Training data for sentiment analysis are abundant in multiple domains, yet scarce for other domains. It is useful to leveraging data available for all existing domains to enhance performance on different domains. We investigate this problem by learning domain-specific representations of input sentences using neural network. In particular, a descriptor vector is learned for representing each domain, which is used to map adversarially trained domain-general Bi-LSTM input representations into domain-specific representations. Based on this model, we further expand the input representation with exemplary domain knowledge, collected by attending over a memory network of domain training data. Results show that our model outperforms existing methods on multi-domain sentiment analysis significantly, giving the best accuracies on two different benchmarks.

1 Introduction

Sentiment analysis has received constant research attention due to its importance to business (Pang et al., 2002; Hu and Liu, 2004; Choi and Cardie, 2008; Socher et al., 2012; Vo and Zhang, 2015; Tang et al., 2014). For multiple domains, such as movies, restaurants and digital products, manually annotated datasets have been made available. A useful research question is how to leverage resources available across *all* domains to improve sentiment classification on *a certain* domain.

One naive domain-agnostic baseline is to combine all training data, ignoring domain differences. However, domain knowledge is one valuable source of information available. To utilize this, there has been recent work on *domain-aware* models via multi-task learning (Liu et al., 2016; Nam and Han, 2016), building an output layer for each domain while sharing a representation network. Given an input sentence and a specific test domain, the output layer of the test domain is chosen for calculating the output.

These methods have been shown to improve over the naive domain-agnostic baseline. However, a limitation is that outputs for different domains are constructed using the same domain-agnostic input representation, which leads to weak utilization of domain knowledge. For different domains, sentiment words can differ. For example, the word "beast" can be a positive indicator of camera quality, but irrelevant to restaurants or movies. Also, "easy" is frequently used in the electronics domain to express positive sentiment (e.g. the camera is easy to use), while expressing negative sentiment in the movie domain (e.g. the ending of this movie is easy to guess).

We address this issue by investigating a model that learns domain-specific input representations for multi-domain sentiment analysis. In particular, given an input sentence, our model first uses a bi-directional LSTM to learn a general sentence-level representation. For better utilizing data from all domains, we use adversarial training (Ganin and Lempitsky, 2015; Goodfellow et al., 2014) on the Bi-LSTM representation.

The general sentence representation is then mapped into a domain-specific representation by attention over the input sentence using explicitly learned *domain descriptors*, so that the most salient parts of the input are selected for the specific domain for sentiment classification. Some examples are shown in Figure 2, where our model pays attention to word "engaging" for movie reviews, but not for laptops, restaurants or cameras. Similarly, the word "beast" receives attention for laptops and cameras, but not for restaurants or movies.

In addition to the domain descriptors, we further introduce a memory network for explicitly representing *domain knowledge*. Here domain knowl-

Proceedings of NAACL-HLT 2018, pages 541–550

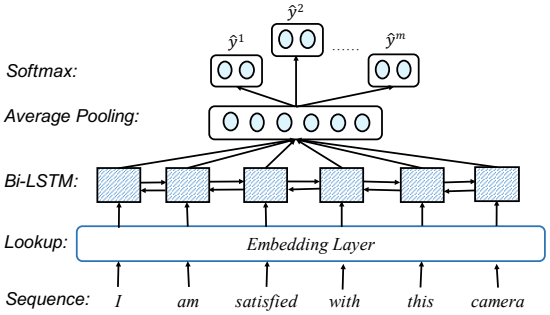
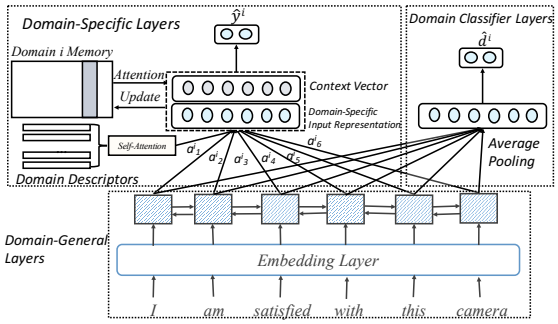
(a) **Mix**: shared parameters for all domains.



(b) **Multi**: shared input representations and domain-specific prediction layers.



(c) Our model: domain knowledge is better utilized by domain descriptors, memories and adversarial training.

Figure 1: Models.

edge refers to example training data in a specific domain, which can offer useful background context. For example, given a sentence 'Keep cool if you think it's a wonderful life will be a heart-warming tale about life like finding nemo', algorithms can mistakenly classify it as positive based on 'wonderful' and 'heartwarming', ignoring the fact that 'it's a wonderful life' is a movie. In this case, necessary domain knowledge revealed in other sentences, such as 'The last few minutes of the movie: it's a wonderful life don't cancel out all the misery the movie contained' is helpful. Given a domain-specific input representation, we make attention over the domain knowledge memory network to obtain a background context vector, which is used in conjunction with the input representation for sentiment classification.

Results on two real-world datasets show that our model outperforms the aforementioned multi-task learning methods for domain-aware training, and also generalizes to unseen domains. Our code is released[1].

2 Problem Definition

Formally, we assume the existence of m sentiment datasets $\{D_i\}_{i=1}^m$, each being drawn from a domain i. D_i contains $|D_i|$ data points (s_j^i, d_i, y_j^i), where s_j^i is a sequence of words $w_1, w_2 ... w_{|s_j^i|}$, each being drawn from a vocabulary V, y_j^i indicates the sentiment label (e.g. $y_j^i \in \{-1, +1\}$ for binary sentiment classification) and d_i is a domain indicator (since we use 1 to m to number each domain, $d_i = i$). The task is to learn a function f which maps each input (s_j^i, d_i) to its corresponding sentiment label y_j^i. The challenge of the task lies in how to improve the generalization performance of mapping function f both in-domain and cross-domain by exploring the correlations between different domains.

3 Baselines

3.1 Domain-Agnostic Model

One naive baseline solution ignores the domain characteristics when learning f. It simply combines the datasets $\{D_i\}_{i=1}^m$ into one and learns a single mapping function f. We refer to this baseline as **Mix**, which is depicted in Figure 1 (a).

Given an input s_j^i, its word sequence $w_1, w_2 ... w_{|s_j^i|}$ is fed into a word embedding layer to obtain embedding vectors $x_1, x_2 ... x_{|s_j^i|}$. The word embedding layer is parameterized by an embedding matrix $E_w \in R^{K \times |V|}$, where K is the embedding dimension.

Bidirectional LSTM: To acquire a semantic representation of input s_j^i, a bidirectional extension (Graves and Schmidhuber, 2005) of Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is applied to capture sentence-level semantics both left-to-right and right-to-left. As a result, two sequences of hidden states are obtained, denoted as $\overrightarrow{h}_1, \overrightarrow{h}_2 ... \overrightarrow{h}_{|s_j^i|}$ and $\overleftarrow{h}_1, \overleftarrow{h}_2 ... \overleftarrow{h}_{|s_j^i|}$, respectively. We concatenate $\overrightarrow{h}_t$

[1] https://github.com/leuchine/multi-domain-sentiment

and $\overleftarrow{h}_t$ at each time step to obtain the hidden states $h_1, h_2 ... h_{|s^i_j|}$, which are of sizes $2K$.

Output Layer: Average pooling (Boureau et al., 2010) is applied on the hidden states $h_1, h_2 ... h_{|s^i_j|}$ to obtain an input representation I^i_j for s^i_j,

$$I^i_j = \frac{\sum_{t=1}^{|s^i_j|} h_t}{|s^i_j|} \quad (1)$$

Finally, softmax is applied over I^i_j to obtain a probability distribution of all sentiment labels. During training, cross entropy is used as loss function, denoted as $L(f(s^i_j), y^i_j)$ for data points (s^i_j, d_i, y^i_j), and AdaGrad (Duchi et al., 2011) is applied to update parameters.

3.2 Multi-Domain Training

We build a second baseline for domain-aware sentiment analysis. A state-of-the-art architecture (Liu et al., 2016; Nam and Han, 2016) is used as depicted in Figure 1 (b), where m mapping functions f_i are learned for each domain. Given the input representation I^i_j obtained in Equation 1, multi-task learning is conducted, where each domain has a domain-specific set of parameters for softmax to predict sentiment labels with shared input representation layers. The input domain indicator d_i instructs which set of softmax parameters to use here and each domain has its own cross entropy loss $L_i(f_i(s^i_j, d_i), y^i_j)$ for data points (s^i_j, d_i, y^i_j). We denote this baseline as **Multi**.

4 Method

4.1 Domain-Aware Input Representation

The above baseline **Multi** achieves state-of-the-art performance for multi-domain sentiment analysis (Liu et al., 2016), yet the domain indicator d_i is used solely to select softmax parameters. As a result, domain knowledge is hidden and under-utilized. Similar to **Mix** and **Multi**, we use a Bi-LSTM to learn representations shared across domains. However, we introduce domain-specific layers to better capture domain characteristics as shown in Figure 1 (c).

Different domains have their own sentiment lexicons and domain differences largely lie in which words are relatively more important for deciding the sentiment signals. We use the neural attention mechanism (Bahdanau et al., 2014) to select words, obtaining domain-specific input representations.

In our model, *domain descriptors* are introduced to explicitly capture domain characteristics, which are parametrized by a matrix $N \in R^{2K \times m}$. Each domain descriptor corresponds to one column of N and has a length of $2K$, the same as the bidirectional LSTM hidden states h_t. This matrix is automatically learned during training.

Given an input (s^i_j, d_i), we apply an embedding layer and Bi-LSTM to generate its domain-general representation $h_1, h_2, ..., h_{|s^i_j|}$ and use the corresponding domain descriptor N_i to weigh $h_1, h_2, ..., h_{|s^i_j|}$ for obtaining a domain-specific representation. To this end, there are two most commonly used attention mechanisms: additive attention (Bahdanau et al., 2014) and dot product attention (Ashish Vaswani, 2017). We choose additive attention here, which utilizes a feed-forward network with a single hidden layer, since it achieves better accuracies in our development. The input representation I^i_j becomes a weighted sum of hidden states:

$$I^i_j = \sum_{t=1}^{|s^i_j|} a^i_{jt} h_t \quad s.t. \sum_{t=1}^{|s^i_j|} a^i_{jt} = 1 \quad (2)$$

The weight a^i_{jt} reflects the similarity between the domain i's descriptor N_i and the hidden state h_t. a^i_{jt} is evaluated as:

$$l^i_{jt} = v^T tanh(PN_i + Qh_t)$$
$$a^i_{jt} = \frac{exp(l^i_{jt})}{\sum_{p=1}^{|s^i_j|} exp(l^i_{jp})} \quad (3)$$

Here $P \in R^{4K \times 2K}$, $Q \in R^{4K \times 2K}$ and $v \in R^{4K}$ are parameters of additive attention. P and Q linearly project N_i and h_t to a hidden layer, respectively. The projected space is set as $4K$ empirically, since we find it beneficial to project the vectors into a larger layer. v serves as the output layer. Softmax is applied to normalize l^i_{jt}. We name this method **DSR** for learning domain-specific representations.

4.2 Self-Attention over Domain Descriptors

DSR uses a single domain descriptor to attend over input words. However, relations between domains are not considered (e.g. sentiment lexicons for domain 'camera' are more similar to the lexicons of domain 'laptop' than those of domain

'restaurant'). To model the interaction between domains, a self-attention layer is applied using dot product attention empirically, as shown in Figure 1 (c):

$$N_i^{new} = N\ softmax(N^T N_i) \quad (4)$$

We compute dot products between N_i and every domain descriptors. The dot products are normalized using the softmax function, and N_i^{new} is a weighted sum of all domain descriptors. N_i^{new} is used to attend over hidden states, employing Equation 2 and 3. During back propagation training, domain descriptors of similar domains could be updated simultaneously. We name this method **DSR-sa**, which denotes domain-specific representation with self-attention.

4.3 Explicit Domain Knowledge

To further capture domain characteristics, we devise a memory network (Weston et al., 2014; Sukhbaatar et al., 2015; Kumar et al., 2016) framework to explicitly represent domain knowledge. Our memory networks hold example training data of a specific domain for retrieving context data during predictions.

Formally, we use a memory $M^i \in R^{2K \times |D_i|}$ ($|D_i|$ is the total number of training instances of domain i) to hold domain-specific representations I_j^i of training instances for the domain i.

Memory Network: We directly set I_j^i as the jth column of the memory M^i. Formally,

$$M_j^i = I_j^i \quad (5)$$

Obtaining A Context Vector Using Background Knowledge: Given an input I_j^i, we generate a context vector C_j^i to support predictions by memory reading:

$$C_j^i = M^i\ softmax((M^i)^T I_j^i) \quad (6)$$

Dot product attention is applied here, which is faster and more space-efficient than additive attention, since it can be implemented using highly optimized matrix multiplication. Dot products are performed between I_j^i and each column of M^i and the scores are normalized using the softmax function. The final context vector is a weighted sum of M^i's columns.

Output: We concatenate the context vector and the domain-specific input representation, feeding the result to softmax layers. Similar to the baseline **Multi**, each domain has its own loss $L_i(f_i(s_j^i, d_i), y_j^i)$. We name this method as **DSR-ctx** for context vector enhancements.

Reducing Memory Size: In the naive implementation, the memory size $|M^i|$ is equal to the total number of saved sequences, which can be very large in practice. We explore two ways to reduce memory size.

(1) Organizing memory by the vocabulary. We set $|M^i| = |V|$, where each memory column of M^i corresponds to a word in the vocabulary. During memory writing, I_j^i updates all the columns that correspond to the words w in its input sequence s_j^i by exponential moving average:

$$M_w^i = decay * M_w^i + (1 - decay) I_j^i$$

In this way, two input representations update the same column of the memory network if and only if they share at least one common word.

(2) Fixing the memory size by clustering. $|M^i|$ is set to a fixed size and I_j^i only updates the memory column that is most similar to I_j^i, i.e. I_j^i only update the column $arg\,max\,(M^i)^T I_j^i$. In this way, semantically similar inputs are clustered and update the same column.

4.4 Adversarial Training

We use embeddings and Bi-LSTM, parametrized by θ_{dg}, to generate domain-general representations. However, the distributions of domain-general representations for all domains can be different (Goodfellow et al., 2014), which contaminates the representations (Liu et al., 2017) and imposes negative effects for in-domain predictions. For cross-domain testing, the discrepancies cause domain shift, which harms prediction accuracies on target domains (Ganin and Lempitsky, 2015). Thus, models that can generate domain-invariant representations for all domains are favorable for utilizing multi-domain datasets.

We incorporate adversarial training to enhance the domain-general representations. As shown in Figure 1 (c), domain classifier layers are introduced, parametrized by θ_{dc}, which predicts how likely the input sequence s_j^i comes from each domain i. We denote its cross entropy loss as $L_{at}(f_{at}(s_j^i), d_i)$ for data points (s_j^i, d_i, y_j^i) from domain i (note that we use d_i as its label instead of input here).

Now consisting of domain-general layers, domain-specific layers and domain classifier lay-

ers, the model is trained by a minimax game. For dataset D_i drawn from domain i, we minimize its loss $L_i(f_i(s^i_j, d_i), y^i_j)$ for sentiment predictions, while maximizing the domain classifier loss $L_{at}(f_{at}(s^i_j), d_i)$, controlled by λ:

$$\min_{\theta_{dg},\theta_{ds}} \sum_{D_i} L_i(f_i(s^i_j, d_i), y^i_j) - \lambda L_{at}(f_{at}(s^i_j), d_i), \tag{7}$$

where θ_{ds} is the set of domain-specific parameters including domain descriptors, attention weights and softmax parameters. We fix θ_{dc} and update θ_{dg} and θ_{ds} here. Its adversarial part maximizes the loss by updating θ_{dc}, while fixing θ_{dg} and θ_{ds}.

$$\max_{\theta_{dc}} \sum_{D_i} L_i(f_i(s^i_j, d_i), y^i_j) - \lambda L_{at}(f_{at}(s^i_j), d_i) \tag{8}$$

Equations 7 and 8 are performed iteratively to generate domain-invariant representations. We name this method **DSR-at**.

5 Experiments

We evaluate the effectiveness of the model both in-domain and cross-domain. The former refers to the setting where the domain of the test data falls into one of the m training data domains, and the latter refers to the setting where the test data comes from one unknown domain.

5.1 Experimental Settings

We conduct experiments on two benchmark datasets. The datasets are balanced, so we use accuracy as the evaluation metric in the experiments.

The dataset 1 contains four domains. The statistics are shown in Table 1 , which also shows the accuracies using baseline method **Mix** trained and tested on each domain. *Camera*[2] consists of reviews with respect to digital products such as cameras and MP3 players (Hu and Liu, 2004). *Laptop* and *Restaurant* are laptop and restaurant reviews, respectively, obtained from SemEval 2015 Task 12[3]. Movie[4] are movie reviews provided by Pang and Lee (2004).

The dataset 2 is Blitzer's multi-domain sentiment dataset (Blitzer et al., 2007), which contains product reviews taken from Amazon.com, including 25 product types (domains) such as books, beauty and music. More statistics can be found at its official website[5].

Domain	Instance	Vocab Size	Accuracy
Camera (CR)	3770	5340	0.802
Laptop (LT)	1907	2837	0.871
Restaurant (RT)	1572	2930	0.783
Movie (M)	10662	18765	0.773

Table 1: Dataset 1 statistics.

Given each dataset, we randomly select 80%, 10% and 10% of the instances as training, development and testing sets, respectively.

5.2 Baselines and Hyperparameters

In addition to the **Mix** baseline, the **Multi** baseline (Liu et al., 2016) and our domain-aware models, **DSR**, **DSR-sa**, **DSR-ctx**, **DSR-at**, we also experiment with the following baselines:

MTRL (Zhang and Yeung, 2012) is a state-of-the-art multi-task learning method with discrete features. The method models covariances between task classifiers, and in turn the covariances regularize task-specific parameters. The feature extraction for **MTRL** follows (Blitzer et al., 2007). We use this baseline to demonstrate the effectiveness of dense features generated by neural models.

MDA (Chen et al., 2012) is a cross-domain baseline, which utilizes marginalized de-noising auto-encoders to learn a shared hidden representation by reconstructing pivot features from corrupted inputs.

FEMA (Yang and Eisenstein, 2015) is a cross-domain baseline, which utilizes techniques from neural language models to directly learn feature embeddings and is more robust to domain shift.

NDA (Kim et al., 2016) is a cross-domain baseline, which uses $m + 1$ LSTMs, where one LSTM captures global information across all m domains and the remaining m LSTM capture domain-specific information.

We set the size of word embeddings K to 300, which are initialized using the word2vec model[6] on news. To obtain the best performance, the parameters are set using grid search based on development results. The dropout ratio is chosen from $[0.3, , 1]$. Learning rate is chosen from

[2] http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html

[3] Since the original dataset targets aspect-level sentiment analysis, we remove the sentences with opposite polarities on different aspects. The remaining sentences are labeled with the unambiguous polarity.

Table 2: Results using two training domains on dataset 1. * denotes $p < 0.01$ VS. the second best using McNemar's test.

$[0.0001, 0.001, , 1]$. The vocabulary size is chosen from $[6000, 8000, , 16000]$. The batch size is chosen from $[10, , 100]$. λ is chosen from $[0.0001, 0.001, , 1]$. As a result, the mini-batch size, the size of the vocabulary V, dropout rate, learning rate for AdaGra and λ for adversarial training are set to 50, 10000, 0.4, 0.5 and 0.1, respectively. Also, gradient clipping (Pascanu et al., 2013) is adopted to prevent gradient exploding and vanishing during training process. Since all datasets only have thousands of instances, we set memory network sizes as training instance sizes in the experiments.

5.3 Working with Known Domains

In this section, we perform in-domain validations. We first combine two datasets for training and test on each domain's hold-out testing dataset. The results on dataset 1 are shown in Table 2 (the results on Blitzer's dataset exhibit similar results and are omitted due to space constraints).

The accuracies of **MTRL** are significantly lower than the neural models, which demonstrates the effectiveness of dense features over discrete features. The baseline **Mix** improves the average accuracy from 0.778 to 0.818, and most multi-domain training accuracies are better compared to single-domain training in Table 1. **Mix** simply combines the two datasets for trainings and ignores domain characteristics, yet improves over single dataset training. This demonstrates that more data reduces over-fitting and leads to better generalization capabilities. **Multi** further improves the average accuracy by 1.4%, which confirms the effectiveness of utilizing domain information.

Among our models, **DSR** further improves the accuracy over **Multi** by 1%, which confirms the effectiveness of domain-specific input representations in multi-domain sentiment analysis. **DSR-sa** slightly outperforms **DSR** by 0.03%. Adopting an additional self-attention layer, **DSR-sa** trains similar domain descriptors together, thus better modeling domain relations, which will be further studied in Section 5.5.2. **DSR-ctx** outperforms **DSR-sa** by 1.2%, which demonstrates the effectiveness of memory networks in utilizing domain-specific example knowledge. **DSR-at** gives significantly the best results, confirming that domain-invariant representations achieved by adversarial training indeed benefit in-domain training. The results are significant using McNeymar's test.

The results combining all the 4 domains and the 25 domains of the two datasets are shown in the 'In domain' sections of Table 3 and Table 4, respectively. Here the models are trained using all domains' training data, and tested on each domain's hold-out test data. Similar patterns are observed as in Table 2 and **DSR-at** achieves significantly the best accuracies (0.867 and 0.907 for the two datasets, respectively).

5.4 Working with Unknown New Domains

We validate the algorithms cross-domain. For dataset 1, models are trained on three domains, yet validated and tested on the other domain. For dataset 2, models are trained on 24 domains, yet validated and tested on the 25th.

Since **DSR-at** has m outputs (one for each training domain), we adopt an ensemble approach to obtain a single output for unknown test domains. In particular, since the domain classifier outputs probabilities on how likely the test data come from each training domain, we use these probabilities as weights to average the m outputs.

For **NDA**, **Multi**, **DSR** and **DSR-sa** and **DSR-ctx**, we use average pooling to combine the m outputs. Since **MDA** and **FEMA** are devised to train on a single source domain, we combine the training data of m domains for training.

The results are shown in the 'Cross domain' section of Table 3 and Table 4, respectively. One observation is that cross-domain accuracies are worse than in-domain accuracies, showing challenges in unknown-domain testing.

Contrast between our models and **FEMA/NDA** shows the advantage of leveraging resources from all domains, versus a single source domain for cross-domain modelling. Among the baselines,

Table 4: In-domain learning and cross-domain results on dataset 2. * denotes $p < 0.01$ VS. the second best.

NDA also considered domain-specific representations. On the other hand, it duplicates the full set of model parameters for each domain, yet underperforms **DSR** and **DSR-sa**, which records only one domain descriptor vector for each domain. The contrast shows the advantages of learning domain descriptors explicitly in terms of both efficiency and accuracy.

Similar to the known domain results, **DST-sa** and **DSR-ctx** further improve upon **DSR** and **DSR-sa**, showing the effectiveness of domain memory and adversarial learning. On both datasets, **DSR-at** achieves significantly the best performances, which shows the advantages of domain-invariant representations for unknown-domain testing.

5.5 Case Study

5.5.1 Input Attention

To obtain a better understanding of input attention with domain descriptors, we examine the attention weights of inputs and three examples are displayed in Figure 2, where the x axis denotes the four domains from the first dataset and the y axis shows the words.

In Figure 2 (a), the domain-specific word 'ease' is only selected for the domains *LT* and *CR*, while the domain-independent word 'great' is salient in all domains. Similarly, in Figure 2 (b), 'meaty' and 'engaging' are only salient in *RT* and *M*, respectively. In Figure 2 (c), the domain-specific word 'beast' is chosen in **LT** and **CR**.

These confirm the effectiveness of input attention and **DSR-ctx** has the capability to pick out sentiment lexicons in conformity with domain characteristics.

5.5.2 Domain Descriptors

With the self-attention layer, one interesting question is whether learned domain descriptors can reflect domain similarities/dissimilarities.

We take out the twenty-five domain descriptors for Blitzer's dataset and calculate the cosine similarities between each pair. Also, we calculate the cosine similarities of twenty-five domains based on unigram and bigram representations for ground truth. Pearson correlation coefficient is used to measure the correlations between two sets of cosine values. The final score is 0.796, which shows that domain descriptor similarities can serve as indicators for domain similarities.

This place blew me away. By far my new favorite restaurant on the upper-east side.
(a1) This is one of my favorite spot, very relaxing. The food is great all the times. Celebrated my engagement and my wedding here. It was very well organized.
(a2) This is one of my favorite restaurants and it is not to be missed.
(a3) I didn't complain. I liked the atmosphere so much.
I started accessing and transferring files to find it to be extremely slow.
(b1) Only thing I don't like about it is slow in changing apps, boot up, and sometime it has problem connect through bluetooth.
(b2) I must say, this one is quite slow to open an application.
(b3) The subscription files are still a little slower to transfer, but it 's only by about 10% or so.
Keep cool if you think it's a wonderful life will be a heartwarming tale about life like finding nemo.
(c1) I heard so much about It's a wonderful life's happy ending and I just wasn't prepared for so much misery.
(c2) The last few minutes of the movie: its a wonderful life dont cancel out all the misery the movie contained.
(c3) It's a wonderful life was so incredibly over-sentimental and highly manipulative.

Table 5: Memory Network Attention.

5.5.3 Memory Network Attention

We further study the attention of memory networks by randomly picking instances in the test sets and listing the context instances with the greatest attention weights obtained from Equation 6. The results of three test instances and their context instances are shown in Table .

One observation is that semantically similar instances are selected to provide extra knowledge for predictions (e.g. a1, a2, b3, c1, c2, c3). Another observation is that the sentiment polarities between test instances and selected context instances are usually the same. We conclude that the memory networks are capable of selecting instructive instances for facilitating predictions.

6 Related Work

Domain Adaptation (Blitzer et al., 2007; Titov, 2011; Yu and Jiang, 2015) adapts classifiers trained on a source domain to an unseen target domain. One stream of work focuses on learning a general representation for different domains based on the co-occurrences of domain-specific and domain-independent features (Blitzer et al., 2007; Pan et al., 2011; Yu and Jiang, 2015; Yang et al., 2017). Another stream of work tries to identify domain-specific words to improve cross-domain classification (Bollegala et al., 2011; Li et al., 2012; Zhang et al., 2014; Qiu and Zhang, 2015). Different from previous work, we utilize *multiple* source domains for cross-domain validation, which makes our method more general and domain-aware.

Multi-domain Learning jointly learn multiple domains to improve generalization. One strand of work (Dredze and Crammer, 2008; Saha et al., 2011; Zhang and Yeung, 2012) uses covariance matrix to model domain relatedness, jointly learns domain-specific parameters and domain-independent parameters of linear classifiers. Another strand of work (Liu et al., 2016; Nam and Han, 2016) adopts neural network with shared input layers and multiple output layers for prediction. Our work belongs to the latter, yet we introduce domain descriptor matrix and memory networks to better capture domain characteristics and achieve better performance.

Memory Networks reason with inference components combined with a long-term memory component. Weston et al. (2014) devise a memory network to explicitly store the entire input sequences for question answering. An end-to-end memory network is further proposed by Sukhbaatar et al. (2015) by storing embeddings of input sequences, which requires much less supervision compared to Weston et al. (2014). Kumar et al. (2016) introduces a general dynamic memory network, which iteratively attends over episodic memories to generate answers. Xiong et al. (2016) extends Kumar et al. (2016) by introducing a new architecture to cater image inputs and better capture input dependencies. In similar spirits, our memory network stores the domain-specific training instances for obtaining context knowledge.

7 Conclusion

We investigated domain representations in multi-task learning for multi-domain sentiment analysis, showing that leveraging domain descriptors, examples and adversarial training to learn domain representations give significant improve-

ments compared with strong multi-task learning baselines.

Learning Sentence Representations over Tree Structures for Target-dependent Classification

Junwen Duan, Xiao Ding, Ting Liu*

Abstract

Target-dependent classification tasks, such as aspect-level sentiment analysis, perform fine-grained classifications towards specific targets. Semantic compositions over tree structures are promising for such tasks, as they can potentially capture long-distance interactions between targets and their contexts. However, previous work that operates on tree structures resorts to syntactic parsers or Treebank annotations, which are either subject to noise in informal texts or highly expensive to obtain. To address above issues, we propose a reinforcement learning based approach, which automatically induces target-specific sentence representations over tree structures. The underlying model is a RNN encoder-decoder that explores possible binary tree structures and a reward mechanism that encourages structures that improve performances on downstream tasks. We evaluate our approach on two benchmark tasks: firm-specific cumulative abnormal return prediction (based on formal news texts) and aspect-level sentiment analysis (based on informal social media texts). Experimental results show that our model gives superior performances compared to previous work that operates on parsed trees. Moreover, our approach gives some intuitions on how target-specific sentence representations can be achieved from its word constituents.

1 Introduction

We investigate target-dependent classification problem in this paper, with a special focus on the sentence level. Target-dependent classification aims to identify the fine-grained polarities of sentences towards specific targets, which is challenging but also important for deep text understanding. The definitions of polarity vary across different tasks, which can be *positive* or *negative* in aspect-level sentiment analysis, *favor* or *against* in stance detection, and *rise* or *drop* in financial news analysis towards the stock price movement of a particular firm.

Task	Example
Aspect-level Sentiment Analysis	The **food** is good but the **service** is dreadful.
Stance Detection	I don't care about **global climate change**.
Firm-specific Financial News Analysis	**Nike** sues **Wal-Mart** for Patent Infringement.

Table 1: Samples of target-dependent classification tasks. The targets of interest are in bold.

Table 1 gives examples of three target-dependent classification tasks. We can find that there can be multiple target mentions in the same text scope, which makes it challenging for generic sentence representation approaches. For the first example, a restaurant manager or a potential customer may be interested in both *food* and *service*; however, the sentiment polarities towards the two targets are different. Hence, it would be beneficial for such tasks to tailor the sentence representations with respect to particular targets.

Tree structures are promising for such tasks, as they can potentially capture long-distance dependencies between target words and their contexts (Li et al., 2015). Therefore, it is not surprising to find work that exploits the syntactically parsed trees for learning target-specific sentence representations. Dong et al. (2014) and Chang et al. (2016) adapted the word orders in a parsed tree, depending on their distances to the target entities. Nguyen et al. (2015) extended Dong et al. (2014) by combining the constituency tree and the dependency tree of a sentence. An important assumption of such work is that different tree structures lead to different semantic representations even for the same sentence. However, they all resort to ex-

New Orleans, Louisiana, June 1 - 6, 2018.

ternal syntactic resources, such as parse trees or Treebank annotations (Marcus et al., 1993), which limits their broader applications. On the one hand, annotated data are highly expensive to produce; and informal texts, such those on the social media, remain a challenge for syntactic parsers (Kong et al., 2014). On the other hand, the tree structures in their pipeline-style architecture are fixed during training, which cascade errors to later representation learning stage.

A desirable solution would be to automatically and dynamically induce the tree structures for target-specific sentence representations. However, the challenge is that the absence of external supervisions makes it difficult to evaluate the quality of the tree structures and train the parameters. Inspired by Yogatama et al. (2016), we propose a reinforcement learning based approach that integrates target information and generates target-specific tree structures that benefit downstream classification tasks.

The underlying framework consists of two key components, a RNN encoder-decoder that explores possible binary tree structures according to a given target, and a tree-structured neural network that composes the input words into sentence representation based on the structure. The REINFORCE algorithm with the self-critic baseline (Rennie et al., 2016) is applied to update the parameters of the two components.

We evaluate our approach on two benchmark tasks: a firm-specific cumulative abnormal return prediction task (based on formal news texts) and an aspect-level sentiment analysis task (based on informal social media texts). Experimental results show that our approach achieves superior performances compared to baseline methods that operate on parsed trees. Moreover, our model sheds lights on understanding how sentences are composed from its word constituents towards specific targets.

2 Problem Definition

We formalize the problem of learning sentence representations for target-dependent classification tasks as constructing and semantically composing the target-specific binary syntactic trees of sentences. The input of the model is a tuple $(\mathbf{x}, x_{target}, c_{target})$, in which $\mathbf{x}$ is a sentence of n words $\{x_1, x_2, \cdots, x_n\}$; x_{target} is the target of interest mentioned in the sentence and c_{target} is the polarity regarding the target. For sentence $\mathbf{x}$, we can construct a valid binary syntactic tree by n SHIFT and $n-1$ REDUCE transitions $\mathbf{a} = \{a_0, a_1, \cdots, a_{2n-1}\}$, in which $a_t \in \{\text{SHIFT}, \text{REDUCE}\}$ specifies the transition taken at step t. The SHIFT transition adds a leaf node to the tree while the REDUCE transition combines two leaf nodes to form a parent node.

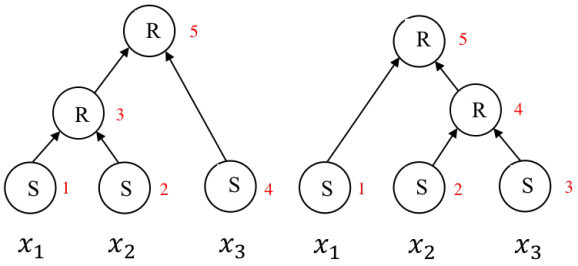

Figure 1: For input sequence $\{x_1, x_2, x_3\}$, the shift-reduce orders can be {S,S,R,S,R} and {S,S,S,R,R}, where **S** stands for SHIFT and **R** stands for REDUCE.

Figure 1 illustrates two examples on how can we construct a binary tree by only using SHIFT and REDUCE transitions and how can we obtain different binary trees by varying the SHIFT-REDUCE transition orders.

We design a transition generator $\mathbf{G}$ (Section 3.1) for generating transition orders $\mathbf{a}$, $\mathbf{G}(\mathbf{x}, x_{target}) \rightarrow \mathbf{a}$ and a composition function $\mathbf{C}$ (Section 3.2) that composes sentence $\mathbf{x}$ following the transition orders $\mathbf{a}$ into sentence representation $\mathbf{s}$, $\mathbf{C}(\mathbf{a}, \mathbf{x}) \rightarrow \mathbf{s}$.

Our ultimate goal is to use the sentence representation $\mathbf{s}$ for target-dependent classification. The objective is thus to minimize the negative log-likelihood Eq 1 with L2 norm, in which θ denotes all the parameters of our model.

$$J(\theta) = -\log P(c_{target}|\mathbf{s}; \theta) + \lambda||\theta||_2 \quad (1)$$

3 Model

The architecture of our proposed approach is illustrated in Figure 2, which is made up of two main components, a transition generator $\mathbf{G}$ and a composition function $\mathbf{C}$. The transition generator is a RNN encoder-decoder that generates discrete target-specific SHIFT-REDUCE transition orders, given a sentence and the target of interest. The composition function is a tree-structured neural network that semantically composes the word constituents following the transition orders. The main challenges for such a framework are two-fold. On

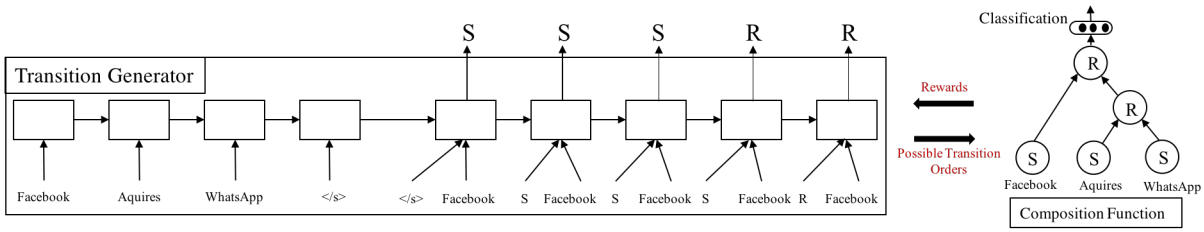

Figure 2: The framework of our proposed method. The left side is a variant of standard encoder-decoder that generates discrete SHIFT-REDUCE transition orders. It considers the target information at decoding. The right side is a composition function that semantically composes word representations into sentence representation following the transition orders. REINFORCE with the self-critical baseline is applied to reward the generated structures and update the parameters.

the one hand, the transition generator is fully unsupervised as we do not resort to external syntactic resources. On the other hand, the transitions generated at each step are discrete, making it difficult to train and propagate errors to update the model parameters. We give details of the two components and how we address the challenges in this section.

3.1 Transition Generator

The basic idea of the transition generator is to generate different transition orders given different targets. We propose using the RNN encoder-decoder framework (Cho et al., 2014), which has shown capacity in shift-reduce parsing (Vinyals et al., 2015; Liu and Zhang, 2017b). A standard RNN encoder-decoder contains two recurrent neural networks, one for encoding a sequence of variable-length into a vector representation and the other for decoding the representation back into another variable-length sequence.

Encoder We employ a standard Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) as our encoder. Given the input sentence $\{x_1, x_2, \cdots, x_n\}$, we first obtain their word vectors $\{\overrightarrow{e}(x_1), \overrightarrow{e}(x_2), \cdots, \overrightarrow{e}(x_n)\}$ by looking them up from a pre-trained embedding matrix $\overrightarrow{e}$. We reverse the input sentence and feed their word embeddings sequentially to the LSTM. The hidden states of each token $\{h_1, h_2, \cdots, h_n\}$ are kept for the decoding stage. The hidden state and cell state of the last LSTM unit are used as the initial states for decoder.

Decoder Following Bahdanau et al. (2014), we use an attention-based decoder. The decoder aligns with all the encoder hidden states at each step of decoding to obtain a context vector c_t, such that each input words show different weights at decoding. We denote the hidden states of our decoder as $\{d_1, d_2, \cdots, d_{2n-1}\}$. The attention score over each of the encoder hidden state h_i is computed by:

$$u_t^i = d_{t-1} \odot h_i \tag{2}$$

$$a_t^i = \frac{\exp(u_t^i)}{\sum_{i'} \exp(u_t^{i'})} \tag{3}$$

$$c_t = \sum_{i=1}^{n} a_t^i \cdot h_i, \tag{4}$$

in which $\odot$ denotes element-wise dot product; a_t^i is the normalized attention score and the context vector c_t is a weighted sum of all the encoder hidden states.

To enable the target of interest to influence the decoding process, we enrich the input of the decoder by concatenating the target entity. The hidden state of the decoder at time t is obtained by:

$$d_t = \text{LSTM}(c_t \oplus \overrightarrow{e}(a_{t-1}) \oplus \overrightarrow{e}(x_{target}), d_{t-1}), \tag{5}$$

in which $\oplus$ denotes concatenation operation; x_{target} is the embedding of the target entity; $\overrightarrow{e}(a_{t-1})$ is the embedding of the last decoded transition and c_t is the context vector.

Decoding In a supervised RNN decoder setting, the goal of each step is to estimate the conditional probability

$$P(a_t|a_{1:t-1}, c_t, d_t) = g(a_{t-1}, c_t, d_t), \tag{6}$$

in which $a_{1:t-1}$ are previously decoded transitions, c_t is the context vector, d_t is current decoder hidden state and g is non-linear network. $P(a_t|a_{1:t-1}, c_t, d_t\}$ is a distribution over the transition space $\{\text{SHIFT}, \text{REDUCE}\}$. By comparing

the decoded outputs with the ground-truth labels, the prediction errors can back-propagate to update parameters of the encoder-decoder network.

However, it is no more applicable in our settings, as we do not have any explicit supervisions from external syntactic resources. To make training the transition generator possible, we resort to a reinforcement learning framework, obtaining the transitions by sampling from a policy network. We represent the current state $\mathbb{S}_t$ by concatenating $\overrightarrow{e}(a_{t-1}), \overrightarrow{e}(x_{target}), c_t, d_t$.

$$\mathbb{S}_t = [\overrightarrow{e}(a_{t-1}) \oplus \overrightarrow{e}(x_{target}) \oplus c_t \oplus d_t] \quad (7)$$

The policy network $\pi(a_t|\mathbb{S}_t)$ is defined by Eq 8,

$$\pi(a_t|\mathbb{S}_t) \propto \exp(g(\mathbb{S}_t)), \quad (8)$$

in which g is a one-layer non-linear feed-forward neural network. We decode the transition a_t by sampling from the distributions given by the policy network.

3.2 Composition Function

When a valid binary tree of a sentence is generated, we use the composition function to obtain the representation following the transition orders. We maintain two data structures at composition; a buffer that stores words yet to be processed and a stack that stores the partially completed subtrees. Initially, the stack is empty, and the buffer stores all the words in the sentence. The operations specified by SHIFT and REDUCE are as follows.

- For a SHIFT transition, the buffer pops the topmost word out and pushes it to the top of the stack.
- For a REDUCE transition, the topmost two elements of the stack are popped out and composed. Their compositions are then pushed back to the stack.

To produce a valid binary tree, we follow Yogatama et al. (2016) to disallow SHIFT transition when the buffer is empty and forbid REDUCE transition when the stack has no more than two elements.

We use a tree-LSTM (Tai et al., 2015) to semantically compose the top two elements of the stack. Initially, the hidden state h_t and the cell state s_t of leaf nodes are given by another LSTM. The tree-LSTM works as follows,

$$\begin{bmatrix} i_t \\ f_t^l \\ f_t^r \\ o_t \\ g_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} \cdot W \cdot \begin{bmatrix} h_t^l \\ h_t^r \end{bmatrix} \quad (9)$$

$$s_t = f_t^l \odot s_t^l + f_t^r \odot s_t^r + i_t \odot g_t$$
$$h_t = o_t \odot \tanh(\hat{s}_t),$$

in which $\odot$ denotes element-wise dot product; i_t and o_t are the input and output gate, respectively; f_t^l and f_t^r are the left and right forget gates; $h_t^l, h_t^r, s_t^l, s_t^r$ are the hidden and cell states of the left and right nodes in the subtree. The hidden state of the topmost node is used as the representation for the input sentence.

3.3 Training with REINFORCE

The goal for training is to optimize the parameters of the transition generator θ_G and the composition function θ_C. It is easy to optimize θ_C, the output of which is directly connected to the classifier, the classification loss can back-propagate to update its parameters.

However, the transitions sampled from the policy network $\pi(\mathbf{a}|\mathbb{S})$ are discrete, which makes θ_G no more differentiable to our objective. A possible solution is to maximize the expected reward $\mathbb{E}_{p(\mathbf{a};\theta_G)}R(\mathbf{a})$. As we are in a reinforcement learning setting, we can immediately receive a reward $\mathrm{R}(\mathbf{a})$ for transitions $\mathbf{a} = \{a_1, a_2, \cdots, a_t\}$ at the end of the classification. The reward is defined as the logarithm of classification probability for the right label c_{target}, $R(\mathbf{a}) = \log P(c_{target}|C(\mathbf{a}, \mathbf{x}))$.

However, it is computationally intractable to compute $\mathbb{E}_{p(\mathbf{a};\theta_G)}R(\mathbf{a})$, as the number of possible transition orders $\mathbf{a}$ is exponentially large. To address this, we use the REINFORCE algorithm to approximate the gradients by running M examples.

$$\bigtriangledown_{\theta_G} J(\theta_G) \approx -\frac{1}{M}\sum_{m=1}^{M}[\bigtriangledown_{\theta_G} \log p(\mathbf{a}) R^m(\mathbf{a})] \quad (10)$$

The $\bigtriangledown_{\theta_G} \log p(\mathbf{a})$ can be used to update θ_G.

REINFORCE algorithm is non-biased but may have high variance. To reduce the variance, a widely used trick is to subtract a baseline from the reward. It has been theoretically proven that

any baselines that do not depend on the actions are applicable. In this paper, we follow Rennie et al. (2016) to apply a self-critical baseline to the rewards. Rather than estimating a baseline reward, the self-critical method uses the outputs given by the test-time inference algorithm as the baselines. This can thus alleviate the over-fitting problem on test dataset.

At inference, we use a greedy decoding strategy by selecting the most probable transitions given by the policy network (Eq 8).

$$\hat{a}_i = \arg\max_{a_i} \pi(a_i|\mathbb{S}_t) \tag{11}$$

The self-critical baseline reward is $R(\hat{\mathbf{a}}) = \log P(c_{target}|C(\hat{\mathbf{a}}, \mathbf{x}))$, the formula to update θ_G become Eq 12.

$$\begin{aligned} &\nabla_{\theta_G} J(\theta_G) \approx \\ &-\frac{1}{M}\sum_{m=1}^{M}[\nabla_{\theta_G} \log p(\mathbf{a})(R^m(\mathbf{a}) - R^m(\hat{\mathbf{a}}))] \end{aligned} \tag{12}$$

4 Experiments and Results

The proposed approach is evaluated on two aspect-level tasks: (1) firm-oriented cumulative abnormal return prediction on formal financial news texts and (2) aspect-level sentiment analysis on informal social media texts.

4.1 Firm-specific cumulative abnormal return prediction

Firm-specific Cumulative Abnormal Return (CAR) prediction task (Chang et al., 2016) studies the impact of new information towards a specific firm. Multiple firms may be involved in the same new event, however, the event can present different impacts to these firms. Conceptually, **Abnormal Return** is the difference between the actual return of a stock and its expected return. The expected return can be approximated by daily indexes, such as S&P 500 index. For example, if a stock is expected to rise by 5%, but on the event day, it rises by 2%, although it gives a positive return, the abnormal return is -3%. **Cumulative Abnormal Return** is the accumulated abnormal return in an event window, which is usually triggered by new events. We use a three-day window (-1, 0, 1), denoted as CAR_3, with event day centering at day 0. We predict whether an event has positive or negative impact to the cumulative abnormal return of a given firm.

	Training	Development	Test
$+CAR_3$	7167	354	728
$-CAR_3$	7102	387	731
Total	14269	741	1459
Firms	1216	302	424

Table 2: Number of CAR_3 in the datasets

4.1.1 Data

We use the same news dataset as Chang et al. (2016), which are abstracts extracted from the Reuters news dataset released by Ding et al. (2014; 2015; 2016). Compared to the full texts of news documents, abstracts are supposed to be more informative and less noisy. Ding et al. (2014) show that modeling abstracts alone can achieve comparable or even better performances compared to full texts in stock market prediction. To better interpret our approach, we only extract event days with a single news document, which covers over 70% cases in the dataset. This final dataset yields a total of 16469 instances, including 1291 firms, of which 10% are reserved for validation, and 20% are used for testing. The numbers of positive and negative CAR_3 examples and number of firms in the subsets are listed in Table 2.

4.1.2 Baseline

To evaluate the performance of our approach on formal news texts, we compare with state-of-the-art target-independent and target-dependent baselines. Among the baselines, *Sentiment-based* and *Bi-LSTM* are target-independent, which learn generic representations for sentences, while *Bi-LSTM + Attention* and *TGT-CTX-TLSTM* are target-dependent.

Sentiment-Based Sentiments among breaking news, earning reports and online message boards, are found to be correlated with market volatility (Schumaker and Chen, 2009; Das and Chen, 2007). We adopt lexicon-based sentiment analysis as our baseline, using the sentiment lexicons released by Loughran and McDonald (2011). We follow the prior literature (Mayew and Venkatachalam, 2012) and use the count of positive words, negative words, the differences between positives and negatives, and their length-normalized values as our feature vectors.

Bi-LSTM We stack a forward and a backward LSTM to capture the contextual representations for the sentence. The last hidden states of both

Parameters	Value
word dimension	200
LSTM hidden dimension	200
dropout probablity	0.5
batch size	64
initial learning rate	0.0005

Table 3: Hyper-parameters for firm-oriented cumulative abnormal return task

directions are concatenated and then used for classification.

Bi-LSTM + Attention We extend vanilla Bi-LSTM by adding an attention mechanism over the hidden states. We concatenated the hidden states $\hat{h}_t = \{h_t^l, h_t^r\}$ of each input token x_t, the target representation $\overrightarrow{e}_{target}$ is adopted to weigh each of the hidden states.

$$u_t = v^\top \tanh(W_1 \overrightarrow{e}(x_{target}) + W_2 h_t + b) \quad (13)$$

$$a_t = softmax(u_t) \quad (14)$$

$$d_t = \sum a_t h_t \quad (15)$$

TGT-CTX-TLSTM The method of Chang et al. (2016), which we follow and is used as our main baseline. It is a hybrid model which integrates both sequential information and syntactic parse tree information. As the first step, the abstract is parsed with an external syntactic parser to obtain the dependency relations between the words. The parse tree are then adapted and binarized depending on their distances to targets in the dependency graph. A tree-structured Long Short-Term Memory Network (Tai et al., 2015) is then applied to learn a vector representation of the binarized tree structure.

4.1.3 Parameters & Metrics

The hyper-parameters used in this paper are listed in Table 3. We pretrain word vectors with the Word2Vec (Mikolov et al., 2013) tool on the news dataset released by Ding et al. (2014), which are fine-tuned during training. The embeddings of target firms are obtained by averaging their words of constituents.

We use macro-F1 to evaluate the performance on both positive and negative classes.

4.1.4 Test Results

The macro-F1 scores of our method and baselines are presented in Table 4. Sentiment-based method

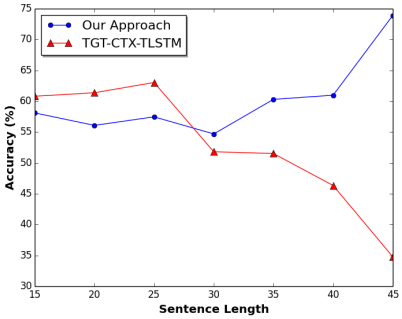

Figure 3: Accuracy with respect to sentence length.

gives the highest F1 score on the positive class. However, its performance is not consistent on the negative class, which suggests that it tends to misclassify the sentence as positive. Bi-LSTM + Attention outperforms the vanilla one without attention and is much robust in both positive and negative analysis. Our approach achieves an overall Macro-F1 of 58.2%, with an F1 score of 57.2% and 59.2% on positive and negative classes, respectively. Compared to the state-of-the-art model that exploits automatically parsed structures, we obtain an over 2% absolute gains without using explicit supervisions in learning the structures.

Method	**Class**	**F1-score**
Sentiment-based	+CAR$_3$	**0.597**
	-CAR$_3$	0.476
	Macro	0.536
Bi-LSTM	+CAR$_3$	0.557
	-CAR$_3$	0.490
	Macro	0.523
Bi-LSTM + Attention	+CAR$_3$	0.575
	-CAR$_3$	0.523
	Macro	0.549
TD-CTX-TLSTM	+CAR$_3$	0.552
	-CAR$_3$	0.570
	Macro	0.561
Our Approach	+CAR$_3$	0.572
	-CAR$_3$	**0.592**
	Macro	**0.582**

Table 4: Results for cumulative abnormal return prediction task

4.1.5 Accuracy Versus Sentence Length

Longer sentences are much more challenging for syntactic parsers. To gain insights on the performances of our approach on long sentences, we further inspect the accuracies with regards to different sentence lengths. As shown in Figure 3, we compare with structure-dependent baseline TGT-CTX-TLSTM. We divide the sentences into seven bins, each of which contains sentences with length $[5 *$

$i, 5 * (i + 1)]$. TGT-CTX-TLSTM gives higher accuracies over sentences with shorter lengths, while the accuracies decline sharply over sentences with lengths of over 30. Our approach is more consistent on both long and short sentences. As the sentence length grows, the accuracy our model gradually increases, showing its robustness and effectiveness across sentences of variable lengths.

4.2 Aspect-level Sentiment Analysis

To verify our proposed approach on informal social media texts, we apply it to aspect-level sentiment analysis on tweets. Aspect-level sentiment analysis aims to identify sentiment polarities towards specific targets mentioned in a sentence. Target-specific sentence representations can be naturally applied to this task.

Dataset	#Target	#Positive	#Negative	#Neutral
Training	6248	1568	1560	3127
Testing	692	173	173	346

Table 5: Statistics of aspect-level sentiment analysis datasets

4.2.1 Dataset

We apply our model to a benchmark aspect-level sentiment analysis dataset used in previous work (Dong et al., 2014). The statistics of the dataset are shown in Table 5. The target entities and corresponding ground-truth labels are annotated. The labels belong to one of {positive, neutral, negative}, thus the task is a three-way classification.

4.2.2 Baselines

We compare our approach with feature-based and neural-based models.

Jiang et al. (2011) They extract rich target-dependent and target-independent lexical and syntactic features for classification.

Dong et al. (2014) They adapt the parse tree of a sentence concerning the target with predefined rules and use recursive neural network (Socher et al., 2013) to learn a target-specific sentence representation.

4.2.3 Parameters & Metrics

The parameter settings are listed in Table 6. We use 100-dimension GloVe vectors which are pre-trained on a large Twitter Corpus (Pennington et al., 2014) and fine-tuned during training.

Parameters	Value
word dimension	100
LSTM hidden dimension	100
dropout probablity	0.5
batch size	32
initial learning rate	0.0005

Table 6: Hyper-parameters for aspect-level sentiment analysis

The commonly-used metrics classification accuracy and macro-F1 are adopted to evaluate the performances.

Model	Acc	F1
Jiang et al.(2011)	63.4	63.3
Dong et al.(2014)	66.3	65.9
Our Method	**68.2**	**66.3**

Table 7: Final results on aspect-level sentiment analysis task

4.2.4 Final Results

The final results on aspect-level sentiment analysis task are shown in Table 7. Dong et al. (2014) are used as our main baseline, as they build target-specific sentence representation over adapted tree structures. Neural-based models outperform Jiang et al. (2011), which did a lot of feature engineerings, showing the effectiveness of automatically induced features. Our approach gives superior performances compared to Dong et al. (2014), which operates on parsed trees. We achieve 68.2% classification accuracy and 66.3 macro-F1. We do not rely on a preprocessing syntactic parser as the first step to obtain the tree structures. On the one hand, social media texts are informal and extremely noisy, which remains a challenge for syntactic parsers. The pipeline-style architecture of Dong et al. (2014) cascades parse errors to later stages, which will hurt the performances on downstream tasks. On the other hand, the adapted tree structures in Dong et al. (2014), while in our approach, the tree structures are also tuned dynamically during training, so as to find the optimal structures that would benefit downstream classification tasks.

4.3 Case Study

To gain further insights on the induced structures, we inspect the shift-reduce trees our approach generated in this section. We present two examples that our model gives high confidences in Figure 4. For the sentence *"Nike NKE.N has sued Wal-Mart WMT.N, saying the world 's largest retailer*

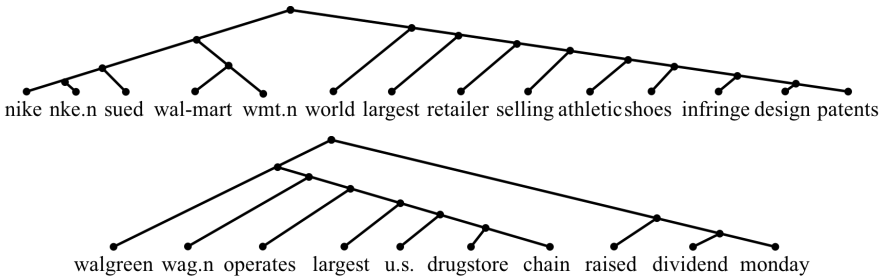

Figure 4: Two tree structures generated by our model. We removed stop words and punctuations. The upper tree structure is for the sentence *"Nike NKE.N has sued Wal-Mart WMT.N, saying the world 's largest retailer is selling athletic shoes that infringe on its design patents"* and the bottom one is for the sentence *"Walgreen WAG.N , which operates the largest U.S. drugstore chain , raised its dividend on Monday."*

is selling athletic shoes that infringe on its design patents", the core part *"Nike sued Wal-mart"* and the rest of the sentence are in two separate subtrees, which reduces potentially information loss about the key event when composing them into sentence representation. Similarly, for the sentence *"Walgreen WAG.N , which operates the largest U.S. drugstore chain , raised its dividend on Monday."*, the model learns to make the target *"Walgreen"* and key event *"raised its dividend on Monday"* close to each other in the tree, although there are sequentially many words in between. These are good examples given by our model, we also find a lot of highly left- or right-biased tree structures. Intuitively, the completely left- and right-biased tree structures are equivalent to forward and backward sequential structures, respectively.

5 Related Work

Our model is related to the following research areas, each having tremendous literatures.

5.1 Target-specific Sentence Representation

It is beneficial for numerous tasks, such as aspect-level sentiment analysis and stance detection, to have the sentence representations being tailored to specific targets. Early approaches rely on feature engineering by extracting target-dependent features (Jiang et al., 2011), while recent work mainly focuses on semantic compositions over the vector space with deep neural models. Depending on how they model the target and context, we further classify related work into three categories.

The first category relies on syntactic parse trees. Dong et al. (2014) are among the first to exploit tree structures, in which they adapt the parse trees based on the dependency relations between the words and the target, and then use a recursive neural network to learn the sentence representations. Similarly, Chang et al. (2016) explore a hybrid model that considers both sequential and structural information of a sentence. Nguyen et al. (2015) extend Dong et al. (2014) by combining the constituency tree and the dependency tree of a sentence. The performances of their methods highly rely on external parsers, which is subject to noise in informal social media texts.

The second category models the interactions between the target and its left context and right context. Vo and Zhang (2015) split a sentence into three parts and use pooling function to automatic inducing features for a given target. Similar to Vo and Zhang (2015), Zhang et al. (2016) exploit the gates instead of pooling functions to control the information flow of contexts. Tang et al. (2015) model by concatenating the word embeddings and target entity embeddings and use two LSTMs to encode left- and right contexts. Liu et al. (2017a) propose to use the attention mechanism to assign different weights to the left and right context depending on the target.

The third category controls the information flow from the target to the sentence representation. Augenstein et al. (2016) use conditional encoding to encode the target and use it as the initial states for the sentence representation.

Our method belongs to the first category that exploits tree structures. The main difference is we do not use external supervision from dependency parser or treebank annotations.

5.2 Neural-based Syntactic Constituency Parsing

Our work is related to syntactic constituency parsing as we build the tree structure in a transition

manner. Syntactic constituency parsing is a fundamental task in natural language processing, which uses phrase structure to organize words into nested constituents. Early approaches rely on probabilistic context-free grammars or transition-based models with rich features (Collins, 1997; Klein and Manning, 2003). Recently, recursive neural network (Socher et al., 2013) and neural-based transition model (Liu and Zhang, 2009) are also applied, which achieve competitive or even better performances compared to traditional state-of-the-art approaches that rely on hand-crafted features. Vinyals et al. (2015), from which we get inspirations, use the RNN Encoder-Decoder to encode the sentence and generate its corresponding full parse tree. Bowman et al. (2016) propose a Stack SPINN framework that integrates parsing and interpreting the sentence in a hybrid model. Yogatama et al. (2016) extend their model by using reinforcement learning to build the tree structures that can improve performances of end tasks.

We differ from the aforementioned approaches in two aspects. First, we do not use any explicit supervisions to guide the decoder. The parameters of our framework are optimized by the objective of end tasks. Another difference is that we learn target-specific instead of general-purpose sentence representations.

6 Conclusion

In this paper, we propose a framework that automatically induces target-specific sentence representations over tree structures without recourse to external syntactic resources. Experimental results on formal and informal texts showed that our approach is both robust and effective compared to previous work that operates on parsed trees. Moreover, the approach gives intuitions on how sentence structures are composed from their word constituents concerning a specific target.

Abstract

Text might contain or invoke multiple emotions with varying intensities. As such, emotion detection, to predict multiple emotions associated with a given text, can be cast into a multi-label classification problem. We would like to go one step further so that a ranked list of relevant emotions are generated where top ranked emotions are more intensely associated with text compared to lower ranked emotions, whereas the rankings of irrelevant emotions are not important. A novel framework of relevant emotion ranking is proposed to tackle the problem. In the framework, the objective loss function is designed elaborately so that both emotion prediction and rankings of only relevant emotions can be achieved. Moreover, we observe that some emotions co-occur more often while other emotions rarely coexist. Such information is incorporated into the framework as constraints to improve the accuracy of emotion detection. Experimental results on two real-world corpora show that the proposed framework can effectively deal with emotion detection and performs remarkably better than the state-of-the-art emotion detection approaches and multi-label learning methods.

1 Introduction

With the growing prosperity of Web 2.0, people tend to share their feelings, attitudes and opinions through the social platforms such as online news sites, blogs. Detecting emotions from text can enhance the understanding of users' emotional states, which is useful in many downstream applications, such as human-computer interaction and personalized recommendation. Therefore, it is crucial to analyze and predict emotions from text accurately (Picard and Picard, 1997).

Research on emotion detection can be roughly categorized into two types: lexicon-based and learning-based approaches. Lexicon-based approaches usually rely on emotion lexicons (Lei et al., 2014; Rao et al., 2012). They cannot deal with text when words can't be found in emotion lexicons. Learning-based approaches can be furthered classified into unsupervised and supervised learning methods. Unsupervised approaches do not require annotated data for training. For example, by adding an emotion layer into traditional topic models, emotion-topic models were constructed to detect users' emotions (Bao et al., 2012, 2009). Supervised learning approaches consider each emotion category as a class label and emotion detection is cast as a classification problem. If only choosing the strongest emotion as the emotion label for a given text, emotion detection is essentially a single-label classification problem (Lin et al., 2008; Quan et al., 2015). To predict multiple emotions simultaneously, emotion detection can be solved in the multi-label classification framework (Bhowmick, 2009). Moreover, to predict both multiple emotions and their intensities, some approaches have been proposed using emotion distribution learning (Zhou et al., 2016). Some lexicon-based approaches such as (Wang and Pal, 2015) can also output multiple emotions with intensities using non-negative matrix factorization.

In this paper, we are interested in exploring emotion ranking from either readers' perspective or writers' perspective in two different real-world corpora. In both cases, a given text is associated with multiple emotions. For example, Figure 1 illustrates an online news article crawled from Sina News *Society* Channel together with readers' emotion votes. It can be observed that when reading the news article, readers expressed different emotions with the majority showed "*Sadness*" and "*Anger*". We notice that some emotions such as "*Touching*", "*Curiosity*" and "*Amusement*" on-

New Orleans, Louisiana, June 1 - 6, 2018.

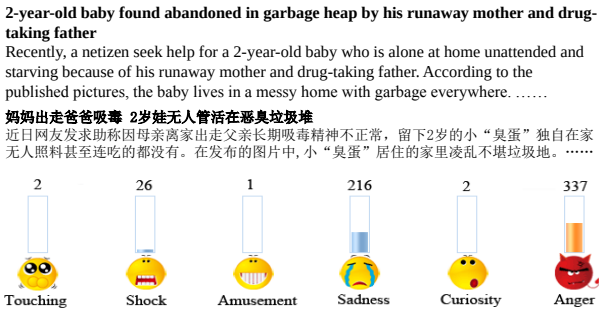

Figure 1: An example of an online news article from Sina *Society* Channel with voted emotions.

ly received 1 to 3 votes. In comparison to the total number of votes received, these votes could be considered as outliers or irrelevances. Also, the extremely low emotion votes might be due to readers' clicking errors. Taking into account such emotions during the learning process could introduce bias. Therefore, we aim to differentiate relevant emotions from irrelevant ones and only learn the rankings of relevant emotions while neglecting the irrelevant ones.

Our work makes the following contributions:

- We propose a novel framework based on relevant emotion ranking to identify multiple emotions and produce the rankings of relevant emotions from text. In the framework, the objective emotion loss function is designed elaborately so that both emotion prediction and rankings for only relevant emotions are achieved without being affected by irrelevant ones. To the best of our knowledge, it is the first attempt to perform emotion detection and relevant emotion ranking at the same time.

- As some emotions co-occur more often while others rarely co-exist, the prior knowledge of emotion relationships is incorporated into the framework as a constraint. Such emotion relationship can provide important cues for emotion detection.

- Experimental results on two real-world corpora show that the proposed framework can effectively deal with the emotion detection problem and performs better than the state-of-the-art emotion detection methods and multi-label learning methods.

2 Related work

Emotion detection is one of the subfields of sentiment analysis where emotions are more fine-grained and expressive. In general, emotion detection approaches can be categorized into two types: lexicon-based and learning-based approaches.

Lexicon-based approaches usually rely on emotion lexicons consisting of words and their corresponding emotion labels. For example, Aman and Szpakowicz (2007) classified emotional and non-emotional sentences with a predefined emotion lexicon. Emotional dictionaries could also be constructed from training corpora of news articles and be used to predict the readers' emotion of a new articles (Lei et al., 2014; Rao et al., 2012). Agrawal and An (2012) proposed a context-based approach to detect emotions from text at sentence level. An emotion vector for each potential affect bearing word based on the semantic relation between emotion concepts and words was generated. The emotion vector was then tuned based on the syntactic dependencies within a sentence structure. Other lexicon-based approach such as (Wang and Pal, 2015) can also output multiple emotions with intensities using non-negative matrix factorization with constraints derived based on an emotion lexicon.

Learning-based approaches can be further categoried as unsupervised and supervised learning methods. Unsupervised learning approaches do not require labelled data for training. For example, the emotion-topic models (Bao et al., 2012, 2009) were proposed by adding an extra emotion layer into traditional topic models such as Latent Dirichlet Allocation (Blei et al., 2003), thus capturing the generation of both emotion and text at the same time.

Supervised learning approaches typically cast emotion detection as a classification problem by considering each emotion category as a class label. If only choosing the strongest emotion as the label for a given text, emotion detection is essentially a single-label classification problem. Lin, Yang and Chen (2008) studied the classification of news articles into different categories based on readers' emotions with various combinations of feature sets. Strapparava and Mihalcea (2008) proposed several knowledge-based and corpus-based methods for emotion classification. Quan et al. (2015) proposed a logistic regression model with emotion dependency for emotion detection. Latent vari-

ables were introduced to model the latent structure of input text. To predict multiple emotions simultaneously, emotion detection can be solved using multi-label classification. Bhowmick (2009) presented a method for classifying news sentences into multiple emotion categories using an ensemble based multi-label classification technique. Zhou et al. (2016) proposed a novel approach based on emotion distribution learning to predict multiple emotions with different intensities in a single sentence.

3 Methodology

Assuming a set of T emotions $E = \{e_1, e_2, ...e_T\}$ and a set of n instances $X = \{x_1, x_2, x_3, ..., x_n\}$, each instance $x_i \in \mathbb{R}^d$ is associated with a ranked list of its relevant emotions $R_i \subseteq E$ and also a list of irrelevant emotions $\overline{R_i} = E - R_i$. Relevant emotion ranking aims to learn a score function $\mathbf{g}(x_i) = [g_1(x_i), ..., g_T(x_i)]$ assigning a score $g_t(x_i)$ to each emotion $e_t, (t \in \{1, ..., T\})$. As mentioned before, it is unnecessary to consider the rankings of irrelevant emotions since they might introduce errors into the model during the learning process. In order to differentiate relevant emotions from irrelevant ones, we need to define a threshold $g_\Theta(x)$ which could be simply set to 0 or learned from data (Fürnkranz et al., 2008). Those emotions with scores lower than the threshold will be considered as irrelevant and hence discarded. The identification of relevant emotions and their ranking can be obtained simultaneously according to their scores assigned by the ranking function $\mathbf{g}$. Here, the predicted relevant emotions of instance x_i are denoted as $\hat{R}_i = \{e_t \in E | g_t(x_i) > g_\Theta(x_i)\}$.

3.1 Emotion Loss Function

The goal of relevant emotion ranking is to learn the parameter of the ranking function $\mathbf{g}$. Without loss of generality, we assume that $\mathbf{g}$ are linear models, i.e., $g_t(x_i) = w_t^\intercal \cdot x_i$, $t \in \{1, 2, 3, ..., T\} \cup \{\Theta\}$, where Θ denotes the threshold. Relevant emotion ranking can be regarded as a special case of multi-label learning. Several evaluation criteria typically used in multi-label learning can also be used to measure the ranking function's ability of distinguishing relevant emotions from irrelevant ones, such as hamming loss, one error, coverage, ranking loss, and average precision as suggested in (Zhang and Zhou, 2014). However, these multi-label criteria cannot meet our requirement exactly as none of them considers the ranking among emotions which are considered relevant. Therefore, by incorporating PRO loss (Xu et al., 2013), the loss function for the instance x_i is defined as follows:

$$L(x_i, R_i, \prec, \mathbf{g}) = \sum_{e_t \in R_i \cup \{\Theta\}} \sum_{e_s \in \prec(e_t)} \frac{1}{norm_{t,s}} l_{t,s} \tag{1}$$

where e_t refers to the emotion belonging to relevant emotion set R_i or the threshold Θ of instance x_i while e_s refers to the emotion which is less relevant than e_t denoted as $\prec$. Thus, (e_t, e_s) represents four types of emotion pairs: i.e., *(relevant, relevant)*, *(relevant, irrelevant)*, *(relevant, threshold)*, and *(threshold, irrelevant)*. The normalization term $norm_{t,s}$ is used to balance those four types of emotion pairs to avoid dominated terms by their respective set sizes. The set sizes of the four different types of emotion pairs mentioned above are $|R_i| \times (|R_i| - 1)/2$, $|R_i| \times |\overline{R_i}|$, $|R_i|$, and $|\overline{R_i}|$, respectively. Here, $l_{t,s}$ refers to a modified 0-1 error. Specifically,

$$l_{t,s} = \begin{cases} 1, & g_t(x_i) < g_s(x_i) \\ \frac{1}{2}, & g_t(x_i) = g_s(x_i) \\ 0, & \text{otherwise} \end{cases}$$

Note that $l_{t,s}$ is non-convex and difficult to optimize. Thus, a large margin surrogate convex loss (Vapnik and Vapnik, 1998) implemented in hinge form is used instead as follows:

$$\hat{L}(x_i, R_i, \prec, \mathbf{g}) = \sum_{e_t \in R_i \cup \{\Theta\}} \sum_{e_s \in \prec(e_t)} \frac{1}{norm_{t,s}} (1 + g_s(x_i) - g_t(x_i))_+ \tag{2}$$

where $(u)_+ = \max\{0, u\}$.

However, Eq. 2 ignores the relationships between different emotions. As mentioned in Introduction section, some emotions often co-occur such as "*joy*" and "*love*" while some rarely coexist such as "*joy*" and "*anger*". Such relationship information among emotions can provide important clues for emotion ranking. Therefore, we incorporate this information into the emotion loss function as constraints. The objective function

$\hat{L}(x_i, R_i, \prec, \mathbf{g})$ can be redefined as:

$$\hat{L_\omega}(x_i, R_i, \prec, \mathbf{g}) = \sum_{e_t \in R_i \cup \{\Theta\}} \sum_{e_s \in \prec(e_t)} \frac{1}{norm_{t,s}} \times (1 + g_s(x_i) - g_t(x_i) + \omega_{ts}(w_t - w_s))_+ \quad (3)$$

where the weight ω_{ts} models the relationship between the *t*-th emotion and the *s*-th emotion in the emotion set and can be calculated in multiple ways. Since the Pearson correlation coefficient (Nicewander, 1988) is the most familiar measure of relationship between two variables, we use it to measure the relationship of two emotions using their original emotion scores across each corpus.

From the above, it can be observed that the goal of relevant emotion ranking can be achieved through predicting an accurate relevant emotion set as well as the ranking of relevant emotions.

3.2 Relevant Emotion Ranking

After defining an appropriate loss function, we need to define a way to minimize the empirical error measured by the appropriate loss function and at the same time to control the complexity of the resulting model. It can be done by introducing a maximum margin strategy and regularization to deal with emotion ranking data, where a set of linear classifiers are optimized to minimize the emotion loss function mentioned before while having a large margin. We could potentially use an approach based on a label ranking method (Elisseeff and Weston, 2001). It is worth mentioning that the margin of the *(relevant, relevant)* label pair needs to be dealt with carefully, which is not considered in (Elisseeff and Weston, 2001).

The learning procedure of relevant emotion ranking (RER) is illustrated in Figure 2. The big rectangular dash line boxes denoted by x_1 to x_n represent n instances in the training set. In each small box, $e_i, i \in \{1, ...T\} \cup \{\Theta\}$ represents an emotion of the instance where the shaded small boxes represent the relevant emotions while the dashed small boxes represent irrelevant ones and the last one e_Θ is the threshold. Each emotion's corresponding weight vector is w_i. We use $m_{t,s}$ to represents the margin between label e_t and e_s. There are four types of emotion pairs' margins in total, i.e., *(relevant, relevant)*, *(relevant, irrelevant)*, *(relevant, threshold)*, and *(threshold, irrelevant)*. Different types of emotion pairs' margins are denoted using different text/line colors. For each training instance x_i, $margin(x_i)$ represents the margin of instance x_i which can be obtained by taking the minimum margin of all its possible label pairs $m_{t,s}$. Similarly, the margin of the learning system $margin(learningsystem)$ can be obtained by taking the minimum margin of all the training instances. By maximizing the margin of the learning system, the weight vector of each emotion can be derived from which the predicted emotion set and the ranking of relevant emotions can be obtained.

The learning system is composed of $T + 1$ linear classifiers $[w_1; ...; w_T; w_\Theta]$ with one classifier for each emotion label and the threshold, where $w_t, t \in \{1, ...T\} \cup \{\Theta\}$ is the weight vector for the t-th classifier of emotion e_t. For a training instance x_i and its corresponding emotion label set E_i, the learning system's margin on instance x_i is defined as follows by considering its ranking ability on x_i's four types of emotion pairs, i.e., *(relevant, relevant)*, *(relevant, irrelevant)*, *(relevant, threshold)*, and *(threshold, irrelevant)*:

$$\min_{e_t \in R_i \cup \{\Theta\}, e_s \in \prec(e_t)} \frac{\langle w_t - w_s, x_i \rangle}{||w_t - w_s||} \quad (4)$$

Here, $\langle u, v \rangle$ returns the inner product $u^\top v$. For each emotion pair (e_t, e_s), its discrimination boundary corresponds to the hyperplane $\langle w_t - w_s, x_i \rangle = 0$. Therefore, Eq. 4 returns the minimum value as the margin on instance x_i. The margin on the whole training set G can be calculated as follows:

$$\min_{x_i \in G} \min_{e_t \in R_i \cup \{\Theta\}, e_s \in \prec(e_t)} \frac{\langle w_t - w_s, x_i \rangle}{||w_t - w_s||} \quad (5)$$

If the learning algorithm is capable of properly ranking the four types of label pairs for each training instance, Eq. 5 will return a positive margin. In this ideal case, the final goal is to maximize the margin in Eq. 5:

$$\max_{w_j} \min_{x_i \in G} \min_{e_t \in R_i \cup \{\Theta\}, e_s \in \prec(e_t)} \frac{1}{||w_t - w_s||} \quad s.t. \langle w_t - w_s, x_i \rangle \geq 1, 1 \leq i \leq n, 1 \leq j \leq T + 1 \quad (6)$$

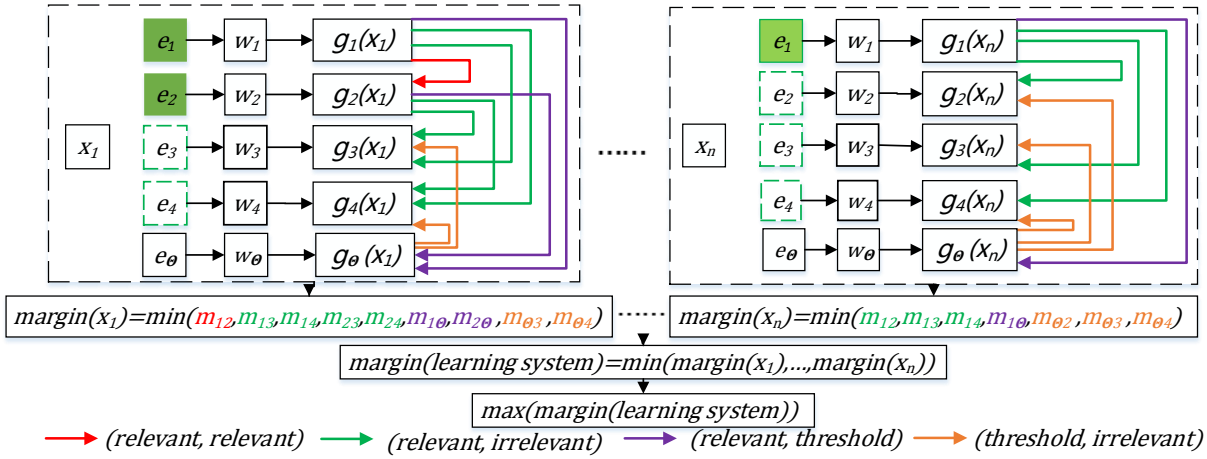

Figure 2: The overall framework of our proposed Relevant Emotion Ranking (RER) method.

Suppose we have sufficient training examples such that for each label pair (e_t, e_s), there exists $x_i \in G$satisfying $e_t \in R_i \cup \{\Theta\}, e_s \in \prec (e_t)$. Thus, the objective in Eq.6 becomes equivalent to $\max_{w_j} \min_{1 \le s < t \le T+1} \frac{1}{||w_t - w_s||}$ and can be rewritten as $\min_{w_j} \max_{1 \le s < t \le T+1} ||w_t - w_s||$.

Moreover, to overcome the complexity brought in by the max operator, the objective of the optimization problem can be re-written by approximating the max operator with the sum operator. Thus, the objective of Eq. 6 can be transformed as:

$$\begin{aligned} &\min_{w_j} \sum_{t=1}^{T+1} ||w_t||^2 \\ &s.t.\ \langle w_t - w_s, x_i \rangle \ge 1, 1 \le i \le n, \\ &1 \le j \le T+1, e_t \in R_i \cup \{\Theta\}, e_s \in \prec (e_t) \end{aligned} \tag{7}$$

To accommodate real-world scenarios where constraints in Eq. 7 can not be fully satisfied, slack variables can be incorporated into the objective function:

$$\begin{aligned} &\min_{w_j, \xi_{its}} \sum_{t=1}^{T+1} ||w_t||^2 + \lambda \sum_{i=1}^{n} \sum_{e_t \in R_i \cup \{\Theta\}} \sum_{e_s \in \prec (e_t)} \frac{1}{norm_{t,s}} \xi_{its} \\ &s.t. \langle w_t - w_s, x_i \rangle \ge 1 - \xi_{its}, 1 \le j \le T+1, \xi_{its} \ge 0 \end{aligned} \tag{8}$$

Since ξ_{its} does not need to be optimized since it can be easily determined by w_t, w_s. The final objective function can be reformulated as:

$$\min_{w_t, \hat{L}} \sum_{t=1}^{T+1} ||w_t||^2 + \lambda \sum_{i=1}^{n} \hat{L}(x_i, R_i, \prec, \mathbf{g}) \tag{9}$$

As can be seen, Eq.9 consists of two parts balanced by the trade-off parameter λ. Specifically, the first part corresponds to the maximum margin of the learning system and it can also represent the complexity of the learning system, while the second part corresponds to the emotion loss function of the learning system implemented in hinge form.

3.3 Parameter Estimation

Let $\mathbf{w} = [w_1; ...; w_T; w_\Theta]$, Eq. 9 is cast into a general form in SVM-type:

$$\begin{aligned} &\min_{\mathbf{w}, \boldsymbol{\xi}} \frac{1}{2} ||\mathbf{w}||^2 + \lambda C^\top \boldsymbol{\xi} \\ &s.t.\ A\mathbf{w} \ge \mathbf{1}_p - \boldsymbol{\xi}, \boldsymbol{\xi} \ge \mathbf{0}_p \end{aligned} \tag{10}$$

where p is the total number of label pairs, calculated by $\sum_{i=1}^{n} \sum_{e_t \in R_i \cup \{\Theta\}} \sum_{e_s \in \prec (e_t)} norm_{t,s}$ and $\mathbf{1}_p (\mathbf{0}_p)$ is the $p \times 1$ all one (zero) vector. The entries in vector C correspond to the weights of hinge losses, i.e., the normalization term to balance the four kinds of label pairs. The matrix A corresponds to the constraints for instances which reflects the emotion relationships and the margin of the label pairs.

$\boldsymbol{\xi}$ does not need to be optimized since it can be easily determined by $\mathbf{w}$. Hence the objective function can be reformulated into the following form without $\boldsymbol{\xi}$:

$$\min_{\mathbf{w}} F(\mathbf{w}, G) = \frac{1}{2} ||\mathbf{w}||^2 + \lambda C^\top (1_p - A\mathbf{w})_+ \tag{11}$$

Through minimizing the objective function $F(\mathbf{w}, G)$, we can finally obtain parameter $\mathbf{w}$ and the ranking function $\mathbf{g}$. Eq. 11 involves a large scale optimization. To address Eq. 11, we consider an efficient Alternating Direction Method of Multipliers (ADMM) solution (Bertsekas and Tsitsiklis, 1989). The basic idea of ADMM is to take the decomposition-coordinate procedure such that the solution of subproblems can be coordinated to find the solution to the original problem. We decompose G into M disjoint subsets, i.e., $\{G_1, G_2, ..., G_M\}$ and then Eq. 11 is converted into the following form:

$$\begin{aligned} &\min_{\mathbf{w}^0, \mathbf{w}^1, \mathbf{w}^m} \sum_{m=1}^{M} F(\mathbf{w}^m, G^m), \\ &s.t.\ \ \mathbf{w}^m = \mathbf{w}^0, \forall m = 1, ..., M \end{aligned} \tag{12}$$

The surrogate augmented Lagrangian Function (LF) was introduced into Eq. 12 and it was cast into the following form:

$$\begin{aligned} LF(\{\mathbf{w}^0, \mathbf{w}^1, ..., \mathbf{w}^m\}, \{\alpha^m\}_{m=1}^M, \beta) = \sum_{m=1}^{M} F(\mathbf{w}^m, G^m) \\ + \sum_{m=1}^{M} (\alpha^m)^\top (\mathbf{w}^m - \mathbf{w}^0) + \frac{\beta}{2} \sum_{m=1}^{M} ||\mathbf{w}^m - \mathbf{w}^0||^2 \end{aligned} \tag{13}$$

where α, β are the Lagrange multiplies. The updating process of Eq. 13 is shown in Algorithm 1.

Algorithm 1 Parameter updating process.

1: Decompose data set G into M disjoint subsets i.e., $\{G_1, G_2, ..., G_M\}$. Set iteration $i = 0$.
2: Initialize $\{\mathbf{w}_0^0, \mathbf{w}_0^1, ..., \mathbf{w}_0^M, \alpha_0^1, ..., \alpha_0^M\}$ as zeros.
3: **while** not converged **do**
4: Set $i = i + 1$
5: Update $\mathbf{w}_i^0, \{\mathbf{w}_i^m, \alpha_i^m\}_{m=1}^M$ as:
$\{\mathbf{w}_i^m\}_{m=1}^M = \underset{\mathbf{w}^1..\mathbf{w}^m}{\operatorname{argmin}} LF(\mathbf{w}_{i-1}^0, \{\mathbf{w}_{i-1}^m, \alpha_{i-1}^m\}_{m=1}^M, \beta)$
$\mathbf{w}_i^0 = \underset{\mathbf{w}^0}{\operatorname{argmin}} LF(\mathbf{w}^0, \{\mathbf{w}_{i-1}^m, \alpha_{i-1}^m\}_{m=1}^M, \beta$
$\alpha_i^m = \alpha_{i-1}^m + \beta(\mathbf{w}_i^m - \mathbf{w}_i^0)^\top, \forall m = 1, 2, ..., M$
6: **end while**
Output: Final $\mathbf{w}^0$

4 Experiments

4.1 Setup

We evaluate the proposed approach on two real-world corpora, one is document level and the other is sentence level:

Sina Social News (News) was collected from the Sina news *Society* channel where readers can choose one of the six emotions such as *Amusement*, *Touching*, *Anger*, *Sadness*, *Curiosity*, and *Shock* after reading a news article. As Sina is one of the largest online news sites in China, it is sensible to carry out experiments to explore the readers' emotion (social emotion). News articles with less than 20 votes were discarded since few votes can not be considered as proper representation of social emotion. In total, 5,586 news articles published from January 2014 to July 2016 were kept, together with the readers' emotion votes.

Ren-CECps corpus (Blogs) (Quan and Ren, 2010) contains 34,719 sentences selected from blogs in Chinese. Each sentence is annotated with eight basic emotions from writer's perspective, including *anger*, *anxiety*, *expect*, *hate*, *joy*, *love*, *sorrow* and *surprise*, together with their emotion scores indicating the level of emotion intensity which range from 0 to 1. Higher scores represents higher emotion intensity.

The statistics of the two corpora are shown in Table 1.

Sina Social News		**Ren-CECps Corpus**	
Category	#Votes	Category	#Scores
Touching	694,006	Joy	1,349.6
Shock	572,651	Hate	6,103.9
Amusement	869,464	Love	2,911.1
Sadness	837,431	Sorrow	2,042.5
Curiosity	212,559	Surprise	3,873.9
Anger	1,109,315	Anger	7,832.1
		Anxiety	5,006.4
		Expect	610.4
All	4,295,426	All	29,729.9

Table 1: Statistics for the two corpora used in our experiments.

The two corpora were preprocessed by using word segmentation and filtering. The python jieba segmenter is used for the segmentation and a removal of stop words is performed based on a stop word thesaurus. Words appeared only once or appeared in less than two documents were re-

moved to alleviate data sparsity. We used the single layer long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) to extract the features of each text. LSTM is one kind of recurrent neural networks, which can capture sequence information from text and can represent meanings of inputs in the reduced dimensional space. It treats text as a sequence of word embeddings and outputs a state vector over each word, which contains the information of the previous words. The final state vector can be used as the representation of the text. In our experiments, we set the dimension of each text representation to 100. During LSTM model training, we optimized the hyper parameters using a development dataset which is built using external data. We train LSTM using a learning rate of 0.001, a dropout rate of 0.3 and categorical cross-entropy as the loss function. The mini batch (Cotter et al., 2011) size is set to 32. After that, the learned text representations are fed into the proposed system for relevant emotion ranking as has been previously presented in the Methodology section.

4.2 Comparison with Baselines

There are only few baselines which address multiple emotions learning from text. We first compare the proposed framework with two baselines which have previously achieved the state-of-the-art performances on multi-emotion detection.

- **Emotion Distribution Learning (EDL)** (Zhou et al., 2016): It learns a mapping function from texts to their emotion distributions describing multiple emotions and their respective intensities based on label distribution learning. Moreover, the relationships of emotions are captured based on the Plutchik's wheel of emotions which are subsequently incorporated into the learning algorithm in order to improve the accuracy of emotion detection.

- **EmoDetect** (Wang and Pal, 2015): It outputs the emotion distribution based on a dimensionality reduction method using non-negative matrix factorization which combines several constraints such as emotions bindings, topic correlations and emotion lexicons in a constraint optimization framework.

For each method, 10-fold cross validation is conducted using the same feature construction

Name	Definition
PRO Loss	$\frac{1}{n}\sum_{i=1}^{n}\sum_{e_t\in R_i\cup\{\Theta\}}\sum_{e_s\in\prec(e_t)}\frac{1}{norm_{t,s}}l_{t,s}$ $l_{t,s}$ is a modified 0-1 error;$norm_{t,s}$is the set size of label pair(t,s)
Hamming Loss	$\frac{1}{nT}\sum_{i=1}^{n}\lvert\hat{R}_i\triangle R_i\rvert$
Ranking Loss	$\frac{1}{n}\sum_{i=1}^{n}(\sum_{(e_t,e_s)\in R_i\times\overline{R_i}}\delta[g_t(x_i)<g_s(x_i)])/(\lvert R_i\rvert\times\lvert\overline{R_i}\rvert)$ where δ is the indicator function.
One Error	$\frac{1}{n}\sum_{i=1}^{n}\delta[\operatorname{argmax}_{e_t} g_t(x_i)\notin R_i]$
Average Precision	$\frac{1}{n}\sum_{i=1}^{n}\frac{1}{\lvert R_i\rvert}\times$ $(\sum_{t:e_t\in R_i}\lvert\{e_s\in R_i\lvert g_s(x_i)>g_t(x_i)\}\rvert)/(\lvert\{e_s\lvert g_s(x_i)>g_t(x_i)\}\rvert)$
Coverage	$\frac{1}{n}\sum_{i=1}^{n}\max_{t:e_t\in R_i}\lvert\{e_s\lvert g_s(x_i)>g_t(x_i)\}\rvert$
Subset Accuracy	$\frac{1}{n}\sum_{i=1}^{n}\delta[\hat{R}_i=R_i]$
$F1_{exam}$	$\frac{1}{n}\sum_{i=1}^{n}2\lvert R_i\cap\hat{R}_i\rvert/(\lvert R_i\rvert+\lvert\hat{R}_i\rvert)$
MicroF1	$F1(\sum_{t=1}^{T}TP_t,\sum_{t=1}^{T}FP_t,\sum_{t=1}^{T}TN_t,\sum_{t=1}^{T}FN_t)$
MacroF1	$\frac{1}{T}\sum_{t=1}^{T}F1(TP_t,FP_t,TN_t,FN_t)$

Table 2: Evaluation criteria for the Multi-Label Learning (MLL) methods. TP_t, FP_t, TN_t, FN_t represent the number of true positive, false positive, true negative, and false negative test examples with respect to emotion t respectively. $F1(TP_t, FP_t, TN_t, FN_t)$ represent specific binary classification metric F1 (Manning et al., 2008).

method to get the final performance. Supposing n test instances and T emotion categories, several evaluation criteria as presented in Table 2 typically used in multi-label learning can be used to measure the efficiency of the proposed framework and the baseline approaches. PRO Loss concerning the prediction on all labels as well as the rankings of only relevant labels. Hamming loss evaluates how many times an emotion label is misclassified. Ranking loss evaluates the fraction of reversely ordered emotion pairs. One-error evaluates the fraction of sentences whose top-ranked emotion is not in the relevant emotion set. Average precision evaluates the average fraction of the relevant emotions ranked higher than a particular emotion. Coverage evaluates how many steps are needed to move down the ranked emotion list so as to cover all the relevant emotions of the example. Subset Accuracy evaluates the fraction of correctly classified examples, i.e. the predicted label set is identical to the ground-truth label set. $F1_{exam}$ evaluates the averaged F1 (Manning et al., 2008) over instances. MicroF1 pools each document decisions across categories, and then computes an effectiveness measure on the pooled contingency table. MacroF1 take the average of F1 for all categories. Note that the threshold Θ is removed before evaluation. It should be pointed out that metrics from PRO Loss to $F1_{exam}$ work by evaluating the learning systems performance on each test ex-

ample separately, and then returning the mean value across the test set. MicroF1 and MacroF1 work by evaluating the learning systems performance on each emotion category separately, and then returning the macro/micro-averaged value across all emotion categories.

The evaluation results using 10 different evaluation criteria are shown in Table 3. It can be observed that our proposed method Relevant Emotion Ranking(RER) outperforms baseline approaches on all 10 evaluation metrics on both datasets.

Table 3: Comparison with emotion detection baselines. "↓" indicates "the smaller the better", while "↑" indicates "the larger the better". The best performance on each evaluation measure is highlighted by boldface.

We have also extended RER by incorporating emotion relationships as constraints into the learning framework, denoted as RERc in Table 3. The correlation of every pair of emotions is calculated based on their respective votes from news articles or scores from blogs. It can be observed from Table 3 that in almost all cases, incorporating the constraints gives better performance. It should be pointed out that the results of the baseline approach EDL are slightly different from those reported in (Zhou et al., 2016) since we employ LSTM for feature construction instead of recursive autoencoders.

Since relevant emotion ranking can be seen as an extension of multi-label learning, the proposed framework is also compared with 8 widely used multi-label learning methods using the threshold Θ which is initialized as 0.15 after normalization, such as ML-KNN (Zhang and Zhou, 2007), LIFT (Zhang, 2011), CLR (Fürnkranz et al., 2008), Rank-SVM (Zhang and Zhou, 2014) , MLLOC (Huang and Zhou, 2012), BP-MLL (Zhang and Zhou, 2006), ECC (Read et al., 2009) and ML-RBF (Zhang, 2009). ML-KNN is based on the traditional k-nearest neighbor (KNN) algorithm. LIFT constructs features specific to each emotion by conducting clustering analysis on its positive or negative instances. CLR transforms MLL into a label ranking problem by pairwise comparison which considers each label pairs and rank all the labels without recognizing that only the rankings of relevant ones are crucial. Rank-SVM focuses on distinguishing relevant from irrelevant while neglecting the rankings of relevant ones. MLLOC tries to exploit emotion correlations in the expression data locally. The global discrimination fitting and local correlation sensitivity are incorporated into a unified framework. BP-MLL is derived from the back propagation algorithm through employing a novel error function capturing the characteristics of multi-label learning. ECC applies classifier chains in an ensemble framework. ML-RBF gets the multi-label neural networks adopted from the traditional Radial Basis Function (RBF) neural networks.

Table 4: Comparison with Multi-Label Learning (MLL) Methods."↓" indicates "the smaller the better", while "↑" indicates "the larger the better". The best performance on each evaluation measure is highlighted by boldface.

approach in comparison to all MLL baselines are presented in Table 4. RERc performs the best on all evaluation measures. It verifies the advantage of RERc due to its consideration of varying intensities of the emotion labels and the ignorance of irrelevant ones during the learning of the relevant emotion ranking model. We also observe that, in most cases, the performance on the News dataset is better than that in the Blogs dataset. This may due to different types of text observed in these two platforms. News articles are more formal while bogs typically contain informal language and are more colloquial.

4.3 Result Analysis

To fully understand the emotion detection results, we generate the top 10 most frequent words in the test set for each emotion label from Blogs dataset presented in Figure 3. Intuitively, we can find that most top words are quite expressive of their associated emotions. For example, the word "happy" delivers the emotion of *Joy* and the word "tears" tells *Sorrow*, etc. Moreover, we also observe that there are some common words across multiple emotion categories. For instance, "friend" appears in both *Joy* and *Love*. The results demonstrate that the proposed framework can learn emotions from text precisely.

5 Conclusions

In this paper, we have proposed a novel framework to detect multiple emotions from text based on relevant emotion ranking. Moreover, the relationships between emotions are incorporated into the learning framework as constraints. Experimental results on both News and Blogs datasets show that the proposed framework is able to detect multiple emotions as well as generating rankings of relevant emotions. It performs remarkably better than the state-of-the-art baselines on multi-emotion detection and also outperforms several different methods used for multi-label learning. In the future, we will explore the possibility of extending the current framework by detecting emotions at more fine-grained level, for example, emotions associated with specific events reported in text.

Abstract

Efficient word representations play an important role in solving various problems related to Natural Language Processing (NLP), data mining, text mining etc. The issue of data sparsity poses a great challenge in creating efficient word representation model for solving the underlying problem. The problem is more intensified in resource-poor scenario due to the absence of sufficient amount of corpus. In this work, we propose to minimize the effect of data sparsity by leveraging bilingual word embeddings learned through a parallel corpus. We train and evaluate Long Short Term Memory (LSTM) based architecture for aspect level sentiment classification. The neural network architecture is further assisted by the hand-crafted features for the prediction. We show the efficacy of the proposed model against state-of-the-art methods in two experimental setups i.e. multi-lingual and cross-lingual.

1 Introduction

Sentiment analysis (Pang and Lee, 2005) tries to automatically extract the subjective information from a user written textual content and classifies it into one of the predefined set of classes, e.g. *positive*, *negative*, *neutral* or *conflict*. Sentiment analysis performed on coarser level (i.e. document or sentence level) does not provide enough information for a user who is critical of finer details such as *battery life* of a laptop or *service* of a restaurant etc. Aspect level sentiment analysis (ABSA) (Pontiki et al., 2014) serves such a purpose, which first identifies the features (or aspects) mentioned in the text and then classifies it into one of the target classes. For example, the following review is for a restaurant where the writer shares her/his experience. Though s/he likes the *food* but certainly not happy with the *service*.

*One of the best **food** we had in a while but the **service** was very disappointing.*

Analyzing such reviews on sentence level will reflect only an overall sentiment (i.e. *conflict*) of the sentence ignoring critical information such as *food* and *service* qualities. However, ABSA will first identify all the aspects in the text (i.e. *food* and *service*) and then associate *positive* with *food* and *negative* with *service*. Identification of aspect terms is also known as aspect term extraction or opinion target extraction. In this work, we focus on the second problem i.e. aspect level sentiment classification.

Literature survey suggests a wide range of research on sentiment analysis (at the document or sentence level) is being carried out in recent years (Turney, 2002; Kim and Hovy, 2004; Jagtap and Pawar, 2013; Poria et al., 2016; Kaljahi and Foster, 2016; Gupta et al., 2015). However, most of these researches are focused on resource-rich language like English. Like many other Natural Language Processing (NLP) problems, research on sentiment analysis involving Indian languages (e.g. Hindi, Bengali etc.) are very limited (Joshi et al., 2010; Bakliwal et al., 2012; Kumar et al., 2015; Balamurali et al., 2012; Singhal and Bhattacharyya, 2016). Due to the scarcity of various qualitative resources and/or tools in such languages, the problems have become more challenging and non-trivial to solve. The research on ABSA involving Indian languages has started only very recently, for e.g. (Akhtar et al., 2016a,b).

2 Motivation and Problem Definition

Indian languages are resource-constrained in nature as there is a lack of ready availability of different qualitative lexical resources and tools. In a supervised machine learning framework, good amount of training data always have a great impact on the overall system performance. Low-resource languages (such as the Indian [Hindi etc.]) usu-

Proceedings of NAACL-HLT 2018, pages 572–582
New Orleans, Louisiana, June 1 - 6, 2018.

ally suffer due to the non-availability of sufficient training data instances. In order to solve the data and resource scarcity problem in one language, researchers often utilize cross-lingual setup to leverage the resource-richness of other languages by projecting the task into a common problem space (Zhou et al., 2016; Balamurali et al., 2012; Singhal and Bhattacharyya, 2016; Barnes et al., 2016). The projection is often performed with the help of machine translation or bilingual dictionaries.

In recent times, deep learning (DL) techniques have shown success in solving several NLP problems. A good word representation is the essence of any deep learning approach. In the absence of qualitative word embeddings, it turns out to be a non-trivial task for any DL framework to effectively learn hidden features (e.g. lexical, syntactic, semantics etc.), which may effect the performance. The quality of word embeddings can be preserved by employing state-of-the-art distributed word representation models such as Word2Vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014) provided a huge corpus to train on. Due to this limitation, quality of word embeddings in Indian languages usually are not at par with that of resource-rich languages like English.

Data sparsity in word representation (i.e. absence of representation of any word) is another problem that often has to be dealt with. In order to solve any NLP task, out-of-vocabulary (OOV) words in a word embedding model pose a serious challenge to the underlying learning algorithm. For a missing word representation, the literature suggests two possible solutions: a) zero vector (Bahdanau et al., 2017) or b) random vector (Dhingra et al., 2017). However, in both the cases the resultant vector could be completely out of context and often does not fit well with others. Further, word embedding of a word in a source language has absolutely no correlation with the word embedding of the same word (translated) in the target language, hence, it cannot be directly used for training and/or testing in a cross-lingual setup. The prime motivation of the work is to minimize the effect of *data sparsity* and thereby, enabling any deep learning framework to effectively learn its hidden features.

In this paper, we propose to solve the *data sparsity* problem in a resource-scarce language scenario (here, primarily Hindi and also French embeddings)[1]. We hypothesize that addressing data sparsity in an intelligent manner would yield increased performance. We utilize bi-lingual word embedding (Luong et al., 2015) trained on English-Hindi and English-French parallel corpus to bridge the language divergence in the vector space. The proposed method is based on a deep learning (DL) architecture named Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997). We try to establish our hypothesis through experiments on *aspect based sentiment classification* task in both the setups i.e. multi-lingual and cross-lingual for *English-Hindi* and *English-French* language pairs. Aspect based sentiment classification deals with assigning the sentiment polarity (i.e. *positive*, *negative*, *neutral* or *conflict*) to the aspect terms. For evaluation, we use the datasets provided in (Akhtar et al., 2016a) for Hindi, SemEval-2014 shared task on ABSA (Pontiki et al., 2014) for English and SemEval-2016 shared task on ABSA (Pontiki et al., 2016) dataset for French.

2.1 Contributions

Major contributions of our current work are as follows: **a)** we train and use bilingual embeddings on Amazon product review corpus consisting of parallel sentences of English-Hindi and English-French, which serve as a bridge between the two languages; **b)** we propose to solve the problem of *data sparsity* in low-resource language word embedding by utilizing the word embedding created on resource-rich language; and **c)** to further improve the system's prediction we extract and use various English side semantic features of the machine translated words.

As we already mentioned, the research on ABSA involving Indian languages are limited. Some of the recent works include the one reported in (Akhtar et al., 2016a,b). The authors in (Barnes et al., 2016) employed bilingual word embeddings for sentiment classification in a cross-lingual setup. To the best of our knowledge, our current attempt is the very first of its kind to employ bilingual word embeddings for a multi-lingual scenario. Our proposed system differs with the existing systems in the following ways.

1. **Setup**: System (Barnes et al., 2016) defines a cross-lingual setup while (Singhal and Bhat-

[1] We use French to show how generic our proposed approach is. Compared to English, French does not have enough sentiment annotated data

tacharyya, 2016) is multi-lingual in nature. In contrast, our proposed system is applied to both multi-lingual and cross-lingual setups.

2. **Approach**: System (Akhtar et al., 2016a) defines classical feature driven approach while the system (Barnes et al., 2016) utilized bilingual word embeddings as feature values to train a Support Vector Machine (SVM) classifier. Rest of the systems (Akhtar et al., 2016b; Singhal and Bhattacharyya, 2016) (including the proposed one) are based on deep neural network architecture. However, the techniques employed are very much different. Akhtar et al. (2016b) is a CNN-SVM based system with the assistance of multi-objective optimized features, while Singhal and Bhattacharyya (2016) is a CNN based system that translate the source language texts into target language text (English) for training and evaluation. In comparison, our proposed method employ LSTM to solve the data sparsity problem in both multi-lingual as well as cross-lingual setups.

3. **Problem addressed**: Authors in (Singhal and Bhattacharyya, 2016) focused on sentence level sentiment classification while our present work focuses on fine-grained sentiment classification at the aspect level.

4. **Word Embeddings:** The proposed system employs shared vector-space bilingual word embeddings for training and testing while (Singhal and Bhattacharyya, 2016) projected the source language train & test data into target language using machine translation and utilizes target side pre-computed word vectors for training the system. Whereas, the system reported in (Akhtar et al., 2016b) employed mono-lingual word embeddings for training and evaluation.

5. **Data Sparsity:** The system of (Akhtar et al., 2016b) does not address the problem of data sparsity, while our proposed system tries to minimize the effect of data sparsity. Our proposed system tackles the data sparsity problem by replacing the OOV word with its translated form which usually happens to be its closest neighbor in the shared vector space, hence, the semantic closeness is preserved to an extent. Whereas, system (Singhal and Bhattacharyya, 2016) addressed the data sparsity by translating every word of the source language into target language which may introduce loss of sentiment in the target language as a side-effect (Mohammad et al., 2016).

6. **Hand-crafted Features:** The proposed system employs much richer set of lexicon based features than that of (Singhal and Bhattacharyya, 2016). Also, we do not augment polar words in the training instances as done in (Singhal and Bhattacharyya, 2016), rather we use sentiment scores of these lexicons as features themselves in the training and testing instances. Whereas, the authors in (Akhtar et al., 2016b) obtained an optimized feature vector through the application of multi-objective genetic algorithm.

3 Proposed Methodology

We propose to use a Long Short Term Memory (LSTM) architecture on top of bilingual word embeddings for the prediction. LSTM is a special kind of recurrent neural network (RNN) which efficiently captures long term dependencies. Bidirectional LSTM is an extended version of LSTM which takes both forward and backward sequences into account. Our model consists of two bidirectional LSTM layers followed by two fully-connected layers and an output layer.

3.1 Bilingual Word Embedding

We employ bilingual word embeddings (Luong et al., 2015) trained on a parallel *English-Hindi* (and *English-French*) corpus. We generate a parallel corpus for Amazon product review datasets[2] (consisting of approx. 7.2M sentences) using an in-house product review domain based *English→Hindi* (*English→French*) Statistical Machine Translation (SMT) system (*English→Hindi*: 39.5 BLEU score and *English→French*: 37.9 BLEU score). We employ widely used and standard machine translation tool *Moses* (Koehn et al., 2007) to train the phrase-based SMT system. The alignment information are obtained from the *mosesdecoder* (Koehn et al., 2007) during translation of the reviews.

The parallel corpus along with the alignment information are used to train two (English and Hindi)

[2]http://snap.stanford.edu/data/other.html

Skip-Gram word2vec (Mikolov et al., 2013) models which share the common vector space. If a word W_S is aligned to word W_T, then the context information C_T of target word W_T is also used as context of the source word W_S along with its own context C_S for computing word vectors. By utilizing the context information of both source and target side, resultant word embeddings of W_S and W_T are semantically closer to each other in the vector space.

Bilingual skip-gram model creates two separate word embeddings, i.e. one each for source (Hindi) and target language (English). First, we extract word representations for all the words in a sentence from the Hindi bilingual word embeddings. Subsequently at the second step we translate all the OOV words (words whose representations are missing in Hindi bilingual embeddings) into English and then perform another lookup in English embeddings. For instance, if embedding of a word 'अच्छाlachcha' is unknown we translate it in English as '*good*', and use its word embeddings in place of the source word 'अच्छाlachcha'. Thus the missing representation of OOV word is replaced by its translated target side representation. Since, both English and Hindi word embeddings share a common vector space, this replacement strategy proves to be an effective technique. In our case, we observe a reduction of approximately 65% and 37% OOV words, respectively for Hindi and French by our proposed replacement strategy. Consequently, an increase in accuracy value is observed during evaluation.

Hindi is a morphologically rich language. Many inflected words in Hindi share a common translated word in English. For example, based on the gender of the subject Hindi has two forms for word 'goes': 'जाता है | jAtA hai' (male) or 'जाती है | jAtI hai' (female). Therefore, if representation of one word (जाता है | jAtA hai) is missing in Hindi embedding we can still find its representation in English through its translation i.e. 'goes'. Bilingual embedding also helps in addressing the spelling variation cases. For e.g. two differently spelled words in Hindi such as 'कम्बिनेशन | kambineshana' and 'कंबीनेशन | kaMbIneshana' translate to an English word 'combination'.

We repeat the above process for *English-French* language pair to obtain two (English and French) word2vec models. We also released computed bilingual word embeddings for the research community[3].

3.2 Features

We employ various hand-crafted features to assist the network. We try to leverage the effectiveness of English side resources by translating a word into English and then extracting its feature representation. We use following set of features in our task. It should be noted that we do not include any lexical or syntactic features during training as distributed word embedding models are good at capturing such features. So, during the training phase, network adapts its weights to learn the relevant set of these features from the word embeddings itself.

1. **Bing Liu** (Ding et al., 2008) **& MPQA** (Wiebe and Mihalcea, 2006) **lexicons**: We define a feature that marks the positivity/negativity scores of the words in a sentence. We assign a score of +1 & -1, respectively to each positive and negative word in the sentence. For unseen words, we use score as 0. We extract one such feature from each lexicon.

2. **SentiWordNet** (Baccianella et al., 2010): Three features are extracted for every word denoting its positivity (posScore), negativity (negScore) and objectivity (1 - [posScore + negScore]) scores, respectively.

3. **Semantic Orientation (SO)** (Hatzivassiloglou and McKeown, 1997): Semantic orientation defines the association of a word *w.r.t.* its positivity and negativity. Semantic orientation (SO) of a word is the difference of point-wise mutual information of a word w in positive and negative reviews. We calculate the SO score of each word in the context window of size ± 5 and take the cumulative SO score as the feature value.

3.3 Cross-lingual and Multi-lingual Setups

We evaluate our proposed approach for two setups i.e. multi-lingual and cross-lingual setups. In multi-lingual setup, the proposed model is trained and evaluated on datasets of the same language i.e. Hindi or French. We pre-process our datasets to reduce the effect of data sparsity by utilizing the resource-rich language i.e. English. In contrast, the

[3]Bi-lingual word embeddings available at http://www.iitp.ac.in/~ai-nlp-ml/resources.html

cross-lingual setup employs dataset of resource-rich language (i.e. English) for training and during evaluation Hindi or French dataset is used. Similar to the multi-lingual setup, we pre-process the test dataset to reduce the effect of data sparsity in cross-lingual setup as well.

An overall schema of the proposed methodology is depicted in Figure 1 for both multi-lingual and cross-lingual setups. Figures 1a and 1b show the training architectures for the cross-lingual and multi-lingual scenarios, respectively. Since our test datasets for both the variants are in Hindi (or French), testing scenario for cross-lingual and multi-lingual setups are also the same as represented in Figure 1c.

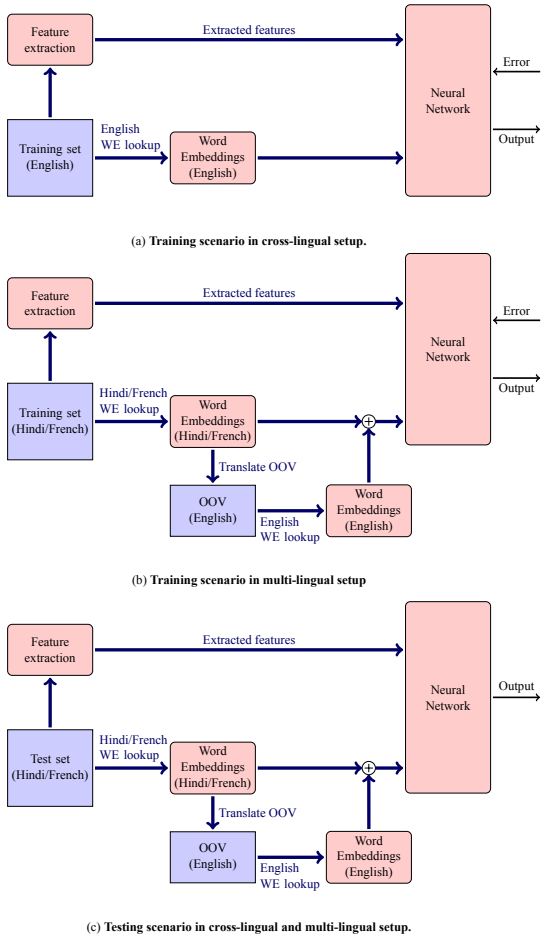

Figure 1: Proposed schema for *English-Hindi* and *English-French* language pairs.

3.4 Neural Network Architecture

For the successful marriage of word embeddings and extracted features, we try three different architectures as depicted in Figure 2. In the first architecture ($A1$, Figure 2a), we concatenate extracted features of each word of an instance with the corresponding word representations and pass it through a LSTM network followed by dense and output layers. In the second architecture ($A2$, Figure 2b), we do not combine features and word representations together. Rather, we learn sentence embeddings through a LSTM network and then concatenate it with the extracted features before feeding to the dense layer. Finally, in the third architecture ($A3$, Figure 2c), we train separate LSTMs for the extracted features and word embeddings. Subsequently, we merge their representations at the dense layer. The choice of separate LSTMs for the hand-crafted features in architecture $A3$ is driven by the fact that the dimension of a word embedding is usually very high as compared to its corresponding hand-crafted features. If trained together, as in architecture $A1$, extracted features of low dimension usually get overshadowed by the high-dimensional word embeddings. Thus making it non-trivial for the network to learn from the extracted features. Further, to exploit the sequence information of words in a sentence we pass hand-crafted features of each word through a separate LSTM layer. For example, in the following review sentence, there are two positive words ('*liking*' and *'recommending'*) and only one negative word ('*far*'). In a model that takes into account only the simple polar word score, the sentence would have high relevance towards the positive sentiment. However, the sequence information of the phrase "*far from liking and recommending*" dictates the negative sentiment of the sentence.

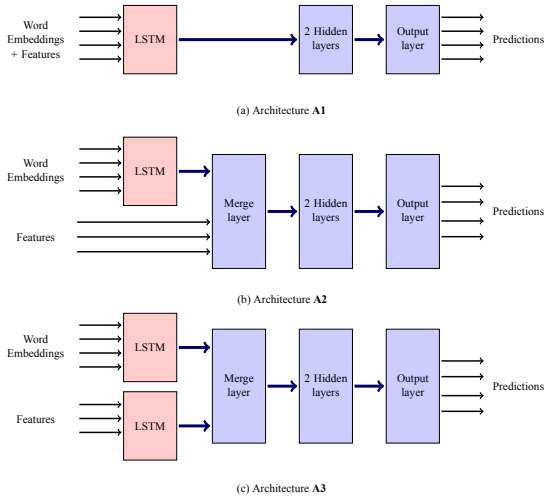

Figure 2: Neural Network Architectures.

"*I'm far from liking and recommending this phone to anyone.*"

In contrast to $A3$, architecture $A2$ does not rely on the sequence information of the extracted features and let the network to learn on its own.

We use 300 dimension word embeddings for the experiments. Each LSTM layer contains 100 neurons while two dense layers contain 100 and 50 neurons respectively.

4 Experimental Results

In this section, we describe the datasets, experimental setup, results and provide necessary analysis.

4.1 Datasets

We use Hindi ABSA dataset released by (Akhtar et al., 2016a) for our evaluation purpose. A total of 5,417 review sentences are present along with 4,509 aspect terms. Each aspect term belongs to one of the four sentiment classes: '*positive*', '*negative*', '*neutral*' and '*conflict*'. We split the dataset into 70%, 10% and 20% as training, development and test, respectively for the experiment. For French case, we use the SemEval-2016 shared task on ABSA (Pontiki et al., 2016) restaurant dataset. It consists of 2,429 review sentences and 3,482 aspect terms. In cross-lingual setup, we utilize English dataset of SemEval-2014 shared task on ABSA (Pontiki et al., 2014) for training and Hindi ABSA dataset for testing. The English dataset comprises of product reviews in two domains i.e. restaurant and laptop. However, we only employ laptop domain dataset as most of the reviews in Hindi ABSA datasets belong to the electronics domain. For training in cross-lingual setup, we combine the training and gold test dataset together. In total, there are 3,845 review sentences comprising of 3,012 aspect terms. For English-French case, we use English restaurant dataset of SemEval-2016 shared task on ABSA (Pontiki et al., 2016) for the training and French ABSA dataset (Pontiki et al., 2016) for evaluation. The SemEval-2016 English restaurant dataset contains 3,365 aspect terms across 2,676 review sentences.

4.2 Experiments

We use Python based neural network library, Keras[4] for implementation. For English-Hindi, all the four classes (namely *positive*, *negative*, *neutral* and *conflict*) were considered, whereas for English-French three classes (all except *conflict* class) were used for classification. Since there is no false class, we use accuracy value as metric to measure the performance of the system. Also, we utilize accuracy value for the direct comparison with the existing state-of-the-art systems. LSTM network is trained with early stopping criteria on (i.e. preserving best learned parameter at each epoch). We set the number of epochs and patience value as 100 & 20 respectively. In other words, we run the experiments for maximum 100 epochs and if validation loss does not reduce for consecutive 20 epochs training stops and reports the best epoch attained so far. As activation function, we utilize *'tanh'* at the intermediate layers, while for classification, we use *'softmax'* at the output layer. To prevent the network from over-fitting, we incorporate an efficient regularization technique called *'Dropout'* (Srivastava et al., 2014). At each layer of training, dropout skips few hidden neurons randomly. We fix dropout rate to be 45% during training while for optimization we use *'adam'* optimizer (Kingma and Ba, 2014).

Experimental results for aspect sentiment classification in multi-lingual and cross-lingual setups are reported in Figure 3 for both the language pairs. In total, we evaluate our model for four cases i.e. **a.** *En-Hi multi-lingual*, **b.** *En-Hi cross-lingual*, **c.** *En-Fr multi-lingual* and **d.** *En-Fr cross-lingual* scenarios. The non-root four-boxed nodes report performance of the respective methods for the four cases. The left subtree represents LSTM based baseline system that utilizes monolingual word embedding (WE) (i.e. word2vec model trained only on 7.2M Hindi and French sentences respectively). Whereas the right subtree represents usage of bilingual word embeddings in all the cases. Comparison between monolingual WE and bilingual WE shows competing results. Monolingual WE (a_M: 63.64%) in multi-lingual scenario performs better than the bilingual WE (a_B: 62.51%) for *English-Hindi* case, while bilingual WE (c_B: 70.89%) reports better performance as compared with monolingual WE (a_M: 66.29%) for *English-French* case. We observe a performance loss of approx. 1 point with bilingual embeddings for English-Hindi case. However, after addressing the problem of data sparsity (i.e. when OOV words are translated and corresponding English word embeddings are computed) the same LSTM network reports an improved accuracy value of 64.83% (a_{BO}) for English-Hindi case, thus observ-

[4] http://keras.io

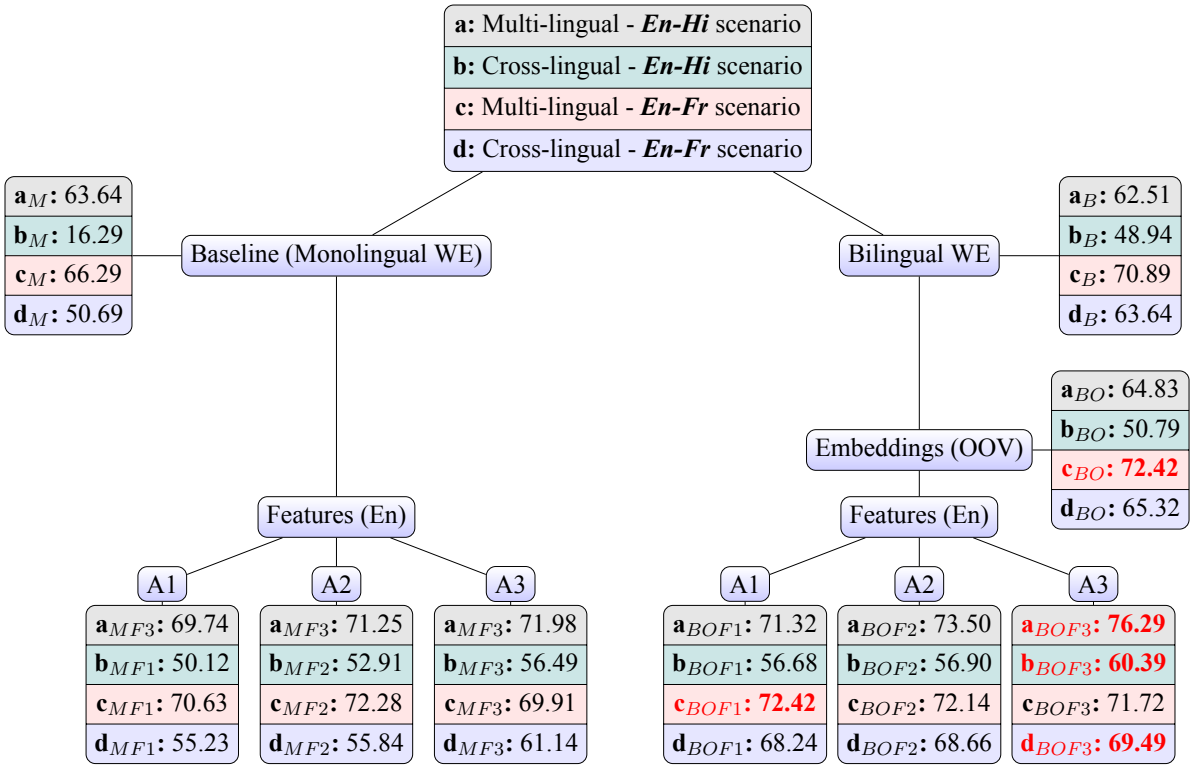

Figure 3: **Aspect classification in Multi-lingual and Cross-lingual setups for English-Hindi and English-French scenarios:** *Left subtree* represents various baselines and their corresponding results. *Right subtree* represents the proposed approach at different levels. Four-box rectangles at non-root levels show accuracy values for **a.** *multi-lingual (En-Hi)*, **b.** *cross-lingual (En-Hi)*, **c.** *multi-lingual (En-Fr)* & **d.** *cross-lingual (En-Fr)* scenarios respectively. **OOV:** Out-of-vocabulary words. **A1:** Word embeddings and extracted features are combined and fed into single LSTM network. **A2:** Extracted features are directly merged with LSTM output of word embedding. **A3:** One LSTM network each for word embeddings and extracted features. Subscripts **M:** *monolingual WE*; **B:** *bilingual WE*; **O:** *Embeddings(OOV)*; **F:** *Features*; **1,2,3:** *Architecture A1, A2 & A3* respectively.

ing a performance increase of more than 2 points. For English-French case, we also observe the improvement with embeddings of OOVs. This suggests that the richness of target language (English) word embeddings helps the system to efficiently solve the problem encountered in resource-poor source language. Since the resources are limited for resource-poor language we try to leverage the high-quality lexicon features of English in our system. Consequently, we introduce the extracted features of Section 3.2 to the network. For English-Hindi multi-lingual scenario, the performance increments from $A1$ to $A2$ to $A3$ indicate that the resource-richness of English language plays a crucial role in classification. While we incorporate English side lexicon features for English-French multi-lingual scenario, we observe no performance improvement like the others. For this case, our system reports an accuracy of 72.42% with (c_{BOF1}) and without (c_{BO}) the use of extra features.

Results of cross-lingual setup for English-Hindi case, where we train the network utilizing English dataset and evaluate the model on Hindi dataset, are reported in row 2 of the four-boxed nodes in Figure 3. The baseline model for cross-lingual setups (left subtree of Figure 3) employs monolingual word embeddings of English and Hindi for training and testing respectively. Since the vector spaces of two different languages are completely unrelated, it is no surprise that the baseline system achieves merely 16.29% (b_M) accuracy. Using only the bilingual word embeddings the system achieves 48.94% (b_B) accuracy. By increasing the coverage of input word embeddings using machine translation the proposed system obtains an increased accuracy of 50.79% (b_{BO}). This improvement in accuracy, again, justifies the use of translated words for obtaining the word embeddings. Further, with the inclusion of target-side lexicon based features our proposed approach reports a significant performance improvement of approximately 6-10 points for all the three archi-

tectures (b_{BOF1}, b_{BOF2} & b_{BOF3}).

Results of English-French cross-lingual scenario are reported in row 4 of the four-boxed nodes in Figure 3. We observe similar phenomenon in cross-lingual setup with the English-French case as well. The baseline system, where we utilize separate monolingual WE for training and testing in English and French respectively, reports an accuracy of 50.69% (d_M), while employing bilingual embeddings the system obtains a sharp jump of approx. 13 points with an accuracy value of 63.64% (d_B). Further, with the inclusion of OOV words and lexicon features performance of the system improves to 65.32% (d_{BO}) and 69.49% (d_{BOF3}), respectively.

We observe four phenomena from these results: i) use of lexicon-based features is the driving force in predicting the sentiment; ii) qualitative lexicons of the resource-rich language can assist in solving the problems of resource-poor languages; iii) embeddings of the OOV words improves the performance of the system with or without assistance of extra features; and iv) use of separate LSTMs (one for word embeddings and the other for features) helps the network to efficiently extract relevant features for prediction without interfering each other (except for the multi-lingual English-French scenario).

4.3 Comparative Analysis

Comparative results reported in Figure 4 show that our proposed system clearly outperforms the baseline model in both the setups and for both the language pairs. In multi-lingual setup, we compare the proposed model against three state-of-the-art systems (Akhtar et al., 2016a; Singhal and Bhattacharyya, 2016; Akhtar et al., 2016b) for English-Hindi case. An accuracy of 65.96% was reported by the system (Akhtar et al., 2016b), while the system (Singhal and Bhattacharyya, 2016) obtained an accuracy of 68.31%. However, our proposed system reports an accuracy of 76.29%, which is approx. 10% & 8% higher compared to the systems of (Akhtar et al., 2016b) and (Singhal and Bhattacharyya, 2016) respectively. In English-French case, our proposed system reports an improvement of approx. 6 points over the baseline. For cross-lingual setup in English-Hindi case, we compare our proposed method with the state-of-the-art system proposed in (Barnes et al., 2016; Singhal and Bhattacharyya, 2016). On the same dataset their systems reported to have achieved an accuracies

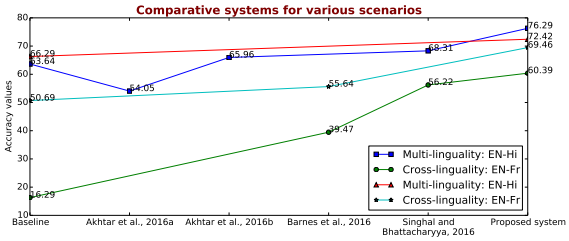

Figure 4: Comparison with the baseline and state-of-the-art methods.

of 39.47% & 56.22% as compared to 60.39% of our proposed system. In English-French case, the system proposed in (Barnes et al., 2016) obtains accuracy value of 55.64% against 69.49% in our proposed architecture. Statistical significance tests (*t*-test) confirm that performance increments in the proposed model are significant w.r.t. state-of-the-art methods with *p*-value=0.03 and *p*-value=0.01 respectively in multi-lingual and cross-lingual setups.

4.4 Discussions

The prime motivation of our current work is to minimize the effect of *data sparsity* while learning through deep neural network architecture. For this, we propose to use bilingual embeddings computed from a parallel corpus, which is created utilizing a MT system. Similarly, absence of a large aligned corpus in resource-poor language can be addressed through the application of a MT system. Since, the MT system is not fully accurate, there must be some errors introduced while translating. This, in turn, affects the bilingual word embedding. Another limitation of our work is that 7.2M sentences is not a big number in terms of word embedding computation. However, the underlying method performs considerably better compared to the state-of-the-art systems, even with all these constraints.

To show the effectiveness of bilingual embeddings in minimizing data sparsity, we also experiment with a mono-lingual Hindi embeddings computed on 53M sentences. Following the proposed approach (except computing embeddings for OOV words), we obtain an accuracy of 77.74% in aspect classification task. Table 1 shows comparison with mono-lingual and multi-lingual approach for classification. Despite all those limitations discussed above (i.e. SMT error & corpus size), the proposed method with bilingual embeddings (76.29%) performs considerably at par against the monolin-

gual embeddings created from a very large corpus of 53M (77.74%). However, the monolingual WE computed using the same amount of corpus (i.e. 7.2M sentences) produces an accuracy of only 63.64%. Further with the help of lexicon based features accuracy of this system increases to 70.86% (compared to 76.29% of our proposed model). It is also to be observed that performance of the system is improved by just including representations of the OOV words. Performance of the proposed system would have been much better if we would not have above mentioned limitations.

Models	Bilingual	Models	Monolingual	
	Size = 7.2M		Size = 7.2M	Size = 53M
Bilingual	62.51	Monolingual	63.64	68.74
Bilingual + Embedding (OOV)	64.83			
Bilingual + Embedding (OOV) + Feature (Eng)	76.29	Monolingual + Feature (Eng)	70.86	77.74

Table 1: Comparative analysis of monolingual embeddings and bilingual embeddings in multi-lingual setup.

4.5 Error Analysis

We perform error analysis on the obtained results. Quantitatively, '*neutral*' is the most problematic class in both multi-lingual and cross-lingual setups. It mainly confuses with '*positive*' class. Approximately, 20% & 40% of '*neutral*' instances are tagged as '*positive*' in multi-lingual and cross-lingual setups, respectively. Our system does not predict '*conflict*' class at all, possibly due to the insufficient number of instances for training. Qualitatively, following are the few cases where our system performs below par.

- **Lack of polar information inside context:** Our system finds it challenging to classify sentiment of the aspect terms whose polar information lie outside the context window. In the following sentence aspect term is 'वज़न |weight' and the actual sentiment towards it is positive. The polar information 'तुलना में लगभग आधा |about half as compared' and 'हल्का |lighter' are far from the aspect term, hence, not captured within the context window.
  Devanagari: इसका वज़न नए आईपैड की तुलना में लगभग आधा है और यह अन्य उपलब्ध 7-इंच टेबलेट्स से भी हल्का है।
  Transliteration: isakA vaZana nae AIpaiDa kI tulanA meM lagabhaga AdhA hai aura yaha anya upalabdha 7-iMcha TebaleTsa se bhI halkA hai.
  Translation: Its weight is about half as compared to the new iPad and it is lighter than other available 7-inch tablets.

- **Implicit sentiment:** Presence of implicit sentiment is not correctly classified by the proposed system. Following review contains 'बनावट |built' as an aspect term and its negative sentiment is derived from the phrase 'प्लास्टिक फील |plastic feel'.
  Devanagari: इस टेबलेट की बनावट काफी प्लास्टिक फील देता है।
  Transliteration: isa TebaleTa kI banAvaTa kAphI plAsTika phIla detA hai.
  Translation: The built of this tablet gives a fairly plastic feel.

5 Conclusion

In this paper, we present a deep learning based LSTM architecture built on top of bilingual word embeddings for aspect level sentiment classification. Bilingual word embeddings try to bridge the language barrier between a resource-rich and resource-poor languages in a shared vector space. We propose to reduce the effect of data sparsity in a resource-poor language word embeddings by projecting OOV words into target side and utilize the target side word embeddings. In addition, we also exploit various resources of English for assisting the proposed model. We show the effectiveness of the proposed method in two different setups, i.e. multi-lingual and cross-lingual. Experimental results show that the proposed system outperforms various state-of-the-art systems in both the setups. In future, we would like to explore the application of proposed method in another aspect level sentiment analysis task known as aspect term extraction or opinion target extraction.

SRL4ORL: Improving Opinion Role Labeling Using Multi-Task Learning With Semantic Role Labeling

Ana Marasović and **Anette Frank**
Research Training Group AIPHES
Department of Computational Linguistics
Heidelberg University
{marasovic,frank}@cl.uni-heidelberg.de

Abstract

For over a decade, machine learning has been used to extract *opinion-holder-target structures* from text to answer the question *Who expressed what kind of sentiment towards what?*. Recent neural approaches do not outperform the state-of-the-art feature-based models for Opinion Role Labeling (ORL). We suspect this is due to the scarcity of labeled training data and address this issue using different multi-task learning (MTL) techniques with a related task which has substantially more data, i.e. Semantic Role Labeling (SRL). We show that two MTL models improve significantly over the single-task model for labeling of both holders and targets, on the development and the test sets. We found that the vanilla MTL model which makes predictions using only shared ORL and SRL features, performs the best. With deeper analysis we determine what works and what might be done to make further improvements for ORL.

1 Introduction

Fine-Grained Opinion Analysis (FGOA) aims to: (i) detect opinion expressions (O) that convey attitudes such as sentiments, agreements, beliefs or intentions (like *feared* in example (1)), (ii) measure their intensity (e.g. strong), (iii) identify their holders (H), i.e. entities that express an attitude (e.g. *it*), (iv) identify their targets (T), i.e. entities or propositions at which the attitude is directed (e.g. *violence*) and (v) classify their target-dependent attitude (e.g. negative sentiment)[1].

(1) Australia said [it]$_H$ [**feared**]$_{O_{neg}}$ [violence]$_T$ if voters thought the election had been stolen.

As the commonly accepted benchmark corpus MPQA (Wiebe et al., 2005) uses span-based annotations to represent *opinion entities* (opinions, holders and targets), the task is usually approached with sequence labeling techniques and the BIO encoding scheme (Choi et al., 2006; Yang and Cardie, 2013; Katiyar and Cardie, 2016). Initially pipeline models were proposed which first predict opinion expressions and then, given an opinion, label its *opinion roles*, i.e. holders and targets (Kim and Hovy, 2006; Johansson and Moschitti, 2013). Pipeline models have been substituted with so-called joint models that simultaneously identify all opinion entities, and predict which opinion role is related to which opinion (Choi et al., 2006; Yang and Cardie, 2013; Katiyar and Cardie, 2016). Recently an LSTM-based joint model was proposed (Katiyar and Cardie, 2016) that unlike the prior work (Choi et al., 2006; Yang and Cardie, 2013) does not depend on external resources (such as syntactic parsers or named entity recognizers). The neural variant does not outperform the feature-based CRF model (Yang and Cardie, 2013) in Opinion Role Labeling (ORL).

Both the neural and the CRF joint models achieve about 55% F1 score for predicting which targets relate to which opinions in MPQA. Thus, these models are not yet ready to answer the question this line of research is usually motivated with: *Who expressed what kind of sentiment towards what?*. Our goal is to investigate the limitations of neural models in solving different subtasks of FGOA on MPQA and to gain a better understanding of what is solved and what is next.

We suspect that one of the fundamental obstacles for neural models trained on MPQA is its small size. One way to address scarcity of labeled data is to use multi-task learning (MTL) with appropriate auxiliary tasks. A promising auxiliary task candidate for ORL is Semantic Role Labeling (SRL), the task of predicting predicate-argument structure of a sentence, which answers the question *Who did what to whom, where and when?*.

[1] Examples are drawn from MPQA (Wiebe et al., 2005).

Proceedings of NAACL-HLT 2018, pages 583–594

Table 1: Output of the SRL demo.

Table 1 illustrates the output of the SRL demo[2] for example (1), following the PropBank SRL scheme (Palmer et al., 2005)[3].

SRL4ORL. The semantic roles of the predicate *fear* (marked blue bold) correspond to the opinion roles H and T, according to MPQA. For this reason, the output of SRL systems has been commonly used for feature-based FGOA models (Kim and Hovy, 2006; Johansson and Moschitti, 2013; Choi et al., 2006; Yang and Cardie, 2013). Additionally, a considerable amount of training data is available for training SRL models (Table 2 in Sec. 3), which made neural SRL models successful (Zhou and Xu, 2015; Yang and Mitchell, 2017).

Obstacles. Although SRL is similar in nature to ORL, it cannot solve ORL for all cases (Ruppenhofer et al., 2008). In example (2) holder and target of the predicate *please* correspond to A1, A0 semantic roles respectively, wheres for the predicate *fear* in (1) holder and target correspond to A0, A1 respectively. We took into account this observation when deciding on an appropriate MTL model by splitting its parameters into shared and task-specific ones (i.e. hard-parameter sharing).

(2) $[\text{I}]_H^{A1}$ am very $[\textbf{pleased}]_{O_{pos}}$ that [the Council has now approved the Kyoto Protocol thus enabling the EU to proceed with its ratification$]_T^{A0}$.

A further obstacle for properly exploiting SRL training data with MTL could be specificities, inconsistency and incompleteness of the MPQA annotations. In example (3), *Rice* expressed his negative sentiment towards *the three countries in question* by *setting the criteria* which states something negative about those countries: they *are repressive and grave human rights violators [...]*. In this case, the model should not pick any local semantic role for the target.

(3) The criteria $[\textbf{set by}]_{O_{neg}}$ $[\text{Rice}]_H$ are the following: $[\text{the three countries in question}]_T$ are repressive and grave human rights violators, and aggressively seeking weapons [...].

In examples (4–5), the same opinion expression *concerned* realizes different scopes for the target. A model which exploits SRL knowledge could be biased to always label targets as complete SRL role constituents, as in example (5).

(4) Rice told us $[\text{the administration}]_H$ was $[\textbf{concerned}]_{O_{neg}}$ that $[\text{Iraq}]_T$ would take advantage of the 9/11 attacks.

(5) $[\text{The Chinese government}]_H$ is deeply $[\textbf{concerned}]_{O_{neg}}$ about [the sudden deterioration in the Middle East situation$]_T$, Tang said.

Regarding incompleteness, prior work (Katiyar and Cardie, 2016) has shown that their model makes reasonable predictions in sentences which do not have annotations at all, e.g. $[\text{mothers}]_H$ $[\textbf{care}]_O$ for $[\text{their young}]_T$, in: *From the fact that mothers care for their young, we can not deduce that they ought to do so, Hume argued.*

The examples above show that incorporating SRL knowledge via multi-task learning is a reasonable way to improve ORL, but at the same time they alert us that given the specificities of MPQA and ORL annotations in general, it is not obvious whether MTL can overcome divergences in the annotation schemes of opinion and semantic role labeling. We investigate this research question by adopting one of the recent successful architectures for SRL (Zhou and Xu, 2015) and experiment with different multi-task learning frameworks.

Our contributions are: (i) we adapt a recently proposed neural SRL model for ORL, (ii) we enhance the model using different MTL techniques with SRL to tackle the problem of scarcity of labeled data for ORL, (iii) we show that most of the MTL models improve the single-task model for labeling of both holders and targets on development and test sets, and two of them make yield significant improvements, (iv) by deeper analysis we provide a better understanding of what is solved and where to head next for neural ORL.

[2] http://barbar.cs.lth.se:8081

[3] Henceforth we use the PropBank SRL framework.

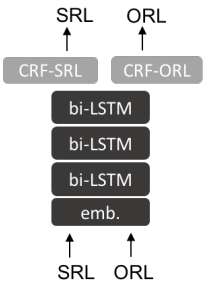

Figure 1: Fully-shared (FS) MTL.

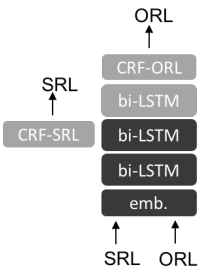

Figure 2: Hierarchical-MTL (H-MTL).

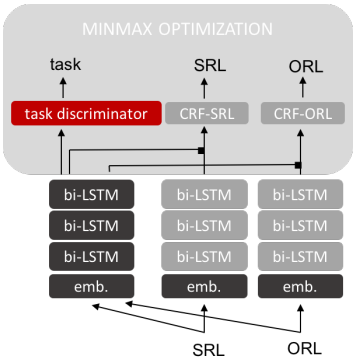

Figure 3: (Adversarial) state-private ((A)SP) MTL.

2 Neural MTL for SRL and ORL

Neural multi-task learning (MTL) receives a lot of attention and new MTL architectures emerge regularly. Yet there is no clear consensus which MTL architecture to use in which conditions. We experiment with well-received architectures that could adapt to different cases of ORL from Section 1.

As a general neural architecture for single- and multi-task learning we use the recently proposed SRL model (Zhou and Xu, 2015) (Z&X-STL) which successfully labels semantic roles without any syntactic guidance. This model consists of a stack of bi-directional LSTMs and a CRF which makes the final prediction. The inputs to the first LSTM are not only token embeddings but three additional features: embedding of the predicate, embedding of the context of the predicate and an indicator feature (1 if the current token is in the predicate context, 0 otherwise). Thus, every sentence is processed as many times as there are predicates in it. Adapting this model for labeling of opinion roles is straightforward, the only difference being that opinion expressions can be multi-words and only two opinion roles are assigned.

MTL techniques aim to learn several tasks jointly by leveraging knowledge from all tasks. In the context of neural networks, MTL is commonly used in such a way that it is predefined which layers have tied parameters and which are task-specific (i.e. hard-parameter sharing). There are various ways of defining which parameters should be shared and how to train them.

Fully-shared (FS) MTL model. A fully-shared model (Fig. 1) shares all parameters of the general model except the output layer. Each task has a task-specific output layer which makes the prediction based on the representation produced by the final LSTM. When training on a mini-batch of a certain task, parameters of the output layer of the other tasks are not updated. This model should be effective for constructions with a clear mapping between opinion and semantic roles such as $\{\text{H} \mapsto \text{A0}, \text{T} \mapsto \text{A1}\}$ as in example (1) (Sec. 1).

Hierarchical MTL (H-MTL) model. For NLP applications, often some given (high-level) task is supposed to benefit from another (low-level) task more than the other way around, e.g. parsing from POS tagging. This intuition lead to designing hierarchical MTL models (Søgaard and Goldberg, 2016; Hashimoto et al., 2017) in which predictions for low-level tasks are not made on the basis of the representation produced at the final LSTM, but on the representation produced by a lower-layer LSTM (Fig. 2). Task-specific layers atop shared layers could potentially give the model more power to distinguish or ignore certain semantic roles. If so, this MTL model is more suitable for examples like (2) and (3) (Sec. 1).

Shared-private (SP) MTL model. In the state-private model, in addition to the stack of shared LSTMs, each task has a stack of task-specific LSTMs (Liu et al., 2017) (Fig. 3). Representations at the outermost shared LSTM and the task-specific LSTM are concatenated and passed to the task-specific output layer. The ORL representation produced independently from SRL gives the model the ability to utilize the shared and entirely task-specific information. For labeling of targets, it is expected that for examples (1) & (5) the model relies mostly on the shared representation, for examples (2) & (4) on both shared and ORL-specific representations, and for example (3) solely on the ORL-specific representation.

Adversarial shared-private (ASP) model. The limitation of the SP model is that it does not prevent the shared layers from capturing task-specific features. To ensure this, ASP extends the

	task	train size	dev size	test size	$\lvert\mathcal{Y}\rvert$
CoNLL'05	SRL	90750	3248	6071	106
MPQA (4-CV)	ORL	3141.25	1055	1036.75	7
MPQA (10-CV)	ORL	3516.3	1326	349.3	7

Table 2: Datasets w/ nb. of SRL predicates/ORL opinions in train, dev & test set, size of label inventory.

SP model with a *task discriminator* (Liu et al., 2017). The task discriminator (Fig. 3, marked red) predicts to which task the current batch of data belongs, based on the representation produced by the shared LSTMs. If the shared LSTMs are task-invariant, the discriminator should perform badly. Thus, we update the shared parameters to maximize the discriminator's cross-entropy loss. At the same time we want the discriminator to challenge the shared LSTMs, so we update the discriminator's parameters to minimize its cross-entropy loss. This minmax optimization is known as *adversarial training* and recently it gained a lot of attention for NLP applications (Liu et al., 2017; Chen et al., 2017; Kim et al., 2017; Qin et al., 2017; Wu et al., 2017; Gui et al., 2017; Li et al., 2017; Zhang et al., 2017; Joty et al., 2017).

3 Experimental setup

3.1 Datasets

For SRL we use the newswire CoNLL-2005 shared task dataset (Carreras and Màrquez, 2005), annotated with PropBank predicate-argument structures. Sections 2-21 of the WSJ corpus (Charniak et al., 2000) are used for training and section 24 as dev set. The test set consists of section 23 of WSJ and 3 sections of the Brown corpus.

For ORL we use the manually annotated MPQA 2.0. corpus (Wiebe et al., 2005; Wilson, 2008). It mostly contains news documents, but also travel guides, transcripts of spoken conversations, e-mails, fundraising letters, textbook chapters and translations of Arabic source texts.

We report detailed pre-processing of MPQA[4] and data statistics in the Supplementary Material.

3.2 Evaluation metrics

For both tasks we adopt evaluation metrics from prior work. For SRL, precision is defined as the proportion of semantic roles predicted by a system which are correct, recall is the proportion of gold roles which are predicted by a system, F1 score is the harmonic mean of precision and recall.

In case of ORL, we report 10-fold CV[5] and repeated 4-fold CV with *binary F1 score* and *proportional F1 score*, for holders and targets separately. *Binary precision* is defined as the proportion of predicted holders (targets) that overlap with the gold holder (target), *binary recall* is the proportion of gold holders (targets) for which the model predicts an overlapping holder (target). *Proportional recall* measures the proportion of the overlap between a gold holder (target) and an overlapping predicted holder (target), *proportional precision* measures the proportion of the overlap between a predicted holder (target) and an overlapping gold holder (target). F1 scores are the harmonic means of the corresponding precision and recall.

3.3 Training details

We evaluate our models using two evaluation settings. First, we follow Katiyar and Cardie (2016) which set aside 132 documents for development and used the remaining 350 documents for 10-fold CV. However, in the 10-fold CV setting, the size of the tests sets is 3 times smaller than the dev set size (Table 2, row 3), and, consequently, results in high-variance estimates on the test sets. Therefore we additionally evaluate our models with 4-fold CV. We set aside 100 documents for development and use 25% of the remaining documents for testing. The resulting test sets are comparable in size to the dev set (Table 2, row 2). We run 4-fold CV twice with two different random seeds. We do not tune hyperparameters (HPs), but follow suggestions proposed in the thorough HP study for sequence labeling tasks (Reimers and Gurevych, 2017). HPs can be found in the Supplementary Material.

4 Results

We evaluate all models after every $\lceil \frac{\text{train size}}{\text{batch size}} \rceil$ iteration on the ORL dev set and save them if they achieve a higher arithmetic mean of proportional F1 scores of holders and targets on the ORL dev set. The saved models are used for testing.

We report the mean of F1 scores over 10 folds and the standard deviation (appears as a subscript) of all models in Table 3. We report the mean of F1 scores over 4 folds and 2 different seed (8 evalua-

[4]Examples how to use our scripts can be found at https://github.com/amarasovic/naacl-mpqa-srl4orl/blob/master/generate_mpqa_jsons.py.

[5]We used the same splits as the prior work (Katiyar and Cardie, 2016). We thank the authors for providing the splits.

Table 4: ORL repeated 4-fold CV results.

tions) and the standard deviation of all models in Table 4. Evaluation metrics follow Section 3.2.

We mark significant difference between MTL models and the single-task (Z&X-STL) model, observed using a Kolmogorov-Smirnov significance test ($p < 0.05$) (Massey Jr, 1951), with $\bullet$ in superscript and between the FS-MTL model and other MTL models with $\diamond$.

STL vs. MTL. In the 10-fold CV evaluation setting (Table 3), the FS-MTL and the H-MTL models improve over the Z&X-STL model in all evaluation measures, for both holders and targets. When evaluated in the repeated 4-fold CV setting (Table 4), all MTL models improve over the Z&X-STL model in all evaluation measures, for both holders and targets.

The FS-MTL and the H-MTL models improve *significantly* in all evaluation measures, for both holders and targets, on both dev and test sets, when evaluated with repeated 4-fold CV. With 10-fold CV the improvements are also significant, except for targets on the test set. This is probably due to the small size of the test sets (Table 2, row 3), which results in a high-variance estimate. Indeed, standard deviations on the 10-fold CV test sets are always much higher compared to the dev set or to the test sets of 4-fold CV.

It is not surprising that larger improvements are visible in the labeling of holders. They are usually short, less ambiguous and often presented with the A0 semantic role, whereas annotating targets is a challenging task even for humans.[6]

Larger improvements are visible for proportional F1 score than for binary F1 score. That is, more data and SRL knowledge helps the model to better annotate the scope of opinion roles.

Comparing MTL models. In Section 2 we introduced MTL models with task-specific LSTM layers hypothesizing that these layers should give MTL models more power to adapt to a variety of potentially problematic cases that we illustrated in the Introduction. However, our results show that the FS-MTL model performs significantly better or comparable to MTL models that include task-specific layers. Reimers and Gurevych (2017) show that MTL is especially sensitive to the selection of HPs. Thus, a firm and solid comparison of the different MTL models requires thorough HP optimization, to properly control the number of parameters and regularization of the models. We leave HP optimization for future work.

5 Analysis

Our aim in this section is to analyze what the proposed models are good at, in which ways MTL improves over the single-task ORL model and what could be done to achieve further progress.

We evaluate the FS-MTL and the Z&X-STL

Table 8: Statistics of *target* prediction.

models on the ORL dev set using 4-fold CV repeated twice with different seeds (8 evaluation trials). We say that a model predicts a role of a given opinion expression *correctly* if the model predicts a role that overlaps with the correct role in at least 6 out of 8 evaluation trials. If a model predicts a role that overlaps with the correct role in at most 2 out of 8 trials, we say that the model predicts the role *incorrectly*. The requirement on 6-8 (in)correct predictions reduces the risk of analyzing inconsistent predictions and enables us to draw firmer conclusions. We analyze the following scenarios:

(i) both the FS-MTL model and the Z&X-STL model make correct predictions (Tables 5–6)

(ii) the FS-MTL model makes a correct prediction, while the Z&X-STL makes an incorrect prediction (Tables 11–12)

(iii) both models make wrong predictions (Tables 9–10)

In the following, we categorize predictions in case (i) as *easy cases*, and predictions in case (iii) as *hard cases*.

In Tables 5–6 and 9–12, the opinion expression is bolded, the correct role is italicized, predictions of the FS-MTL model are colored blue (subscript *FS*), predictions of the Z&X-STL model are colored yellow (subscript *ZX*) and green marks predictions where both models agree. For simplicity, we show only holders or targets, although the models predict both roles jointly.

What works well? There are 668/1055 instances in the dev set for which both models predict holders correctly, and 663/1055 for targets.

Examples 1–5 in Table 5 suggest that holders that can be properly labeled by both models (*easy*

1	It would be entirely improper if , in *its* **defense of** Israel $_{FS}$, the United States continues to exert pressure on [...] .
2	Indonesia $_{FS,ZX}$ **has come under pressure** from *several quarters* to take tougher action against alleged terrorist leaders but has played down the threat .

4	*The department* said that it will cost $ 600 for an HIV/AIDS patient per year at this time , and the following years this cost is **expected** to stand at just $ 400/year for one patient as the production of such drugs becomes stable .
5	The Organisation of African Unity OAU $_{ZX}$ also backed Zimbabwean President Robert Mugabe 's re-election , with its observer team $_{FS,ZX}$ **describing** the poll as " transparent , credible , free and fair " .
6	Regarding the American proposed Anti-Missile Defense System too , neither Russia , China , Japan , nor even the European Union , had shown any enthusiasm ; rather *they* $_{FS}$ had all $_{FS,ZX}$ **expressed** their reserves on the project .
7	The president renewed his pledge to thwart terrorist groups $_{FS,ZX}$ *who* **want** to " mate up " with regimes hoping to acquire weapons of mass destruction and said " nations will come with us " if the US-led war on terrorism is extended .

Table 9: The dev examples for which both models (FS-MTL, Z&X-STL) *incorrectly* predict the *holder* in 6/8 trials.

1	*State-sanctioned land invasions* , several times **declared** illegal by Zimbabwe 's courts , as well as a drought have disrupted Zimbabwe 's food production and famine is already looming in much of the country .
2	But he **told** the nation $_{FS,ZX}$ that in spite of *stiff opposition to the agrarian reforms from powerful Western countries , especially the country 's former colonial power of Britain* , he would press ahead to seize farms from whites and [...] .
3	If the Europeans wish to influence Israel in the political arena – in *a direction* that many in Israel **would support wholeheartedly** – they will not be able to promote their positions in such a manner .
4	They $_{FS,ZX}$ are fully aware that these are dangerous *individuals* , he **said** during a press conference [...] .
5	And her little girl **just complained** , " I don't want to *wash the dishes* " .
6	During *President Bush's speech* , I **thought** of heckling $_{ZX}$; ' What are you going to do with the Kyoto Protocol ? $_{FS}$'
7	At first I **didn't want** to apply for it $_{FS,ZX}$, but the principal called me during the summer months and said , " Sandra the time is running out , you need to apply ".

Table 10: The dev examples for which both models (FS-MTL, Z&X-STL) *incorrectly* predict the *target* in 6/8 trials.

cases) are subjects of their governing heads or A0 roles. The statistics in Table 7 (col. 1, rows 2–3) supports this observation.[7] In contrast, holders that both models predict incorrectly (*hard* cases) are less frequently subjects or A0 roles (col. 2, rows 2–3). Also, *easy* holders are close to the corresponding opinion expression: the average distance is 1.54 tokens (Table 7, row 4), contrary to the *hard* holders with the average distance of 7.56.

Examples 1–5 in Table 6 suggest that targets that can be properly labeled by both models are objects of their governing heads or A1 roles. Table 8, row 3, shows that the majority of the *easy* targets are indeed A1 roles, in contrast to the *hard* targets. Similar to holders, the *easy* targets are in average 7 tokens closer to the opinion expression.

What to do for further improvement? There are 165/1055 instances in the dev set for which both models predict holders incorrectly, and 176 for targets.

As we have seen so far, many holders that are subjects or A0 roles, and targets that are A1 roles, are properly labeled by both models. However, a considerable amount of such holders and targets are not correctly predicted (Table 7–8, col. 2, rows 2–3). Thus our models do not work flawlessly for all such cases. A distinguishing property of the *hard* cases is the distance of the role from the opinion. Thus, future work should advance the model' s ability to capture long-range dependencies.

Examples in Table 9 demonstrate that holders, harder to label with our models, occur with the corresponding opinions in more complicated syntactic constructions. In the first example, the FS-MTL model does not recognize the possessive and is possibly biased towards picking the country (*Israel*), which occurs immediately after the opinion. In the second example, the opinion expression is

[7] The statistics is calculated using the output of mate-tools (Björkelund et al., 2010).

1	Yoshihisa Murasawa , a management consultant for Booz-Allen & Hamilton Japan Inc. , said *his firm* $_{FS,ZX}$ will likely be recommending acquisitions of Japanese companies more $_{ZX}$ often to foreign clients in the future .
2	*The source* $_{FS}$, interviewed by Interfax in Grozny , **expressed confidence** that that the command of the Russian forces in Chechnya would soon " be able to obtain documentary confirmation " that Khattab was dead .
3	*The Commonwealth team earlier* this week $_{FS}$ **said** that " the conditions in Zimbabwe did not adequately allow the free and fair expression of will by the electorate ".
4	Publishing such biased reports will only create **mistrust** among nations $_{FS}$ regarding the objectives and independence of the UN Commission on Human Rights .
5	The Inkatha Freedom Party , Democratic Alliance , New National Party , African Christian Democratic Party , the Pan Africanist Congress and the United Christian Democratic Party $_{ZX}$ had disagreed with the ANC $_{FS}$ **conclusion** .

7	US diplomats $_{ZX}$ say *Bush* $_{FS,ZX}$ **will seek to support** Kim 's Nobel Prize winning policy by offering new talks with the North , while remaining firm about North Korea 's missile sales and its feared chemical and biological weapons programmes.

Table 11: The dev examples for which the FS-MTL model *correctly* predicts the *holder* in 6/8 trials, whereas the Z&X-STL model predicts *incorrectly* in 6/8 trials.

1	In most cases he **described** *the legal punishments* $_{FS}$ *like floggings and executions of murderers and major drug traffickers that are applied based on the Shria , or Islamic law as human rights violations* .
2	In another **verbal attack** Kharazi accused *the United States* $_{FS}$ of wanting to exercise " world dictatorship " since the " horrible attacks " of September 11 .
3	He said those who thought the election process would be rigged were supporters of the MDC party , adding that they **were prejudging** and wanted to direct the process $_{ZX}$.
4	However , the fact that certain countries have a more balanced view of the conflict $_{ZX}$ is not the only reason to doubt that *anti-Israeli decisions* $_{FS}$ will , in fact , **be adopted** .
5	But *his tough stand on P'yongyang* $_{FS}$ **has provoked concern** in Seoul $_{ZX}$, where President Kim Tae-chung , who is in the last year of his five-year term , has been trying to prise the hermit state out of isolation .

Table 12: The dev examples for which the FS-MTL model *correctly* predicts the *target* in 6/8 trials, whereas the Z&X-STL model predicts *incorrectly* in 6/8 trials.

a nominal predicate and the holder is its object. The sentence is in passive voice but the models probably interpret it in the active voice and thus make the wrong prediction. In the third example, the opinion expression is the head of the relative clause that modifies the holder. These examples raise the following questions: would improved consistency with syntax lead to improvements for ORL and could we train a dependency parsing model with SRL and ORL to help the models handle syntactically harder cases?

Example 4 shows that holders specific to the MPQA annotation schema are hard to label as they require inference skills: from *the department said*, we can defeasibly infer that it is *the department* who *expects [this cost] to stand at just $400/year [...]*. To handle such cases, it would be worth trying training our models jointly with models for recognizing textual entailment.

Examples 6–7 illustrate that some gap in performance stems from difficulties in processing MPQA. Example 5 has no gold holder, but the models make plausible predictions. For example 6, FS-MTL predicts the discontinuous holder *they ... all*, while MPQA allows only contiguous entities. Therefor our evaluation scripts interpret *they* and *all* as two separate holders and deem *all* as incorrect, resulting with lower precision. Finally, for example 7 our models make plausible predictions. However, the gold holder is always the entity from the coreference cluster that is the closest to the opinion.[8] The evaluation scripts needs to be extended such that predicting any entity from the coreference cluster is considered to be correct. To conclude, to better evaluate future developments, it would be worth curating MPQA instances with missing roles and extending evaluation to account for coreferent holders and discontinuous roles.

The examples in Table 10 demonstrate that dif-

[8] We followed the prior work (Katiyar and Cardie, 2016).

ficulties in labeling targets originate from similar reasons as for holders. Examples 1–3 demonstrate complex syntactic constructions, examples 4–6 MPQA-specific annotations that require inference and example 7 exemplifies a missing target.

How does MTL help? There are 18/1055 instances in the dev set for which the FS model predicts the holder correctly and the Z&X-STL model does not, and 19/1055 for targets.

For holders, for 9 out 18 of such examples, the Z&X-STL model does not predict anything (as in examples 2–5 in Table 11). From examples 1–5 we notice that SRL data helps to handle more complex syntactic constructions. From examples 5–7 we observed that using MTL with SRL helps to handle cases when more than one person or organization is present in the close neighborhood of the opinion. For targets, for 11 out of 18 cases the Z&X-STL model does not predict anything as in examples 1–2 in Table 11. We conclude that the greatest improvements from the FS-MTL model comes from having far fewer missing roles.

6 Related work

FGOA. Closest to our work are Yang and Cardie (2013) (Y&C) and Katiyar and Cardie (2016) (K&C). They as well label both holders and targets in MPQA. By contrast, our focus is on the task of ORL. We thus refrain from predicting opinion expressions first, to ensure a reproducible evaluation setup on a fixed set of gold opinion expressions. The MTL models we develop in this work will, however, be the basis for the full task in a later stage. Because of these differences, direct comparison to Y&C and K&C is not possible. However, if we compare our results we notice a big gap that demonstrates that opinion expression extraction is the import step in FGOA. Similar to K&C, Liu et al. (2015) jointly labels opinion expressions and their targets in reviews.

Some work focuses entirely on labeling of opinion expressions (Yang and Cardie, 2014; Irsoy and Cardie, 2014). Other work looks into specific subcategories of ORL: opinion role induction for verbal predicates (Wiegand and Ruppenhofer, 2015), categorization of opinion words into actor and speaker view (Wiegand et al., 2016b), opinion roles extraction on opinion compounds (Wiegand et al., 2016a). Wiegand and Ruppenhofer (2015) report 72.54 binary F1 score for labeling of holders in MPQA (results for targets are not reported).

Neural SRL. New neural SRL models have emerged (He et al., 2017; Yang and Mitchell, 2017; Marcheggiani and Titov, 2017) since we started this work. In future work we can improve our models with such new proposals.

Auxiliary tasks for MTL. Other work investigates under which conditions MTL is effective. Martínez Alonso and Plank (2017) show that the best auxiliary tasks have low kurtosis of labels (usually a small label set) and high entropy (labels occur uniformly). We show that the best MTL model for ORL is the model which uses shared layers only. Thus it seems reasonable to consider only a small and uniform SRL label set {A0, A1}.

Bingel and Søgaard (2017) show that MTL works when the main task has a flattening learning curve, but the auxiliary task curve is still steep. We notice such behavior in our learning curves.

7 Conclusions

We address the problem of scarcity of annotated training data for labeling of opinion holders and targets (ORL) using multi-task learning (MTL) with Semantic Role Labeling (SRL). We adapted a recently proposed neural SRL model for ORL and enhanced it with different MTL techniques. Two MTL models achieve significant improvements with all evaluation measures, for both holders and targets, on both dev and test set, when evaluated with repeated 4-fold CV. We recommend evaluation with comparable dev and test set sizes for future work, as this enables more reliable evaluation.

With deeper analysis we show that future developments should improve the ability of the models to capture long-range dependencies, investigate if consistency with syntax can improve ORL, and consider other auxiliary tasks such as dependency parsing or recognizing textual entailment. We emphasize that future improvements can be measured more reliably if opinion expressions with missing roles are curated and if the evaluation considers all mentions in opinion role coreference chains as well as discontinuous roles.

Abstract

Previously, neural methods in grammatical error correction (GEC) did not reach state-of-the-art results compared to phrase-based statistical machine translation (SMT) baselines. We demonstrate parallels between neural GEC and low-resource neural MT and successfully adapt several methods from low-resource MT to neural GEC. We further establish guidelines for trustable results in neural GEC and propose a set of model-independent methods for neural GEC that can be easily applied in most GEC settings. Proposed methods include adding source-side noise, domain-adaptation techniques, a GEC-specific training-objective, transfer learning with monolingual data, and ensembling of independently trained GEC models and language models. The combined effects of these methods result in better than state-of-the-art neural GEC models that outperform previously best neural GEC systems by more than 10% M^2 on the CoNLL-2014 benchmark and 5.9% on the JFLEG test set. Non-neural state-of-the-art systems are outperformed by more than 2% on the CoNLL-2014 benchmark and by 4% on JFLEG.

1 Introduction

Most successful approaches to automated grammatical error correction (GEC) are based on methods from statistical machine translation (SMT), especially the phrase-based variant. For the CoNLL 2014 benchmark on grammatical error correction (Ng et al., 2014), Junczys-Dowmunt and Grundkiewicz (2016) established a set of methods for GEC by SMT that remain state-of-the-art. Systems (Chollampatt and Ng, 2017; Yannakoudakis et al., 2017) that improve on results by Junczys-Dowmunt and Grundkiewicz (2016) use their set-up as a backbone for more complex systems.

The view that GEC can be approached as a machine translation problem by translating from erroneous to correct text originates from Brockett et al. (2006) and resulted in many systems (e.g. Felice et al., 2014; Susanto et al., 2014) that represented the current state-of-the-art at the time.

In the field of machine translation proper, the emergence of neural sequence-to-sequence methods and their impressive results have lead to a paradigm shift away from phrase-based SMT towards neural machine translation (NMT). During WMT 2017 (Bojar et al., 2017) authors of pure phrase-based systems offered "unconditional surrender"[1] to NMT-based methods.

Based on these developments, one would expect to see a rise of state-of-the-art neural methods for GEC, but as Junczys-Dowmunt and Grundkiewicz (2016) already noted, this is not the case. Interestingly, even today, the top systems on established GEC benchmarks are still mostly phrase-based or hybrid systems (Chollampatt and Ng, 2017; Yannakoudakis et al., 2017; Napoles and Callison-Burch, 2017). The best "pure" neural systems (Ji et al., 2017; Sakaguchi et al., 2017; Schmaltz et al., 2017) are several percent behind.[2]

If we look at recent MT work with this in mind, we find one area where phrased-based SMT dominates over NMT: low-resource machine translation. Koehn and Knowles (2017) analyze the behavior of NMT versus SMT for English-Spanish systems trained on 0.4 million to 385.7 million words of parallel data, illustrated in Figure 1. Quality for NMT

[1] Ding et al. (2017) on their news translation shared task poster http://www.cs.jhu.edu/~huda/papers/jhu-wmt-2017.pdf

[2] After submission of this work, Chollampatt and Ng (2018) published impressive new results for neural GEC with some overlap with our methods. However, our results stay ahead on all benchmarks while using simpler models.

Corpus	Sent.	Tokens	Public
NUCLE*	57.1K	1.2M	Yes
Lang-8 NAIST*	1.9M	25.0M	Yes
CLC FCE	30.9K	0.5M	Yes
CLC	1.9M	29.2M	No

Table 1: Statistics for existing GEC training data sets. Data sets marked with * are used in this work.

starts low for small corpora, outperforms SMT at a corpus size of about 15 million words, and with increasing size beats SMT with a large in-domain language model.

Table 1 lists existing training resources for the English as-a-second-language (ESL) grammatical error correction task. Publicly available resources, NUS Corpus of Learner English (NUCLE) by Dahlmeier et al. (2013), Lang-8 NAIST (Mizumoto et al., 2012) and CLC FCE (Yannakoudakis et al., 2011) amount to about 27M tokens. Among these the Lang-8 corpus is quite noisy and of low quality. The Cambridge Learner Corpus (CLC) by Nicholls (2003) — probably the best resource in this list — is non-public and we would strongly discourage reporting results that include it as training data as this makes comparisons difficult.

Contrasting this with Fig. 1, we see that for about 20M tokens NMT systems start outperforming SMT models without additional large language models. Current state-of-the-art GEC systems based on SMT, however, all include large-scale in-domain language models either following the steps outlined in Junczys-Dowmunt and Grundkiewicz (2016) or directly re-using their domain-adapted Common-Crawl language model.

It seems that the current state of neural methods in GEC reflects the behavior for NMT systems trained on smaller data sets. Based on this, we conclude that we can think of GEC as a low-resource, or at most mid-resource, machine translation problem. This means that techniques proposed for low-resource (neural) MT should be applicable to improving neural GEC results.

In this work we show that adapting techniques from low-resource (neural) MT and SMT-based GEC methods allows neural GEC systems to catch up to and outperform SMT-based systems. We improve over the previously best-reported neural GEC system (Ji et al., 2017) on the CoNLL 2014 test set by more than 10% M^2, over a comparable pure SMT system by Junczys-Dowmunt and Grundkiewicz (2016) by 6%, and outperform the state-of-the-art result of Chollampatt and Ng (2017) by 2%. On the JFLEG data set, we report the currently best results, outperforming the previously best pure neural system (Sakaguchi et al., 2017) by 5.9% GLEU and the best reported results (Chollampatt and Ng, 2017) by 3% GLEU.

In Section 2, we describe our NMT-based baseline for GEC, and follow recommendations from the MT community for a trustable neural GEC system. In Section 3, we adapt neural models to make better use of sparse error-annotated data, transferring low-resource MT and GEC-specific SMT methods to neural GEC. This includes a novel training objective for GEC. We investigate how to leverage monolingual data for neural GEC by transfer learning in Section 4 and experiment with language model ensembling in Section 5. Section 6 explores deep NMT architectures. In Section 7, we provide an overview of the experiments and how results relate to the JFLEG benchmark. We also recommend a model-independent toolbox for neural GEC.

2 A trustable baseline for neural GEC

In this section, we combine insights from Junczys-Dowmunt and Grundkiewicz (2016) for grammatical error correction by phrase-based statistical machine translation and from Denkowski and Neubig (2017) for trustable results in neural machine translation to propose a trustable baseline for neural grammatical error correction.

Test/Dev set	Sent.	Annot.	Metric
CoNLL-2013 test	1,381	1	M^2
CoNLL-2014 test	1,312	2	M^2
JFLEG dev	754	4	GLEU
JFLEG test	747	4	GLEU

Table 2: Statistics for test and development data.

2.1 Training and test data

To make our results comparable to state-of-the-art results in the field of GEC, we limit our training data strictly to public resources. In the case of error-annotated data, as marked in Table 1, these are the NUCLE (Dahlmeier et al., 2013) and Lang-8 NAIST (Mizumoto et al., 2012) data sets. We do not include the FCE corpus (Yannakoudakis et al., 2011) to maintain comparability to Junczys-Dowmunt and Grundkiewicz (2016) and Chollampatt and Ng (2017). We strongly urge the community to not use the non-public CLC corpus for training, unless contrastive results without this corpus are provided as well.

We choose the CoNLL-2014 shared task test set (Ng et al., 2014) as our main benchmark and the test set from the 2013 edition of the shared task (Ng et al., 2013) as a development set. For these benchmarks we report MaxMatch (M^2) scores (Dahlmeier and Ng, 2012). Where appropriate, we will provide results on the JFLEG dev and test sets (Napoles et al., 2017) using the GLEU metric (Sakaguchi et al., 2016) to demonstrate the generality of our methods. Table 2 summarizes test/dev set statistics for both tasks.

For most our experiments, we report M^2 on CoNLL-2013 test (Dev) and precision (Prec.), recall (Rec.), M^2 (Test) on the CoNLL-2014 test set.

2.2 Preprocessing and sub-words

As both benchmarks, CoNLL and JFLEG, are provided in NLTK-style tokenization (Bird et al., 2009), we use the same tokenization scheme for our training data. We truecase line beginnings and escape special characters using scripts included with Moses (Koehn et al., 2007). Following Sakaguchi et al. (2017), we apply the Enchant[3] spell-checker to the JFLEG data before evaluation. No spell-checking is used for the CoNLL test sets.

We follow the recommendation by Denkowski and Neubig (2017) to use byte-pair encoding (BPE) sub-word units (Sennrich et al., 2016b) to solve the large-vocabulary problem of NMT. This is a well established procedure in neural machine translation and has been demonstrated to be generally superior to UNK-replacement methods. It has been largely ignored in the field of grammatical error correction even when word segmentation issues have been explored (Ji et al., 2017; Schmaltz et al., 2017). To our knowledge, this is the first work to use BPE sub-words for GEC, however, an analysis on advantages of word versus sub-word or character level segmentation is beyond the scope of this paper. A set of 50,000 monolingual BPE units is trained on the error-annotated data and we segment training and test/dev data accordingly. Segmentation is reversed before evaluation.

2.3 Model and training procedure

Implementations of all models explored in this work[4] are available in the Marian[5] toolkit (Junczys-Dowmunt et al., 2018). The attentional encoder-decoder model in Marian is a re-implementation of the NMT model in Nematus (Sennrich et al., 2017b). The model differs from the model introduced by Bahdanau et al. (2014) by several aspects, the most important being the conditional GRU with attention for which Sennrich et al. (2017b) provide a concise description.

All embedding vectors consist of 512 units; the RNN states of 1024 units. The number of BPE segments determines the size of the vocabulary of our models, i.e. 50,000 entries. Source and target side use the same vocabulary. To avoid overfitting, we use variational dropout (Gal and Ghahramani, 2016) over GRU steps and input embeddings with probability 0.2. We optimize with Adam (Kingma and Ba, 2014) with an average mini-batch size of ca. 200. All models are trained until convergence (early-stopping with a patience of 10 based on development set cross-entropy cost), saving model checkpoints every 10,000 mini-batches. The best eight model checkpoints w.r.t. the development set M^2 score of each training run are averaged element-wise (Junczys-Dowmunt et al., 2016) resulting in a final single model. During decoding we use a beam-size of 24 and normalize model scores by length.[6]

[3] https://github.com/AbiWord/enchant

[4] Models, system configurations and outputs are available from https://github.com/grammatical/neural-naacl2018

[5] https://github.com/marian-nmt/marian

[6] We used a larger beam-size than usual due to experiments with re-ranking of n-best lists not included in the paper. We did not see any differences compared to smaller beams.

	CoNLL				JFLEG	
Run	Dev	Prec.	Rec.	Test	Dev	Test
1	20.2	68.6	11.8	34.9	47.6	52.3

3	21.7	64.8	10.6	32.0	47.1	52.4
4	22.0	67.1	10.9	33.0	47.1	52.0
Avg	21.3	–	–	32.9	47.2	52.1
Ens	19.3	70.8	9.5	30.9	47.0	52.5

Table 3: Instable results for multiple baseline runs versus average and ensemble — for the CoNLL benchmark.

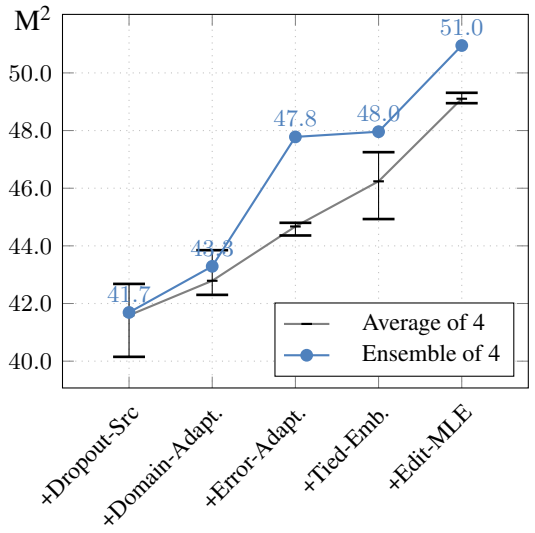
2.4 Optimizer instability

Junczys-Dowmunt and Grundkiewicz (2016) noticed that discriminative parameter tuning for GEC by phrase-based SMT leads to unstable M^2 results between tuning runs. This is a well-known effect for SMT parameter tuning and Clark et al. (2011) recommend reporting results for multiple tuning runs. Junczys-Dowmunt and Grundkiewicz (2016) perform four tuning runs and calculate parameter centroids following Cettolo et al. (2011).

Neural sequence-to-sequence training is discriminative optimization and as such prone to instability. We already try to alleviate this by averaging over eight best checkpoints, but as seen in Table 3, results for M^2 remain unstable for runs with differently initialized weights. An amplitude of 3 points M^2 on the CoNLL-2014 test set is larger than most improvements reported in recent papers. None of the recent works on neural GEC account for instability, hence it is unclear if observed outcomes are actual improvements or lucky picks among by-products of instability. We therefore strongly suggest to provide results for multiple independently trained models. Otherwise improvements of less than 2 or 3 points of M^2 remain doubtful. Interestingly, GLEU on the JFLEG data seems to be more stable than M^2 on CoNLL data.

2.5 Ensembling of independent models

Running multiple experiments to provide averaged results seems prohibitively expensive, but Denkowski and Neubig (2017) and others (e.g. Sutskever et al., 2014; Sennrich et al., 2017a) show that ensembling of independently trained models leads to consistent rewards for MT. For our baseline in Table 3 the opposite seems to be true for M^2. This is likely the reason why no other work on neural GEC mentions results for ensembles.



Model	Dev	Prec.	Rec.	Test
Baseline	19.3	70.8	9.5	30.9
+Dropout-Src.	27.5	72.4	15.5	41.7
+Domain-Adapt.	30.0	69.2	17.3	43.3
+Error-Adapt.	34.5	70.8	20.8	47.8
+Tied-Emb.	33.0	73.0	20.2	48.0
+Edit-MLE	37.6	65.3	27.1	51.0

Table 4: Results (M^2) on the CoNLL benchmark for GEC-specific adaptations.

On closer inspection, however, we see that the drop in M^2 for ensembles is due to a precision bias. M^2 being an F-score penalizes increasing distance between precision and recall. The increase in precision for ensembles is to be expected and we see it later consistently for all experiments. Ensembles choose corrections for which all independent models are fairly confident. This leads to fewer but better corrections, hence an increase in precision and a drop in recall. If the models are weak as our baseline, this can result in a lower score. It would, however, be unwise to dismiss ensembles, as we can use their bias towards precision to our advantage whenever they are combined with methods that aim to increase recall. This is true for nearly all remaining experiments.

3 Adaptations for GEC

The methods described in this section turn our baseline into a more GEC-specific system. Most have been inspired by techniques from low-resource MT or closely related domain-adaptation techniques for NMT. All modifications are applied incrementally, later models include enhancements from the previous ones.

3.1 Source-word dropout as corruption

GEC can be treated as a denoising task where grammatical errors are corruptions that have to be reduced. By introducing more corruption on the source side during training we can teach the model to reduce trust into the source input and to apply corrections more freely. Dropout is one way to introduce noise, but for now we only drop out single units in the embedding or GRU layers, something the model can easily recover from. To make the task harder, we add dropout over source words, setting the full embedding vector for a source word to $1/p_{\text{src}}$ with a probability of p_{src}. During our experiments, we found $p_{\text{src}} = 0.2$ to work best.

Table 4 show impressive gains for this simple method (+Dropout-Src.). Results for the ensemble match the previously best results on the CoNLL-2014 test set for pure neural systems (without the use of an additional monolingual language model) by Ji et al. (2017) and Schmaltz et al. (2017).

3.2 Domain adaptation

The NUCLE corpus matches the domain of the CoNLL benchmarks perfectly. It is however much smaller than the Lang-8 corpus. A setting like this seems to be a good fit for domain-adaptation techniques. Sennrich et al. (2016a) oversample in-domain news data in a larger non-news training corpus. We do the same by adding the NUCLE corpus ten times to the training corpus. This can also be seen as similar to Junczys-Dowmunt and Grundkiewicz (2016) who tune phrase-based SMT parameters on the entire NUCLE corpus. Respectable improvements on both CoNLL test sets (+Domain-Adapt. in Table 4) are achieved.

3.3 Error adaptation

Junczys-Dowmunt and Grundkiewicz (2016) noticed that when tuning on the entire NUCLE corpus, even better results can be achieved if the error rate of NUCLE is adapted to the error rate of the original dev set. In NUCLE only 6% of tokens contain errors, while the CoNLL-2013 test set has an error-rate of about 15%. Following Junczys-Dowmunt and Grundkiewicz (2016), we remove correct sentences from the ten-fold oversampled NUCLE data greedily until an error-rate of 15% is achieved. This can be interpreted as a type of GEC-specific domain adaptation. We mark this method as +Domain-Adapt. in Table 4 and report for the ensemble the so far strongest results for any neural GEC system on the CoNLL benchmark.

	CoNLL				JFLEG	
Λ	Dev	Prec.	Rec.	Test	Dev	Test
1	33.5	67.5	20.8	46.6	48.9	53.9
3	36.8	59.8	28.8	49.2	51.2	56.5
5	36.2	54.0	30.8	47.0	50.9	55.7

Table 5: Results for model type +Tied-Emb. trained with edit-weighted MLE and chosen Λ.

3.4 Tied embeddings

Press and Wolf (2016) showed that parameter tying between input and output embeddings[7] for language models leads to improved perplexity. Similarly, three-way weight-tying between source, target and output embeddings for neural machine translation seems to improve translation quality in terms of BLEU while also significantly decreasing the number of parameters in the model. In monolingual cases like GEC, where source and target vocabularies are (mostly) equal, embedding-tying seems to arise naturally. Output layer, decoder and encoder embeddings all share information which may further enhance the signal from corrective edits. The M^2 scores for +Tied-Emb. in Table 4 are inconclusive, but we see improvements in conjunction with later modifications.

3.5 Edit-weighted MLE objective

Previously, we applied error-rate adaptation to strengthen the signal from corrective edits in the training data. In this section, we investigate the effects of directly modifying the training loss to incorporate weights for corrective edits.

Assuming that each target token y_j has been generated by a source token x_i, we scale the loss for each target token y_j by a factor Λ if y_j differs from x_i, i.e. if y_j is part of an edit. Hence, log-likelihood loss takes the following form:

$$L(x, y, a) = -\sum_{t=1}^{T_y} \lambda(x_{a_t}, y_t) \log P(y_t | x, y_{<t}),$$

$$\lambda(x_{a_t}, y_t) = \begin{cases} \Lambda & \text{if } x_{a_t} \neq y_t \\ 1 & \text{otherwise} \end{cases},$$

where (x, y) is a training sentence pair and a is a word alignment $a_t \in \{0, 1, \ldots, T_x\}$ such that source token x_{a_t} generates target token y_t. Alignments are computed for each sentence pair with fast-align (Dyer et al., 2013).

[7] Output embeddings are encoded in the last output layer of a neural language or translation model.

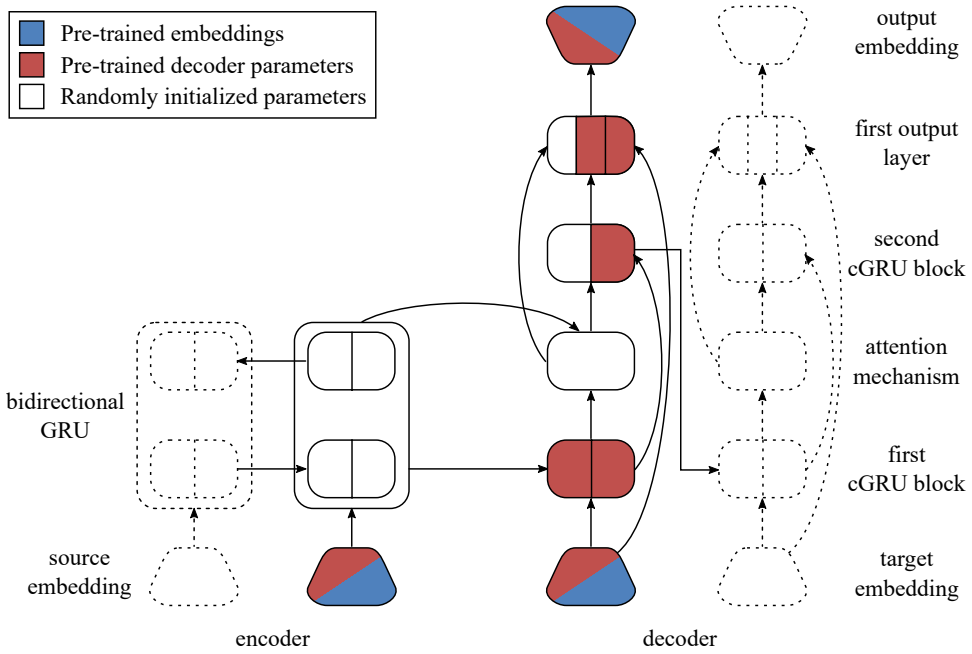


Figure 2: Parameters pretrained on monolingual data are marked with colors. Blue indicates pre-trained embeddings with word2vec, red parameters have been pre-trained with the GRU-based language model only. All embedding layers have tied parameters.

This is comparable to reinforcement learning towards GLEU as introduced by Sakaguchi et al. (2017) or training against diffs by Schmaltz et al. (2017). In combination with previous modifications, edit-weighted Maximum Likelihood Estimation (MLE) weighting seem to outperform both methods. The parameter Λ introduces an additional hyper-parameter that requires tuning for specific tasks and affects the precision/recall trade-off. Table 5 shows $\Lambda = 3$ seems to work best among the tested values when chosen to maximize M^2 on the CoNLL-2013 dev set.

For this setting, we achieve our strongest results of 50.95 M^2 on the CoNLL benchmark (system +Edit-MLE) yet. This outperforms the results of a phrase-based SMT system with a large domain-adapted language model from Junczys-Dowmunt and Grundkiewicz (2016) by 1% M^2 and is the first neural system to beat this strong SMT baseline.

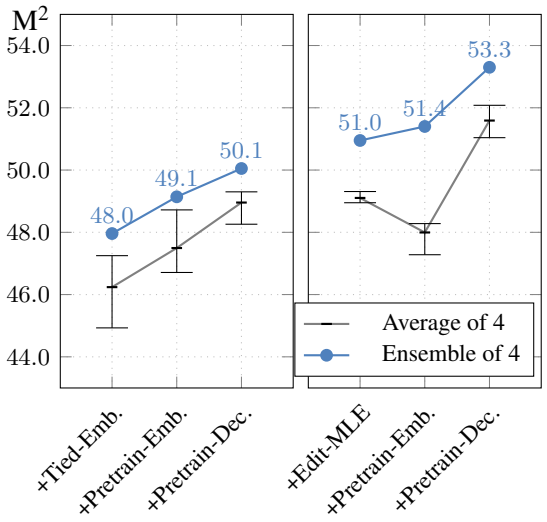
4 Transfer learning for GEC

Many ideas in low-resource neural MT are rooted in transfer learning. In general, one first trains a neural model on high-resource data and then uses the resulting parameters to initialize parameters of a new model meant to be trained on low-resource data only. Various settings are possible, e.g. initializing from models trained on large out-of-domain data and continuing on in-domain data (Miceli Barone et al., 2017) or using related language pairs (Zoph et al., 2016). Models can also be partially initialized by pre-training monolingual language models (Ramachandran et al., 2017) or only word-embeddings (Gangi and Federico, 2017). In GEC, Yannakoudakis et al. (2017) apply pre-trained monolingual word-embeddings as initializations for error-detection models to re-rank SMT n-best lists. Approaches based on pre-training with monolingual data appear to be particularly well-suited to the GEC task. Junczys-Dowmunt and Grundkiewicz (2016) published 300GB of compressed monolingual data used in their work to create a large domain-adapted Common-Crawl n-gram language model.[8] We use the first 100M lines. Preprocessing follows section 2.2 including BPE segmentation.

4.1 Pre-training embeddings

Similarly to Gangi and Federico (2017) or Yannakoudakis et al. (2017), we use Word2vec (Mikolov et al., 2013) with standard settings to create word vectors. Since weights between source, target and output embeddings are tied, these embeddings are inserted once into the model, but affect computations three-fold, see the blue elements in Figure 2. The remaining parameters of the model are initialized randomly. We refer to this adaptation as +Pretrain-Emb.

[8] https://github.com/grammatical/baselines-emnlp2016



Model	Dev	Prec.	Rec.	Test
+Tied-Emb.	33.0	73.0	20.2	48.0
+Pretrain-Emb.	35.5	69.1	22.8	49.1
+Pretrain-Dec.	36.2	69.1	23.8	50.1
+Edit-MLE	37.6	65.3	27.1	51.0
+Pretrain-Emb.	38.2	64.4	28.4	51.4
+Pretrain-Dec.	40.3	65.2	32.2	54.1

Table 6: Results (M^2) on the CoNLL benchmark set for GEC-specific adaptations.

4.2 Pre-training decoder parameters

Following Ramachandran et al. (2017), we first train a GRU-based language model on the monolingual data. The architecture of the language model corresponds as much as possible to the structure of the decoder of the sequence-to-sequence model. All pieces that rely on the attention mechanism or the encoder have been removed. After training for two epochs, all red parameters (including embedding layers) in Figure 2 are copied from the language model to the decoder. Remaining parameters are initialized randomly. This configuration is called +Pretrain-Dec. We pretrain each model separately to make sure that all weights have been initialized randomly.

4.3 Results for transfer learning

Table 6 summarizes the results for our transfer learning experiments. We compare the effects of pre-training with and without the edit-weighted MLE objective and can see that pre-training has significantly positive effects in both settings.

The last result of 53.3% M^2 on the CoNLL-2014 benchmark matches the currently highest reported numbers (53.14% M^2) by Chollampatt and Ng (2017) for a much more complex system and outperforms the highest neural GEC system (Ji et al., 2017) by 8% M^2.

Model	Dev	Prec.	Rec.	Test
+Tied-Emb	33.0	73.0	20.2	48.0
+GRU-LM	40.2	59.8	36.2	52.9
+Edit-MLE	37.6	65.3	27.1	51.0
+GRU-LM	40.3	61.9	34.5	53.4
+Pretrain-Dec.	40.3	65.2	32.2	54.1
+GRU-LM	41.6	62.2	36.6	54.6

Table 7: Ensembling with a neural language model.

5 Ensembling with language models

Phrase-based SMT systems benefit naturally from large monolingual language models, also in the case of GEC as shown by Junczys-Dowmunt and Grundkiewicz (2016). Previous work (Xie et al., 2016; Ji et al., 2017) on neural GEC used n-gram language models to incorporate monolingual data. Xie et al. (2016) built a large 5-gram model and integrated it directly into their beam search algorithm, while Ji et al. (2017) re-use the language model provided by Junczys-Dowmunt and Grundkiewicz (2016) for n-best list re-ranking.

We already combined monolingual data with our GEC models via pre-training, but exploiting separate language models is attractive as no additional training is required. Here, we reuse the neural language model created for pre-training.

Similarly to Xie et al. (2016), the score $s(y|x)$ for a correction y of sentence x is calculated as

$$s(y|x) = \frac{1}{|y|}\left[\sum_{i=1}^{4} \log P_i(y|x) + \alpha \log P_{\text{LM}}(y)\right],$$

where $P_i(y|x)$ is a translation probability for the i-th model in an ensemble of 4. $P_{\text{LM}}(y)$ is the language model probability for y weighted by α. We normalize by sentence length $|y|$. Using the dev set, we choose α that maximizes this score via linear search in range $[0, 2]$ with step 0.1.

Table 7 summarizes results for language model ensembling with three of our intermediate configurations. All configurations benefit from the language model in the ensemble, although gains for the pre-trained model are rather small.

6 Deeper NMT models

So far we analyzed model-independent[9] methods — only training data, hyper-parameters, parameter initialization, and the objective function were modified. In this section we investigate if these techniques can be generalized to deeper or different architectures.

6.1 Architectures

We consider two state-of-the-art NMT architectures implemented in Marian:

Deep RNN A deep RNN-based model (Miceli Barone et al., 2017) proposed by Sennrich et al. (2017a) for their WMT 2017 submissions. This model is based on the shallow model we used until now. It has single layer RNNs in the encoder and decoder, but increases depth by stacking multiple GRU-style blocks inside one RNN cell. A single RNN step passes through all blocks before recursion. The encoder RNN contains 4 stacked GRU blocks, the decoder 8 (1 + 7 due to the conditional GRU). Following Sennrich et al. (2017a), we enable layer-normalization in the RNN-layers. State and embedding dimensions used throughout this work and in Sennrich et al. (2017a) are the same.

Transformer The self-attention-based model by Vaswani et al. (2017). We base our model on their default architecture of 6 complex attention/self-attention blocks in the encoder and decoder and use the same model dimensions — embeddings vector size is 512 (as before), filter size is 2048.

6.2 Training settings

As the deep models are less reliably trained with asynchronous SGD, we change the training algorithm to synchronous SGD and for both models follow the recipe proposed in Vaswani et al. (2017), with an effective base learning rate of 0.0003, learning rate warm-up during the first 16,000 iterations, and an inverse square-root decay after the warm-up. As before, we average the best 8 checkpoints. We increase dropout probability over RNN layers to 0.3 for Deep-RNN and similarly set dropout between transformer layers to 0.3. Source-word dropout as a noising technique remains unchanged.

[9]The pre-training procedure however needs to be adapted to model architecture if we want to take advantage of every shared parameter, otherwise matching parameter subsets could probably be used successfully.

Model	Dev	Prec.	Rec.	Test
+Pretrain-Dec.	40.3	65.2	32.2	54.1
+GRU-LM	41.6	62.2	36.6	54.6
+Deep-RNN	41.1	64.3	35.2	55.2
+Deep-RNN-LM	41.9	61.3	40.2	55.5
+Transformer	41.5	63.0	38.9	56.1
+Transformer-LM	42.9	61.9	40.2	55.8

Table 8: Shallow (Pretrain-Dec.) versus deep ensembles, with and without corresponding language models.

6.3 Pre-training deep models

We reuse all methods included up to +Pretrain-Dec. The pre-training procedure as described in section 4.1 needs to be modified in order to maximize the number of pre-trained parameters for the larger model architectures. Again, we train decoder-only models as typical language models by removing all elements that depend on the encoder, including attention-mechanisms over the source context. We can keep the decoder self-attention layers in the transformer model. We train for two epochs on our monolingual data reusing the hyper-parameters for the parallel case above.

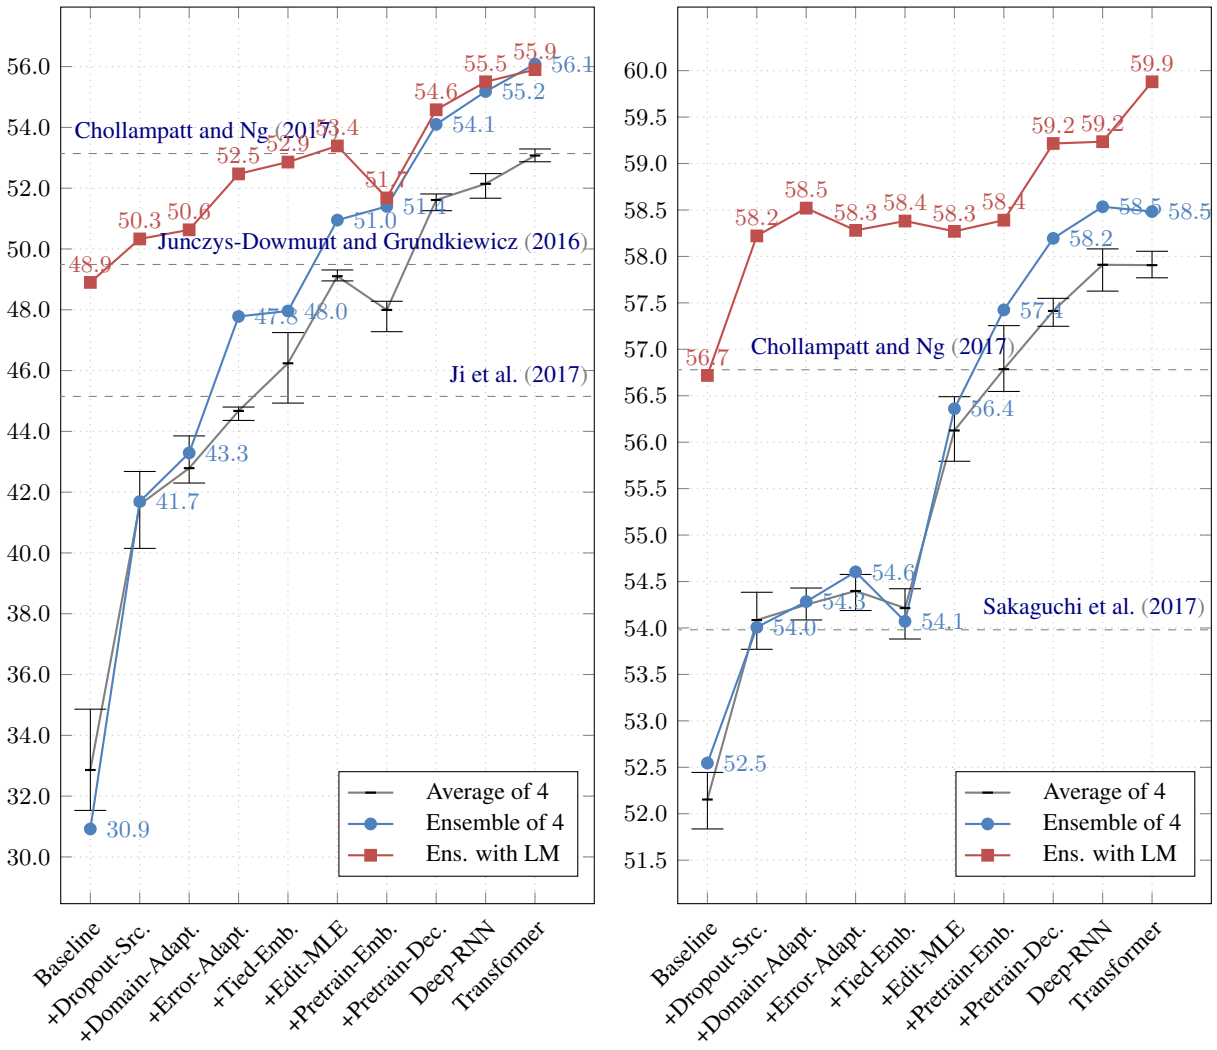
6.4 Results

Table 8 summarizes the results for deeper models on the CoNLL dev and test set. Both deep models improve significantly over the shallow model with the transformer model reaching our best result reported on the CoNLL 2014 test set. For that test set it seems that ensembling with language models that were used for pre-training is ineffective when measured with M^2; while on the JFLEG data measured with GLEU we see strong improvements (Fig. 3b).

7 A standard tool set for neural GEC

We summarize the results for our experiments in Figure 3 and provide results on the JFLEG test set. Weights for the independent language model in the full ensemble were chosen on the respective dev sets for both tasks. Comparing results according to both benchmarks and evaluation metrics (M^2 for CoNLL, GLEU for JFLEG), it seems we can isolate the following set of reliable methods for state-of-the-art neural grammatical error correction:

- Ensembling neural GEC models with monolingual language models;
- Dropping out entire source embeddings;



(a) CoNLL-2014 test set (M^2)

(b) JFLEG test set (GLEU)

Figure 3: Comparison on the CoNLL-2014 test set and JFLEG test for all investigated methods.

- Weighting edits in the training objective during optimization (+Edit-MLE);
- Pre-training on monolingual data;
- Ensembling of independently trained models;
- Domain and error adaptation (+Domain-Adapt., Error-Adapt.) towards a specific benchmark;
- Increasing model depth.

Combinations of these generally[10] model-independent methods helped raising the performance of pure neural GEC systems by more than 10% M^2 on the CoNLL 2014 benchmark, also outperforming the previous state-of-the-art (Chollampatt and Ng, 2017), a hybrid phrase-based system with a complex spell-checking system by 2%. We also showed that a pure neural system can easily outperform a strong pure phrase-based SMT system (Junczys-Dowmunt and Grundkiewicz, 2016) when similarly adapted to the GEC task.

On the JFLEG benchmark we outperform the previously-best pure neural system (Sakaguchi et al., 2017) by 5.9% GLEU (4.5% if no monolingual data is used). Improvements over SMT-based system like Napoles and Callison-Burch (2017)[11] and Chollampatt and Ng (2017) are significant and constitute the new state-of-the-art on the JFLEG test set.

Robust Cross-lingual Hypernymy Detection using Dependency Context

Abstract

Cross-lingual Hypernymy Detection involves determining if a word in one language ("fruit") is a hypernym of a word in another language ("pomme" i.e. apple in French). The ability to detect hypernymy cross-lingually can aid in solving cross-lingual versions of tasks such as textual entailment and event coreference. We propose BISPARSE-DEP, a family of unsupervised approaches for cross-lingual hypernymy detection, which learns sparse, bilingual word embeddings based on dependency contexts. We show that BISPARSE-DEP can significantly improve performance on this task, compared to approaches based only on lexical context. Our approach is also robust, showing promise for low-resource settings: our dependency-based embeddings can be learned using a parser trained on related languages, with negligible loss in performance. We also crowd-source a challenging dataset for this task on four languages – Russian, French, Arabic, and Chinese. Our embeddings and datasets are publicly available.[1]

1 Introduction

Translation helps identify correspondences in bilingual texts, but other asymmetric semantic relationships can improve language understanding when translations are not exactly equivalent. One such relationship is *cross-lingual hypernymy* – identifying that *écureuil* ("squirrel" in French) is a kind of *rodent*, or ворона ("crow" in Russian) is a kind of *bird*. The ability to detect hypernyms across languages serves as a building block in a range of cross-lingual tasks, including Recognizing Textual Entailment (RTE) (Negri et al., 2012, 2013), constructing multilingual taxonomies (Fu et al., 2014), event coreference across multilingual news sources (Vossen et al., 2015), and evaluating Machine Translation output (Padó et al., 2009).

Building models that can robustly identify hypernymy across the spectrum of human languages is a challenging problem, that is further compounded in low resource settings. At first glance, translating words to English and then identifying hypernyms in a monolingual setting may appear to be a sufficient solution. However, this approach cannot capture many phenomena. For instance, the English words *cook*, *leader* and *supervisor* can all be hypernyms of the French word *chef*, as the French word does not have a exact translation in English covering its possible usages. However, translating *chef* to *cook* and then determining hypernymy monolingually precludes identifying *leader* or *supervisor* as a hypernyms of *chef*. Similarly, language-specific usage patterns can also influence hypernymy decisions. For instance, the French word *chroniqueur* translates to *chronicler* in English, but is more frequently used in French to refer to journalists (making *journalist* its hypernym).[2]

This motivates approaches that *directly* detect hypernymy in the cross-lingual setting by extending distributional methods for detecting monolingual hypernymy, as in our prior work (Vyas and Carpuat, 2016). State-of-the-art distributional approaches (Roller and Erk, 2016; Shwartz et al., 2017) for detecting monolingual hypernymy require syntactic analysis (eg. dependency parsing), which may not available for many languages. Additionally, limited training resources make unsupervised methods more desirable than supervised hypernymy detection approaches (Roller and Erk,

[*] These authors contributed equally.

[2] All examples are from our dataset.

Proceedings of NAACL-HLT 2018, pages 607–618
New Orleans, Louisiana, June 1 - 6, 2018.

2016). Furthermore, monolingual distributional approaches cannot be applied directly to the cross-lingual task, because the vector spaces of two languages need to be aligned using a cross-lingual resource (a bilingual dictionary, for instance).

We tackle these challenges by proposing BISPARSE-DEP - a family of robust, unsupervised approaches for identifying cross-lingual hypernymy. BISPARSE-DEP uses a cross-lingual word embedding model learned from a small bilingual dictionary and a variety of monolingual syntactic context extracted from a dependency parsed corpus. BISPARSE-DEP exhibits robust behavior along multiple dimensions. In the absence of a dependency treebank for a language, it can learn embeddings using a parser trained on related languages. When exposed to less monolingual data, or a lower quality bilingual dictionary, BISPARSE-DEP degrades only marginally. In all these cases, it compares favorably with models that have been supplied with all necessary resources, showing promise for low-resource settings. We extensively evaluate BISPARSE-DEP on a new crowd-sourced cross-lingual dataset, with over 2900 hypernym pairs, spanning four languages from distinct families – French, Russian, Arabic and Chinese – and release the datasets for future evaluations.

2 Related Work

Cross-lingual Distributional Semantics Cross-lingual word embeddings have been shown to encode semantics across languages in tasks such as word similarity (Faruqui and Dyer, 2014) and lexicon induction (Vulić and Moens, 2015). Our works stands apart in two aspects (1) In contrast to tasks involving similarity and synonymy (symmetric relations), the focus of our work is on detecting *asymmetric* relations across languages, using cross-lingual embeddings. (2) Unlike most previous work, we use dependency context instead of lexical context to induce cross-lingual embeddings, which allows us to abstract away from language specific word order, and (as we show) improves hypernymy detection.

More closely related is our prior work (Vyas and Carpuat, 2016) where we used lexical context based embeddings to detect cross-lingual lexical entailment. In contrast, the focus of this work is on hypernymy, a more well-defined relation than entailment. Also, we improve upon our previous approach by using dependency based embeddings (§6.1), and show that the improvements hold even when exposed to data scarce settings (§6.3).

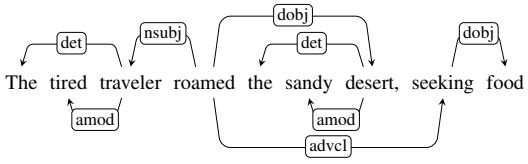

Figure 2: Example Dependency Tree.

We also do a more comprehensive evaluation on four languages paired with English, instead of just French.

Dependency Based Embeddings In monolingual settings, dependency based embeddings have been shown to outperform window based embeddings on many tasks (Bansal et al., 2014; Hill et al., 2014; Melamud et al., 2016). Roller and Erk (2016) showed that dependency embeddings can help in recovering Hearst patterns (Hearst, 1992) like "animals such as cats", which are known to be indicative of hypernymy. Shwartz et al. (2017) demonstrated that dependency based embeddings are almost always superior to window based embeddings for identifying hypernyms in English. Our work uses dependency based embeddings in a cross-lingual setting, a less explored research direction. A key novelty of our work also lies in its use of syntactic transfer to derive dependency contexts. This scenario is more relevant in a cross-lingual setting, where treebanks might not be available for many languages.

3 Our Approach – BISPARSE-DEP

We propose BISPARSE-DEP, a family of approaches that uses sparse, bilingual, dependency based word embeddings to identify cross-lingual hypernymy.

Figure 1 shows an overview of the end-to-end pipeline of BISPARSE-DEP. The two key components of this pipeline are: (1) *Dependency based contexts* (§3.1), which help us generalize across languages with minimal customization by abstracting away language-specific word order. We also discuss how to extract such contexts in the absence of a treebank in the language (§3.2) using a (weak) dependency parser trained on related languages. (2) *Bilingual sparse coding* (§3.3), which allows us to align dependency based word embeddings in a shared semantic space using a small bilingual dictionary. The resulting sparse bilingual embeddings can then be used with a unsupervised entailment scorer (§3.4) to predict hypernymy for cross-lingual word pairs.

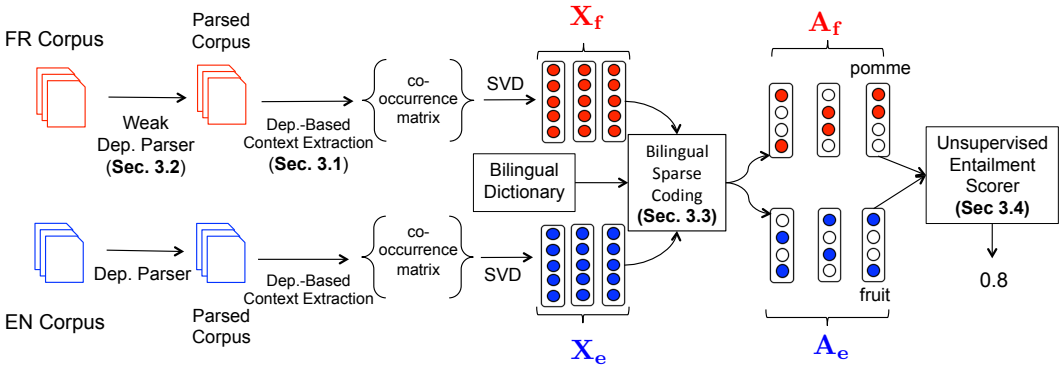

Figure 1: The BISPARSE-DEP approach, which learns sparse bilingual embeddings using dependency based contexts. The resulting sparse embeddings, together with an unsupervised entailment scorer, can detect hypernyms across languages (e.g., *pomme* is a *fruit*).

3.1 Dependency Based Context Extraction

The context of a word can be described in multiple ways using its syntactic neighborhood in a dependency graph. For instance, in Figure 2, we describe the context for a target word (*traveler*) in the following two ways:

- FULL context (Padó and Lapata, 2007; Baroni and Lenci, 2010; Levy and Goldberg, 2014): Children and parent words, concatenated with the label and direction of the relation (eg. *roamed#nsubj*$^{-1}$ and *tired#amod* are contexts for *traveler*).
- JOINT context (Chersoni et al., 2016): Parent concatenated with each of its siblings (eg. *roamed#desert* and *roamed#seeking* are contexts for *traveler*).

These two contexts exploit different amounts of syntactic information – JOINT does not require labeled parses, unlike FULL. The JOINT context combines parent and sibling information, while FULL keeps them as distinct contexts. Both encode directionality into the context, either through label direction or through sibling-parent relations.

We use word-context co-occurrences generated using these contexts in a distributional semantic model (DSM) in lieu of window based contexts to generate dependency based embeddings.

3.2 Dependency Contexts without a Treebank

Using dependency contexts in multilingual settings may not always be possible, as dependency treebanks are not available for many languages. To circumvent this issue, we use related languages to train a weak dependency parser.

We train a *delexicalized* parser using treebanks of related languages, where the word form based features are turned off, so that the parser is trained on purely non-lexical features (e.g. POS tags). The rationale behind this is that related languages show common syntactic structure that can be transferred to the original language, with delexicalized parsing (Zeman and Resnik, 2008; McDonald et al., 2011, *inter alia)* being one popular approach.[3]

3.3 Bilingual Sparse Coding

Given a dependency based co-occurrence matrix described in the previous section(s), we generate BISPARSE-DEP embeddings using the framework from our prior work (Vyas and Carpuat, 2016), which we henceforth call BISPARSE. BISPARSE generates sparse, bilingual word embeddings using a dictionary learning objective with a sparsity inducing l_1 penalty. We give a brief overview of this approach, the full details of which can be found in our prior work.

For two languages with vocabularies v_e and v_f, and monolingual dependency embeddings $\mathbf{X_e}$ and $\mathbf{X_f}$, BISPARSE solves the following objective:

$$\begin{aligned}\underset{\mathbf{A_e},\mathbf{D_e},\mathbf{A_f},\mathbf{D_f}}{\text{argmin}} & \sum_{i=1}^{v_e} \frac{1}{2}||\mathbf{A_e}_i\mathbf{D_e}^{\mathrm{T}} - \mathbf{X_e}_i||_2^2 + \lambda_e||\mathbf{A_e}_i||_1 \\ & + \sum_{j=1}^{v_f} \frac{1}{2}||\mathbf{A_f}_j\mathbf{D_f}^{\mathrm{T}} - \mathbf{X_f}_j||_2^2 + \lambda_f||\mathbf{A_f}_j||_1 \\ & + \sum_{i,j} \frac{1}{2}\lambda_x \mathbf{S}_{ij}||\mathbf{A_e}_i - \mathbf{A_f}_j||_2^2 \qquad (1) \\ \text{s.t. } \mathbf{A_k} > \mathbf{0} \qquad & \|\mathbf{D_k}_i\|_2^2 \leq 1 \qquad \mathbf{k} \in \{\mathbf{e}, \mathbf{f}\}\end{aligned}$$

where $\mathbf{S}$ is a translation matrix, and $\mathbf{A_e}$ and $\mathbf{A_f}$

[3]More sophisticated techniques for transferring syntactic knowledge have been proposed (Ammar et al., 2016; Rasooli and Collins, 2017), but we prioritize simplicity and show that a simple delexicalized parser is effective.

are sparse matrices which are bilingual representations in a shared semantic space. The translation matrix $\mathbf{S}$ (of size $v_e \times v_f$) captures correspondences between the vocabularies (of size v_e and v_f) of two languages. For instance, each row of $\mathbf{S}$ can be a one-hot vector that identifies the word in ***f*** that is most frequently aligned with the ***e*** word for that row in a large parallel corpus, thus building a one-to-many mapping between the two languages.

3.4 Unsupervised Entailment Scorer

A variety of scorers can be used to quantify the directional relationship between two words, given feature representations of these words (Lin, 1998; Weeds and Weir, 2003; Lenci and Benotto, 2012). Once the BISPARSE-DEP embeddings are constructed, we use *BalAPinc* (Kotlerman et al., 2009) to score word pairs for hypernymy. *BalAPinc* is based on the distributional inclusion hypothesis (Geffet and Dagan, 2005) and computes the geometric mean of 1) *LIN* (Lin, 1998), a symmetric score that captures similarity, and 2) *APinc*, an asymmetric score based on average precision.

4 Crowd-Sourcing Annotations

There is no publicly available dataset to evaluate models of hypernymy detection across multiple languages. While ontologies like Open Multilingual WordNet (OMW) (Bond and Foster, 2013) and BabelNet (Navigli and Ponzetto, 2012) contain cross-lingual links, these resources are semi-automatically generated and hence contain noisy edges. Thus, to get reliable and high-quality test beds, we collect evaluation datasets using CrowdFlower[4]. Our datasets span four languages from distinct families - French (Fr), Russian (Ru), Arabic (Ar) and Chinese (Zh) - paired with English.

To begin the annotation process, we first pool candidate pairs using hypernymy edges across languages from OMW and BabelNet, along with translations from monolingual hypernymy datasets (Baroni and Lenci, 2011; Baroni et al., 2012; Kotlerman et al., 2010).

4.1 Annotation Setup

The annotation task requires annotators to be fluent in both English and the non-English language. To ensure only fluent speakers perform the task, for each language, we provide task instructions in the non-English language itself. Also, we restrict the task to annotators verified by CrowdFlower to have those language skills. Finally, annotators also need to pass a quiz based on a small amount of gold standard data to gain access to the task.

[4] http://crowdflower.com

pair	#crowdsourced	#pos (= #neg)
French-English	2115	763
Russian-English	2264	706
Arabic-English	2144	691
Chinese-English	2165	806

Table 1: Crowd-sourced dataset statistics. #pos (#neg) denote positives (negatives) in the evaluation set. We deliberately under-sample negatives to have a balanced evaluation set.

Annotators choose between three options for each word pair (p_f, q_e), where p_f is a non-English word and q_e is a English word : "p_f is a kind of q_e", "q_e is a part of p_f" and "none of the above". Word pairs labeled with the first option are considered as positive examples while those labeled as "none of the above" are considered as negative.[5] The second option was included to filter out meronymy examples that were part of the noisy pool. We leave it to the annotator to infer whether the relation holds between any senses of p_f or q_e, if either of them are polysemous.

For every candidate hypernym pair (p_f, q_e), we also ask annotators to judge its reversed and translated *hyponym* pair (q_f, p_e). For instance, if $(citron, food)$ is a hypernym candidate, we also show annotators $(aliments, lemon)$ which is a potential hyponym candidate (*potential*, because as mentioned in §1, translation need not preserve semantic relationships). The purpose of presenting the hyponym pair, (q_f, p_e), is two-fold. First, it emphasizes the directional nature of the task. Second, it identifies hyponym pairs, which we use as negative examples. The hyponym pairs are challenging since differentiating them from hypernyms truly requires detecting asymmetry.

Each pair was judged by at least 5 annotators, and judgments with 80% agreement (at least 4 annotators agree) are considered for the final dataset. This is a stricter condition than certain monolingual hypernymy datasets - for instance, EVALution (Santus et al., 2015) - where agreement by 3 annotators is deemed sufficient. Inter-annotator agreement measured using Fleiss' Kappa (Fleiss, 1971) was 58.1 (French), 53.7 (Russian), 53.2 (Arabic) and 55.8 (Chinese). This indicates moderate agreement, on par with agreement obtained on related fine-grained semantic tasks (Pavlick et al., 2015). We cannot compare with monolin-

[5] We collected more negative pairs than positive, but sampled so as to keep a balanced dataset for ease of evaluation. We will release all annotated pairs along with the dataset.

gual hypernymy annotator agreement as, to the best of our knowledge, such numbers are not available for existing test sets. Dataset statistics are shown in Table 1.

We observed that annotators were able to agree on pairs containing polysemous words where hypernymy holds for some sense. For instance, for the French-English pair (*avocat*, *professional*), the French word *avocat* can either mean *lawyer* or *avocado*, but the pair was annotated as a positive example. Hence, we leave it to the annotators to handle polysemy by choosing the most appropriate sense.

4.2 Two Evaluation Test Sets

To verify if the crowdsourced hyponyms are challenging negative examples we create two evaluation sets. Both share the (crowdsourced) positive examples, but differ in their negatives:

- HYPER-HYPO – negative examples are the crowdsourced hyponyms.
- HYPER-COHYPO – negative examples are *cohyponyms* drawn from OMW.

Cohyponyms are words sharing a common hypernym. For instance, *bière* ("beer" in French) and *vodka* are cohyponyms since they share a common hypernym in *alcool/alcohol*. We choose cohyponyms for the second test set because: (a) They require differentiating between similarity (a symmetric relation) and hypernymy (an asymmetric relation). For instance, *bière* and *vodka* are highly similar yet, they do not have a hypernymy relationship. (b) Cohyponyms are a popular choice of negative examples in many entailment datasets (Baroni and Lenci, 2011).

5 Experimental Setup

5.1 Data and Evaluation Setup

Training BISPARSE-DEP requires a dependency parsed monolingual corpus, and a translation matrix for jointly aligning the monolingual vectors. We compute the translation matrix using word alignments derived from parallel corpora (see corpus statistics in Table **??**). While we use parallel corpora to generate the translation matrix to be comparable to baselines (§5.2), we can obtain the matrix from any bilingual dictionary.

The monolingual corpora are parsed using `Yara Parser` (Rasooli and Tetreault, 2015), trained on the corresponding treebank from the Universal Dependency Treebank (McDonald et al., 2013) (UDT-v1.4). `Yara Parser` was chosen as it is fast, and competitive with state-of-the-art parsers (Choi et al., 2015). The monolingual corpora was POS-tagged using TurboTagger (Martins et al., 2013). We induce dependency contexts for words by first thresholding the language vocabulary to the top 50,000 nouns, verbs and adjectives. A co-occurrence matrix is computed over this vocabulary using the context types in §3.1.

Inducing Dependency Contexts The entries of the word-context co-occurrence matrix are reweighted using Positive Pointwise Mutual Information (Bullinaria and Levy, 2007). The resulting matrix is reduced to 1000 dimensions using SVD (Golub and Kahan, 1965).[6] These vectors are used as $\mathbf{X_e}, \mathbf{X_f}$ in the setup from §3.3 to generate 100 dimensional sparse bilingual vectors.

Evaluation We use accuracy as our evaluation metric, as it is easy to interpret when the classes are balanced (Turney and Mohammad, 2015). Both evaluation datasets – HYPER-HYPO and HYPER-COHYPO – are split into 1:2 dev/test splits. *BalAPinc* has two tunable parameters - 1) a threshold that indicates the *BalAPinc* score above which all examples are labeled as positive, 2) the maximum number of features to consider for each word. We use the tuning set to tune the two parameters as well as the various hyper-parameters associated with the models.

5.2 Contrastive Approaches

We compare our BISPARSE-DEP embeddings with the following approaches:

MONO-DEP **(Translation baseline)** For word pair (p_f, q_e) in test data, we translate p_f to English using the most common translation in the translation matrix. Hypernymy is then determined using sparse, dependency based embeddings in English.

BISPARSE-LEX **(Window context)** Predecessor of the BISPARSE-DEP model from our previous work (Vyas and Carpuat, 2016). This model induces sparse, cross-lingual embeddings using window based context.

BIVEC+ **(Window context)** Our extension of the BIVEC model of Luong et al. (2015). BIVEC generates dense, cross-lingual embeddings using window based context, by substituting aligned word pairs within a window in parallel sentences. By default, BIVEC only trains using parallel data,

[6] Chosen based on preliminary experiments with {500,1000,2000,3000} dimensional vectors for En-Fr.

Language	Parallel Data	#sent.	Monolingual Data	#sent.

Table 2: Training data statistics for different languages. Note that while we use parallel corpora for computing translation dictionaries, our approach does not require it, and can work with any bilingual dictionary.

and so we initialize it with monolingually trained window based embeddings to ensure fair comparison.

CL-DEP **(Dependency context)** The model from Vulić (2017), which induces dense, dependency based cross-lingual embeddings by translating syntactic word-context pairs using the most common translation, and jointly training a `word2vecf`[7] model for both languages. Vulić (2017) showed improvements for word similarity and bilingual lexicon induction. We report the first results using CL-DEP on this task.

5.3 Evaluating Robustness of BISPARSE-DEP

We investigate how robust BISPARSE-DEP is when exposed to data scarce settings. Evaluating on a truly low resource language is complicated by the fact that obtaining an evaluation dataset for such a language is difficult. Therefore, we simulate such settings for the languages in our dataset in multiple ways.

No Treebank If a treebank is not available for a language, dependency contexts have to be induced using treebanks from other languages (§3.2), which can affect the quality of the dependency-based embeddings. To simulate this, we train a delexicalized parser for the languages in our dataset. We use treebanks from Slovenian, Ukrainian, Serbian, Polish, Bulgarian, Slovak and Czech (40k sentences) for training the Russian parser, and treebanks from English, Spanish, German, Portuguese, Swedish and Italian (66k sentences) for training the French parser. UDT does not (yet) have languages in the same family as Arabic or Chinese, so for the sake of completeness, we train Arabic and Chinese parsers on delexicalized treebanks of the language itself. After delexicalized training, the Labeled Attachment Score (LAS) on the UDT test set dropped by several points for all languages – from 76.6% to 60.0% for Russian, 83.7% to 71.1% for French, from 76.3% to 62.4% for Arabic and from 80.3% to 53.3% for Chinese. The monolingual corpora are then parsed with these weaker parsers, and co-ocurrences and dependency contexts are computed as before.

Subsampling Monolingual Data To simulate low-resource behavior along another axis, we subsample the monolingual corpora used by BISPARSE-DEP to induce monolingual vectors, $\mathbf{X_e}, \mathbf{X_f}$. Specifically, we learn $\mathbf{X_e}$ and $\mathbf{X_f}$ using progressively smaller corpora.

Quality of Bilingual Dictionary We study the impact of the quality of the bilingual dictionary used to create the translation matrix $\mathbf{S}$. This experiment involves using increasingly smaller parallel corpora to induce the translation dictionary.

6 Experiments

We aim to answer the following questions – **(a)** Are dependency based embeddings superior to window based embeddings for identifying cross-lingual hypernymy? (§6.1) **(b)** Does directionality in the dependency context help cross-lingual hypernymy identification? (§6.2) **(c)** Are our models robust in data scarce settings (§6.3)? **(d)** Is the answer to **(a)** predicated on the choice of entailment scorer? (§6.4)?

6.1 Dependency v/s Window Contexts

We compare the performance of models described in §5.2 with the BISPARSE-DEP (FULL and JOINT) models. We evaluate the models on the two test splits described in §4.2 – HYPER-HYPO and HYPER-COHYPO.

BISPARSE-DEP (Unlab)	58.6	66.7	62.4	61.5	62.4

(b) Performance on HYPER-COHYPO.

Table 3: Comparing the different approaches from §5.2 with our BISPARSE-DEP approach on HYPER-HYPO and HYPER-COHYPO (random baseline= 0.5). **Bold** denotes the best score for each language, and the * on the best score indicates a statistically significant ($p < 0.05$) improvement over the next best score, using McNemar's test (McNemar, 1947). Across both datasets, BISPARSE-DEP models outperform window based models and the translation baseline on an average.

Hyper-Hypo Results Table 3a shows the results on HYPER-HYPO. First, the benefit of cross-lingual modeling (as opposed to translation) is evident in that almost all models (except CL-DEP on French) outperform the translation baseline. Among dependency based models, BISPARSE-DEP (FULL) and CL-DEP consistently outperform both window models, while BISPARSE-DEP (JOINT) outperforms them on all except Russian. BISPARSE-DEP (JOINT) is the best model overall for two languages (French and Chinese), CL-DEP for one (Arabic), with no statistically significant differences between BISPARSE-DEP (JOINT) and CL-DEP for Russian. This confirms that dependency context is more useful than window context for cross-lingual hypernymy detection.

Hyper-Cohypo Results The trends observed on HYPER-HYPO also hold on HYPER-COHYPO i.e. dependency based models continue to outperform window based models (Table 3b).

Overall, BISPARSE-DEP (FULL) performs best in this setting, followed closely by BISPARSE-DEP (JOINT). This suggests that the sibling information encoded in JOINT is useful to distinguish hypernyms from hyponyms (HYPER-HYPO results), while the dependency labels encoded in FULL help to distinguish hypernyms from co-hyponyms. Also note that all models improve significantly on the HYPER-COHYPO set, suggesting that discriminating hypernyms from cohyponyms is easier than discriminating them from hyponyms.

While the BISPARSE-DEP models were generally performing better than window models on both test sets, CL-DEP was not as consistent (e.g., it was worse than the best window model on HYPER-COHYPO). As shown by Turney and Mohammad (2015), *BalAPinc* is designed for sparse embeddings and is likely to perform poorly with dense embeddings. This explains the relatively inconsistent performance of CL-DEP.

Besides establishing the challenging nature of our crowd-sourced set, the experiments on HYPER-COHYPO and HYPER-HYPO also demonstrate the ability of the BISPARSE-DEP models to discriminate between different lexical semantic relations (viz. hypernymy and cohyponymy) in a cross-lingual setting. We will investigate this ability more carefully in future work.

6.2 Ablating Directionality in Context

The context described by the FULL and JOINT BISPARSE models encodes directional information (§3.1) either in the form of label direction (FULL), or using sibling information (JOINT). Does such directionality in the context help to capture the asymmetric relationship inherent to hypernymy? To answer this, we evaluate a third BISPARSE-DEP model which uses UNLABELED dependency contexts. This is similar to the FULL context, except we do not concatenate the label of the relation to the context word (parent or children). For instance, for *traveler* in Fig. 2, contexts will be *roamed* and *tired*.

Experiments on both HYPER-HYPO and HYPER-COHYPO (bottom row, Tables 3a and 3b) highlight that directional information is indeed essential - UNLABELED almost always performs worse than FULL and JOINT, and in many cases worse than even window based models.

Model ↓ En With →	Ru	Zh	Ar	Fr	Avg.
Hyper-Hypo					
Best Win.	56.6	53.7	51.5	53.4	53.8
Delex.	59.1*	55.1*	54.6*	56.1*	56.2

Best Dep.	63.6*	67.3*	66.8*	66.7	66.1

Table 4: **Robustness in absence of a treebank**: The delexicalized model is competitive to the best dependency based and the best window based models on both test sets. For each dataset, * indicates a statistically significant ($p < 0.05$) improvement over the next best model in that column, using McNemar's test (McNemar, 1947).

6.3 Evaluating Robustness of BISPARSE-DEP

No Treebank We run experiments (Table 4) for all languages with a version of BISPARSE-DEP that use the FULL context type for both English and the non-English (target) language, but the target language contexts are derived from a corpus parsed using a delexicalized parser (§5.3).

This model compares favorably on all language pairs against the best window based and the best dependency based model. In fact, it almost consistently outperforms the best window based model by several points, and is only slightly worse than the best dependency-based model.

Further analysis revealed that the good performance of the delexicalized model is due to the relative robustness of the delexicalized parser on frequent contexts in the co-occurrence matrix. Specifically, we found that in French and Russian, the most frequent contexts were derived from `amod`, `nmod`, `nsubj` and `dobj` edges.[8] For instance, the `nmod` edge appears in 44% of Russian contexts and 33% of the French contexts. The delexicalized parser predicts both the label and direction of the `nmod` edge correctly with an F1 of 68.6 for Russian and 69.6 for French. In contrast, a fully-trained parser achieves a F1 of 76.7 for Russian and 76.8 for French for the same edge.

Small Monolingual Corpus In Figure 4, we use increasingly smaller monolingual corpora (10%, 20%, 40%, 60% and 80%) sampled at random to induce the monolingual vectors for BISPARSE-DEP (FULL) model. Trends (Figure 4) indicate that BISSPARSE-DEP models that use only 40% of the original data remain competitive with the BISSPARSE-LEX model that has access to the full data. Robust performance with smaller monolingual corpora is helpful since large-enough monolingual corpora are not always easily available.

[8]Together they make up at least 70% of the contexts.

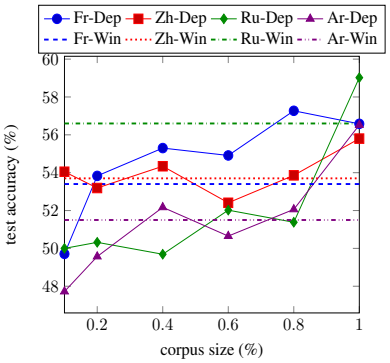

Figure 3: **Robustness to Small Corpus** For most languages, BISPARSE-DEP outperforms the corresponding best window based model for each language on HYPER-HYPO, with about 40% of the monolingual corpora.

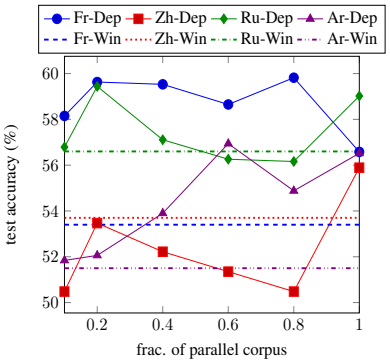

Figure 4: **Robustness to Noisy Dictionary** For most languages, BISPARSE-DEP outperforms the corresponding best window based model on HYPER-HYPO, with increasingly lower quality dictionaries.

Quality of Bilingual Dictionary Bilingual dictionaries derived from smaller amounts of parallel data are likely to be of lower quality than those derived from larger corpora. Hence, to analyze the impact of dictionary quality on BISPARSE-DEP (FULL), we use increasingly smaller parallel corpora to induce bilingual dictionaries used as the score matrix $\mathbf{S}$ (§3.3). We use the top 10%, 20%, 40%, 60% and 80% sentences from the parallel corpora. The trends in Figure 4 show that even with a lower quality dictionary, BISPARSE-DEP performs better than BISPARSE-LEX.

6.4 Choice of Entailment Scorer

We change the entailment scorer from *BalAPinc* to *SLQS* (Santus et al., 2014) and redo experiments from §6.1 to see if the conclusions drawn depend

on the choice of the entailment scorer. *SLQS* is based on the distributional informativeness hypothesis, which states that hypernyms are less "informative" than hyponyms, because they occur in more general contexts. The informativeness E_u of a word u is defined to be the median entropy of its top N dimensions, $E_u = median_{k=1}^{N} H(c_k)$, where $H(c_i)$ denotes the entropy of dimension c_i. The *SLQS* score for a pair (u, v) is the relative difference in entropies,

$$SLQS(u \rightarrow v) = 1 - \frac{E_u}{E_v}$$

Recent work (Shwartz et al., 2017) has found *SLQS* to be more successful than other metrics in monolingual hypernymy detection.

The trends observed in these experiments are consistent with those in §6.1 – both BISPARSE-DEP models still outperform window-based models. Also, the delexicalized version of BISPARSE-DEP outperforms the window-based models, showing that the robust behavior demonstrated in §6.3 is also invariant across metrics.

We also found that using *BalAPinc* led to better results than *SLQS* . For both BISPARSE-DEP models, *BalAPinc* wins across the board for two languages (Russian and Chinese), and wins half the time for the other two languages compared to *SLQS* . We leave detailed comparison of these and other scores to future work.

7 Conclusion

We introduced BISPARSE-DEP, a new distributional approach for identifying cross-lingual hypernymy, based on cross-lingual embeddings derived from dependency contexts. We showed that using BISPARSE-DEP is superior for the cross-lingual hypernymy detection task, when compared to standard window based models and a translation baseline. Further analysis also showed that BISPARSE-DEP is robust to various low-resource settings. In principle, BISPARSE-DEP can be used for any language that has a bilingual dictionary with English and a "related" language with a treebank. We also introduced crowd-sourced cross-lingual hypernymy datasets for four languages for future evaluations.

Our approach has the potential to complement existing work on creating cross-lingual ontologies such as BabelNet and the Open Multilingual Wordnet, which are noisy because they are compiled semi-automatically, and have limited language coverage. In general, distributional approaches can help refine ontology construction for any language where sufficient resources are available.

It remains to be seen how our approach performs for other language pairs beyond simluated low-resource settings. We anticipate that replacing our delexicalized parser with more sophisticated transfer strategies (Rasooli and Collins, 2017; Aufrant et al., 2016) might be beneficial in such settings.While our delexicalized parsing based approach exhibits robustness, it can benefit from more sophisticated approaches for transfer parsing (Rasooli and Collins, 2017; Aufrant et al., 2016) to improve parser performance. We aim to explore these and other directions in the future.

Noising and Denoising Natural Language: Diverse Backtranslation for Grammar Correction

Abstract

Translation-based methods for grammar correction that directly map noisy, ungrammatical text to their clean counterparts are able to correct a broad range of errors; however, such techniques are bottlenecked by the need for a large parallel corpus of noisy and clean sentence pairs. In this paper, we consider synthesizing parallel data by noising a clean monolingual corpus. While most previous approaches introduce perturbations using features computed from local context windows, we instead develop error generation processes using a neural sequence transduction model trained to translate clean examples to their noisy counterparts. Given a corpus of clean examples, we propose beam search noising procedures to synthesize additional noisy examples that human evaluators were nearly unable to discriminate from nonsynthesized examples. Surprisingly, when trained on additional data synthesized using our best-performing noising scheme, our model approaches the same performance as when trained on additional nonsynthesized data.

1 Introduction

Correcting noisy, ungrammatical text remains a challenging task in natural language processing. Ideally, given some piece of writing, an error correction system would be able to fix minor typographical errors, as well as grammatical errors that involve longer dependencies such as nonidiomatic phrasing or errors in subject-verb agreement. Existing methods, however, are often only able to correct highly local errors, such as spelling errors or errors involving articles or prepositions.

Classifier-based approaches to error correction are limited in their ability to capture a broad range of error types (Ng et al., 2014). Machine translation-based approaches—that instead translate noisy, ungrammatical sentences to clean, corrected sentences—can flexibly handle a large variety of errors; however, such approaches are bottlenecked by the need for a large dataset of source-target sentence pairs.

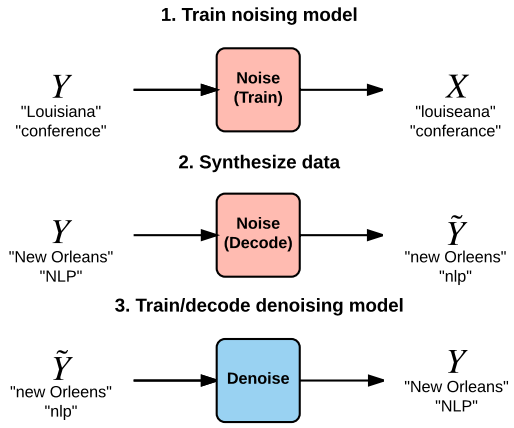

Figure 1: Overview of method. We first train a noise model on a seed corpus, then apply noise during decoding to synthesize data that is in turn used to train the denoising model.

To address this data sparsity problem, we propose methods for synthesizing noisy sentences from clean sentences, thus generating an additional artificial dataset of noisy and clean sentence pairs. A simple approach to noise clean text is to noise individual tokens or bigrams, for example by replacing each token with a random draw from the unigram distribution. This type of approach, however, tends to generate highly unrealistic noise and fails to capture phrase-level phenomena. Other rule-based approaches fail to capture a diverse set of error types.

We consider a method inspired by the backtranslation procedure for machine translation (Sennrich et al., 2015). Our method combines a neural sequence transduction trained on a seed corpus of clean→noisy pairs with *beam search*

Proceedings of NAACL-HLT 2018, pages 619–628
New Orleans, Louisiana, June 1 - 6, 2018.

noising procedures to produce more diversity in the decoded outputs. This technique addresses two issues with existing synthesis techniques for grammar correction:

1. By using a neural model trained end-to-end on a large corpus of noisy and clean sentences, the model is able to generate rich, diverse errors that better capture the noise distribution of real data.

2. By encouraging diversity through applying noise to hypotheses during decoding, we avoid what we refer to as the *one-to-many* problem, where decoding from a model trained on clean→noisy examples results in overly clean output, since clean subphrases still form the majority of noisy examples.

We perform experiments using several noising methods to validate these two claims, yielding gains on two benchmarks. Our main empirical result is that, starting with only clean news data and models trained on a parallel corpus of roughly 1.3 million sentences, we can train models with additional synthesized data that nearly match the performance of models trained on 3 million nonsynthesized examples.

2 Related work

Noising While for images, there are natural noising primitives such as rotations, small translational shifts, and additive Gaussian noise, similar primitives are not as well developed for text data. Similarly, while denoising autoencoders for images have been shown to help with representation learning (Vincent et al., 2010), similar methods for learning representations are not well developed for text. Some recent work has proposed noising—in the form of dropping or replacing individual tokens—as a regularizer when training sequence models, where it has been demonstrated to have a smoothing effect on the softmax output distribution (Bowman et al., 2015; Xie et al., 2017; Dai and Le, 2015; Kumar et al., 2015).

Grammar correction Recent work by Chollampatt and Ng (2018) has achieved impressive performance on the benchmarks we consider using convolutional encoder-decoder models. Previous work using data synthesis for grammatical error correction (GEC) has introduced errors by examining the distribution of error types, then applying errors according to those distributions together with lexical or part-of-speech features based on a small context window (Brockett et al., 2006; Felice, 2016). While these methods can introduce many possible edits, they are not as flexible as our approach inspired by the backtranslation procedure for machine translation (Sennrich et al., 2015). This is important as neural language models not explicitly trained to track long-range linguistic dependencies can fail to capture even simple noun-verb errors (Linzen et al., 2016). Recently, in the work perhaps most similar to ours, Rei et al. (2017) propose using statistical machine translation and backtranslation along with syntactic patterns for generating errors, albeit for the error detection task.

Neural machine translation Recent end-to-end neural network-based approaches to machine translation have demonstrated strong empirical results (Sutskever et al., 2014; Cho et al., 2014). Building off of these strong results on machine translation, we use neural encoder-decoder models with attention (Bahdanau et al., 2014) for both our data synthesis (noising) and grammar correction (denoising) models. Although many recent works on NMT have focused on improving the neural network architecture, the model architecture is orthogonal to the contributions in this work, where we instead focus on data synthesis. In parallel to our work, work on machine translation without parallel corpora has also explored applying noise to avoid copying when pretraining autoencoders by swapping adjacent words (Lample et al., 2017; Artetxe et al., 2017).

Diverse decoding Key to the data generation procedure we describe is adding noise to the scores of hypotheses during beam search–otherwise, decoded outputs tend to contain too few errors. This is inspired by work in dialogue, in which neural network models tend to produce common, overly generic responses such as "*I don't know*" (Sordoni et al., 2015; Serban et al., 2015). To mitigate this issue, Li et al. (2015) and others have proposed methods to increase the diversity of neural network outputs. We adopt a similar approach to Li et al. (2015) to generate noisier hypotheses during decoding.

3 Method

We first briefly describe the neural model we use, then detail the noising schemes we apply when synthesizing examples.

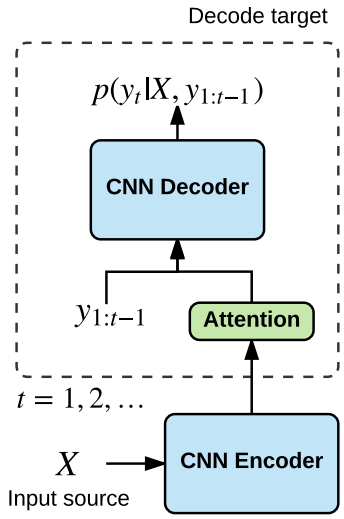

Figure 2: Model architecture used for both noising and denoising networks.

3.1 Model

In order to generate noisy examples as well as to translate ungrammatical examples to their corrected counterparts, we need to choose a sequence transduction model. Based off their strong empirical performance, we use a neural network-based model for this work.

Our method uses two neural encoder-decoder models:

1. The first is the *noising* model, which, given a clean sentence, is used to generate a noised version of that sentence. This model is trained on a *seed corpus* of parallel clean→noisy sentences.

2. The second is the *denoising* model, which, given a noisy, ungrammatical sentence, generates the clean, corrected sentence.

For both models, we use the same convolutional encoder-decoder to model

$$p(Y|X) = \prod_{t=1}^{T_Y} p(y_t|X, y_{1:t-1}; \theta)$$

where $X = (x_1, x_2, \ldots, x_{T_X})$ is the source sequence and $Y = (y_1, y_2, \ldots, y_{T_Y})$ the corresponding target sequence, and we minimize the training loss

$$\ell(\theta) = -\log \sum_{t=1}^{T_Y} p(y_t|X, y_{1:t-1}; \theta)$$

thus maximizing log-likelihood. The model architecture we use is similar to that described by Kalchbrenner et al. (2016) and Gehring et al. (2017). Gated convolutions are applied with masking—to avoid peeking at future inputs when training using teacher forcing—such that they form an autoregressive network similar to a recurrent neural network with gated hidden units. This architecture was selected so that training steps could be parallelized across the time dimension through the use of convolutions. However, we emphasize that the architecture is not a focus of this paper, and we would expect that RNN architectures with LSTM cells would achieve similar results. For simplicity and to avoid handling out-of-vocabulary words, we use character-level tokenization. Figure 2 illustrates the model architecture.

3.2 Noising

The amount of parallel data is often the limiting factor in the performance of neural network systems. In order to obtain more parallel examples for the grammar correction task, we take clean text Y and apply noise, yielding noisy text $\tilde{Y}$, then train a denoising model to map from $\tilde{Y}$ back to Y. The noising process used to generate $\tilde{Y}$ greatly affects final performance. First, we consider noising methods which we use as our baselines, as well as the drawbacks for each method.

- **appending clean examples**: We first consider simply appending clean examples with no noise applied to both the source and the target. The aim is for the decoder to learn a better language model when trained on additional clean text, similar to the motivation described in Dai and Le (2015). However, for the models we consider, the attention mechanism allows copying of source to target. Thus the addition of examples where source and target are identical data may also cause the model to become too conservative with edits and thus reduce the recall of the system.

- **token noising**: Here we simply consider a context window of at most two characters or words and allow word/character deletions and transpositions.

  First, for every *character* in each word we sample deletions, followed by transpositions. Then we sample deletions and transpositions for every *word* in the sentence. Deletion and transposition probabilities were selected such

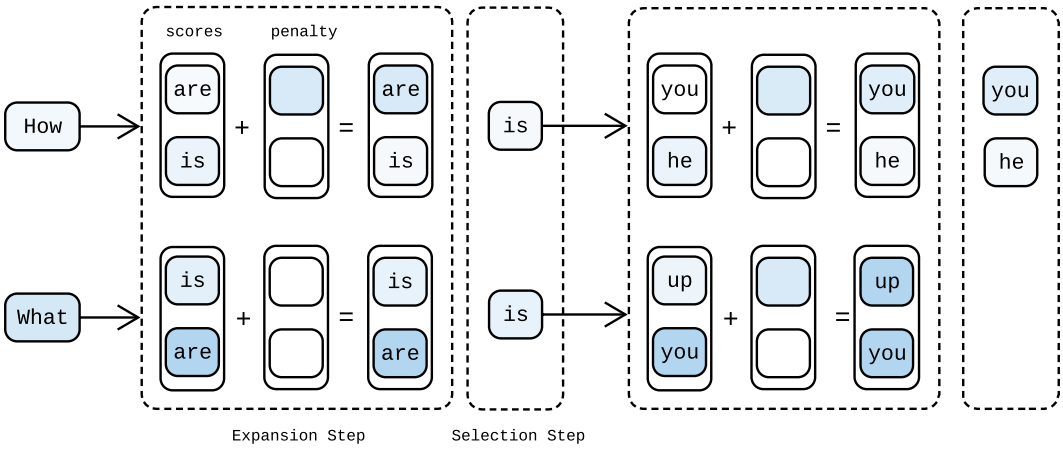

Figure 3: Illustration of random noising with beam width 2. Darker shading indicates less probable expansions. In this example, greedy decoding would yield "How are you". Applying noise penalties, however, results in the hypotheses "How is you/he". Note that applying a penalty does not always result in an expansion falling off the beam.

that overall character and word-level edit distances roughly matched the edit distances between clean and noisy examples in our parallel seed corpus. While this method is fast to apply, it tends to produce highly unrealistic errors leading to a mismatch between the synthesized and real parallel data.

- **reverse noising**: For reverse noising, we simply train a reverse model from $Y \rightarrow X$ using our parallel noisy-clean corpus and run standard beam search to generate noisy targets $\tilde{Y}$ from clean inputs Y. However, we find vanilla reverse noising tends to be too conservative. This is due to the *one-to-many* problem where a clean sentence has many possible noisy outputs which mostly consist of clean phrases. The output then contains far fewer errors on average than the original noisy text.

To address the drawback of the reverse noising scheme, we draw inspiration from ideas for increasing diversity of outputs in dialogue (Li et al., 2016). During the beam search procedure, we add noise to the scores of hypotheses on the beam to encourage decoding to stray from the greedy output. Recall that during beam search, we iteratively grow a set of hypotheses $\mathcal{H} = \{h_1, h_2, \ldots\}$, only keeping the top hypotheses after each step of decoding according to some scoring function $s(h)$. Extending the reverse noising scheme, the *beam search noising* schemes we consider are:

- **rank penalty noising** We directly apply the method of Li et al. (2016). At every step of the search procedure, siblings from the same parent are penalized by adding $k\beta_{\text{rank}}$ to their scores, where k is their rank (in descending log-likelihood) amongst their siblings and β_{rank} is a penalty hyperparameter corresponding to some log-probability.

- **top penalty noising** Only the top (most-probable) hypothesis h_{top} of the beam is penalized by adding β_{top} to its score $s(h_{\text{top}})$.

- **random noising** Every hypothesis is penalized by adding $r\beta_{\text{random}}$ to its score, where r is drawn uniformly from the interval $[0, 1]$. For sufficiently large β_{random}, this leads to a random shuffling of the ranks of the hypotheses according to their scores.

An illustration of the random noising algorithm is shown in Figure 3. Note that although rank penalty noising should encourage hypotheses whose parents have similar scores to remain on the beam, it can also tend to leave the hypothesis from greedy decoding on the beam in the case where softmax output distributions are highly peaked. This is much more of an issue for tasks that involve significant copying of source to target, such as grammar correction. Note also that the random noising can yield more diverse outputs than top penalty noising, depending on the probability with which each is applied. All of the beam search noising methods described are intended to increase the diversity and the amount of noise in the synthe-

Corpus	Sent. Pairs

sized outputs $\tilde{Y}$. By performing beam search noising, we can produce errors such as those shown in Table 4.

3.3 Denoising

Once noised data has been generated, *denoising* simply involves using a neural sequence transduction model to backtranslate the noised text to the original clean text. For denoising, during decoding we apply length normalization as well as a coverage penalty to the scoring function $s(h)$ (Wu et al., 2016). The final scoring function also incorporates a 5-gram language model trained on a subset of Common Crawl, estimated with Kneser-Ney smoothing using KenLM (Heafield, 2011). We incorporate the language model during final reranking by modifying the score for a completed hypothesis $s(h)$ to be

$$s_{\text{LM}}(h) = s(h) + \lambda \log p_{\text{LM}}(h)$$

where λ is a hyperparameter and $p_{\text{LM}}(h)$ is given by the language model.

4 Experiments

To determine the effectiveness of the described noising schemes, we synthesize additional data using each and evaluate the performance of models trainined using the additional data on two benchmarks.

Datasets For training our sequence transduction models, we combine the publicly available English Lang-8 dataset, a parallel corpus collected from a language learner forum, with training data from the CoNLL 2014 challenge (Mizumoto et al., 2011; Ng et al., 2014). We refer to this as the "base" dataset. Junczys-Dowmunt and Grundkiewicz (2016) additionally scraped 3.3M pairs of sentences from Lang-8. Although this expanded dataset, which we call the "expanded" dataset, is not typically used when comparing performance on grammar correction benchmarks, we use it instead to compare performance when training on additional synthesized data versus nonsynthesized data. For clean text to be noised, we use the LDC New York Times corpus for 2007, which yields roughly 1 million sentences. A summary of the data used for training is given in Table 1.

We use the CoNLL 2013 evaluation set as our development set in all cases (Ng et al., 2013). Our test sets are the CoNLL 2014 evaluation set and the JFLEG test set (Ng et al., 2014; Napoles et al., 2017). Because CoNLL 2013 only has a single set of gold annotations while CoNLL 2014 has two, performance metrics tend to be significantly higher on CoNLL 2014. We report precision, recall, and $F_{0.5}$ score, which is standard for the task, as precision is valued over recall. On JFLEG, we report results with the GLEU metric (similar to BLEU) developed for the dataset.

Training and decoding details All models are trained using stochastic gradient descent with annealing based on validation perplexity on a small held-out subset of the Lang-8 corpus. We apply both dropout and weight decay regularization. We observed that performance tended to saturate after 30 epochs. Decoding is done with a beam size of 8; in early experiments, we did not observe significant gains with larger beam sizes (Koehn and Knowles, 2017).

4.1 CoNLL

Results for the CoNLL 2013 (dev) and 2014 (test) datasets but with and without language model reranking are given in Table 2. In general, adding noised data helps, while simply adding clean data leads the model to be too conservative. Overall, we find that the random noising scheme yields the most significant gain of 4.5 F-score. Surprisingly, we find that augmenting the base dataset with synthesized data generated with random noising yields nearly the same performance when compared to using only nonsynthesized examples. To determine whether this might be due to overfitting, we reduced the dropout rate when training on the "expanded" dataset, but did not observe better results.

The random noising scheme achieves the best performance, while the top noising scheme matches the best performance on the development set but not the test set. We believe this is due to a mismatch between the CoNLL 2013 dev and 2014

Table 2: Results on CoNLL 2013 (Dev) and CoNLL 2014 (Test) sets. All results use the "base" parallel corpus of 1.3M sentence pairs along with additional synthesized data (totaling 2.3M sentence pairs) except for "expanded", which uses 3.3M nonsynthesized sentence pairs (and no synthesized data).

tets sets. Since the 2013 dev set has only a single annotator, methods are encouraged to target higher recall, such that the top noising scheme was optimized for precision over recall. To check this, we ran decoding on CoNLL 2014 using the best dev settings with no language model, and found that the top noising scheme yielded an $F_{0.5}$-score of 45.2, behind only random (47.1) and ahead of token (42.0) and reverse (43.9) noising. Overall, we find the data synthesis method we describe to yield large gains in recall.

For completeness, we also compare to other state-of-the-art systems, such as the phrase-based machine translation system by Junczys-Dowmunt and Grundkiewicz (2016), who performed parameter tuning with sparse and dense features by cross-validation on the CoNLL 2014 training set. Chollampatt and Ng (2018) achieve even higher state-of-the-art results using the neural machine translation model of Gehring et al. (2017) along with improvements to the reranking procedure.

4.2 JFLEG

Recently, Napoles et al. (2017) introduced the JFLEG dataset, intended to evaluate the fluency of grammar correction systems rather than simply the precision and recall of edits. The evaluation metric proposed is GLEU, a variant of BLEU score. Most results for this task were reported with hyperparameter settings from the CoNLL task; hence we report results with the best settings on our CoNLL 2013 dev set. Results are shown in Table 3[1]. Token noising performs surprisingly well; we suspect this is because a significant portion of errors in the JFLEG dataset are spelling errors, as demonstrated from strong gains in performance by using a spelling checker reported by Chollampatt and Ng (2018).

5 Discussion

Our experiments illustrate that synthesized parallel data can yield large gains on the grammar correction task. However, what factors make for an effective data synthesis technique? We consider the properties of the noising scheme and the corresponding data that lead to better performance.

5.1 Realism and Human Evaluation

First, we manually compare each of the different noising methods to evaluate how "realistic" the errors introduced are. This is reminiscent of the generative adversarial network setting (Goodfellow et al., 2014), where the generator seeks to produce samples that fool the discriminator. Here the discriminator is a human evaluator who, given the clean sentence Y, tries to determine which of two sentences X and $\tilde{Y}$ is the true noisy sentence, and which is the synthesized sentence. To be clear,

we do not train with a discriminator—the beam search noising procedures we proposed alone are intended to yield convincing errors.

For each noising scheme, we took 100 (X, Y) pairs from the development set (500 randomly chosen pairs combined), then generated $\tilde{Y}$ from Y. We then shuffled the examples and the order of X and $\tilde{Y}$ such that the identity of X and $\tilde{Y}$ *as well as the noising scheme* used to generate $\tilde{Y}$ were unknown[2]. Given Y, the task for human evaluators is to predict whether X or $\tilde{Y}$ was the synthesized example. For every example, we had two separate evaluators label the sentence they thought was synthesized. We chose to do this labeling task ourselves (blind to system) since we were familiar with the noising schemes used to generate examples, which should reduce the number of misclassifications. Results are shown in Figure 4, and examples of the evaluation task are provided in Table 4.

5.2 Noise Frequency and Diversity

Comparing the performance using different noising methods on the CoNLL 2014 dataset to the human evaluation in the previous section, we see that generating errors which *match* the real distribution tends to result in higher performance, as seen by the poor performance of token noising relative

[2]Hence the human labelers cannot favor a particular scheme unless it can be distinguished from $\tilde{Y}$.

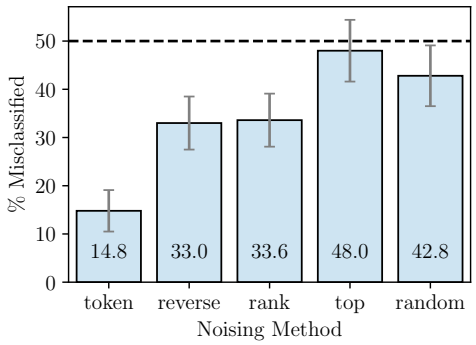

Figure 4: Percentage of time human evaluators misclassified synthesized noisy sentence $\tilde{Y}$ (vs. X) when using each noising scheme, along with 95% confidence intervals. The best we can expect any scheme to do is 50%.

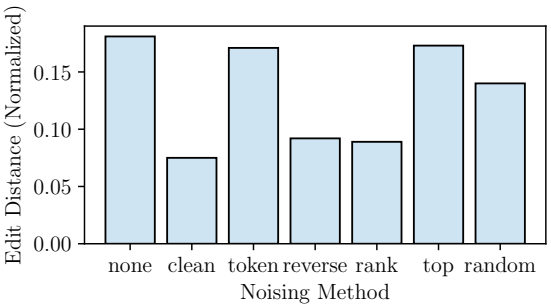

Figure 5: Mean edit distance between sentence pairs in X and Y *after* augmentation with noised sentences. *none* contains no synthesized examples while *clean* refers to the baseline of simply appending clean examples (source = target).

to the other methods. Injecting the appropriate *amount* of noise is important as well, as seen by improved performance when using beam search noising to increase diversity of outputs, and no performance gain when simply adding clean text.

We observe that token noising, despite matching the frequency of errors, fails to generate realistic errors (Figure 4). On the other hand, reverse noising yields significantly more convincing errors, but the edit distance between synthesized examples is significantly lower than in real data (Figure 5). A combination of sufficient amounts of noise and rich, diverse errors appears to lead to better model performance.

5.3 Error Type Distribution Mismatch

Mismatches in the distribution of error types can often severely impact the performance of data synthesis techniques for grammar correction (Felice, 2016). For example, only synthesizing noun number articles or preposition errors based on rules

	Sentence	1 or 2
clean	Day after day , I get up at 8 o‘clock .	
1	I got up at 8 o‘clock day after day .	
2	Day after day , I get up 8 o‘clock in the week .

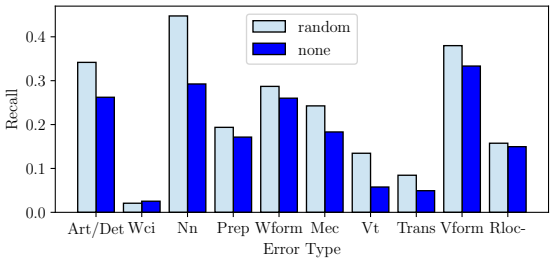

Figure 6: Recall vs. error type for the ten most frequent error types in our dev set. Noising improves recall uniformly across error types (See Ng et al. (2014) for a description of error types).

may improve the performance for those two error types, but may hurt overall performance. In contrast, the approaches we consider, with the exception of token noising, are fully data-driven, and hence we would expect gains across all different error types. We observe this is the case for random noising, as shown in Figure 6.

5.4 Data Sparsity and Domain Adaptation

Domain adaptation can yield significant differences in performance for dissimilar domains (such as those of the datasets used in our experiments) (Daumé III, 2009). The Lang-8, CoNLL, and JFLEG datasets contain online forum data and essay data from English learners. The n-gram language model is estimated using Common Crawl data from the web. The clean data which we noise is collected from a news corpus. Yet each dataset yields significant gains. This suggests that at current levels of system performance, data sparsity remains the key data issue, more so than domain adaptation.

It is also possible that LDC New York Times data is better matched to the CoNLL essay data than the Lang-8 forum data, and this in part accounts for the large gains we observe from training on synthesized data.

6 Conclusion

In this work, we address one of the key issues for developing translation-based grammar correction systems: the need for a large corpus of parallel data. We propose synthesizing parallel data by noising clean text, where instead of applying noise based on finite context windows, we instead train a reverse model and apply noise during the beam search procedure to synthesize noisy examples that human evaluators were nearly unable to distinguish from real examples. Our experiments suggest that the proposed data synthesis technique can yields almost as strong results as when training with additional nonsynthesized data. Hence, we hope that parallel data becomes less of a bottleneck, and more emphasis can be placed on developing better models that can capture the longer dependencies and structure in the text.

Acknowledgments

We thank the anonymous reviewers for their helpful feedback, as well as Steven Tan for comments on an early draft.

Self-Training for Jointly Learning to Ask and Answer Questions

Mrinmaya Sachan **Eric P. Xing**
School of Computer Science
Carnegie Mellon University
{mrinmays, epxing}@cs.cmu.edu

Abstract

Building curious machines that can answer as well as ask questions is an important challenge for AI. The two tasks of question answering and question generation are usually tackled separately in the NLP literature. At the same time, both require significant amounts of supervised data which is hard to obtain in many domains. To alleviate these issues, we propose a self-training method for jointly learning to ask as well as answer questions, leveraging unlabeled text along with labeled question answer pairs for learning. We evaluate our approach on four benchmark datasets: *SQUAD*, *MS MARCO*, *WikiQA* and *TrecQA*, and show significant improvements over a number of established baselines on both question answering and question generation tasks. We also achieved new state-of-the-art results on two competitive answer sentence selection tasks: *WikiQA* and *TrecQA*.

1 Introduction

Question Answering (QA) is a well-studied problem in NLP which focuses on answering questions using some structured or unstructured sources of knowledge. Alongside question answering, there has also been some work on generating questions (QG) (Heilman, 2011; Du et al., 2017; Tang et al., 2017) which focuses on generating questions based on given sources of knowledge.

QA and QG are closely related[1] tasks. However, NLP literature views the two as entirely separate tasks. In this paper, we explore this relationship between the two tasks by jointly learning to generate as well as answer questions. An improved ability to generate as well as answer questions will help us build *curious* machines that can interact with humans in a better manner. Joint modeling of QA and QG is useful as the two can be used in conjunction to generate novel questions from free text and then answers for the generated questions. We use this idea to perform self-training (Nigam and Ghani, 2000) and leverage free text to augment the training of QA and QG models.

QA and QG models are typically trained on question answer pairs which are expensive to obtain in many domains. However, it is cheaper to obtain large quantities of free text. Our self-training procedure leverages unlabeled text to boost the quality of our QA and QG models. This is achieved by a careful data augmentation procedure which uses pre-trained QA and QG models to generate additional labeled question answer pairs. This additional data is then used to retrain our QA and QG models and the procedure is repeated.

This addition of synthetic labeled data needs to be performed carefully. During self-training, typically the most *confident* samples are added to the training set (Zhu, 2005) in each iteration. We use the performance of our QA and QG models as a proxy for estimating the *confidence* value of the questions. We describe a suite of heuristics inspired from curriculum learning (Bengio et al., 2009) to select the questions to be generated and added to the training set at each epoch. Curriculum learning is inspired from the incremental nature of human learning and orders training samples on the *easiness* scale so that *easy* samples can be introduced to the learning algorithm first and *harder* samples can be introduced successively. We show that introducing questions in increasing order of *hardness* leads to improvements over a baseline that introduces questions randomly.

We use a seq2seq model with soft attention (Sutskever et al., 2014; Bahdanau et al., 2014) for QG and a neural model inspired from *Attentive Reader* (Hermann et al., 2015; Chen et al., 2016) for QA. However, these can be any QA

[1] We can think of QA and QG as inverse of each other.

Proceedings of NAACL-HLT 2018, pages 629–640
New Orleans, Louisiana, June 1 - 6, 2018.

and QG models. We evaluate our approach on four datasets: *SQUAD*, *MS MARCO*, *WikiQA* and *TrecQA*. We use a corpus of English Wikipedia as unlabeled text. Our experiments show that the self-training approach leads to significant improvements over a number of established approaches in QA and QG on these benchmarks. On the two answer sentence selection QA tasks: (*WikiQA* and *TrecQA*), we obtain state-of-the-art.

2 Problem Setup

In this work, we focus on the task of machine comprehension where the goal is to answer a question $\mathbf{q}$ based on a passage $\mathbf{p}$. We model this as an answer sentence selection task i.e., given the set of sentences in the passage $\mathbf{p}$, the task is to select the sentence $\mathbf{s} \in \mathbf{p}$ that contains the answer a. Treating QA as an answer sentence selection task is quite common in literature (e.g. see Yu et al., 2014). We model QG as the task of transforming a sentence in the passage into a question. Previous work in QG (Heilman and Smith, 2009) transforms text sentences into questions via some set of manually engineered rules. However, we take an end-to-end neural approach.

Let $\mathcal{D}^0$ be a labeled dataset of (passage, question, answer) triples where the answer is given by selecting a sentence in the passage. We also assume access to unlabeled text $\mathcal{T}$ which will be used to augment the training of the two models.

3 The Question Answering Model

Since we model QA as the task of selecting an answer sentence from the passage, we treat each sentence in the corresponding passage as a candidate answer for every input question.

We employ a neural network model inspired from the *Attentive Reader* framework proposed in Hermann et al. (2015); Chen et al. (2016). We map all words in the vocabulary to corresponding d dimensional vector representations via an embedding matrix $E \in \mathbb{R}^{d \times V}$. Thus, the input passage $\mathbf{p}$ can be denoted by the word sequence $\{p_1, p_2, \ldots p_{|\mathbf{p}|}\}$ and the question $\mathbf{q}$ can similarly be denoted by the word sequence $\{q_1, q_2, \ldots q_{|\mathbf{q}|}\}$ where each token $p_i \in \mathbb{R}^d$ and $q_i \in \mathbb{R}^d$.

We use a bi-directional LSTM (Graves et al., 2005) with dropout regularization as in Zaremba et al. (2014) to encode contextual embeddings of each word in the passage:

$$\vec{\mathbf{h}}_t = \mathit{LSTM}_1\left(p_t, \vec{\mathbf{h}}_{t-1}\right), \overleftarrow{\mathbf{h}}_t = \mathit{LSTM}_2\left(p_t, \overleftarrow{\mathbf{h}}_{t+1}\right)$$

The final contextual embeddings $\mathbf{h}_t$ are given by concatenation of the forward and backward pass embeddings: $\mathbf{h}_t = [\vec{\mathbf{h}}_t; \overleftarrow{\mathbf{h}}_t]$. Similarly, we use another bi-directional LSTM and encode contextual embeddings of each word in the question.

Then, we use attention mechanism (Bahdanau et al., 2014) to compute the alignment distribution a based on the relevance among passage words and the question: $a_i = \mathit{softmax}\left(\mathbf{q}^T \mathbf{W} \mathbf{h}_i\right)$. The output vector o is a weighted combination of all contextual embeddings: $\mathbf{o} = \sum_i a_i \mathbf{h}_i$. Finally, the correct answer a^* among the set of candidate answers $\mathcal{A}$ is given by: $a^* = \arg\max_{a \in \mathcal{A}} \mathbf{w}^T \mathbf{o}$.

We learn the model by maximizing the log-likelihood of correct answers. Given the training set $\{\mathbf{p}^{(i)}, \mathbf{q}^{(i)}, \mathbf{a}^{(i)}\}_{i=1}^N$, the log-likelihood is:

$$\mathcal{L}_{QA} = \sum_{i=1}^{N} \mathit{logP}\left(\mathbf{a}^{(i)} | \mathbf{p}^{(i)}, \mathbf{p}^{(i)}; \theta\right)$$

Here, θ represents all the model parameters to be estimated.

4 The Question Generation Model

We use a seq2seq model (Sutskever et al., 2014) with soft attention (Bahdanau et al., 2014) as our QG model. The model transduces an input sequence $\mathbf{x}$ to an input sequence $\mathbf{y}$. Here, the input sequence is a sentence in the passage and the output sequence is a generated question. Let $\mathbf{x} = \{x_1, x_2, \ldots, x_{|\mathbf{x}|}\}$, $\mathbf{y} = \{y_1, y_2, \ldots, y_{|\mathbf{y}|}\}$ and $\mathcal{Y}$ be the space of all possible output questions. Thus, we can represent the QG task as finding $\hat{\mathbf{y}} \in \mathcal{Y}$ such that: $\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} P(\mathbf{y}|\mathbf{x})$.

Here, $P(\mathbf{y}|\mathbf{x})$ is the conditional probability of a question sequence $\mathbf{y}$ given input sequence $\mathbf{x}$.

Decoder: Following Sutskever et al. (2014), the conditional factorizes over token level predictions:

$$P(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{|\mathbf{y}|} P(y_t | \mathbf{y}_{<t}, \mathbf{x})$$

Here, $\mathbf{y}_{<t}$ represents the subsequence of words generated prior to the time step t. For the decoder, we again follow Sutskever et al. (2014):

$$P(y_t | \mathbf{y}_{<t}, \mathbf{x}) = \mathit{softmax}\left(\mathbf{W} \mathit{tanh}\left(\mathbf{W}_t [\mathbf{h}_t^{(d)}; \mathbf{c}_t]\right)\right)$$

Here, $\mathbf{h}_t^{(d)}$ is the decoder RNN state at time step t, and $\mathbf{c}_t$ is the attention based encoding of the input sequence $\mathbf{x}$ at decoding time step t (described later). Also $\mathbf{W}$ and $\mathbf{W}_t$ are model parameters to be learned. We use an LSTM with dropout (Zaremba et al., 2014) as the decoder RNN. The LSTM generates the new decoder state $\mathbf{h}_t^{(d)}$ given the representation of previously generated word y_{t1} obtained using a look-up dictionary, and the previous decoder state $\mathbf{h}_{t-1}^{(d)}$.

Encoder: We use a bi-directional LSTM (Graves et al., 2005) with attention mechanism as our sentence encoder. We use two LSTM's: one that makes a forward pass in the sequence and another that makes a backward pass as in the QA model described earlier. We use dropout regularization for LSTMs as in Zaremba et al. (2014) in our implementation. The final context dependent token representation $\mathbf{h}_t^{(e)}$ is the concatenation of the forward and backward pass token representations: $\mathbf{h}_t^{(e)} = [\overrightarrow{\mathbf{h}}_t^{(e)}; \overleftarrow{\mathbf{h}}_t^{(e)}]$. To obtain the final context dependent token representation $\mathbf{c}_j$ at the decoding time step j, we take a weighted average over token representations: $\mathbf{c}_j^{(d)} = \sum_{i=1}^{|\mathbf{x}|} a_{ij}\mathbf{h}_i^{(e)}$. Following Bahdanau et al. (2014), the attention weights a_{ij} are calculated by bilinear scoring followed by softmax normalization:

$$\mathbf{a}_{ij} = \frac{\exp\left(\mathbf{h}_j^{(e)^T}\mathbf{W}\,\mathbf{h}_i^{(d)}\right)}{\sum_{i'}\exp\left(\mathbf{h}_j^{(e)^T}\mathbf{W}\,\mathbf{h}_{i'}^{(d)}\right)}$$

Learning and Inference: We train the encoder decoder framework by maximizing data log-likelihood on a large training set with respect to all the model parameters θ. Let $\{\mathbf{x}^{(i)}, \mathbf{y}^{(i)}\}_{i=1}^N$ be the training set. The log-likelihood can be written as:

$$\begin{aligned}\mathcal{L}_{QG} &= \sum_{i=1}^{N} logP\left(\mathbf{y}^{(i)}|\mathbf{x}^{(i)};\theta\right) \\ &= \sum_{i=1}^{N}\sum_{j=1}^{|\mathbf{y}^{(i)}|} logP\left(y_j^{(i)}|\mathbf{x}^{(i)}, \mathbf{y}_{<j}^{(i)};\theta\right)\end{aligned}$$

We use beam search for inference. As in previous works, we introduce a <UNK> token to model rare words during decoding. These <UNK> tokens are finally replaced by the token in the input sentence with the highest attention score.

5 Self-training Framework for Joint Training of QA and QG models

In our self-training framework, we are given unlabeled text in addition to the labeled passages, question and answer pairs. Self-training (Yarowsky, 1995; Riloff et al., 2003), also known as self-teaching, is one of the earliest techniques for using unlabeled data along with labeled data to improve learning. During self-training, the learner keeps on labeling unlabeled examples and retraining itself on an enlarged labeled training set. We extend self-training to jointly learn two models (namely, QA and QG) iteratively. The QA and QG models are first trained on the labeled corpus. Then, the QG model is used to create more questions from the unlabeled text corpus and the QA model is used to answer these newly created questions. These new questions (carefully selected by an oracle – details later) and the original labelled data is then used to (stochastically) update these two models. This procedure can be repeated as long as both the two models continue to improve.

Algorithm 1: Self-training QA and QG.

$\theta_{\mathbf{qa}}^{(\mathbf{0})} \leftarrow$ Train initial QA model.
$\theta_{\mathbf{qg}}^{(\mathbf{0})} \leftarrow$ Train initial QG model.
Init: i = 0
while *performance on dev set rises* **do**
  $\mathbf{CQ_i} \leftarrow$ Set of candidate questions generated using our QG model $\theta_{\mathbf{qg}}^{(\mathbf{i})}$ from the unlabeled text $\mathcal{T}$ which are not in $\mathcal{D}$.
  $\mathbf{Q_i} \leftarrow k \times m^i$ questions drawn from $\mathbf{CQ_i}$ using our question selector oracle $\mathcal{QS}$.
  $\mathbf{A_i} \leftarrow$ Set of answers to questions $\mathbf{Q_i}$ obtained using our QA model $\theta_{\mathbf{qa}}^{(\mathbf{i})}$.
  Let $\mathcal{D}^i$ be the set of chosen questions $\mathbf{Q_i}$ and answers $\mathbf{A_i}$.
  Subsample $\mathcal{S}_1 \subset \mathcal{D}^i$ of size k_1 and $\mathcal{S}_2 \subset \mathcal{D}^0$ of size k_2. Let $\mathcal{S} = \mathcal{S}_1 \cup \mathcal{S}_2$
  $\theta_{\mathbf{qa}}^{(\mathbf{i+1})} \leftarrow$ Update QA model on $\mathcal{S}$.
  $\theta_{\mathbf{qg}}^{(\mathbf{i+1})} \leftarrow$ Update QG model on $\mathcal{S}$.
  i++
end

Algorithm 1 describes the procedure in detail. In each succesive iteration, we allow the addition of more questions than that introduced in the previous iteration by a multiplicative factor. This sheme adds fewer questions initially when the QA and QG models are weak and more questions thereafter when the two models have (hopefully) improved. We found that this scheme works better in practice than addiing a fixed number of questions in each iteration. The two models are

updated on a subsample of the newly generated datapoints and original unlabelled data.

Self-training has been seldom used in NLP. Most prominently, it has been used for WSD (Yarowsky, 1995), noun learning (Riloff et al., 2003) and AMR parsing and generation (Konstas et al., 2017). However, it has not been explored in this way for QA and QG.

5.1 The Question Selection Oracle

A key challenge in self-training is selecting which unlabeled data sample to label (iwhich generated questions to add to the training set). The self-training process may erroneously generate some bad or incorrect questions which can sidetrack the learning process. Thus, we implement a question selection oracle which determines which questions to add among the potentially very large set of questions generated by the QG model in each iteration.

Traditional wisdom in self-training (Yarowsky, 1995; Riloff et al., 2003) advises selecting a subset of questions on which the models have the highest *confidence*. We experiment with this idea, proposing multiple self-training oracles which introduce questions in the order of how *confident* the QA and QG models are on the new potential question:

- **QG:** The QG oracle introduces the question in the order of how confident the QG model is on generating the question. This is calculated by a number of heuristics (described later).
- **QA:** The QA oracle introduces the question in the order of how confident the QA model is on answering the question. This too is calculated by some heuristics (described later).
- **QA+QG:** The QA+QG oracle introduces a question when both QA and QG models are confident about the question. The oracle computes the minimum confidence of the QA and QG models for a question and introduces questions which have the the highest minimum confidence score.

Our question selection heurisitcs are based on the ideas of *curriculum learning* and *diversity*:

1. *Curriculum learning* (Bengio et al., 2009; Sachan and Xing, 2016a) requires ordering questions on the easiness scale, so that easy questions can be introduced to the learning algorithm first and harder questions can be introduced successively. The main challenge in learning the curriculum is that it requires the identification of easy and hard questions. In our setting, such a ranking of easy and hard questions is difficult to obtain. A human judgement of 'easiness' of a question might not correlate with what is easy for our algorithms in its feature and hypothesis space. We explore various heuristics that define a measure of easiness and learn the ordering by selecting questions using this measure.
2. A number of cognitive scientists (Cantor, 1946) argue that alongside curriculum learning, it is important to introduce diverse (even if sometimes hard) samples. Inspired by this, we introduce a measure of *diversity* and show that we can achieve further improvements by coupling the curriculum learning heuristics with a measure for diversity.

Curriculum Learning: Studies in cognitive science (Skinner, 1958; Peterson, 2004; Krueger and Dayan, 2009) have shown that humans learn much better when the training examples are not randomly presented but organized in increasing order of difficulty. In the machine learning community, this idea was introduced with the nomenclature of *curriculum learning* (Bengio et al., 2009), where a curriculum is designed by ranking samples based on manually curated difficulty measures. A manifestation of this idea is self-paced learning (SPL) (Kumar et al., 2010; Jiang et al., 2014, 2015) which selects samples based on the local loss term of the sample. We extend this idea and explore the following heuristics for our various oracles:

1) Greedy Optimal (GO): The simplest greedy heuristic is to pick a question q which has the minimum expected effect on the QA and QG models. The expected effect on adding q can be written as:

$$\sum_{a \in \mathcal{A}} p(a^* = a) \mathbb{E}[\mathcal{L}_{QA/QG}]$$

Here, $\mathcal{L}_{QA/QG}$ is $\mathcal{L}_{QA}$, $\mathcal{L}_{QG}$ or $min\left(\mathcal{L}_{QA}, \mathcal{L}_{QG}\right)$ depending on which oracle we are using. $p(a^* = a)$ can be estimated by computing the scores of each of the answer candidates for q and normalizing them. $\mathbb{E}[\mathcal{L}_{QA/QG}]$ can be estimated by retraining the model(s) after adding this question.

2) Change in Objective (CiO): Choose question q that causes the smallest increase in $\mathcal{L}_{QA/QG}$. If

there are multiple questions with the smallest increase in objective, pick one of them randomly.

3) Mini-max (M^2): Choose question q that minimizes the expected risk when including the question with the answer candidate a that yields the maximum error.

$$\hat{q} = \arg\min_{q} \max_{a \in \mathcal{A}} \mathcal{L}_{QA/QG}$$

4) Expected Change in Objective (ECiO): In this greedy heuristic, we pick a question q which has the minimum expected effect on the model. The expected effect can be written as:

$$\sum_{a} p(a^* = a) \times \mathbb{E}\left[L_{QA/QG}\right]$$

Here, $p(a^* = a)$ can again be achieved by computing the scores of each of the answer candidates for q and normalizing them and $\mathbb{E}\left[L_{QA/QG}\right]$ can be estimated by evaluating the model.

5) Change in Objective-Expected Change in Objective (CiO - ECiO): We pick a question q which has the minimum value of the difference between the change in objective and the expected change in objective described above. Intuitively, the difference represents how much the model is surprised to see this new question.

Time Complexity: GO and CiO require updating the model, M^2 and ECiO require performing inference on candiate questions, and CiO - ECiO requires retraining as well as inference. Thus, M^2 and ECiO are computationally most efficient.

Ensembling: We introduce an ensembling strategy that combines the heuristics into an ensemble. We tried two ensembling strategies. The first strategy computes the average score over all the heuristics for all potential (top-K in beam) questions and picks questions with the highest average. The second strategy uses minimum instead of the average. Minimum works better than average in practice and we use it in our experiments. The use of minimum is inspired by agreement-based learning (Liang et al., 2008), a well-known extension of self-training which uses multiple views of the data (described using different feature sets or models) and adds new unlabeled samples to the training set when multiple models agree on the label.

Diversity: The strategy of introducing easy questions first and then gradually introducing harder questions is intuitive as it allows the learner to improve gradually. Yet, it has one key deficiency. With curriculum learning, by focusing on easy questions first, our learning algorithm is usually not exposed to a diverse set of questions. This is particularly a problem for deep-learning approaches that learn representations during the process of learning. Hence, when a harder question arrives, it can be difficult for the learner to adjust to the new question as the current representation may not be appropriate for the new level of question difficulty. We tackle this by introducing an explore and exploit (**E&E**) strategy. *E&E* ensures that while we still select easy questions first, we also want to make our selection as diverse as possible. We define a measure for diversity as the angle between the question vectors: $\angle \mathbf{q}_i, \mathbf{q}_j = \mathit{Cosine}^{-1}\left(\frac{|\mathbf{q}_i \mathbf{q}_j|}{||\mathbf{q}_i|| ||\mathbf{q}_j||}\right)$. *E&E* picks the question which optimizes a convex combination (tuned on the dev set) of the curriculum learning objective and sum of angles between the candidate questions and the questions in the training set.

6 Experiments

Implementation Details: We perform the same preprocessing on all the text. We lower-case all the text. We use NLTK for word tokenization. For training our neural networks, we only keep the most frequent 50k words (including entity and placeholder markers), and map all other words to a special <UNK> token. We choose word embedding size d = 100, and use the 100-dimensional pretrained GloVe word embeddings (Pennington et al., 2014) for initialization. We set k, m, k_1 and k_2 (hyperparameters for self-training) by grid search on a held-out development set.

Datasets: We report our results on four datasets: *SQUAD* (Rajpurkar et al., 2016), *MS MARCO* (Nguyen et al., 2016), *WikiQA* (Yang et al., 2015) and *TrecQA* (Wang et al., 2007). *SQUAD* is a cloze-style reading comprehension dataset with questions posed by crowd workers on a set of Wikipedia articles, where the answer to each question is a segment of text from the corresponding reading passage. *MS MARCO* contains questions which are real anonymized queries issued through *Bing* or *Cortana* and the documents are related web pages which may or help answer the question. *WikiQA* is also a datset of queries taken from Bing query logs. Based on user clicks, each query is associated with a Wikipedia page. The summary paragraph of the page is taken as candidate answer sentences, with labels on whether the sentence is a correct answer to the question provided by crowd

	SQUAD			MS MARCO			WikiQA			TrecQA

#Question-Answer Pairs	676,193	39,510	42,850	440,573	26,442	26,604	20,360	2,733	6,165	53,417	1,148	1,517

Table 1: Statistics of the four datasets used in evaluating our QA and QG models.

workers. Finally, *TrecQA* is a QA answer sentence selection dataset from the TREC QA track.

While *WikiQA* and *TrecQA* are directly answer sentence selection tasks, the other two are not. Hence, we treat the *SQUAD* and *MS MARCO* tasks as the answer sentence selection task assuming a one to one correspondence between answer sentences and annotated correct answer spans. Note that only a very small proportion of answers ($<$ 0.2% in training set) span two or more sentences. Since *SQUAD* and *MS MARCO* have a hidden test set, we only use the training and development sets for our evaluation purposes and we further split the provided development set into a dev and test set. This is also the data analysis setting used in previous works (Du et al., 2017; Tang et al., 2017). In fact, we use the same setting as in Tang et al. (2017) for comparison. The statistics of the four datasets and the respective train, dev and test splits are given in Table 1. For *WikiQA* and *TrecQA* datasets, we use the standard data splits. We use a large randomly subsampled corpus of English Wikipedia and use the first paragraph of each document as unlabeled text for self-training.

Evaluation Metrics: Following Tang et al. (2017), we evaluate our QA system with three standard evaluation metrics: *Mean Average Precision* (MAP), *Mean Reciprocal Rank* (MRR) and *Precision@1* (P@1). For QG, we follow Du et al. (2017) and use automatic evaluation metrics from MT and summarization: *BLEU-4* (Papineni et al., 2002), *METEOR* (Denkowski and Lavie, 2014) and $Rouge_L$ (Lin, 2004) to measure the overlap between generated and ground truth questions.

Baselines: For *SQUAD* and *MS MARCO* datasets, we use four QA baselines that have been used in previous works (Tang et al., 2017). The first two baselines, *WordCnt* and *NormWordCnt*, have been taken from Yang et al. (2015) and Yin et al. (2015), and are based on simple word overlap which have been shown to be strong baselines. These compute word co-occurrence between a question sentence and the candidate answer sentence. While *WordCnt* uses unnormalized word co-occurrence, *NormWordCnt* uses normalized word co-occurrence. The third and fourth baselines are *CDSSM* (Shen et al., 2014) and *ABCNN* (Yin et al., 2015) which use a neural network approach to model semantic relatedness of sentence pairs. For the *WikiQA* and *TrecQA* dataset, we report results of various existing state-of-the-art approaches on the two datasets[2].

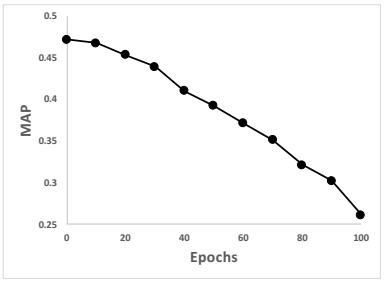

Figure 1: MAP for our best self-trained QA model (with 10,000 Wikipedia paragraphs) without any curriculum learning (i.e. candidate questions are added randomly) vs epochs.

For QG, we compare our model against the following four baselines used in previous work (Du et al., 2017). The first baseline is a simple *IR* baselines taken from Rush et al. (2015) which generates questions by memorizing them from the training set and uses edit distance (Levenshtein, 1966) to calculate distance between a question and the input sentence. The second baseline is a MT system – *MOSES* (Koehn et al., 2007) which models question generation as a translation task where raw sentences are treated as source texts and questions are treated as target texts. The third baseline, *DirectIn*, uses the longest sub-sentence of the input sentence (using a set of simple sentence splitters) as the question. The fourth baseline, *H&S* is a rule-based overgenerate-and-rank system proposed by Heilman and Smith (2010).

The Question Selection Oracle: The first question we wish to answer is: *Is careful question selection even necessary*? To answer this, we plot MAP scores for our best QA model (QA+QG, Ensemble+E&E) when we do not have a curriculum learning based oracle (i.e. an oracle which picks questions to be added to the dataset randomly) in Figure 1 as a function of epochs. We observe that

the MAP score degrades instead of improving with time. This supports our claim that we need to augment the training set by a more careful procedure.

We also plot MAP scores for our best QA model (Ensemble+E&E) when we use various question selection oracles as a function of the amount of unlabeled data in Figure 2. We can observe that when we do not have a curriculum learning based oracle, the MAP score degrades by having more and more unlabeled data. We also observe that the QA+QG oracle performs better than QA and QG which confirms that the best oracle is one that selects questions in increasing degree of hardness in terms of both question answering and question generation. This holds for all the experimental settings. Thus we only show results for the QA+QG strategies in our future experiments.

Evaluating Question Answering: First, we evaluate our models on the question answering task. *Ensemble+E&E(K)* is the variant where we perform self-training using K Wikipedia paragraphs. Hence, *Ensemble+E&E(0)* is the variant of our model without any self-training. We vary K to see the impact of the size of unlabeled Wikipedia paragraphs on the self-training model.

Table 4: Performance of our models and the QA baselines on the *TrecQA* dataset. Shaded part of the table shows the effect of various question selection heuristics when 10000 Wikipedia paragraphs are used as unlabeled data. Our model achieves the state-of-the-art.

Table 2 shows the results of the QA evaluations on the *SQUAD* and *MS MARCO* datasets. We can observe that our QA model has competetive or better performance over all the baselines on both datasets in terms of all the three evaluation metrics. When we incorporate ensembling or diversity, we see a further improvement in the result.

Tables 3 and 4 show results of QA evaluations on the *WikiQA* and *TrecQA* datasets, respectively. We can again observe that our QA model is competitive to all the baselines. When we introduce ensembling and diversity while jointly learning the QA and QG models, we see incremental improvements. In both these answer sentence selection tasks, our approach achieves new state-of-the-art.

Table 5: Performance (B: BLEU4, M: METEOR, and R: ROUGE) of our model variants and various QG baselines on *SQUAD*, *MS MARCO* and *WikiQA* datasets. The shaded part of the table shows the effect of various question selection heuristics when 10000 Wikipedia paragraphs are used as unlabeled data. The performance numbers for Tang et al. (2017) and Du et al. (2017) were not reported for all the settings.

Evaluating Question Generation: Table 5 shows the results for QG on the four datasets on each of the three evaluation metrics on all the four datasets. We can observe that the QG model described in our paper performs much better than all the baselines. We again observe that self-training while jointly training the QA and QG models leads to even better performance. These results show that self-training and leveraging the relationship between QA and QG is very useful for boosting the performance of the QA and QG models, while additionally only using cheap unlabeled data.

Human Evaluations: We asked two people not involved with this research to evaluate 1000 (randomly selected) questions generated by our best QG model and our best performing baseline (Du et al., 2017) on SQUAD for fluency and correctness on a scale of 1 to 5. The raters were also shown the passage sentence used to generate the question. The raters were blind to which system produced which question. The Pearson correlation between the raters' judgments was $r = 0.89$ for fluency and $r = 0.78$ for correctness. In our analyses, we used the averages of the two raters' judgments. The evaluation showed that our system generates questions that are more fluent and correct than those by the baseline. The mean fluency rating of our best system was 4.15 compared to 3.35 for the baseline, a difference which is statistically significant (t-test, $p < 0.001$).

Evaluating the Question Selection Oracle: As discussed earlier, the choice of which subset of questions to add to our labeled dataset while self-training is important. To evaluate the various heuristics proposed in our paper, we show the effect of the question selection oracle on the final QA and QG performance in Tables 2, 3, 4 and 5. These comparisions are shown in the shaded grey portions of the tables for self-training with 10,000 Wikipedia paragraphs as unlabeled data.

We can observe that all the proposed heuristics (and ensembling and diversity strategies) lead to improvements in the final performance of both QA and QG. The heuristics arranged in increasing order of performance are: M^2, *ECiO*, *GO*, *CiO* and *CiO-ECiO*. While the choice of which heuristic to pick seems to make a lesser impact on the final performance, we do see a much more significant performance gain by *ensembling* to combine the various heuristics and using *E&E* to incorporate diversity. The incorporatation of diversity is important because the neural network models which learnt latent represention of data usually find it hard to adjust to new level of difficulty of questions as the current representation may not be appropriate for the new level of difficulty.

Low data scenarios: A key advantage of our self-training approach is that it can leverage unlabeled text, and thus requires less labeled data. To test this, we plot MAP for our best self-training model and various QA baselines as we vary the proportion of labeled training set in Figure 3. However, we keep the unlabeled text fixed (10K Wikipedia paragraphs). We observe that all the baselines significantly drop in performance as we reduce the proportion of labeled training set. However, the drop happens at a much slower rate for our self-trained model. Thus, we can conclude that our approach requires less labeled data as compared to the baselines.

Does more unlabeled text always help?: Another important question is: *Does more unlabeled*

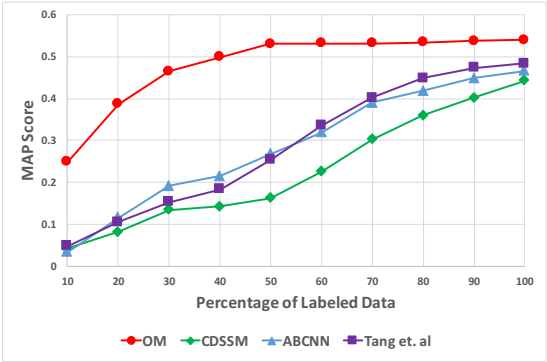

Figure 3: MAP for the best self-training model and QA baselines as we vary the proportion of labeled training set but keep the unlabeled text fixed (10K Wikipedia paragraphs).

text always improve our models? Will the performance improve if we add more and more unsupervised data during self-training. According to our results in Tables 2, 3, 4 and 5, the answer is "probably yes". As we can observe from these tables, the performance of the QA and QG models improves as we increase K, the size of the unsupervised data during training of the various *Ensemble+E&E(K)* models. Having said that, we do see a tapering effect on the performance results, so it is clear that the performance will be capped by some upper-bound and we will need better ways of modeling language and meaning to make progress.

7 Related Work

Our work proposes an approach for joint modeling QA and QG. While QA has recieved a lot of attention from the research community with large scale community evaluations such as *NTCIR*, *TREC*, *CLEF* spurring progress, the focus on QG is much more recent. Recently, there has been a renewed interest in reading comprehensions (also known as *machine comprehension* – a nomenclature popularized by Richardson et al. (2013)). Various approaches (Sachan et al., 2015; Wang et al., 2015; Sachan and Xing, 2016b; Sachan et al., 2016; Narasimhan and Barzilay, 2015) have been proposed for solving this task. After the release of large benchmarks such as *SQUAD*, *MS MARCO* and *WikiQA*, there has been a surge in interest on using neural network or deep-learning models for QA (Yin et al., 2015; Seo et al., 2016; Shen et al., 2016; Chen et al., 2017; Liu et al., 2017; Hu et al., 2017). In our work, we deal with the answer sentence selection task and adapt the *Attentive Reader* framework proposed in Hermann et al. (2015); Chen et al. (2016) as our base model. While, all these models were trained on question answer pairs, we propose a self-training solution to additionally leverage unsupervised text.

Similarly, there have been works on QG. Traditionally, rule based approaches with post-processing (Woo et al., 2016; Heilman and Smith, 2009, 2010) were the norm in QG. However, recent papers build on neural network approaches such as seq2seq (Du et al., 2017; Tang et al., 2017; Zhou et al., 2017), CNNs and RNNs (Duan et al., 2017) for QG. We also choose the seq2seq paradigm in our work. However, we leverage unsupervised text in contrast to these models.

Finally, some very recent works have concurrently recognized the relationship between QA and QG and have proposed joint training (Tang et al., 2017; Wang et al., 2017) for the two. Our work differs from these as we additionally propose self-training to leverage unlabeled data to improve the two models. Self-training has seldom been used in NLP. Most prominently, they have been used for word sense disambiguation (Yarowsky, 1995), noun learning (Riloff et al., 2003) and recently, AMR parsing and generation (Konstas et al., 2017). However, it has not been explored in this way for QA and QG.

An important decision in the workings of our self-training algorithm was the question selection using curriclum learning. While curriculum learning has seldom been used in NLP, we draw some ideas for curriculum learning from Sachan and Xing (2016a) who conduct a case study of curriculum learning for question answering. However, their work focuses only on QA and not QG.

8 Conclusion

We described self-training algorithms for jointly learning to answer and ask questions while leveraging unlabeled data. We experimented with neural models for question answering and question generation and various careful strategies for question filtering based on curriculum learning and diversity promotion. This led to improved performance for both question answering and question generation on multiple datasets and new state-of-the-art results on *WikiQA* and *TrecQA* datasets.

The Web as a Knowledge-base for Answering Complex Questions

Alon Talmor

Jonathan Berant
Tel-Aviv University
joberant@cs.tau.ac.il

Abstract

Answering complex questions is a time-consuming activity for humans that requires reasoning and integration of information. Recent work on reading comprehension made headway in answering simple questions, but tackling complex questions is still an ongoing research challenge. Conversely, semantic parsers have been successful at handling compositionality, but only when the information resides in a target knowledge-base. In this paper, we present a novel framework for answering broad and complex questions, assuming answering simple questions is possible using a search engine and a reading comprehension model. We propose to decompose complex questions into a sequence of simple questions, and compute the final answer from the sequence of answers. To illustrate the viability of our approach, we create a new dataset of complex questions, COMPLEXWEBQUESTIONS, and present a model that decomposes questions and interacts with the web to compute an answer. We empirically demonstrate that question decomposition improves performance from 20.8 precision@1 to 27.5 precision@1 on this new dataset.

1 Introduction

Humans often want to answer complex questions that require reasoning over multiple pieces of evidence, e.g., *"From what country is the winner of the Australian Open women's singles 2008?"*. Answering such questions in broad domains can be quite onerous for humans, because it requires searching and integrating information from multiple sources.

Recently, interest in question answering (QA) has surged in the context of reading comprehension (RC), where an answer is sought for a question given one or more documents (Hermann et al., 2015; Joshi et al., 2017; Rajpurkar et al., 2016).

Figure 1: Given a complex questions q, we decompose the question to a sequence of simple questions $q_1, q_2, \ldots$, use a search engine and a QA model to answer the simple questions, from which we compute the final answer a.

Neural models trained over large datasets led to great progress in RC, nearing human-level performance (Wang et al., 2017). However, analysis of models revealed (Jia and Liang, 2017; Chen et al., 2016) that they mostly excel at matching questions to local contexts, but struggle with questions that require reasoning. Moreover, RC assumes documents with the information relevant for the answer are available – but when questions are complex, even retrieving the documents can be difficult.

Conversely, work on QA through semantic parsing has focused primarily on compositionality: questions are translated to compositional programs that encode a sequence of actions for finding the answer in a knowledge-base (KB) (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Artzi and Zettlemoyer, 2013; Krishnamurthy and Mitchell, 2012; Kwiatkowski et al., 2013; Liang et al., 2011). However, this reliance on a manually-curated KB has limited the coverage and applicability of semantic parsers.

In this paper we present a framework for QA that is *broad*, i.e., it does not assume information is in a KB or in retrieved documents, and *compositional*, i.e., to compute an answer we must perform some computation or reasoning. Our thesis is that answering simple questions can be achieved

Proceedings of NAACL-HLT 2018, pages 641–651
New Orleans, Louisiana, June 1 - 6, 2018.

by combining a search engine with a RC model. Thus, answering complex questions can be addressed by decomposing the question into a sequence of simple questions, and computing the answer from the corresponding answers. Figure 1 illustrates this idea. Our model decomposes the question in the figure into a sequence of simple questions, each is submitted to a search engine, and then an answer is extracted from the search result. Once all answers are gathered, a final answer can be computed using symbolic operations such as union and intersection.

To evaluate our framework we need a dataset of complex questions that calls for reasoning over multiple pieces of information. Because an adequate dataset is missing, we created COMPLEXWEBQUESTIONS, a new dataset for complex questions that builds on WEBQUESTIONSSP, a dataset that includes pairs of simple questions and their corresponding SPARQL query. We take SPARQL queries from WEBQUESTIONSSP and automatically create more complex queries that include phenomena such as function composition, conjunctions, superlatives and comparatives. Then, we use Amazon Mechanical Turk (AMT) to generate natural language questions, and obtain a dataset of 34,689 question-answer pairs (and also SPARQL queries that our model ignores). Data analysis shows that examples are diverse and that AMT workers perform substantial paraphrasing of the original machine-generated question.

We propose a model for answering complex questions through question decomposition. Our model uses a sequence-to-sequence architecture (Sutskever et al., 2014) to map utterances to short programs that indicate how to decompose the question and compose the retrieved answers. To obtain supervision for our model, we perform a noisy alignment from machine-generated questions to natural language questions and automatically generate noisy supervision for training.[1]

We evaluate our model on COMPLEXWEBQUESTIONSand find that question decomposition substantially improves precision@1 from 20.8 to 27.5. We find that humans are able to reach 63.0 precision@1 under a limited time budget, leaving ample room for improvement in future work.

To summarize, our main contributions are:

[1]We differ training from question-answer pairs for future work.

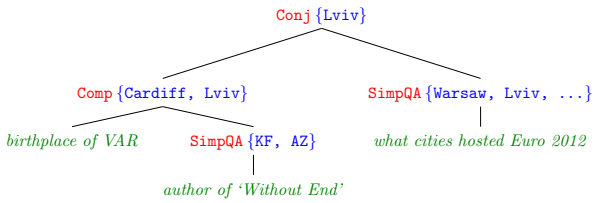

Figure 2: A computation tree for *"What city is the birthplace of the author of 'Without end', and hosted Euro 2012?"*. The leaves are strings, and inner nodes are functions (red) applied to their children to produce answers (blue).

1. A framework for answering complex questions through question decomposition.
2. A sequence-to-sequence model for question decomposition that substantially improves performance.
3. A dataset of 34,689 examples of complex and broad questions, along with answers, web snippets, and SPARQL queries.

Our dataset, COMPLEXWEBQUESTIONS, can be downloaded from http://nlp.cs.tau.ac.il/compwebq and our codebase can be downloaded from https://github.com/alontalmor/WebAsKB.

2 Problem Formulation

Our goal is to learn a model that given a question q and a black box QA model for answering simple questions, SIMPQA$(\cdot)$, produces a *computation tree* t (defined below) that decomposes the question and computes the answer. The model is trained from a set of N question-computation tree pairs $\{q^i, t^i\}_{i=1}^N$ or question-answer pairs $\{q^i, a^i\}_{i=1}^N$.

A computation tree is a tree where leaves are labeled with strings, and inner nodes are labeled with functions. The arguments of a function are its children sub-trees. To compute an answer, or *denotation*, from a tree, we recursively apply the function at the root to its children. More formally, given a tree rooted at node t, labeled by the function f, that has children $c_1(t), \ldots, c_k(t)$, the denotation $[\![t]\!] = f([\![c_1(t)]\!], \ldots, [\![c_k(t)]\!])$ is an arbitrary function applied to the denotations of the root's children. Denotations are computed recursively and the denotation of a string at the leaf is the string itself, i.e., $[\![l]\!] = l$. This is closely related to "semantic functions" in semantic parsing (Berant and Liang, 2015), except that we do not in-

teract with a KB, but rather compute directly over the breadth of the web through a search engine.

Figure 2 provides an example computation tree for our running example. Notice that words at the leaves are not necessarily in the original question, e.g., *"city"* is paraphrased to *"cities"*. More broadly, our framework allows paraphrasing questions in any way that is helpful for the function SIMPQA$(\cdot)$. Paraphrasing for better interaction with a QA model has been recently suggested by Buck et al. (2017) and Nogueira and Cho (2016).

We defined the function SIMPQA$(\cdot)$ for answering simple questions, but in fact it comprises two components in this work. First, the question is submitted to a search engine that retrieves a list of web snippets. Next, a RC model extracts the answer from the snippets. While it is possible to train the RC model jointly with question decomposition, in this work we pre-train it separately, and later treat it as a black box.

The expressivity of our QA model is determined by the functions used, which we turn to next.

3 Formal Language

Functions in our formal language take arguments and return values that can be strings (when decomposing or re-phrasing the question), sets of strings, or sets of numbers. Our set of functions includes:

1. SIMPQA$(\cdot)$: Model for answering simple questions, which takes a string argument and returns a set of strings or numbers as answer.
2. COMP$(\cdot,\cdot)$: This function takes a string containing one unique variable VAR, and a set of answers. E.g., in Figure 2 the first argument is *"birthplace of VAR"*, and the second argument is "{KEN FOLLETT, ADAM ZAGAJEWSKI}". The function replaces the variable with each answer string representation and returns their union. Formally, COMP$(q, \mathcal{A}) = \cup_{a \in \mathcal{A}}$SIMPQA$(q/a)$, where q/a denotes the string produced when replacing VAR in q with a. This is similar to function composition in CCG (Steedman, 2000), or a join operation in λ-DCS (Liang, 2013), where the string is a function applied to previously-computed values.
3. CONJ$(\cdot,\cdot)$: takes two sets and returns their intersection. Other set operations can be defined analogously. As syntactic sugar, we allow CONJ$(\cdot)$ to take strings as input, which means that we run SIMPQA$(\cdot)$ to obtain a set and then perform intersection. The root node in Figure 2 illustrates an application of CONJ.
4. ADD$(\cdot,\cdot)$: takes two singleton sets of numbers and returns a set with their addition. Similar functions can be defined analogously. While we support mathematical operations, they were not required in our dataset.

Other logical operations In semantic parsing superlative and comparative questions like *"What is the highest European mountain?"* or *"What European mountains are higher than Mont Blanc?"* are answered by joining the set of European mountains with their elevation. While we could add such functions to the formal language, answering such questions from the web is cumbersome: we would have to extract a list of entities and a numerical value for each. Instead, we handle such constructions using SIMPQA directly, assuming they are mentioned verbatim on some web document.

Similarly, negation questions (*"What countries are not in the OECD?"*) are difficult to handle when working against a search engine only, as this is an open world setup and we do not hold a closed set of countries over which we can perform set subtraction.

In future work, we plan to interface with tables (Pasupat and Liang, 2015) and KBs (Zhong et al., 2017). This will allow us to perform set operations over well-defined sets, and handle in a compositional manner superlatives and comparatives.

4 Dataset

Evaluating our framework requires a dataset of broad and complex questions that examine the importance of question decomposition. While many QA datasets have been developed recently (Yang et al., 2015; Rajpurkar et al., 2016; Hewlett et al., 2016; Nguyen et al., 2016; Onishi et al., 2016; Hill et al., 2015; Welbl et al., 2017), they lack a focus on the importance of question decomposition.

Most RC datasets contain simple questions that can be answered from a short input document. Recently, TRIVIAQA (Joshi et al., 2017) presented a larger portion of complex questions, but still most do not require reasoning. Moreover, the focus of TRIVIAQA is on answer extraction from documents that are given. We, conversely, highlight question decomposition for finding the relevant documents. Put differently, RC is complementary to question decomposition and can be used as part of the implementation of SIMPQA. In Sec-

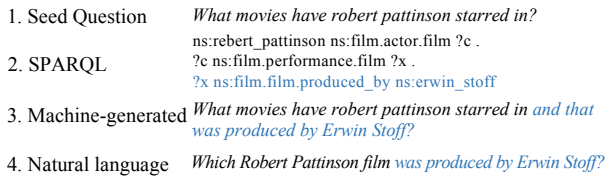

Figure 3: Overview of data collection process.

tion 6 we demonstrate that question decomposition is useful for two different RC approaches.

4.1 Dataset collection

To generate complex questions we use the dataset WEBQUESTIONSSP (Yih et al., 2016), which contains 4,737 questions paired with SPARQL queries for Freebase (Bollacker et al., 2008). Questions are broad but simple. Thus, we sample question-query pairs, automatically create more complex SPARQL queries, generate automatically questions that are understandable to AMT workers, and then have them paraphrase those into natural language (similar to Wang et al. (2015)). We compute answers by executing complex SPARQL queries against Freebase, and obtain broad and complex questions. Figure 3 provides an example for this procedure, and we elaborate next.

Generating SPARQL queries Given a SPARQL query r, we create four types of more complex queries: conjunctions, superlatives, comparatives, and compositions. Table 1 gives the exact rules for generation. For conjunctions, superlatives, and comparatives, we identify queries in WEBQUESTIONSSP whose denotation is a set $\mathcal{A}, |\mathcal{A}| \geq 2$, and generate a new query r' whose denotation is a strict subset $\mathcal{A}', \mathcal{A}' \subset \mathcal{A}, \mathcal{A}' \neq \phi$. For conjunctions this is done by traversing the KB and looking for SPARQL triplets that can be added and will yield a valid set $\mathcal{A}'$. For comparatives and superlatives we find a numerical property common to all $a \in \mathcal{A}$, and add a triplet and restrictor to r accordingly. For compositions, we find an entity e in r, and replace e with a variable y and add to r a triplet such that the denotation of that triplet is $\{e\}$.

Machine-generated (MG) questions To have AMT workers paraphrase SPARQL queries into natural language, we need to present them in an understandable form. Therefore, we automatically generate a question they can paraphrase. When we generate new SPARQL queries, new predicates are added to the query (Table 1). We manually annotated 687 templates mapping KB predicates to text for different compositionality types (with 462 unique KB predicates), and use those templates to modify the original WebQuestionsSP question according to the meaning of the generated SPARQL query. E.g., the template for $?x$ `ns:book.author.works_written obj` is *"the author who wrote OBJ"*. For brevity, we provide the details in the supplementary material.

Question Rephrasing We used AMT workers to paraphrase MG questions into natural language (NL). Each question was paraphrased by one AMT worker and validated by 1-2 other workers. To generate diversity, workers got a bonus if the edit distance of a paraphrase was high compared to the MG question. A total of 200 workers were involved, and 34,689 examples were produced with an average cost of 0.11$ per question. Table 1 gives an example for each compositionality type.

A drawback of our method for generating data is that because queries are generated automatically the question distribution is artificial from a semantic perspective. Still, developing models that are capable of reasoning is an important direction for natural language understanding and COMPLEXWEBQUESTIONS provides an opportunity to develop and evaluate such models.

To summarize, each of our examples contains a question, an answer, a SPARQL query (that our models ignore), and all web snippets harvested by our model when attempting to answer the question. This renders COMPLEXWEBQUESTIONS useful for both the RC and semantic parsing communities.

4.2 Dataset analysis

COMPLEXWEBQUESTIONS builds on the WEBQUESTIONS (Berant et al., 2013). Questions in WEBQUESTIONS are usually about properties of entities (*"What is the capital of France?"*), often with some filter for the semantic type of the answer (*"Which director"*, *"What city"*). WEBQUESTIONS also contains questions that refer to events with multiple entities (*"Who did Brad Pitt play in Troy?"*). COMPLEXWEBQUESTIONS contains all these semantic phenomena, but we add four compositionality types by generating composition questions (45% of the times), conjunctions (45%), superlatives (5%) and comparatives (5%).

Composit.	Complex SPARQL query r'	Example (natural language)
CONJ.	r. $?x$ pred_1 obj. **or** r. $?x$ pred_1 $?c$. $?c$ pred_2 obj.	*"What films star Taylor Lautner and have costume designs by Nina Proctor?"*
SUPER.	r. $?x$ pred_1 $?n$.ORDER BY DESC($?n$) LIMIT 1	*"Which school that Sir Ernest Rutherford attended has the latest founding date?"*
COMPAR.	r. $?x$ pred_1 $?n$. FILTER $?n < V$	*"Which of the countries bordering Mexico have an army size of less than 1050?"*
COMP.	$r[e/y]$. $?y$ pred_1 obj.	*"Where is the end of the river that originates in Shannon Pot?"*

Table 1: Rules for generating a complex query r' from a query r ('.' in SPARQL corresponds to logical and). The query r returns the variable $?x$, and contains an entity e. We denote by $r[e/y]$ the replacement of the entity e with a variable $?y$. pred_1 and pred_2 are any KB predicates, obj is any KB entity, V is a numerical value, and $?c$ is a variable of a CVT type in Freebase which refers to events. The last column provides an example for a NL question for each type.

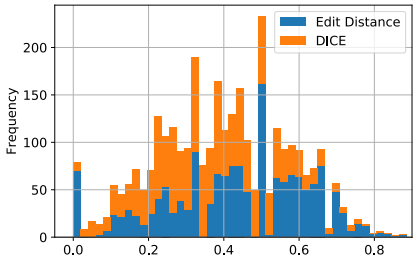

Figure 4: MG and NL questions similarity with normalized edit-distance, and the DICE coefficient (bars are stacked).

Paraphrasing To generate rich paraphrases, we gave a bonus to workers that substantially modified MG questions. To check whether this worked, we measured surface similarity between MG and NL questions, and examined the similarity. Using normalized edit-distance and the DICE coefficient, we found that NL questions are different from MG questions and that the similarity distribution has wide support (Figure 4).

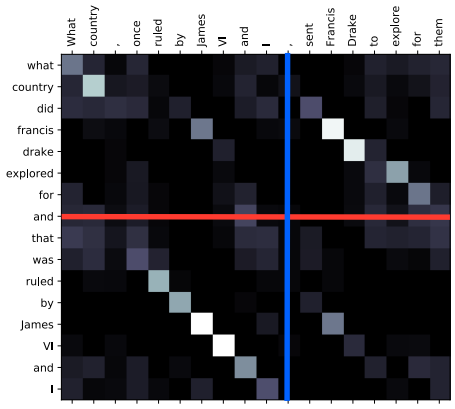

Figure 5: Heat map for similarity matrix between a MG and NL question. The red line indicates a known MG split point. The blue line is the approximated NL split point.

We created a heuristic for approximating the amount of word re-ordering performed by AMT workers. For every question, we constructed a matrix A, where A_{ij} is the similarity between token i in the MG question and token j in the NL question. Similarity is 1 if lemmas match, or cosine similarity according to GloVe embeddings (Pennington et al., 2014), when above a threshold, and 0 otherwise. The matrix A allows us to estimate whether parts of the MG question were re-ordered when paraphrased to NL (details in supplementary material). We find that in 44.7% of the conjunction questions and 13.2% of the composition questions, word re-ordering happened, illustrating that substantial changes to the MG question have been made. Figure 5 illustrates the matrix A for a pair of questions with re-ordering.

Qualitative analysis We randomly sampled 100 examples from the development set and manually identified prevalent phenomena in the data. We present these types in Table 2 along with their frequency. In 18% of the examples a conjunct in the MG question becomes a modifier of a wh-word in the NL question (WH-MODIFIER). In 22% substantial word re-ordering of the MG questions occurred, and in 42% a minor word re-ordering occurred (*"number of building floors is 50"* paraphrased as *"has 50 floors"*). AMT workers used a synonym in 54% of the examples, they omitted words in 27% of the examples and they added new lexical material in 29%.

To obtain intuition for operations that will be useful in our model, we analyzed the 100 examples for the types of operations that should be applied to the NL question during question decomposition. We found that splitting the NL question is insufficient, and that in 53% of the cases a word in the NL question needs to be copied to multiple questions after decomposition (row 3 in Table 3).

Type	MG question	NL question	%
WH-MODIFIER	*what movies does leo howard play in and that is 113.0 minutes long?*	*Which Leo Howard movie lasts 113 minutes?*	18%
MAJOR REORD.	*Where did the actor that played in the film Hancock 2 go to high school?*	*What high school did the actor go to who was in the movie Hancock 2?*	22%
MINOR REORD.	*what to do and see in vienna austria and the number of building floors is 50?*	*What building in Vienna, Austria has 50 floors?*	42%
SYNONYM	*where does the body of water under Kineshma Bridge start?*	*Where does the body of water under Kineshma Bridge originate?*	54%
SKIP WORD	*what movies did miley cyrus play in and involves organization Cirkus?*	*What movie featured Miley Cyrus and involved Cirkus?*	27%
ADD WORD	*what to do if you have one day in bangkok and the place is an amusement park that opened earliest?*	*Which amusement park, that happens to be the one that opened earliest, should you visit if you have only one day to spend in Bangkok?*	29%

Table 2: Examples and frequency of prevalent phenomena in the NL questions for a manually analyzed subset (see text).

Moreover, words that did not appear in the MG question need to be added in 39% of the cases, and words need to be deleted in 28% of the examples.

5 Model and Learning

We would like to develop a model that translates questions into arbitrary computation trees with arbitrary text at the tree leaves. However, this requires training from denotations using methods such as maximum marginal likelihood or reinforcement learning (Guu et al., 2017) that are difficult to optimize. Moreover, such approaches involve issuing large amounts of queries to a search engine at training time, incurring high costs and slowing down training.

Instead, we develop a simple approach in this paper. We consider a subset of all possible computation trees that allows us to automatically generate noisy full supervision. In what follows, we describe the subset of computation trees considered and their representation, a method for automatically generating noisy supervision, and a pointer network model for decoding.

Representation We represent computation trees as a sequence of tokens, and consider trees with at most one compositional operation. We denote a sequence of question tokens $q_{i:j} = (q_i, \ldots, q_j)$, and the decoded sequence by z. We consider the following token sequences (see Table 3):

1. `SimpQA`: The function SIMPQA is applied to the question q without paraphrasing. In prefix notation this is the tree $\text{SIMPQA}(q)$.
2. `Comp` i j: This sequence of tokens corresponds to the following computation tree: $\text{COMP}(q_{1:i-1} \circ \texttt{VAR} \circ q_{j+1:|q|}, \text{SIMPQA}(q_{i:j}))$, where $\circ$ is the concatenation operator. This is used for questions where a substring is answered by SIMPQA and the answers replace a variable before computing a final answer.
3. `Conj` i j: This sequence of tokens corresponds to the computation tree $\text{CONJ}(\text{SIMPQA}(q_{0:i-1}), \text{SIMPQA}(q_j \circ q_{i:|q|}))$. The idea is that conjunction can be answered by splitting the question in a single point, where one token is copied to the second part as well (*"film"* in Table 3). If nothing needs to be copied, then $j = -1$.

This representation supports one compositional operation, and a single copying operation is allowed without any re-phrasing. In future work, we plan to develop a more general representation, which will require training from denotations.

Supervision Training from denotations is difficult as it involves querying a search engine frequently, which is expensive. Therefore, we take advantage of the the original SPARQL queries and MG questions to generate noisy programs for composition and conjunction questions. Note that these noisy programs are only used as supervision to avoid the costly process of manual annotation, but the model itself does not assume SPARQL queries in any way.

We generate noisy programs from SPARQL queries in the following manner: First, we automatically identify composition and conjunction questions. Because we generated the MG question, we can exactly identify the split points (i, j in composition questions and i in conjunction questions) in the MG question. Then, we use a rule-based algorithm that takes the alignment matrix A (Section 4), and approximates the split points in the NL question and the index j to copy in conjunction questions. The red line in Figure 5 corresponds to the known split point in the MG question, and the blue one is the approximated split point in the NL question. The details of this rule-

Program	Question	Split
`SimpQA`	*"What building in Vienna, Austria has 50 floors"*	-
`Comp 5 9`	*"Where is the birthplace of the writer of Standup Shakespeare"*	*"Where is the birthplace of VAR"* *"the writer of Standup Shakespeare"*
`Conj 5 1`	*"What film featured Taylor Swift and was directed by Deborah Aquila"*	*"What film featured Taylor Swift"* *"film and was directed by Deborah Aquila"*

Table 3: Examples for the types of computation trees that can be decoded by our model.

based algorithm are in the supplementary material.

Thus, we obtain noisy supervision for all composition and conjunction questions and can train a model that translates questions q to representations $z = z_1\ z_2\ z_3$, where $z_1 \in \{\texttt{Comp}, \texttt{Conj}\}$ and z_2, z_3 are integer indices.

Pointer network The representation z points to indices in the input, and thus pointer networks (Vinyals et al., 2015) are a sensible choice. Because we also need to decode the tokens COMP and CONJ, we use "augmented pointer networks", (Zhong et al., 2017): For every question q, an augmented question $\hat{q}$ is created by appending the tokens "COMP CONJ" to q. This allows us to decode the representation z with one pointer network that at each decoding step points to one token in the augmented question. We encode $\hat{q}$ with a one-layer GRU (Cho et al., 2014), and decode z with a one-layer GRU with attention as in Jia and Liang (2016). The only difference is that we decode tokens from the augmented question $\hat{q}$ rather than from a fixed vocabulary.

We train the model with token-level cross-entropy loss, minimizing $\sum_j \log p_\theta(z_j|x, z_{1:j-1})$. Parameters θ include the GRU encoder and decoder, and embeddings for unknown tokens (that are not in pre-trained GloVe embeddings (Pennington et al., 2014)).

The trained model decodes COMP and CONJ representations, but sometimes using SIMPQA(q) without decomposition is better. To handle such cases we do the following: We assume that we always have access to a score for every answer, provided by the final invocation of SIMPQA (in CONJ questions this score is the maximum of the scores given by SIMPQA for the two conjuncts), and use the following rule to decide if to use the decoded representation z or SIMPQA(q). Given the scores for answers given by z and the scores given by SIMPQA(q), we return the single answer that has the highest score. The intuition is that the confidence provided by the scores of SIMPQA is correlated with answer correctness. In future work we will train directly from denotations and will handle all logical functions in a uniform manner.

6 Experiments

In this section, we aim to examine whether question decomposition can empirically improve performance of QA models over complex questions.

Experimental setup We used 80% of the examples in COMPLEXWEBQUESTIONS for training, 10% for development, and 10% for test, training the pointer network on 24,708 composition and conjunction examples. The hidden state dimension of the pointer network is 512, and we used Adagrad (Duchi et al., 2010) combined with L_2 regularization and a dropout rate of 0.25. We initialize 50-dimensional word embeddings using GloVe and learn embeddings for missing words.

Simple QA model As our SIMPQA function, we download the web-based QA model of Talmor et al. (2017). This model sends the question to Google's search engine and extracts a distribution over answers from the top-100 web snippets using manually-engineered features. We re-train the model on our data with one new feature: for every question q and candidate answer mention in a snippet, we run RASOR, a RC model by lee et al. (2016), and add the output logit score as a feature. We found that combining the web-facing model of Talmor et al. (2017) and RASOR, resulted in improved performance.

Evaluation For evaluation, we measure precision@1 (p@1), i.e., whether the highest scoring answer returned string-matches one of the correct answers (while answers are sets, 70% of the questions have a single answer, and the average size of the answer set is 2.3).

We evaluate the following models and oracles:

1. SIMPQA: running SIMPQA on the entire question, i.e., without decomposition.
2. SPLITQA: Our main model that answers complex questions by decomposition.
3. SPLITQAORACLE: An *oracle* model that chooses whether to perform question decom-

System	Dev.	Test
SIMPQA	20.4	20.8
SPLITQA	29.0	27.5
SPLITQAORACLE	34.0	33.7
RCQA	18.7	18.6
SPLITRCQA	21.5	22.0
GOOGLEBOX	2.5	-
HUMAN	63.0	-

Table 4: precision@1 results on the development set and test set for COMPLEXWEBQUESTIONS.

position or use SIMPQA in hindsight based on what performs better.

4. RCQA: This is identical to SIMPQA, except that we replace the RC model from Talmor et al. (2017) with the the RC model DOCQA (Clark and Gardner, 2017), whose performance is comparable to state-of-the-art on TRIVIAQA.
5. SPLITRCQA: This is identical to SPLITQA, except that we replace the RC model from Talmor et al. (2017) with DOCQA.
6. GOOGLEBOX: We sample 100 random development set questions and check whether Google returns a box that contains one of the correct answers.
7. HUMAN: We sample 100 random development set questions and manually answer the questions with Google's search engine, including all available information. We limit the amount of time allowed for answering to 4 minutes.

Table 4 presents the results on the development and test sets. SIMPQA, which does not decompose questions obtained 20.8 p@1, while by performing question decomposition we substantially improve performance to 27.5 p@1. An upper bound with perfect knowledge on when to decompose is given by SPLITQAORACLE at 33.7 p@1.

RCQA obtained lower performance SIMPQA, as it was trained on data from a different distribution. More importantly SPLITRCQA outperforms RCQA by 3.4 points, illustrating that this RC model also benefits from question decomposition, despite the fact that it was not created with question decomposition in mind. This shows the importance of question decomposition for retrieving documents from which an RC model can extract answers. GOOGLEBOX finds a correct answer in 2.5% of the cases, showing that complex questions are challenging for search engines.

To conclude, we demonstrated that question decomposition substantially improves performance on answering complex questions using two independent RC models.

Analysis We estimate human performance (HUMAN) at 63.0 p@1. We find that answering complex questions takes roughly 1.3 minutes on average. For questions we were unable to answer, we found that in 27% the answer was correct but exact string match with the gold answers failed; in 23.1% the time required to compute the answer was beyond our capabilities; for 15.4% we could not find an answer on the web; 11.5% were of ambiguous nature; 11.5% involved paraphrasing errors of AMT workers; and an additional 11.5% did not contain a correct gold answer.

SPLITQA decides if to decompose questions or not based on the confidence of SIMPQA. In 61% of the questions the model chooses to decompose the question, and in the rest it sends the question as-is to the search engine. If one of the strategies (decomposition vs. no decomposition) works, our model chooses that right one in 86% of the cases. Moreover, in 71% of these answerable questions, only one strategy yields a correct answer.

We evaluate the ability of the pointer network to mimic our labeling heuristic on the development set. We find that the model outputs the exact correct output sequence 60.9% of the time, and allowing errors of one word to the left and right (this often does not change the final output) accuracy is at 77.1%. Token-level accuracy is 83.0% and allowing one-word errors 89.7%. This shows that SPLITQA learned to identify decomposition points in the questions. We also observed that often SPLITQA produced decomposition points that are better than the heuristic, e.g., for *"What is the place of birth for the lyricist of Roman Holiday"*, SPLITQA produced *"the lyricist of Roman Holiday"*, but the heuristic produced *"the place of birth for the lyricist of Roman Holiday"*. Additional examples of SPLITQA question decompositions are provided in Table 5.

ComplexQuestions To further examine the ability of web-based QA models, we run an experiment against COMPLEXQUESTIONS (Bao et al., 2016), a small dataset of question-answer pairs designed for semantic parsing against Freebase.

We ran SIMPQA on this dataset (Table 6) and obtained 38.6 F_1 (the official metric), slightly lower than COMPQ, the best system, which op-

Question	Split-1	Split-2
"Find the actress who played Hailey Rogers, what label is she signed to"	*"the actress who played Hailey Rogers"*	*"Find VAR, what label is she signed to"*
"What are the colors of the sports team whose arena stadium is the AT&T Stadium"	*"the sports team whose arena stadium is the AT&T Stadium"*	*"What are the colors of VAR"*
"What amusement park is located in Madrid Spain and includes the stunt fall ride"	*"What amusement park is located in Madrid Spain and"*	*"park includes the stunt fall ride"*
"Which university whose mascot is The Trojan did Derek Fisher attend"	*"Which university whose mascot is The Trojan did"*	*"university Derek Fisher attend"*

Table 5: Examples for question decompositions from SPLITQA.

System	Dev. F_1	Test F_1
SIMPQA	40.7	38.6
SPLITQARULE	43.1	39.7
SPLITQARULE++	46.9	-
COMPQ	-	**40.9**

Table 6: F_1 results for COMPLEXQUESTIONS.

erates directly against Freebase. [2] By analyzing the training data, we found that we can decompose COMP questions with a rule that splits the question when the words *"when"* or *"during"* appear, e.g., *"Who was vice president when JFK was president?"*.[3] We decomposed questions with this rule and obtained 39.7 F_1 (SPLITQARULE). Analyzing the development set errors, we found that occasionally SPLITQARULE returns a correct answer that fails to string-match with the gold answer. By manually fixing these cases, our development set F_1 reaches 46.9 (SPLITQARULE++). Note that COMPQ does not suffer from any string matching issue, as it operates directly against the Freebase KB and thus is guaranteed to output the answer in the correct form. This short experiment shows that a web-based QA model can rival a semantic parser that works against a KB, and that simple question decomposition is beneficial and leads to results comparable to state-of-the-art.

7 Related work

This work is related to a body of work in semantic parsing and RC, in particular to datasets that focus on complex questions such as TRIVIAQA (Joshi et al., 2017), WIKIHOP (Welbl et al., 2017) and RACE (Lai et al., 2017). Our distinction is in proposing a framework for complex QA that focuses on question decomposition.

Our work is related to Chen et al. (2017) and Watanabe et al. (2017), who combined retrieval and answer extraction on a large set of documents. We work against the entire web, and propose question decomposition for finding information.

This work is also closely related to Dunn et al. (2017) and Buck et al. (2017): we start with questions directly and do not assume documents are given. Buck et al. (2017) also learn to phrase questions given a black box QA model, but while they focus on paraphrasing, we address decomposition.

Another important related research direction is Iyyer et al. (2016), who answered complex questions by decomposing them. However, they used crowdsourcing to obtain direct supervision for the gold decomposition, while we do not assume such supervision. Moreover, they work against web tables, while we interact with a search engine against the entire web.

8 Conclusion

In this paper we propose a new framework for answering complex questions that is based on question decomposition and interaction with the web. We develop a model under this framework and demonstrate it improves complex QA performance on two datasets and using two RC models. We also release a new dataset, COMPLEXWEBQUESTIONS, including questions, SPARQL programs, answers, and web snippets harvested by our model. We believe this dataset will serve the QA and semantic parsing communities, drive research on compositionality, and push the community to work on holistic solutions for QA.

In future work, we plan to train our model directly from weak supervision, i.e., denotations, and to extract information not only from the web, but also from structured information sources such as web tables and KBs.

Acknowledgements

We thank Jonatahn Herzig, Ni Lao, and the anonymous reviewers for their constructive feedback. This work was supported by the Samsung runway project and the Israel Science Foundation, grant 942/16.

[2] By adding the output logit from RASOR, we improved test F_1 from 32.6, as reported by Talmor et al. (2017), to 38.6.

[3] The data is too small to train our decomposition model.

Abstract

We introduce *MeSys*, a *meaning-based* approach, for solving English math word problems (MWPs) via *understanding and reasoning* in this paper. It first analyzes the text, transforms both body and question parts into their corresponding logic forms, and then performs inference on them. The associated context of each quantity is represented with proposed *role-tags* (e.g., *nsubj*, *verb*, etc.), which provides the flexibility for annotating an extracted *math quantity* with its associated context information (i.e., the *physical meaning* of this quantity). Statistical models are proposed to select the operator and operands. A noisy dataset is designed to assess if a solver solves MWPs mainly via understanding or mechanical pattern matching. Experimental results show that our approach outperforms existing systems on both benchmark datasets and the noisy dataset, which demonstrates that the proposed approach understands the meaning of each quantity in the text more.

1 Introduction

The *math word problem* (MWP) (see Figure 1) is frequently chosen to study natural language understanding and simulate human problem solving (Bakman, 2007; Hosseini et al., 2014; Liang et al., 2016) for the following reasons: (1) the answer to the MWP cannot be simply extracted by performing keyword/pattern matching. It thus shows the merit of understanding and inference.

Math Word Problem
Mike takes 88 minutes to walk to school. If he rides a bicycle to school, it would save him 64 minutes. How much time did Mike save?
Solution
88 – 64 = 22

Figure 1: An example of math word problem.

(2) An MWP usually possesses less complicated syntax and requires less amount of domain knowledge, so the researchers can focus on the task of understanding and reasoning. (3) The body part of MWP that provides the given information for solving the problem consists of only a few sentences. The understanding and reasoning procedures thus could be more efficiently checked. (4) The MWP solver has its own applications such as *Computer Math Tutor* (for students in primary school) and *Helper for Math in Daily Life* (for adults who are not good in solving mathematics related real problems).

According to the approaches used to identify entities, quantities, and to select operations and operands, previous MWP solvers can be classified into: (1) Rule-based approaches (Mukherjee and Garain, 2008[1]; Hosseini et al., 2014), which make all related decisions based on a set of rules; (2) Purely statistics-based approaches (Kushman et al., 2014; Roy et al., 2015; Zhou et al., 2015; Upadhyay et al., 2016), in which all related decisions are done via a statistical classifier; (3) DNN-based approaches (Ling et al., 2017; Wang et al., 2017), which map the given text into the corresponding math operation/equation via a DNN; and (4) Mixed approaches, which identify entities and quantities with rules, yet, decide operands and operations via statistical/DNN classifiers. This category can be further divided into two subtypes: (a) Without understanding (Roy and Roth, 2015; Koncel-Kedziorski et al., 2015; Huang et al., 2017; Shrivastava et al., 2017), which does not check the entity-attribute consistency between each quantity and the target of the given question; and (b) With understanding (Lin et al., 2015; Mitra and Baral, 2016; Roy and Roth, 2017), which also checks the entity-attribute consistency while solving the problem.

[1] It is a survey paper which reviews most of the rule-based approaches before 2008.

Proceedings of NAACL-HLT 2018, pages 652–662
New Orleans, Louisiana, June 1 - 6, 2018.

However, a widely covered rule-set is difficult to construct for the rule-based approach. Also, it is awkward in resolving ambiguity problem. In contrast, the performance of purely statistics-based approaches deteriorates significantly when the MWP includes either irrelevant information or information gaps (Hosseini et al., 2014), as it is solved without first understanding the meaning.

For the category (4a), since the physical meaning is only implicitly utilized and the result is not generated via inference, it would be difficult to explain how the answer is obtained in a human comprehensible way. Therefore, the categories (2), (3) and (4a) belong to the less favored direct translation approach[2] (Pape, 2004).

In contrast, the approaches of (4b) can avoid the problems mentioned above. However, among them, Mitra and Baral (2016) merely handled *Addition* and *Subtraction*. Only the *meaning-based framework* proposed by Lin et al. (2015) can handle general MWPs via understanding and reasoning. Therefore, it is possible to explain how the answer is obtained in a human comprehensible way (Huang et al., 2015). However, although their design looks promising, only a few Chinese MWPs had been tested and performance was not evaluated. Accordingly, it is hard to make a fair comparison between their approach and other state-of-the-art methods. In addition, in their prototype system, the desired operands of arithmetic operations are identified with predefined lexico-syntactic patterns and ad-hoc rules. Reusing the patterns/rules designed for Chinese in another language is thus difficult even if it is possible.

In this paper, we adopt the framework proposed by Lin et al. (2015) to solve English MWPs (for its potential in solving difficult/complex MWPs and providing more human comprehensible explanations). Additionally, we make the following improvements: (1) A new statistical model is proposed to select operands for arithmetic operations, and its model parameters can be automatically learnt via weakly supervised learning (Artzi and Zettlemoyer, 2013). (2) A new informative and robust feature-set is proposed to select the desired arithmetic operation. (3) We show the proposed approach significantly outperforms other existing systems on the common benchmark datasets reported in the literature. (4) A noisy dataset with more irrelevant quantities in MWPs is created and released. It could be used to check if an approach really understands what a given MWP looks for. (5) An experiment is conducted to compare various approaches on this new dataset. The superior performance of our system demonstrates that the proposed meaning-based approach has good potential in handling difficult/complex MWPs.

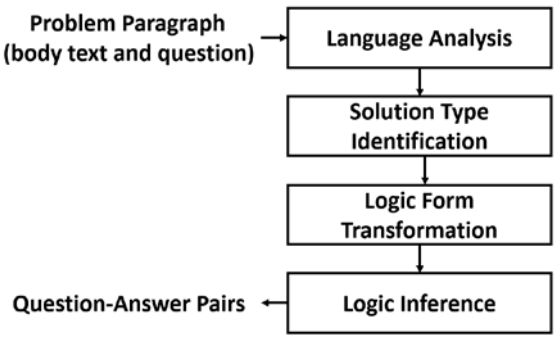

Figure 2: The diagram of *MeSys* framework

2 System Description

The adopted meaning-based framework (Lin et al., 2015) is a pipeline with following four stages (see Figure 2): (1) *Language Analysis*, (2) *Solution Type Identification*, (3) *Logic Form Transformation* and (4) *Logic Inference*. We use the Stanford CoreNLP suite (Manning et al., 2014) as the language analysis module. The other three modules are briefly described below. Last, we adopt the *weakly supervised learning* (Artzi and Zettlemoyer, 2013; Kushman et al., 2014) to automatically learn the model parameters without manually annotating each MWP with the adopted solution type and selected operands benchmark.

2.1 Solution Type Identification (STI)

After language analysis, each MWP is assigned with a specific solution type (such as *Addition*, *Multiplication*, etc.) which indicates the stereotype math operation pattern that should be adopted to solve this problem. We classify the English MWPs released by Hosseini et al. (2014) and Roy and Roth (2015) into 6 different types: *Addition*, *Subtraction*, *Multiplication*, *Division*, *Sum* and *TVQ-F*[3]. An SVM (Chang and Lin, 2011) is used to identify the solution type with 26 features. Most of them are derived from some important properties associated with each quantity.

[2] According to (Pape, 2004), the meaning-based approach of solving MWPs achieves the best performance among various behaviors adopted by middle school children.

[3] *TVQ-F* means to get the final state of a Time-Variant-Quantity that involves both Addition and Subtraction.

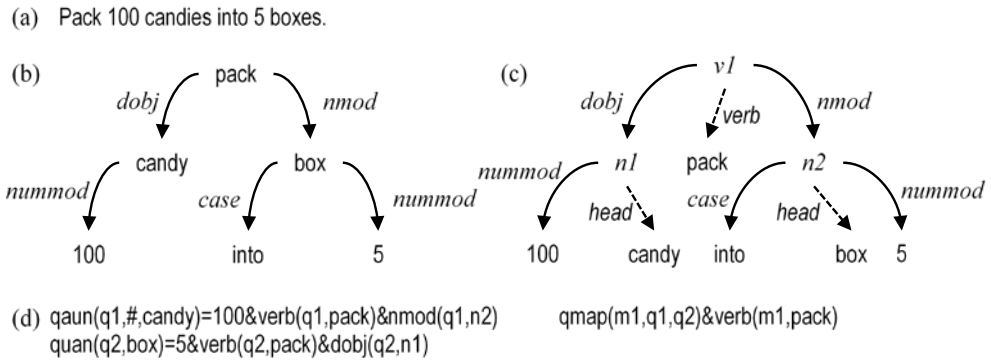

Figure 3: An example of logic form transformation

In addition to the properties *Entity*[4] and *Verb* (Hosseini et al., 2014) associated with the *quantity*, we also introduce a new property *Time* which encodes the tense and aspect of a verb into an integer to specify a point in the timeline. We assign 2, 4, and 6 to the tenses *Past*, *Present* and *Future*, respectively, and then adjust it with the aspect-values -1, 0 and 1 for *Perfect*, *Simple*, and *Progressive*, respectively.

Another property *Anchor* is associated with the *unknown quantity* asked in the question sentence. If the subject of the question sentence is a noun phrase (e.g., "*how many apples does **John** have?*"), *Anchor* is the *subject* (i.e., *John*). If the subject is an expletive nominal (e.g. "*how many apples are there in the box?*"), then *Anchor* is the associated nominal modifier *nmod* (i.e., "*box*"). Otherwise, *Anchor* is set to "*Unknown*".

Inspired by (Hosseini et al., 2014), we transform *Verb* to *Verb-Class* (*VC*) which is *positive*, *negative* or *stative*. A verb is *positive/negative* if it increases/decreases the associated quantity of the subject. For example, in the sentence "*Tom borrowed 3 dollars from Mike*", the verb is *positive* because the money of subject "*Tom*" increases.

However, a *positive* verb does not always imply the *Addition* operation. If the question is "*How much money does Mike have now?*" for the above body sentence, *the operation* should be *Subtraction*. Two new properties *Anchor-Role* (*AR*) and *Action* (*A*) are thus proposed: AR_i indicates the role that *Anchor* associated with q_i, and is set to *nsubj*/*obj*/*nmod*/ϕ. A_i is determined by following rules: (1) A_i=*positive if* (VC_i, AR_i) is either (*positive*, *nsubj*) or (*negative*, *obj*/*nmod*). (2) A_i=*negative if* (VC_i, AR_i) is either (*negative*, *nsubj*) or (*positive*, *obj*/*nmod*). (3) Otherwise, $A_i=VC_i$.

To rule out the noisy quantities introduced by irrelevant information, we further associate each known quantity with the property *Relevance* (*R*) according to the unknown quantity asked in the question sentence. Let q_i denote the *i*-th known quantity, E_i denote the entity of q_i, X_i denote the property *X* of q_i, q_U denote the unknown quantity asked, and X_U denote the property *X* of q_U. R_i is specified with following rules: (1) $R_i=2$ (Directly-Related) if either {*Anchor is Unknown* & E_i *entails* E_U} or {*Anchor is not Unknown* & $AR_i \neq \phi$ & E_i entails E_U} (2) $R_i=1$ (Indirectly-Related) if there is a q_j which maps[5] to q_i and $R_j=2$ (i.e., q_j is Directly-Related). (3) $R_i=0$ (Unrelated) otherwise.

The solution type is identified by an SVM based on 26 binary features. Let the symbols **p**, **n**, **s**, *A*, *E*, *R*, *T*, *V*, S_B, S_Q and w_Q stand for *positive*, *negative*, *stative*, *Action*, *Entity*, *Relevance*, *Time*, *Verb*, "*a body sentence*", "*the question sentence*" and "*a word in question sentence*" respectively. Also, let $I(x)$ be the indicator function to check if x is true. The 26 features are briefly described as follows:

(1) VC_U=**p**; (2) $\exists R_i$=2 s.t. A_i=**p**; (3) $\exists R_i$=2 s.t. A_i=**n**;
(4) $\exists R_i$=2 s.t. A_i=**s**; (5) $\sum_i I(R_i=2) > 2$;
(6) $\sum_i I(R_i=2 \,\&\, A_i \in \{\mathbf{p}, \mathbf{n}\}) = 2$;
(7) $\exists R_i$=2 s.t. A_i=**p** & $T_U<T_i$;
(8) $\exists R_i$=2 s.t. A_i=**n** & $T_U<T_i$;
(9) $\exists R_i$=2 s.t. A_i=**s** & T_i=max T_j;
(10) $\exists R_i$=2 s.t. A_i=**s** & $T_i<T_U$;
(11) $T_U \geq \max T_i$; (12) $T_U \leq \min T_i$;
(13) $\forall R_i$=2, V_i are the same; (14) $\forall R_i$=2 s.t. $T_i=T_U$;
(15) $\forall R_i$=2, T_i are the same;
(16) $\exists R_i$=2, $\exists R_j$=1 s.t. q_i maps to q_j & $q_i > q_j$;

[4] In our works, the term "*Entity*" also includes the unit of the quantity (e.g., "*cup of coffee*").

[5] That is, q_i is linked to a directly-related quantity q_j under an expression such as "*2 pencils weigh 30 grams*".

(a) A sandwich is priced at $0.75. A pudding is priced at $0.25. Tim bought 2 sandwiches and 4 puddings. Mary bought 2 puddings. How much money should Tim pay?

(b) …price(sandwich,0.75)&price(pudding,0.25)… quan(q1,#,sandwich)=2&verb(q1,buy)&nsubj(q1,Tim)… quan(q2,#,pudding)=4&verb(q2,buy)&nsubj(q2,Tim)… quan(q3,#,pudding)=2&verb(q3,buy)&nsubj(q3,Mary)… ASK Sum(quan(?q,dollar,#),verb(?q,pay)&nsubj(?q,Tim))

(c) quan(?q,?u,?o)&verb(?q,buy)&nsubj(?q,?a)&price(?o,?p) → quan($q,dollar,#)=quan(?q,?u,?o)×?p & verb($q,pay) & nsubj($q,?a)

(d) quan(q4,dollar,#)=1.5&verb(q4,pay)&nsubj(q4,Tim)… quan(q5,dollar,#)=1&verb(q5,pay)&nsubj(q5,Tim)… quan(q6,dollar,#)=0.5&verb(q6,pay)&nsubj(q6,Mary)

Figure 4: A logic inference example

(17) $\exists R_i$=2, $\exists R_j$=1 s.t. q_i maps to q_j & q_i is associated with a word "each/every/per/a/an";
(18) $\exists R_i$=2, $\exists R_j$=1 s.t. q_i maps to q_j & q_j is associated with a word "each/every/per/a/an";
(19) $\exists q_i, q_j, q_k$ s.t. $R_i = R_j = R_k$ =2 & $V_i = V_j = V_k$;
(20) $\exists w_Q \in$ {*total, in all, altogether, sum*};
(21) $\exists w_Q \in$ {*more, than}* or $\exists w_Q$ s.t. w_Q-POS=RBR;
(22) $\exists w_Q$ ="*left*"; (23). $\exists q_i$ appears in S_Q;
(24) "the rest ∨ E_U" appears in S_B (∨ for any verb);
(25) "each NN" appears in S_Q (NN for any noun);
(26) *Anchor*$_U$ is *Unknown*/*nmod* & VC_U = **s**.

2.2 Logic Form Transformation (LFT)

The results of language analysis are transformed into a logic form, which is expressed with the *first-order logic* (FOL) formalism (Russell and Norvig, 2009). Figure 3 shows how to transform the sentence (a) "*Pack 100 candies into 5 boxes.*" into the corresponding logic form (d). First, the dependency tree (b) is transformed into the semantic representation tree (c) adopted by Lin et al., (2015). Afterwards, according to the procedure proposed in (Lin et al., 2015), the domain-dependent logic expressions are generated in (d).

The domain-dependent logic expressions are related to crucial generic math facts, such as *quantities* and *relations* between quantities. The FOL function *quan(quan$_{id}$, unit[6],entity)=number* is for describing the quantity fact. The first argument denotes its unique *identifier*. The other arguments and the function value describe its meaning. Another FOL predicate *qmap(map$_{id}$, quan$_{id1}$, quan$_{id2}$)* (denotes the mapping from *quan$_{id1}$* to *quan$_{id2}$*) is for describing a relation between two quantity facts, where the first argument is a unique identifier to represent this relation.

The role-tags (e.g., *verb*, *dobj*, etc.) associated with *quan$_{id}$* and *map$_{id}$* denote entity attributes (i.e., the physical meaning of the quantity), are created to help the logic inference module find the solution. For example, *quan(q_2,#,box) = 5 & verb(q_2,pack) &…* means that q_2 is the quantity of boxes being packed. With those role-tags, the system can select the operands more reliably, and the inference engine can also derive new quantities to solve complex MWPs which require multi-step arithmetic operations (see section 2.3).

The question in the MWP is also transformed into an FOL-like utility function according to the solution type to ask the logic inference module to find out the answer. For example, the utility function instance *Division(quan(q_1, #, candy), quan(q_2, #, box))* asks the inference module to divide "*100 candies*" by "*5 boxes*". Since associated operands must be specified before calling those utility functions, a statistical model (see section 2.4) is used to identify the appropriate quantities.

2.3 Logic Inference

The logic inference module adopts the inference engine from (Lin et al., 2015). Figure 4 shows how it uses inference rules to derive new facts from the initial facts directly provided from the description. The MWP (a) provides some facts (b) generated from the LFT module. An inference rule (c)[7], which implements the common sense that people must pay money to buy something, is unified with the given facts (b) and derives new facts (d). The facts associated with *q6* can be interpreted as "*Mary paid 0.5 dollar for two puddings*".

The inference engine (IE) also provides 5 utility functions, including *Addition*, *Subtraction*, *Multiplication* and *Division*, and *Sum*. The first four utilities all return a value by performing the named math operation on its two input arguments. On the other hand, *Sum(function,condition)* returns the sum of the values of FOL *function instances* which can be unified with the first argument (i.e., *function*) and satisfy the second argument (i.e., *condition*). For example, according to

[6] This second argument denotes the associated unit used to count the entity. It is set to "#" if the unit of the entity is not specified.

[7] In the inference rule, $q is a meta symbol to ask the inference engine to generate a unique identifier for the newly derived quantity fact.

(a) Tim bought 2 roses and 3 lilies. Mary bought 4 roses and 5 lilies. How many flowers did Tim buy?

(b) quan(q1,#,rose)=2&verb(q1,buy)&nsubj(q1,Tim)…
quan(q2,#,lily)=3&verb(q2,buy)&nsubj(q2,Tim)…
quan(q3,#,rose)=4&verb(q3,buy)&nsubj(q3,Mary)…
quan(q4,#,lily)=5&verb(q4,buy)&nsubj(q4,Mary)…
quan(q_Q,#,flower)&verb(q_Q,buy)&nsubj(q_Q,Tim)…

Figure 5: An example for operand selection

the last line in Figure 4(b), three newly derived quantity facts *q4*, *q5* and *q6* (in 4(d)) can be unified with the first argument *quan(?q,dollar,#)* in 4(c), but only *q4* and *q5* satisfy the second argument *verb(?q,pay)&nsubj(?q,Tim)*. As a result, the answer 2.5 is returned by taking sum on the values of the quantity facts *quan(q4,dollar,#)* and *quan(q5,dollar,#)*.

2.4 Probabilistic Operand Selection

The most error-prone part in the LFT module is instantiating the utility function of math operation especially if many irrelevant quantity facts appear in the given MWP. Figure 5 shows the LFT module needs to select two quantity facts (among 4) for *Addition*. Please note that the *question quantity* q_Q, transformed from "*how many flowers*", is not a candidate for operand selection.

Lin et al., (2015) used predefined lexico-syntactic patterns and ad-hoc rules to instantiate utility functions. However, their rule-based approach fails when the MWP involves more quantities. Therefore, we propose a statistical model to select operands for the utility functions *Addition*, *Subtraction*, *Multiplication* and *Division*. The operand selection procedure can be regarded as finding the most likely configuration (o_1^n, r), where $o_1^n = o_1, \cdots, o_n$ is a sequence of random indicators which denote if the corresponding quantity will be selected as an operand, and r is a tri-state variable to represent the relation between the values of two operands (i.e., $r = -1, 0$ or 1 ; which denote that the first operand is less than, equal to, or greater than the second operand, respectively). Given a solution type s, the MWP logic expressions $\mathbb{L}$ and the n quantities $q_1^n = q_1, \cdots, q_n$ in $\mathbb{L}$. The procedure is formulated as:

$$P(r, o_1^n | q_1^n, \mathbb{L}, s) \approx P(r|s) \times P(o_1^n | q_1^n, \mathbb{L}, s), \quad (1)$$

$P(r|s)$ simply refers to *Relative Frequency* (as it has only a few parameters and we have enough training samples). $P(o_1^n | q_1^n, \mathbb{L}, s)$ is further derived as:

$$P(o_1^n | q_1^n, \mathbb{L}, s) \approx \prod_{i=1}^{n} P(o_i | q_i, \mathbb{L}, s) \approx \prod_{i=1}^{n} P\big(o_i \big| \Phi(q_i, \mathbb{L}, s)\big), \quad (2)$$

where $\Phi(\cdot)$ is a feature extraction function to map q_i and its context into a feature vector. Here, the probabilistic factor $P\big(o_i \big| \Phi(q_i, \mathbb{L}, s)\big)$ is obtained via an SVM classifier (Chang and Lin, 2011).

$\Phi(\cdot)$ extracts total 25 features (specified as follows, and 24 of them are binary) for q_i. The following 11 of them are independent on the question in the MWP:

1. Four features to indicate if s is *Addition*, *Subtraction*, *Multiplication* or *Division*.
2. A feature to indicate if q_i is within a *qmap*(…).
3. A feature to indicate if $q_i = 1$.
4. Five features to indicate if $n < 2$, $n = 2$, $n = 3$, $n = 4$ or $n > 4$; where n is the number of quantities in Eq (1).

$\Phi(\cdot)$ also extracts features by matching the logic expressions of q_i with those of *question quantity* $\mathrm{q_Q}$ to check the role-tag consistencies between q_i and $\mathrm{q_Q}$. Another fourteen features are extracted with three indicator functions $I_m(\cdot)$, $I_e(\cdot)$, $I_\exists(\cdot)$ and one tri-state function $T_m(\cdot)$ as follows:

$$\begin{aligned}[& I_m(q_i, \mathrm{q_Q}, \text{entity}), I_e(q_i, \mathrm{q_Q}, \text{entity}),\\ & I_m(q_i, \mathrm{q_Q}, \text{verb}), I_e(q_i, \mathrm{q_Q}, \text{verb}),\\ & I_\exists(\mathrm{q_Q}, \text{nsubj}), T_m(q_i, \mathrm{q_Q}, \text{nsubj}),\\ & I_\exists(\mathrm{q_Q}, \textit{modifier}), I_m(q_i, \mathrm{q_Q}, \textit{modifier}),\\ & I_\exists(\mathrm{q_Q}, \textit{place}), I_m(q_i, \mathrm{q_Q}, \textit{place}),\\ & I_\exists(\mathrm{q_Q}, \textit{temporal}), I_m(q_i, \mathrm{q_Q}, \textit{temporal}),\\ & I_\exists(\mathrm{q_Q}, \textit{xcomp}), I_m(q_i, \mathrm{q_Q}, \textit{xcomp})]\end{aligned}$$

where the indicator functions $I_m(x, y, z)$ checks if the z of x matches the z of y, $I_e(x, y, z)$ checks if the z of x entails the z of y and $I_\exists(y, z)$ checks if the z of y exists. $T_m(q_i, \mathrm{q_Q}, \text{nsubj})$ returns "exact-match" (if *nsubj* of q_i matches *nsubj* of $\mathrm{q_Q}$), "quasi-match" (if *nsubj* of $\mathrm{q_Q}$ does not exist or is a plural pronoun), and "unmatch".

$I_e(\cdot)$ uses the WordNet hypernym and hyponym relationship to judge whether one entity/verb entails another one or not via checking if they are in an inherited hypernym-path in WordNet. The *entity*, *verb* and *nsubj* of a quantity are determined according to the logic expressions. The modifier, place, temporal and *xcomp* of a quantity are extracted from the dependency tree with some lexico-syntactic patterns. For example, the *modifier* and *place* of the quantity in the sentence "*There are 30 red flowers in the garden.*" are "*red*" and "*garden*" respectively. The *temporal*

and *xcomp* of a quantity are extracted according to the dependency relations "*tmod*" (i.e., *temporal modifier*) and "*xcomp*" (i.e., *open clausal complement*), respectively.

3 Datasets for Performance Evaluation

The AI2 dataset provided by Hosseini et al. (2014) and the IL dataset released by Roy and Roth (2015) are adopted to compare our approach with other state-of-the-art methods. The AI2 dataset has 395 MWPs on addition and subtraction, with 121 MWPs containing irrelevant information (Hosseini et al., 2014). It is the most popular one for comparing different approaches. On the other hand, the IL dataset consists of 562 elementary MWPs which can be solved by one of the four arithmetic operations (i.e., +, −, ×, and ÷) without any irrelevant quantity. It is the first publicly available dataset for comparing performances that covers all four arithmetic operations.

However, the difficulty of solving an MWP depends not only on the number of arithmetic operations required, but also on how many irrelevant quantities inside, and even on how the quantities are described. One way to test if a proposed approach solves the MWPs with understanding is to check whether it is robust to those irrelevant quantities. Therefore, it is desirable to have a big enough dataset that contains irrelevant quantities which are created under different situations (e.g., confusing with an irrelevant agent, entity, or modifier, etc.) and allow us to probe the system weakness from different angles. We thus create a new dataset with more irrelevant quantities[8]. But before we do that, we need to know how difficult the task of solving the given MWPs is. Therefore, we first propose a way to measure how easy that a system solves the problem by simply guessing.

3.1 Perplexity-flavor Measure

We propose to adopt the *Perplexity* to measure the task difficulty, which evaluates how likely a solver will get the correct answer by guessing. Every MWP in the datasets can be associated with a solution expression template, such as "$\boxdot + \boxdot$" or "$\boxdot - \boxdot$", where the symbol $\boxdot$ represents a slot to hold a quantity. The solution can be obtained by placing correct quantities at appropriate slots. A random baseline is to solve an MWP by guessing. It first selects a solution expression template according to the prior distribution of the templates and then places quantities into the selected template according to the uniform distribution.

The expected accuracy of the random baseline on solving an MWP is a trivial combination and permutation exercise[9]. For example, the expected accuracy of solving an MWP associated with "$\boxdot + \boxdot$" template is $p_{\boxdot+\boxdot} \times {}_nC_2^{-1}$, where the factor $p_{\boxdot+\boxdot}$ denotes the prior probability of the template "$\boxdot + \boxdot$" and n is the total number of quantities (including irrelevant ones) in the MWP. On the other hand, expected accuracy of solving an MWP associated with "$\boxdot - \boxdot$"[10] template is $p_{\boxdot-\boxdot} \times {}_nP_2^{-1}$. Let A_i denote the expected accuracy of solving the i-th MWP in a dataset. The accuracy of the random baseline on the dataset of size N is then computed as $A = (1/N) \times \sum_{i=1}^{N} A_i$.

The word "*Accuracy*" comprises the opposite sense of the word "*Perplexity*"[11] (i.e., in the sense of how hard a prediction problem is). The lower the *Accuracy* is, the higher the *Perplexity* is. Therefore, we transform the *Accuracy* measure into a *Perplexity-Flavor* measure (PP) via the formula:

$$\mathrm{PP} = 2^{-\log_2 A}$$

For instance, the *Perplexity-Flavor* measures of AI2 and IL datasets are 4.46 and 8.32 respectively.

3.2 Noisy Dataset

Human Math/Science tests have been considered more suitable for judging AI progress than Turing test (Clark and Etzioni, 2016). In our task, solving MWPs is mainly regarded as a test for intelligence (not just for creating a *Math Solver* package). By injecting various irrelevant quantities into original MWPs, a noisy dataset is thus created to assess if a solver solves the MWPs mainly via *understanding* or via *mechanical/statistical pattern matching*. If a system solves an MWP mainly via pattern matching, it would have difficulty in solving a similar MWP augmented from the original one with some irrelevant quantities. Therefore, we first create a noisy dataset by selecting some

[8] The IL dataset does not include any irrelevant information; on the other hand, the AI2 dataset only contains 121 MWPS with irrelevant information (but not systematically created).

[9] Let ${}_nC_k$ denote k-combinations of n and ${}_nP_k$ denote k-permutations of n.

[10] We assume the operands have different values and, therefore, they are not permutable for the *subtraction* operator.

[11] The *Perplexity* of a uniform distribution over *k* discrete events (such as casting a fair *k*-sided dice) is *k*.

(a) Tim has 10 yellow flowers and 12 red flowers. How many flowers does Tim have?

(a.1) Tim has … Mary has 3 yellow flowers. How many …

(a.2) Tim has … Tim also has 3 books. How many …

Figure 6: Examples of noisy sentences

MWPs that can be correctly solved, and then augmenting each of them with an additional noisy sentence which involves an irrelevant quantity. This dataset is created to examine if the solver knows that this newly added quantity is irrelevant.

Figure 6 shows how we inject noise into an MWP (a). (a.1) is created by associating an irrelevant quantity to a new subject (i.e., *Mary*). Here the ellipse symbol "…" denotes unchanged text. (a.2) is obtained by associating an irrelevant quantity to a new entity (i.e., *books*). In addition, we also change modifiers (such as *yellow*, *red*, …) to add new noisy sentence (not shown here). Since the noisy dataset is not designed to assess the lexicon coverage rate of a solver, we reuse the words in the original dataset as much as possible while adding new subjects, entities and modifiers.

136 MWPs that both Illinois Math Solver [12] (Roy and Roth, 2016) and our system can correctly solve are selected from the AI2 and IL datasets. This subset is denoted as OSS (Original Sub-Set). Afterwards, based on the 136 MWPs of OSS, we create a noisy dataset of 396 MWPs by adding irrelevant quantities. This noisy dataset is named as NDS [13]. Table 1 lists the size of MWPs, *Perplexities* (PP), and the average numbers of quantities in each MWP of these two datasets.

4 Experimental Results and Discussion

We compare our approach with (Roy and Roth, 2015) and (Roy and Roth, 2017) because they achieved the state-of-the-art performance on the IL dataset. In the approach of (Roy and Roth, 2015), each quantity in the MWP was associated with a *quantity schema* whose attributes are extracted from the context of the quantity. Based on the attributes, several statistical classifiers were used to select operands and determine the operator. They also reported the performances on the AI2 dataset to compare their approach with those of others (e.g., Kushman et al. (2014), which is a purely statistical approach that aligns the text with various pre-extracted equation templates). Roy and Roth (2017) further introduced the concept of *Unit Dependency Graphs* to reinforce the consistency of physical units among selected operands associated with the same operator.

	OSS	NDS
# MWPs	136	396
Perplexity (PP)	7.42	18.83
#Quantities	2.64	3.62

Table 1: *Perplexity* measures of OSS and NDS

	AI2	IL
Our system (Statistical)	**81.5**	**81.0**
Our system (DNN)	69.8	70.6
(Roy and Roth, 2017)	76.2	74.4
(Roy and Roth, 2015)	78.0	73.9
(Kushman et al., 2014)	64.0	73.7

Table 2: Performances of various approaches

	AI2	IL
STI (Statistical)	83.0	83.1
STI (DNN)	74.5	68.8
LFT	92.1	94.8

Table 3: Performances of *different* STIs and LFT

To compare the performance of the statistical method with the DNN approach, we only implement a Bi-directional RNN-based *Solution Type Identifier* (as our original statistical *Operand Selector* is relatively much better). It consists of a word embedding layer (for both body and question parts), and a bidirectional GRU layer as an encoder. We apply the attention mechanism to scan all hidden state sequence of body by the last hidden state of question to pay more attention to those more important (i.e., more similar between the body and the question) words. Lastly, it outputs the solution type by a softmax function. We train it for 100 epochs, with mini-batch-size = 128 and learning-rate = 0.001; the number of nodes in the hidden layer is 200, and the drop-out rate is 0.7 [14].

We follow the same n-fold cross-validation evaluation setting adopted in (Roy and Roth, 2015) exactly. Therefore, various performances could be directly compared. Table 2 lists the accuracies of different systems in solving the MWPs

[12] We submit MWPs to Illinois Math Solver (https://cogcomp.cs.illinois.edu/page/demo_view/Math) in May and June, 2017.

[13] The noisy dataset can be downloaded from https://github.com /chaochun/nlu-mwp-noise-dataset. It includes 102 Addition, 147 Subtraction, 101 Multiplication and 46 Division MWPs.

[14] Since the dataset is not large enough for splitting a development set, we choose those hyper parameters based on the test set in coarse grain. Therefore, the DNN performance we show here might be a bit optimistic.

of various datasets. The performance of (Roy and Roth, 2017) system is directly delivered by their code[15]. The last two rows are extracted from (Roy and Roth, 2015). The results show that our performances of the statistical approach significantly outperform that of our DNN approach and other systems on every dataset.

The performances of STI and LFT modules are listed in Table 3. As described in section 2, the benchmark for both solution type and the operand selection benchmark are automatically determined by weakly supervised learning. The first and second rows of Table 3 show the solution type accuracies of our statistical and DNN approaches, respectively. The third row shows the operand selection accuracy obtained by given the solution type benchmark. Basically, LFT accuracies are from 92% to 95%, and the system accuracies are dominated by STI. We analyzed errors resulted from our statistical STI on AI2 and IL datasets, respectively. For AI2, major errors come from: (1) failure of ruling out some irrelevant quantities (40%), and (2) making confusion between *TVQ-F* and *Sum* these two solution types (20%) for those cases that only involve addition operation (however, both types would return the same answer). For IL, major errors come from: (1) requiring additional information (35%), and (2) not knowing Part-Whole relation (17%). Table 4 shows a few examples for different STI error types.

The left-half of Table 5 shows the performances on the OSS and NDS datasets. Recall that OSS is created by selecting some MWPs which both Illinois Math Solver (Roy and Roth, 2016) and our system[16] can correctly solve. Therefore, both systems have 100% accuracy in solving the OSS dataset. However, these two systems behave very differently while solving the noisy dataset. The much higher accuracy of our system on the noisy dataset shows that our meaning-based approach understands the meaning of each quantity more. Therefore, it is less confused[17] with the irrelevant quantities.

One MWP in the noisy dataset that confuses *Illinois Math Solver* (IMS) is "*Tom has 9 yellow balloons. Sara has 8 yellow balloons. Bob has 5 yellow flowers. How many yellow balloons do they have in total?*", where the underlined sentence is the added noisy sentence. The solver sums all quantities and gives the wrong answer 22, which reveals that IMS cannot understand that the quantity "*5 yellow flowers*" is irrelevant to the question "*How many yellow balloons?*". On the contrary, our system avoids this mistake.

Error Type	Example
Confusing *TVQ-F* and *Sum* solution type	Sally found 9 seashells, Tom found 7 seashells, and Jessica found 5 seashells on the beach. How many seashells did they find together?
Requiring additional information	A garden has 52 rows and 15 columns of bean plans. How many plants are there in all?
Not knowing Part-Whole relationship	Eric wants to split a collection of peanuts into groups of 8. Eric has 64 peanuts. How many groups will be created?

Table 4: Examples for different STI error types

	Statistical	R&R, 2016		Statistical	DNN
OSS	100	100	OSS′	100	100
NDS	82.1	28.5	NDS′	81.4	75.4

Table 5: Performances on the OSS and NDS

Although the meaning of each quantity is explicitly checked in our LFT module, our system still cannot correctly solve all MWPs in NDS. The error analysis reveals that the top-4 error sources are STI, LFT, CoreNLP and incorrect problem construction (for 27%, 27%, 18%, 18%), which indicates that our STI and LFT still cannot completely prevent the damage caused from the noisy sentences (which implies that more consistency check for quantity meaning should be done). The remaining errors are due to incorrect quantity extraction, lacking common-sense or not knowing entailment relationship between two entities.

A similar experiment is performed to check if the DNN approach will be affected by the noisy information more. We first select 124 MWPs (denoted as OSS′) from OSS that can be correctly solved by both our statistical and DNN approaches and then filter out 350 derived MWPs (denotes as NDS′) from NDS. The right-half of Table 5 shows that the performance of the DNN approach drops more than the statistical approach does in the noisy dataset, which indicates that our statistical approach is less sensitive to the irrelevant quantities and more close to human's approach.

[15] https://github.com/CogComp/arithmetic.

[16] In evaluating the performances on OSS and NDS datasets, our system is trained on the folds 2-5 of the IL dataset.

[17] Since the gap between two different types of approaches is quite big, those 396 examples on OSS and 196 examples on NDS are sufficient to confirm the conclusion.

5 Related Work

To the best of our knowledge, MWP solvers proposed before 2014 all adopted the rule-based approach. Mukherjee and Garain (2008) had given a good survey for all related approaches before 2008. Afterwards, Ma et al. (2010) proposed a MSWPAS system to simulate human arithmetic multi-step addition and subtraction behavior without evaluation. Besides, Liguda and Pfeiffer (2012) proposed a model based on augmented semantic networks, and claimed that it could solve multi-step MWPs and complex equation systems and was more robust to irrelevant information (also no evaluation).

Recently, Hosseini et al. (2014) proposed a *Container-Entity* based approach, which solved the MWP with a sequence of state transition. And Kushman et al. (2014) proposed the first statistical approach, which heuristically extracts some algebraic templates from labeled equations, and then aligns them with the given sentence. Since no semantic analysis is conducted, the performance is quite limited.

In more recent researches (Roy and Roth, 2015; Koncel-Kedziorski et al., 2015; Roy and Roth, 2017), quantities in an MWP were associated with attributes extracted from their contexts. Based on the attributes, several statistical classifiers were used to select operands and determine operators to solve multi-step MWPs. Since the physical meaning of each quantity is not explicitly considered in getting the answer, the reasoning process cannot be explained in a human comprehensible way. Besides, Shi et al. (2015) attacked the *number word problem*, which only deal with numbers, with a semantic parser. Mitra and Baral (2016) mapped MWPs into three types of problems, including Part-Whole, Change and Comparison. Each problem was associated with a generic formula. They used a log-linear model to determine how to instantiate the formula with quantities and solve the only one *Unknown* variable. They achieved the best performance on the AI2 dataset. However, their approach cannot handle *Multiplication* or *Division* related MWPs. Recently, DNN-based approaches (Ling et al, 2017; Wang et al, 2017) have emerged. However, they only attacked algebraic word problems, and required a very large training-set.

Our proposed approach mainly differs from those previous approaches in *combining the statistical framework with logic inference*, and also in *adopting the meaning-based statistical approach for selecting the desired operands*.

6 Conclusion

A *meaning-based* logic form represented with *role-tags* (e.g., *nsubj*, *verb*, etc.) is first proposed to associate the extracted math quantity with its physical meaning, which then can be used to identify the desired operands and filter out irrelevant quantities. Afterwards, a statistical framework is proposed to perform understanding and reasoning based on those logic expressions. We further compare the performance with a typical DNN approach, the results show the proposed approach is still better. We will try to integrate domain concepts into the DNN approach to improve the learning efficiency in the future.

The main contributions of our work are: (1) Adopting a meaning-based approach to solve English math word problems and showing its superiority over other state-of-the-art systems on common datasets. (2) Proposing a statistical model to select operands by explicitly checking the meanings of quantities against the meaning of the question sentence. (3) Designing a noisy dataset to test if a system solves the problems by understanding. (4) Proposing a perplexity-flavor measure to assess the complexity of a dataset.

Abstract

Temporal orientation refers to an individual's tendency to connect to the psychological concepts of *past*, *present* or *future*, and it affects personality, motivation, emotion, decision making and stress coping processes. The study of the social media users' psycho-demographic attributes from the perspective of human temporal orientation can be of utmost interest and importance to the business and administrative decision makers as it can provide an extra precious information for them to make informed decisions. In this paper, we propose a very first study to demonstrate the association between the sentiment view of the temporal orientation of the users and their different psycho-demographic attributes by analyzing their tweets. We first create a temporal orientation classifier in a minimally supervised way which classifies each tweet of the users in one of the three temporal categories, namely *past*, *present*, and *future*. A deep Bi-directional Long Short Term Memory (BLSTM) is used for the tweet classification task. Our tweet classifier achieves an accuracy of 78.27% when tested on a manually created test set. We then determine the users' overall temporal orientation based on their tweets on the social media. The sentiment is added to the tweets at the fine-grained level where each temporal tweet is given a sentiment with either of the positive, negative or neutral. Our experiment reveals that depending upon the sentiment view of temporal orientation, a user's attributes vary. We finally measure the correlation between the users' sentiment view of temporal orientation and their different psycho-demographic factors using regression.

1 Introduction

The rapid growth of social media data in recent years has encouraged different studies which only existed at the psychological level (theory or pure logic). Various attributes of users can be analyzed from the texts they write on the social media platform. The studies include age, gender prediction (Marquardt et al., 2014; Sap et al., 2014), psychological well being (Dodds et al., 2011; Choudhury et al., 2013), and a host of other behavioural, psychological and medical phenomena (Kosinski et al., 2013). However, a few works exist which analyze these factors using socio-economic characteristics of the Twitter users.

Time is generally defined by a dimension where the events are ordered from the past through the *present* into the *future* which includes duration and intervals. Major studies on time have been done for event detection (Ihler et al., 2006; Batal et al., 2012; Sakaki et al., 2013) which are mainly of the subjective consent. In contrast, temporal orientation of a user is defined by his/her tendency to emphasize *past*, *present* or *future* (Zimbardo and Boyd, 2015) which gives more objective consent of time. The growth of social media content has enabled us to study this objective consent more precisely.

Past studies have established a consistent link between the temporal orientation and several user characteristics such as age, gender, education, and psychological traits (Webley and Nyhus, 2006; Adams and Nettle, 2009; Schwartz et al., 2013; Zimbardo and Boyd, 2015). However, the sentiment dimension (positive, negative or neutral) of the temporal orientation is merely studied at the empirical level on a large-scale. For example, people who are optimistic are future-oriented and positive at the same time. So, only defining the temporal orientation cannot specify the optimistic people correctly. We need the sentiment dimension as well to find the exact correlation.

In this paper, we first develop a temporal-orientation classifier to classify tweets into *past*, *present*, and *future* and then group over the users

Proceedings of NAACL-HLT 2018, pages 663–674
New Orleans, Louisiana, June 1 - 6, 2018.

to create user-level assessments. We use a Bidirectional Long Short Term Memory (Bi-LSTM) network for tweet temporal classification where tweet vectors are fed to generate the classification model. We propose a hash tag-based *minimally supervised* method with the two-pass filtering to create the *past*, *present* and *future*-oriented tweets for the training of the Bi-LSTM network. We manually examined trending hashtags in Twitter for a specific period of time and selected hashtags which represent *past, present/ongoing*, or *future* events. The English tweets containing one of the selected hashtags are crawled using Twitter streaming API.[1] The tweet temporal orientation classifier is validated on a manually annotated test set. Finally, we use this classifier to automatically classify a large dataset consisting of ≈10 million tweets from 5,191 users mapped to their user-level features.

Besides these three temporal categories (*past*, *present* or *future*), we have considered the positive, negative and neutral sentiments of the tweets for the fine-grained classification. The user-level tweets with a particular temporal orientation is further subdivided into either positive, negative or neutral sentiment. Finally, we evaluated whether the sentiment view of temporal orientation (i.e. past-positive, past-negative, past-neutral, present-positive, present-negative, present-neutral, future-positive, future-negative, and future-neutral) of the users is related to their several psycho-demographic attributes. In this research, we have considered five psycho-demographic attributes, namely age, eduction, relationship, intelligence, and optimism.

Our contributions are summarised as below:

- We introduce the sentiment dimensions in the human temporal orientation to infer the social media users' psycho-demographic attributes on a large-scale.
- We propose a minimally supervised approach to the temporal orientation classification task that leverages large quantities of unlabeled data and requires no hand-annotated training corpora. The empirical evidence shows that the method performs reasonably well.
- We create a gold-standard temporal orientation tweet corpus.
- We define a way to find a novel association between the sentiment view of temporal orientation and the different psycho-demographic factors of the tweet users.

2 Related Background

The temporal study has recently received an increased attention in several application domains of Natural Language Processing (NLP) and Information Retrieval (IR). The introduction of the TempEval task (Verhagen et al., 2009) and the subsequent challenges i.e. TempEval-2 and -3 (Verhagen et al., 2010; UzZaman et al., 2013) in the Semantic Evaluation workshop series have clearly established the importance of time in dealing with the different NLP tasks. Alonso et al. (2011) reviewed the current research trends and presented a number of interesting applications along with the open problems.

The shared task like the NTCIR-11 Temporalia task (Joho et al., 2014) further pushed this idea and proposed to distinguish whether a given query is related to *past*, *recency*, *future* or *atemporal*. It is the first such challenge, which is organized to provide a common platform for designing and analyzing the time-aware information access systems. In parallel, new trends have emerged in the context of the human temporal orientation (Schwartz et al., 2013; Sap et al., 2014; Park et al., 2015; Schwartz et al., 2015; Park et al., 2017). The underlying idea is to understand how the past, present, and future emphasis in the text may affect people's finances, health, and happiness. For that purpose, the temporal classifiers are built to detect the overall temporal dimension of a given sentence. For instance, the following sentence "*can't wait to get a pint tonight*" would be tagged as *future*.

In summary, most of the temporal text processing applications have been mainly relying on the rule-based time taggers, for e.g. HeidelTime (Strötgen and Gertz, 2015) or SUTime (Chang and Manning, 2012) to identify and normalize time mentions in the texts. Although interesting results have been reported (UzZaman et al., 2013), but the coverage is limited to the finite number of rules they implement.

The time perspective and its importance in various social science and psychological studies is well established in literature. It plays a fundamental role in our interpersonal relation influenced by cognitive process (Zimbardo and Boyd, 2015).

This is also useful in forming goals, expectations and imaginations. Time perspective is a fundamental process, which intern, influenced by many user attributes such as age, religion, education etc. In their research, Zimbardo and Boyd (2015) have shown that the negative view of the past is related to depression, anxiety, unhappiness, and low self-esteem but the positive view of the past is related to self-esteem and happiness. The hedonistic view of the present is related to novelty seeking and sensation seeking whereas the fatalistic view of the present is related to aggression, anxiety and depression. The future is related to conscientiousness but negatively correlated with depression and anxiety.

Another research suggests that the satisfaction with life of the older adults depends on their positive views of past (Kazakina, 1999). In their research, Drake et al. (2008) described that the past-positive is positively correlated to happiness. The link between the past-negative and many psychological distress like depression and anxiety has been well established in literature (Cully et al., 2001). A focus on the future is very effective for functioning positively. The future orientation also helps in better health in later life (Kahana et al., 2005). In a research, George (2009) evaluated that subjective well-being, happiness, psychological well-being, positive effects and morale refer to the positive orientation towards life.

Past research has established that the time perspective is an important factor to determine the human emotional intelligence (Stolarski et al., 2011). In our work, we measure the relationship with different level of intelligence and the sentiment view of the temporal orientation by more objective consent of the time perspective, i.e. temporal orientation from the tweets on the social media. In a social science research, Guthrie et al. (2009) have shown that the future time perspective is associated with the current socioeconomic status, and the past-fatalistic time perspective is associated with the both current and childhood socioeconomic status.

Although these kinds of research exist extensively in the psychological study, it is not well explored with the empirical study using more objective consent of the time perspective, i.e the temporal orientation. As per our best knowledge, only a very few studies exist that focus on the temporal orientation where only the coarse-grained classes have been considered (Schwartz et al., 2015; Park et al., 2017). In these researches, many user attributes were correlated with the temporal orientation which include conscientiousness, age, gender, openness, extraversion, agreeableness, neuroticism, satisfaction with life, depression, IQ, number of friends etc. In our work, we incorporated fine-grained temporal orientation and found the correlation with the users' age, education, relationship, intelligence, and optimism. The fine-grained study of the temporal orientation only existed at the theoretical level validated with very limited user dataset. Besides validating these findings in the empirical way for the large number of users, we also discuss some previously unexplored relationships.

3 Methodology

We first create a deep temporal-orientation classifier to capture the temporal orientation (*past*, *present* and *future*) of the users' tweets. Thereafter we further classify the users' tweets at the fine-grained level by associating sentiment, i.e. positive, negative or neutral for each temporal category. We compare our temporal-orientation classifier with an existing state-of-the-art method.

3.1 Temporal Orientation Classification

The temporal orientation of tweets is defined by classifying each tweet T in one of the temporal categories t, where $t \in \{$ *past, present*, or *future*$\}$. Given the following tweet *"Let me change lanes and turn left legally"*, the temporal orientation classifier should predict it as an instance of *future* orientation. At first we create a temporal oriented tweet dataset in a minimally supervised way by exploiting the hashtag information. Deep Bi-LSTM network is then trained on this dataset. We use LSTM networks (Hochreiter and Schmidhuber, 1997) as these are well known for capturing the long-term dependencies within the text.

Many times we fail to capture the temporal orientation of a text using just the tense information or the existing temporal keywords. In particular, the tweet *"Today I have a plan for a meeting at night."* is future-oriented. Here, the temporal keyword *'Today'* has a time sense of *present* whereas the tense of the verb is also *present*. The deep learning networks have been very useful to correctly capture the temporal dimension of these kinds of tweets. Although the basic Artifi-

cial Neural Networks (ANNs) (Schalkoff, 1997) and Convolutional Neural Network (CNN) (LeCun et al., 1995) capture the temporal orientation of many tweets correctly, they fail to properly identify where the validating temporal information in the tweet has a long dependency between them. For example, the tweet *"Working in the same unit today with different staff was much better."* has temporal orientation as *past*. Here, the word which has a temporal sense (*i.e. working, today, was*) are placed at a distance from each other. This motivates us to use the LSTM network.

Bidirectional Long Short Term Memory Networks (Bi-LSTM): LSTMs are a special kind of recurrent neural network (RNN) capable of learning long-term dependencies in the text by effectively handling the vanishing or exploding gradient problem. The Bidirectional LSTMs (Schuster and Paliwal, 1997) train two LSTMs, instead of one, on the input sequence. The first on the input sequence and the second on a reversed copy of the input sequence. It is designed to capture information of the sequential dataset and maintain the contextual features from the past and the future. This can provide an additional context to the network and result in faster and even fuller learning on the problem without keeping the redundant context information.

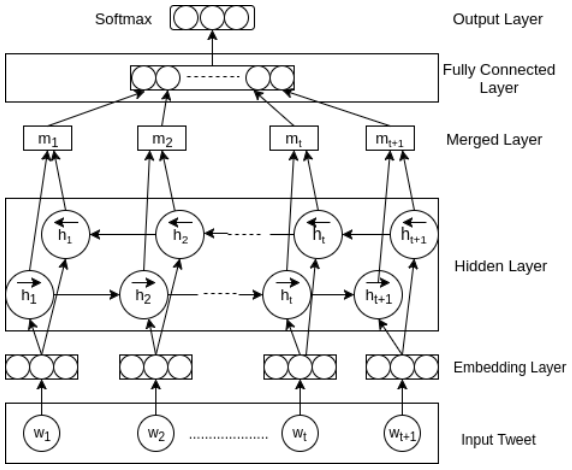

Figure 1: Temporal Orientation learning architecture.

The previous study on the temporal orientation classification based on machine learning includes a supervised classification based on the manually created training set (Schwartz et al., 2015). The multi-class classification was based on a one vs rest approach. But adapting the multiple binary classifiers is not always the best way to deal with a multi-class classification problem. It requires building of three independent classifiers for each temporal category, which consumes more time. Unlike this approach, we incorporate a deep learning-based multi-class classification method for the temporal orientation. The training corpus is generated in a minimally supervised way and fitted to the Bi-LSTM network.

Our experiment uses Bi-LSTM with 200 neurons at the input layer. The loss function we used is *categorical cross-entropy* and the optimizer used is *Root Mean Square Propagation (rmsprop)*. We repeat the training for 100 *number of epochs* with *batch size* set to 128. We also employ dropout (Srivastava et al., 2014) for regularization with a *dropout rate* of 0.2 to prevent over-fitting. All of these attributes are finalized by parameter tuning with the performance obtained on 10-fold cross-validation using the grid search method. Tweet vectors are generated by existing Glove vectors (Pennington et al., 2014) for tweets[2] of 200 dimensions which are trained on 27 billion tweets. We also validate our model on the validation set which was 10% of the training set.

3.2 Sentiment View of Temporal Orientation

We use an existing sentiment classifier available with the NLTK toolkit (Bird, 2006) to classify the *user-level* tweets into positive, negative or neutral.[3] Sentiment is added at the fine-grained level of the temporal orientation. Given the tweets of a user, the sentiment view of temporal orientation of that user is defined by the following equation:

$$orientation_{s,t}(user) = \frac{|tweets_{s/t}(user)|}{|tweets_t(user)|} \quad (1)$$

where, ($t \in$ { *past, present*, or *future*}), and ($s \in$ { *positive, negative*, or *neutral*}), in equation (1). Here, we first classify each user's tweet into the past, present or future temporal category. Then for each temporal category, we find the percentage of each sentiment class (i.e positive, negative or neutral) to obtain the sentiment view of temporal orientation.

We measure the correlation between a user's sentiment view of temporal orientation with their

[2] https://nlp.stanford.edu/projects/glove/

[3] As we are using a sentiment classifier from well known NLTK library, we are not validating it on a manually-tagged test set.

age, education, intelligence, optimism, and relationship using a linear regression (LR) classifier (Neter et al., 1996).

4 Data Sets

For experiments we categorize the datasets into three kinds: training, test and user-level. Training set consists of 27k tweets, whereas the test set is manually annotated with 741 tweets.[4] The user-level tweets consist of ≈10 million tweets from 5,191 users mapped to their user-level features.

4.1 Training Set

Training tweets are collected using the Twitter streaming API.[5] The tweets are collected for the duration of September 2017 and October 2017. We consider day-wise trending topics during this period.[6] We only consider those hashtags which signify a temporal event. Finally, we chose world-wide trending events and collected the tweets based on the hashtags.

The collection of the temporal tweets are based on the following three hypotheses: (a) if a trending topic is of a future event then mostly people would write the futuristic tweets; (b) if a trending topic is about a past incident, then the people would write more about the past but they also write about the present effects of that event; (c) the tweets of trending present event are most critical to handle as besides writing about the present incidents, people always join the links with the past incidents and also give opinion about the future effects.

The task was challenging as the tweets contain a lot of noises and people use various ways to refer to the past, the present and the future. To deal with the pitfalls described in the hypotheses, we filter the tweets using a two-pass filtering method. The method is based on two assumptions (a) every meaningful sentence should contain a verb. (b) mostly past-oriented tweets have tense of the verb as past.

The first assumption is well-established in literature, whereas the second assumption is based on our observation on the tweets and validation against a tense-based classifier. In the first pass of the filtering method, we filter out the tweets which do not contain a verb. The verb part-of-speech tag is determined using the CMU tweet-tagger (Gimpel et al., 2011). In the second pass of the filtering method, we removed the tweets having tense as past from the tweets of the present and future events.

The CMU tweet-tagger does not provide verbs in different sub-categories. For this reason, we also retrieve the Part-of-Speech (PoS) tag information from the Standford PoS-tagger (Manning et al., 2014) for all the tweets to get the sub-categories of verb (i.e. VB, VBD, VBG, VBN, VBP, VBZ). We observed that although Standford PoS-tagger assigned the required verb sub-categories, it also incorrectly tagged some non-verbs as verbs. This is the reason why we considered only those verbs for sub-categorization which were identified (as verbs) by the CMU tweet-tagger.

We varied the training set starting from 3K (equally distributed) to 30K and observed that the accuracy on the gold standard test set did not improve after 27K training instances. Few example tweets with the trending topics are depicted in Table 1.

4.2 Test Set

We evaluate our temporal-orientation classifier on a manually created test set. To get proper assessment on the user-level test set, we randomly selected 800 tweets from the user-level test tweets. Three annotators (post-graduate level students) were asked to tag the tweets in one of the four available classes, namely *past*, *present*, *future* and *other*. The annotation guidelines were as follows:

- Tag a tweet as *past* if it talks about an event which has started as well as ended or the underlaying temporal connotation of the tweet refers to the *past* time.
- Tag a tweet as *present* if it talks about an event which started but not ended yet or the tweet has a *present* temporal connotation,
- Tag a tweet as *future* if it talks about an event which is yet to happen.
- Tag a tweet as *other* in case they found it difficult to get the exact temporal tag for the tweets.

[4] All the developed resources are available at http://www.iitp.ac.in/~ai-nlp-ml/resources.html

[5] https://developer.twitter.com/en/docs

[6] The reason for this selection strategy was the fact that during the passage of time, the future events become present event and the present event becomes past event.

Temporal Orientation	Hashtag	Example Sentence
Past	#Elections2016	did it have influence? of course it did.
	#CPC17	just heard gazza made a guest appearance outside the tory conference.
Present	#HappyHalloween	when you leave for work early but atlanta traffic has other ideas.
	#LHHH	i am trying to figure out who this is
	#WorldTeachersDay	hats off to all the teachers who work hard to not only educate but protect kids everyday.
Future	#U17WC	2017 fifa u17 world cup starts in 3 days
	#2Point0	gonna treat us with 3d visual extravaganza!
	#FutureDecoded	want to get your hands on a new? enter our giveaway at for your chance to win.

Table 1: Example tweets for different temporal orientation categories with trending topics.

We measured the multi-rater kappa agreement (Fleiss, 1971) among the annotators and it was found to have a substantial kappa value of 0.82. The higher kappa value indicates that associating text with temporal dimensions, namely, *past, present, future,* and *other* is relatively straightforward task for humans by using world knowledge than words (Dias et al., 2014). Moreover, our inter-annotator agreement value is in line with the literature.[7] Finally, we select the temporal class of a tweet based on the majority voting among the annotators. The distribution of annotated tweets is as follows:

- *Past*- 375 Tweets
- *Present*- 164 Tweets
- *Future*- 202 Tweets
- *Other*- 59 Tweets

We removed tweets tagged as *Other* and used 741 tweets as the test set.[8]

4.3 User-level Test Set

The user-level tweets consist of ≈10 million tweets from 5,191 users mapped to their user-level psycho-demographic features developed by Preoţiuc-Pietro et al. (2015) are used for this current work. In particular, we use five psycho-demographic attributes such as *age*, *education*, *intelligence*, *optimism*, and *relationship* for our experiment. The users' psycho-demographic features are automatically deduced based on the users' published texts. Preoţiuc-Pietro et al. (2015) used a predictive model to automatically infer user-level features. The method uses various user properties (annotated using crowdsourcing) including age, gender, income, education, relationship status, optimism and life satisfaction as well as all the tweets published by a user to infer user-level features.

5 Experimental Results

We first evaluate our temporal orientation classifier which measures the orientation of each tweet as either of *past*, *present* or *future*. The classifier was trained on the training set and evaluated on the test set. We obtain the highest accuracy of 78.27% over 741 test samples. For comparative evaluation, we can consider a strong baseline system proposed by Schwartz et al. (2015). The baseline system was built following a supervised learning strategy over different features such as ngrams, time expression, PoS tags, tweet length, and temporal class-specific lexicons. The system achieved an accuracy of 71.8% when tested over 500 manually annotated data. The baseline was not reproducible as both the training and test set were manually tagged and the datasets were not available.[9] The baseline model was constructed using the manually annotated data, creation of which involved considerable efforts and expenses. In contrast, we follow a minimally supervised method (does not incur any manual effort) to create our own datasets which are of acceptable quality. We show the results in Table 2.

Orientation	Precision	Recall	F1-measure
Past	81.75	92.0	86.57
Present	79.04	50.61	61.71
Future	71.02	75.24	73.07

Table 2: Precision, Recall and F1-measure of our proposed temporal orientation classification model on manually annotated test data.

[7] Inter-annotator agreement value for the same task in Schwartz et al. (2015) is 0.83.

[8] We only considered *past*, *present* and *future* classes for the reason justified in Schwartz et al. (2015).

[9] We approached the authors of Schwartz et al. (2015) for the data. They did not share the data due to copyright issues. This is the reason for generating our own gold-standard test set.

Results in Table 2 show that the past class is the most correctly classified followed by the future and the present. We observe low recall for the *present* class as many present tweets were mis-classified into either *past* or *present* class. The confusion matrix is shown in Figure 2. The

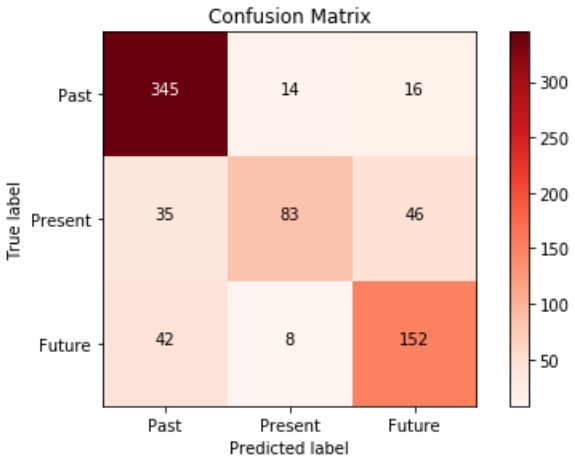

Figure 2: Confusion matrix for the temporal orientation classification.

present class is mis-classified into future when the tweet is of the declarative type. For example, the tweet "*Its not a casserole as theres no binding matrix*" has *present* orientation but our classifier classifies it as of *future* orientation. Another reason could be the fact that the words in the sentence representing *present* temporal orientation are not in the correct form (Its, theres). The *present* classes are mis-classified into the past classes in those cases where mainly the existence of the tense of a verb is *past* but actually the tweet has *present* orientation. For example, the tweet "*For me gloves and mitts made for Cross Country skiing work well for ventilated warmth*" is mis-classified into *past* because of the existence of the word (made) which has tense as *past*. The tweets with *future* orientation are mostly mis-classified into *past* orientation. These kinds of mis-classification is due to either for the presence of past tense or the tweet is a compound sentence which has an independent clause of the past orientation. For example, the tweet "*Hoping to have fun among my friends but wishing I were with you instead*" has a future orientation but it is mis-classified into the past orientation.

We measure the potential limitations of the NLTK sentiment classifier on 100 randomly selected tweets from the test set. The manual observation shows that the classifier generally misclassifies where the sentiment of the tweet is not well understood (example: "Big Trucks parked all over). In some cases, the tweets having conflict sentiment are mis-classified in either of positive or negative class. For example, the tweet "I am very sorry that is a working weekend for me but thanking you very much for the invitation has a conflict sentiment but the classifier classified it into an instance of negative sentiment.

We measure the predictive power of the sentiment view of temporal orientation by performing regression on different psycho-demographic factors. The correlation results between the users' sentiment view of temporal orientation and their psycho-demographic factors using linear regression are presented in Table 3 and Table 4. The performance is measured using a standard metric, namely *Pearson's correlation coefficient r* between the inferred and the target values. All the results in Table 3 and Table 4 are statistically significant when tested against null hypothesis (p_value <0.05).

6 Discussion and Findings

We measure the correlation between the Twitter users' psycho-demographic features and their sentiment view of temporal orientation. In this section, all the discussions and analyses are based on the correlation results over the user test set.

6.1 Demographic Correlates

We select 'age', 'education' and 'relationship' as demographic features for this study. The correlation coefficients between the users' demographic attributes and their sentiment view of temporal orientation are shown in Table 3.

Results in Table 3 demonstrate that any user's past-orientation is significantly correlated (0.4677) with their age. In other words, it suggests that when people age they think more about the past than the present and future. To the best of our knowledge, psychology literature (Nurmi, 2005; Steinberg et al., 2009) has not established the correlation of the past orientation with age. Our finding is consistent with a recent computational study on the human temporal orientation (Schwartz et al., 2015) which shows positive correlation between age and the past orientation. However, we also observed that the users' age has the highest positive correlation (0.5235) with the

Table 4: Correlation between users sentiment view of temporal orientation and their different psychological features using LR. Here, pos-positive, neg-negative, neu-neutral.

future-positive. It indicates that people become positively future-orientated when they age, though not surprising, yet somewhat novel. The results indicate that only considering the temporal orientation without the sentiment dimensions can be sometimes misleading as we can observe that the negative future-orientation has a negative correlation (-0.4547) with age while the future-positive has a positive correlation with age.

Figure 3 explains how the trends of the sentiment view of temporal orientation varies from age 10 to 60. We observe that for all the temporal classes, the positive sentiment increases rapidly with the increase of age. Most interestingly, for all the temporal orientation people become negative up to the age of 28 and then their negative sentiment steadily reduces. We also observe that human's neutral sentiment rapidly decreases up to the age of 27 and then it decreases steadily.

The second demographic attribute we considered is 'education'. We measure the correlation between the temporal orientation and three different levels of education: *degree*, *graduate_degree*, and *high_school*. In the psychological literature (Horstmanshof and Zimitat, 2007; Richardson et al., 2012), it was reviewed that the students' temporal orientations is a new dimension to approaches in enhancing student engagement in the academics. It was found that the first year students of university were more *future-oriented* rather than present or past oriented. From our results in Table 3, we found that the users who have education of *degree* level are *present-oriented*. But interestingly they neither think positively nor negatively-they express more neutral sentiment. Users with education of *graduate_degree* are found to be *future-oriented*. Here, the fine-grained classification suggests that they also express the *neutral* sentiment. Interestingly, we found that the users with education of *high_school* had *positive* correlation with *past orientation*. However, when we considered the sentiment dimension, we found that it was actually correlated with *present orientation* with *negative sentiment*.

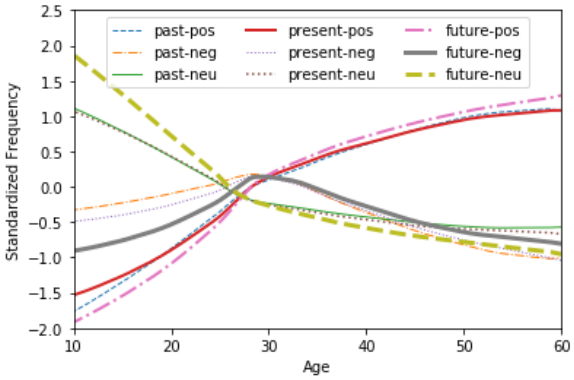

Figure 3: Standardized sentiment view of temporal orientation of the users over their age. Smoothing was done using loess smoothing estimates. Here, pos-positive, neg-negative, neu-neutral.

Our third and final demographic feature 'relationship' is categorized into four types in our current study: *divorced*, *in_a_relationship*, *married*, and *single*. From the results in Table 3, we observe that the users who are *divorced* found to be more future oriented and they seem to express the neu-

tral sentiment. The *in_a_relationship* users seem to be more past-oriented. They also found to be negative minded. Married people are found to be present oriented while expressing the neutral sentiment. The users who are single, are generally futuristic but they are negative about it.

6.2 Psychological Correlates

We chose two psychological factors, intelligence and optimism. The correlation coefficient results are shown in Table 4.

The intelligence level of the users was measured in three sub-categories: *intelligence:below_average*, *intelligence:average* and *intelligence:much_above*. Some novel findings have been observed through our results. We found a modest yet significant positive correlation between intelligence below_average and negative view of the present orientation. It suggests that the users having intelligence below average are present oriented but they seem to have negative view of it. Surprisingly, we found that average intelligent users are past-oriented but considering the sentiment dimension they seem to be more future-positive. However, this should be validated with further investigation. We found that the users who have intelligence much_above are more future orientated. Interestingly, we found a negative correlation with the future-positive. However, we found a positive correlation (0.3614) with the future-neutral which suggests that the users with much above intelligence are futuristic and they express a neutral view.

We chose three categories of optimism: optimistic, pessimistic, and neither for our observation. The result shown in Table 4 suggests that the optimistic people are future oriented. They also seem to have positive sentiment. Although the link between the future orientation and optimism is well established in literature (Lennings, 2000; Busseri et al., 2013), there is no empirical study for a large number of users. We find a relatively higher positive correlation between the pessimist and the present-negative which suggests that the pessimistic people are negative minded and focus more on present. People who are neither optimistic nor pessimistic are found to be future oriented with the neutral sentiment which is also a novel finding.

7 Conclusion and Future Work

This paper presents a first large-scale study to associate the psycho-demographic profile of the Twitter users with their sentiment view of temporal orientation based on language they use in Twitter. We first detect the temporal orientation of the tweets using the Bi-LSTM based temporal orientation classifier. We generated the temporal categories of our training set in a minimally supervised way. We created a benchmark dataset for the evaluation of our temporal orientation classifier. The temporal orientation classifier achieved an accuracy of 78.27% when run on the manually tagged test data. We added the sentiment dimension at the fine-grained level of the temporal orientation. The associations between the users' sentiment view of temporal orientation and their different psycho-demographic attributes (age, education, intelligence, optimism, and relationship) are somewhat novel in the context of the computational social science studies. Whereas the study on the temporal orientation concentrated on a coarse-grained level, we focused on the fine-grained level of temporal orientation which opens more aspects of the social, economic, and psychological research which was not possible previously on a large scale.

Acknowledging the possible limitations of this study including the quality of the sentiment classifier and a low recall of the present temporal orientation, in future, we will consider more sophisticated sentiment classifier for better performance and explore more linguistic insight into consideration to improve the performance of the temporal orientation classifier. We also like to extend our work with the link to more behavioral study and analysis.

Abstract

Word embeddings obtained from neural network models such as Word2Vec Skipgram have become popular representations of word meaning and have been evaluated on a variety of word similarity and relatedness norming data. Skipgram generates a set of word and context embeddings, the latter typically discarded after training. We demonstrate the usefulness of context embeddings in predicting asymmetric association between words from a recently published dataset of production norms (Jouravlev and McRae, 2016). Our findings suggest that humans respond with words closer to the cue within the context embedding space (rather than the word embedding space), when asked to generate thematically related words.

1 Introduction

Modern distributional semantic models such as Word2Vec (Mikolov et al., 2013a,b) and GloVe (Pennington et al., 2014) have been evaluated on a variety of word similarity and relatedness datasets. A considerable amount of attention has been paid to what models and, more recently, what parameter settings and input data produce embedding representations that better reflect similarity/relatedness between words, taking human normative judgments as the gold standard (Baroni et al., 2014; Kiela et al., 2015; Levy et al., 2015; Melamud et al., 2016; Sahlgren and Lenci, 2016).

Similarity between two words is often assumed to be a direction-less measure (e.g., *car* and *truck* are similar due to feature overlap), whereas relatedness is inherently directional (e.g., *broom* and *floor* share a functional relationship). In addition, it is well established in human behavioral data that similarity and relatedness judgments are both asymmetric. For example, humans judge *leopard* to be much more similar to *tiger* than *tiger* is to *leopard* (Tversky and Gati, 1982). A concordant asymmetry is seen in relation tasks: in free association data, *baby* is a much more likely response when cued with *stork* than *stork* would be as a response when cued with *baby* (Nelson et al., 1999). The distinction between similarity and relatedness, and the asymmetry of the judgments have typically been ignored in recent evaluations of popular embedding models.

There is ample experimental evidence in the psycholinguistic literature that similarity and relatedness are both well represented in human behavior (see Hutchison (2003), for a review), and are qualitatively distinct representations or processes. In semantic priming paradigms, a target word is processed more efficiently when briefly preceded by a related or similar word (e.g., *honey-bee* or *wasp-bee*) relative to a neutral or unrelated prime (e.g., chair-bee). Facilitation is seen for word pairs that are purely category coordinates (*lawyer-surgeon*) or purely associates (*scalpel-surgeon*), and pairs that share both types of relations (*nurse-surgeon*) tend to see an additive processing benefit that reflects the privilege of both similarity and relatedness, an effect generally referred to as the "associative boost" (Chiarello et al., 1990; Lucas, 2000). Asymmetries are the norm in semantic priming data, leading to the early theoretical prominence of spreading activation models to account for human data.

Free association data provide complimentary evidence of the qualitative distinction between relatedness and similarity in human memory. In a free association task, participants are provided with a cue word and are asked to rapidly respond with a word that comes to mind first. Huge norms of human responses have been collected over the years; for example, (Nelson et al., 1999) early norms contain three-quarters of a million responses to over 5,000 cue words across 6,000 par-

Proceedings of NAACL-HLT 2018, pages 675–684
New Orleans, Louisiana, June 1 - 6, 2018.

ticipants. More recently, (De Deyne et al., 2016) have more than doubled the size of Nelsons norms in multiple languages by gamifying the task[1] . The majority of responses in free association data are based on thematic relatedness rather than similarity per se (De Deyne and Storms, 2008). As with semantic priming, free association norms are dominated by asymmetric relations: While *stork* has a very high probability of eliciting *baby* as a response across participants, cuing with *baby* brings so many competitors to mind that it is extremely unlikely to respond with *stork* (Hutchison, 2003).

The difficulty of accounting for similarity and relatedness with a single vector representation for each word has led to the suggestion that distinct representations, and perhaps even distinct learning models, are needed for optimal performance on these distinct tasks (Mandera et al., 2017). It may be unrealistic to expect a single vector representation to account for qualitatively distinct similarity and relatedness data. Further, asymmetries in human similarity and relatedness tasks have been used as strong evidence against spatial models of semantics such as word embedding models, and in favor of Bayesian models (Griffiths et al., 2007); but see (Jones et al., 2017). The cosine between two word vectors is inherently symmetric: *leopard-tiger* has the same cosine as *tiger-leopard*.

In order to understand how distributional representation of words reflect similarity and relatedness one should study the algorithms. Each cell of a word vector in a count model indicates the first-order association between the target word and a context word, document, or topic. Dimensionality reduction algorithms are applied to obtain denser representations that can demonstrate second-order relatedness/similarity between words (e.g. applying SVD to PMI matrix). Relative to these classic models, predictive distributional models such as Word2Vec are generally more complicated. Decomposition and interpretation of the neural word embeddings is less straightforward because the final vectors incrementally converge from a predict-and-update process based on a local objective function rather than by global counting or a batch abstraction process. Most evaluative studies of predictive distributional semantics have viewed these models as a black box, considering only at the output vectors. For example, the Word2Vec Skipgram architecture has easily taken the lead and become representative of the predictive distributional semantic models, but little attention has been paid to what statistical information is best represented in the two resulting embedding sets. The Skipgram is a feed-forward network with localist input and output layers, and one hidden layer which determines the dimensionality of the final vectors. It is trained on word-context pairs with an objective function trying to minimize the error of predicting context words within a specific window around the center word. At the end of training, two matrices are produced, one representing **word embeddings** and the other representing **context embeddings** for each and every vocabulary word. While word embeddings have been used as the output of Skipgram in many previous studies, little attention has been paid to the context embeddings and the usefulness of these vectors in performing lexical semantic tasks (Levy et al., 2015; Melamud et al., 2015; Aoki et al., 2017).

Recently, Asr and Jones (2017) used an artificial language to evaluate how hyperparameter settings affected the Skipgrams representation of first- vs. second-order statistical sources. In natural languages, paradigmatic and syntagmatic information sources are non-independent, confounding similarity and relatedness judgments. Words that are more similar tend to also share functional, script, or thematic relations (Hutchison, 2003; Lucas, 2000); e.g., *surgeon-nurse*. Asr and Jones artificial language was engineered to disentangle the two sources of statistical information. Following on suggestions by Levy et al. (2015), Asr and Jones found that averaging context vectors with the word vectors (w+c post-processing) produced optimal organization of the semantic space for both paradigmatic and syntagmatic structure. The goal of the current work is to more systematically explore the integration of word and context vectors in similarity and relatedness data; our two core objectives are:

1. To evaluate the Skipgram model on thematic relatedness production norms, which implicitly manifests asymmetric relations between words compared to the typical evaluation on direction-less similarity/relatedness.
2. To explore novel ways of computing relatedness scores by contributing both word and context embeddings produced by Word2Vecs Skipgram architecture.

[1] https://smallworldofwords.org

2 Similarity vs. Relatedness Data

One of the famous datasets on word similarity/relatedness is Wordsim353 (Finkelstein et al., 2001) including 353 English word pairs, and a revised version (Agirre et al., 2009) splitting similar from related word pairs (WrordSim). These data have been repeatedly used in comparative studies on distributional semantic models. Recently, the division between similarity and relatedness judgments has been highlighted in the literature, resulting in development of new datasets with more specific annotation instructions.

Hill et al. (2015) introduced the SimLex-999 dataset (SimLex) for purified evaluation of word similarity by asking the annotators explicitly not to score based on degree of relatedness. For example, the word pair coast-shore received an average similarity score of 9.00 in SimLex and 9.10 in WordSim, while the related word pair clothes-closet was assigned an average score of 1.96 in SimLex and 8.00 in WordSim. More recently, Jouravlev and McRae (2016) collected pure relatedness data through a production experiment. They presented participants with cue words and instructed them to response only with directly related words and not taxonomically similar words. This database (ProNorm) includes responses to 100 object words, providing us with directional relatedness score for 1,169 word pairs.

The important distinction of SimLex and ProNorm datasets compared to other available similarity/relatedness data is the explicit instruction of participants to pay attention to one aspect of word relations and not the other. The ProNorm dataset, also has an advantage of a more natural setup, where associatively related words were generated by participants, rather than being selected by language experts and only rated by the participants. In this paper, we use ProNorm as the main dataset to investigate how word embedings should be used to measure relatedness between two words and how the free recall experiment can be simulated for the model. The SimLex dataset is used to set a baseline for comparison against the similarity measurement task, which is the most common intrinsic benchmark for evaluation of word embeddings. Finally, we use the WordSim dataset to explore whether the observed differences between vector-based measures of similarity and relatedness come out if the benchmark data is collected in implicit setup, where participants did not know they were rating for similarity or relatedness.

3 Word and Context Embeddings

Word embeddings produced by the Skipgram architecture have been used in many previous studies as the word meaning representation and are the main output of the model. In the original implementation of Word2Vec, the context embeddings (weights on the hidden to output layer of the neural network) were discarded after learning was complete. Inspired by Pennington et al. (2014) in the architecture of the GloVe model, Levy et al. (2015) proposed that the final word embeddings in Word2Vec could be obtained from the average of word and context embeddings. They implemented word + context (w+c) as a useful post processing option for the Word2Vec Skipgram algorithm in their published version of the model[2]. The w+c option allows computation of word similarity based upon both first and second-order co-occurrence information. The cosine similarity between two words based on the dot product of their w+c embeddings, which we call the AA measure (*A* standing for the average of word and context embeddings of a word), includes the following terms:

$$cos(a,b) = \frac{W_aW_b + C_aC_b + W_aC_b + C_aW_a}{2\sqrt{W_aC_a + 1}\sqrt{W_bC_b + 1}} \quad (1)$$

While traditional measures, i.e., WW (cosine similarity of the word embeddings), and AA (cosine similarity of the word+context embeddings) are suitable predictors for words similarity, we hypothesize that the asymmetric measures WC (word embedding of the first word and context embedding of the second) and CW (context embedding of the first word and word embedding of the second) should be better indicators of relatedness. This decomposition of similarity measures is especially useful when asymmetric associations between words are being inferred: the asymmetric measures reserve the direction and the type of relation: WC reflects the likelihood of the second word occurring in the context of the first word, and CW reflects the likelihood of the first word occurring in the context of the second word. These two quantities are different, given that the W and C matrices are obtained from two different layers

[2] https://bitbucket.org/omerlevy/hyperwords

of the neural network, one connected to the input layer and the other to the output layer.

4 Experiments

SimLex and ProNorm provide complementary scores on similarity and relatedness between words. In order to demonstrate and examine how word embeddings should be used in asymmetric relatedness measurement, we designed two experiments. In both experiments word and context embeddings were obtained from Skipgram models trained on a tokenized English Wikipedia dump[3]. We slightly modified the original Word2Vec Skipgram implementation by Levy et al. (2015) to save both word and context vectors.

We tested vector spaces with varying dimensionalities (*dim*=100/200/300) and number of context words (*win*=3/6/10), as well as minimum occurrence cutoff (*min*=1/5), negative samples (*neg*=1/5) and iterations (*iter*=1/5). These variations were tested to ensure the observed patterns reported in the experiments, but we report numerical results only for best performing models. In particular, higher dimensional vectors with *dim*=300 produced consistently better alignment with human scoring data. We also found *min*=1, *neg*=5 and *iter*=5 to be the optimal parameter settings across all experiments.

5 Quantitative Evaluation

Our first experiment follows an established evaluation strategy by computing the Spearman correlation coefficient between the set of similarity measures produced by the word embedding model (WW/CC/WC/CW/AA) and the similarity/relatedness scores taken from the SimLex and ProNorm datasets. As ProNorm score of a word pair (w_1, w_2), we simply use the total number of times a response word w_2 was produced by all subjects given w_1 as a cue word. Interested readers are encouraged to see Jouravlev and McRae (2016) for more details on the data collection procedure.

Our hypothesis is that for taxonomic similarity judgment the classic WW measure, i.e., the cosine of the word vectors of w_1 and w_2 would perform best, especially given the fact that in collection of similarity norms the direction between two words was not a factor. For explicit relatedness judgment, on the other hand, we expect one of the asymmetric measures to be the best predictor. WC, which is the cosine between the word embedding of the cue w_1 and the context embedding of the response w_2 tells us how likely we would see w_2 and similar words in the context of w_1. CW reflects the opposite way relatedness, meaning how likely it is to see w_1 and similar words in the context of w_2. Note that these two quantities are different both mathematically and conceptually, because they are obtained from generalization over word occurrences in many different contexts. We hypothesize that WC should be the best predictor for the ProNorm score of (w_1, w_2) given that production in the constrained setup of the ProNorm experiment was guided by thematic relatedness, making it more like a non-syntactic language modeling task: guessing which other words/concepts might appear within the context of the current word.

SimLex and ProNorm collections have almost the same number of word pairs. However, it is important to note that ordering ProNorm word pairs based on their relatedness scores is probably more difficult than ordering the SimLex list of word pairs. This is because in the ProNorm data collection setup, all word pairs were basically generated based on relatedness, whereas in SimLex, experimental items were pre-designed in a way they covered a wide range of closely similar to totally different word pairs. Ordering SimLex should in turn be harder than ordering words in the old WordSim353 similar and related word pair collections, because each of the latter subsets has a much smaller number of items compared to SimLex collection.

In order to demonstrate the difference between the tasks of ordering words based on similarity vs. relatedness in an explicit setup (SimLex and ProNorm) with an implicit, i.e., a mixed setup we include WordSim353 (Agirre et al., 2009) in our experiment. We hypothesize that the patterns of superiority of one vector-based measure to another in ranking word pairs based on their similarity and relatedness should come out even if people were not explicitly instructed to pay attention to a specific aspect.

5.1 Results

Table 1 displays correlation scores between similarity ratings in SimLex and Skipgram similarity measures introduced in the previous section (all

AllReg	**0.24**	**0.27**	**0.27**

Table 2: Spearman correlation between forward relatedness scores (ProNorm) and Skipgram measures.

significant at $p < 0.001$). Results on models with *dim*=300 and *win*=3/6/10 are reported (see Appendix for supplementary results). The WW measure exhibits consistently a better alignment with the human rating data compared to the all other measure. This suggests that second-order co-occurrence information plays the main role in similarity between two words. In collection of SimLex, subjects were asked explicitly not to rate similarity based on thematic relatedness. It is likely that the human ratings were affected not only by co-occurrence information encoded in word embeddings but also in context embeddings. As we expected, the best predictors of this data are the symmetric similarity measures, and in particular, WW. The last row of the table includes Spearman correlation between human similarity judgment and a linear regression model using all Skipgram measures as predictors. Thus, numbers in this row show an upper bound for Spearman scores of the individual measures (obtained from an optimal weighting of all individual measures).

Table 2 shows the Spearman correlation between ProNorm scores and the Skipgram measures (all significant at $p < 0.001$). As we hypothesized, WC stands out as the best predictor, suggesting that human responses to a cue word (when asked to name related words) are more likely to be found in the vicinity of the cue word within the context embedding space rather than within the word embedding space. The correlation between the ProNorm scores with WC is larger than with WW or AA scores. This indicates the importance of the knowledge encoded in the context embeddings, but specifically the prediction power of the asymmetric similarity measure compared to the symmetric ones. Interestingly, CW is not as good as WC in this task. This reveals the importance of the direction in associative relatedness between words such as baby and stork, which seems to correlate with their vector representations. Finally, the regression model, which applies an optimal weighing on different Skipgram measures finds the best fit, whereas AA which gives equal weights to symmetric and asymmetric measures fails to compete with WC alone. Comparisons between Tables 1 and 2 suggest that, similarity and relatedness are best approximated by symmetric and asymmetric measures, respectively.

We next examined the WordSim353 data to evaluate whether above implications apply also to ratings collected in implicit setup, i.e., where human subjects were not instructed to response based either on taxonomic similarity or associative relatedness. We examine each subset of WordSim353 separately and treat them like similarity and relatedness data. Table 3 shows results on these two collections of word pairs with best parameter setup; i.e., with *dim*=300 and *win*=3 and 6[4]. Similar to our previous experiments on the other datasets, relative ranking of similar word pairs is best predicted with commonly used measure WW alone, which is indicative of second-order co-occurrence similarity. For related word pairs, asymmetric measures WC and CW, which are indicative of first-level co-occurrence come out as better individual predictors compared to WW. However, the balanced combination of all, i.e., the AA measure seems to be the consistent winner across both datasets. This finding suggests that when similarity/relatedness is scored by people as an overall degree of closeness between words and without explicit instruction to focus on one aspect, the most reliable predictor would be a cosine measure that considers both symmetric and asymmetric types of relations between words.

[4]Results for *win*=10 were not as good as in other conditions for this experiment, therefore we only report the very best setups with *win*=3 and 6.

	Similar pairs		Related pairs	
	300-3	300-6	300-3	300-6
WW	0.79	**0.81**	0.62	0.63
CC	0.76	0.77	0.58	0.61
WC	0.76	0.79	**0.65**	**0.69**
CW	0.76	0.78	**0.65**	0.67
AA	**0.80**	**0.81**	**0.65**	0.67
AllReg	**0.80**	**0.82**	**0.69**	**0.70**

Table 3: Spearman correlation between scores from WordSim353 subsets and Skipgram measures.

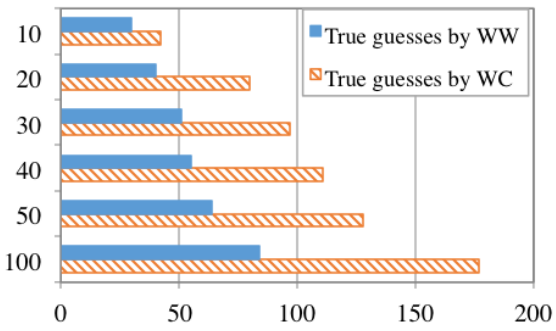

Figure 1: Number of human responses found in word and context embedding spaces near the word embedding of the cue (x-axis) as the search space is increased (y-axis).

6 Qualitative Evaluation

Our first experiment focused on discovering the best vector-based predictor for similarity and relatedness between two words. We found that considering context vectors in calculation of the similarity score produces a superior predictor, specially for relatedness, compared to the traditionally used measure (WW) based only on word vectors. The experiment in this section is a more tangible evaluation of the Word2Vec model in a relatedness task when a cue word is given. The aim is to simulate the production experiment with which the ProNorm data were collected and to evaluate whether using the WC measure will give us more true responses than WW.

For the purpose of this experiment, we use the Skipgram model with *dim*=300 and *win*=10 as these settings produced the best overall performance in the quantitative experiment on ProNorm data. The simulation procedure is as follows: For each cue word w_1 in the ProNorm dataset, each model generates the n most similar words in the vocabulary and we count how many of the human responses were contained in each set. The first model looks up nearest neighbors of w_1 within the word space (thus using WW as the proximity measure) and the second model searches for the nearest neighbors of w_1 within the Context space (thus using WC as the proximity measure). Variable n indicates the total number of guesses a model is allowed to make when responding to a given cue word. In other words, n is the size of the subspace explored around the cue word within each distributional semantic space. Since our previous experiment showed a higher correlation between WC and the relatedness norms, we expect that neighboring words within the context embedding space (in the vicinity of the cues word embedding) should be more populated with related words (i.e., human responses) compared to neighboring words within the word embedding space. Regarding the above procedure, we first extract the word embedding of the cue w_1 and then consider all human responses for that cue, i.e. w_2 of all existing pairs (w_1, w_2) in the dataset, within both the word and context embedding spaces. If, as results of the previous experiment suggest, WC is a better measure of forward relatedness, then a larger portion of human responses should be found in neighboring words within the context space than within the word space surrounding the cue word.

6.1 Results

Our distributional spaces are constructed based on Wikipedia text; therefore, the model vocabulary is very large and noisy. While the top-rank guesses of the model (both measures) are indeed similar/related to the cue words, a lot of them are more frequent in the training corpus genre, i.e. Wikipedia language, than in the simpler language humans (e.g., subjects of the ProNorm study) use when recalling direct relations. For example, in response to the cue word *restaurant* subjects of the ProNorm study generated words such as *plate*, *food*, *menu*, *drink*, and *chef*. In addition to correct guesses, both WW and WC models trained on web corpora generated words such as *bistro*, *eatery*, *hotel*, *grill* and *buffet* as closest words to *restaurant*. Another example would be the cue word *house*, which in the ProNorm experiment triggered *door*, *family*, *bricks*, *bed*, *window*, *roof*, *furniture*, *fireplace*, *chimney*, and *kitchen*. The WW model generated the following words as top candidates, which are in fact taxonomically sim-

ilar, to *house*: *mansion*, *farmhouse*, and *cottage*. WC model generates relatively more thematically related words, some of which are correct guesses (overlapping with human data) and some are not: *barn*, *residence*, *estate*, *dining*, *room*, *stables*, *fireplace*, *family*, and *kitchen*. On average, only one human response per cue can be found in the top 30 model responses. Blue and candy bars in Figure 6 show the total number of correct guesses by the model using WW and WC measures, respectively. This quantity is the total correct guesses for all 100 cues in the ProNorm dataset (x-axis), when the n most similar neighboring words are examined in each space (y-axis). We explored n values between 10 and 100.

Table 4 shows an example of our simulation for the word *car*. As the search space widens up to 100 most similar words in the vicinity of the cue word embedding, more overlap is observed between human responses and model responses. In addition to synonymous words such as *automobile*, the majority of incorrect guesses for the cue word *car* are names of automobile models such as *suv* and *bmw*. The W space around the cue word embedding is more populated with such taxonomically similar words compared to the C space around the cue word. On the other hand, as the results suggest, thematically related words such as *driver* and *steering wheel* can more easily be found within the surrounding C space. This pattern is very consistent across all the cue words in the ProNorm dataset, suggesting that WC is a more valid measure of forward thematic relatedness. This qualitative observation suggests that the differences between the Spearman correlations in Table 2 were meaningful, and vector-based measures of similarity and relatedness, i.e., WW and WC, return different sets of neighboring words to a given cue word.

n		Correct guesses by each measure
20	WW	tires
	WC	tires|driver
50	WW	tires
	WC	tires|driver|driving
100	WW	tires
	WC	tires|driver|driving|steering wheel

Table 4: Human responses for the cue word *car* found in top-n neighboring words within the word and context embedding spaces using WW and WC measures.

7 Related Work

Word embeddings learned from unlabeled text using different models such as Word2Vec and Glove are currently being used for representation of input to deep neural networks that carry out a variety of NLP tasks. Word similarity/relatedness datasets have been the basis for intrinsic evaluation of word embeddings. These datasets provide researchers with insights about how word relations are demonstrated in a distributional space. Previous work has employed WordSim353, SimLex999 and several other established similarity/relatedness datasets for evaluation of word embeddings (Baroni et al., 2014; Kiela et al., 2015; Levy et al., 2015; Melamud et al., 2016; Sahlgren and Lenci, 2016).

A closely related previous study to the current study is the comprehensive evaluation of Word2Vec and three other distributional semantic models by Levy et al. (2015), where they demonstrated that all the models could learn word relations to similar extent if hyper-parameters were carefully tuned. In particular, Levy et al. discussed the effect of averaging word and context vectors on capturing first and second-order similarity. However, the w+c option did not make it to their result tables because it was not selected as one of the generally optimal settings, while mentioned to be useful to test.

Asr and Jones (2017) looked more closely into this optional parameter setting in their study of count-based vs. predictive distributional semantic models (Word2Vec Skipgram vs. PPMI SVD). Using an artificial language framework, they showed that considering the w+c option would extend the range of word-to-word cosine similarity scores, and directly affect the topology of word clusters in the distributional space. However, none of the mentioned works studied the individual terms in the cosine similarity obtained from Word2Vec Skipgram when the w+c option is used, thus they left the question of using these terms for replicating psycholinguistic data on asymmetric association open. Another related line of research in NLP is work on retrofitting of word embeddings using additional lexical resources to reflect specific relations between words more strongly (Faruqui et al., 2015; Kiela et al., 2015). Kiela et al. (2015) looked into the particular case of similarity and relatedness. They pro-

posed using Thesaurus synonymy data and free-association data in training of the word embeddings to obtain vectors suitable for similarity and relatedness, respectively. In contrast to this category of work though, the objective of our research is elaborating the functionality of the word embedding algorithms and how their general-purpose output should be interpreted and queried rather than trying to maximize the performance of the model on a given task by modifying training data or the training mechanism.

Our study adds to the existing body of research by employing word relatedness data collected within a standard psychology experiment and showing how first- vs. second-order information accumulated on the two layers of the popular Skipgram model can be used for different tasks. We showed that the distributional measure for capturing asymmetric relatedness between two words is different from a measure that captures taxonomic similarity even though both types of information are obtained from a unified model trained on a single source of co-occurrence data.

8 Conclusions

Word and context embeddings produced by Word2Vec Skipgram are two different semantic representations of the vocabulary words within the same Euclidean space. We proposed several measures for complementary similarity and relatedness judgments computed based on these embeddings. Asymmetric measures obtained from the inner product of a vector from the word embedding space and a vector from the context embedding space are representative of first-order thematic relations between words.

We examined our proposal using a recently published dataset of production norms (Jouravlev and McRae, 2016) and confirmed when people were explicitly asked to recall thematically related words, their responses were more likely located within the context embedding space in the vicinity of the cues word embedding. In other words, WC, where W is the word embedding of the cue and C is the context embedding of the response, best measures forward thematic relatedness.

We also ran experiments on pure similarity judgment by employing a commonly used dataset of word pairs scored according to taxonomic similarity rather than other types of relations (Hill et al., 2015). Human judgments on word similarity taken from this data were best predicted by a symmetric measure, the classic WW cosine similarity between the word vectors. This suggests that the best measures of taxonomic similarity and thematic relatedness are different in distributional space, even though information involved in both measurements is collected from the same set of co-occurrence features.

Based on the observations made in the paper, we can also argue that the free recall task in the constraint manner where people are asked to name related words (such as in Jouravlev and McRae's study) is similar to the task of predicting context words for the given cue word. This is an important finding for the psycholinguitic research trying to study the mechanisms in lexical production tasks. For NLP research, these findings motivate taking different approaches in problems where thematic relations between words is important for the task, e.g., in assessment of text coherence, question answering, or language generation.

Finally, our experiments elaborated the functionality of the two transformation matrices in Word2Vec architecture. We repeated some of our experiments with GloVe, another popular word embedding model with two final sets of (word/context) vectors. We found similar patterns of relative goodness of measures: WW was consistently better in scoring similarity between two words and WC was better in measuring the thematic relatedness. However, the asymmetry between WC and CW did not come out clearly in these experiments and the overall performance of the GloVe model in the similarity task was much lower than Skipgram. A closer investigation of the GloVe model architecture will be necessary for argumentation about its different results (B Appendix includes results of our preliminary experiments with GloVe). Other vector space models obtained from non-neural architectures can also be examined in this framework. For example, Levy et al. (2015) showed that the w+c option (using the average of word and context embeddings as word vectors) could be simulated in a count-based model that applies SVD to the PMI matrix of word-context co-occurrences. Examining these models on similarity vs. relatedness using our proposed measures will be left for the future.[5]

A Appendix

Supplementary results on SimLex and ProNorm datasets using Skipgram with *dim*=100 & 200 are presented here. Patterns of how WW and CW measures predict similarity and relatedness are consistently repeated in these parameter settings.

Measure	100-3	100-6	100-10
WW	**0.36**	**0.36**	**0.34**
WC	0.31	0.32	0.33
Measure	200-3	200-6	200-10
WW	**0.42**	**0.40**	**0.39**
WC	0.34	0.35	0.35

Table 5: Spearman correlation between similarity scores (SimLex) and Skipgram measures.

Measure	100-3	100-6	100-10
WW	0.18	0.19	0.19
WC	**0.19**	**0.21**	**0.21**
Measure	200-3	200-6	200-10
WW	0.19	0.20	0.21
WC	**0.22**	**0.24**	**0.24**

Table 6: Spearman correlation between similarity scores (ProNorm) and Skipgram measures.

B Supplementary Results using GloVe

Supplementary result on SimLex and ProNorm datasets using GloVe models with *dim*=300 and *win*=3/6/10 are presented in this section. GloVe had a general disadvantage in learning word similarity (SimLex) compared to Skipgram. Patterns of how WW and CW measures predict similarity and relatedness are nevertheless similar across models: WC is much better than WW for relatedness prediction.

Measure	300-3	300-6	300-10

Semantic Structural Evaluation for Text Simplification

Elior Sulem, Omri Abend, Ari Rappoport
Department of Computer Science, The Hebrew University of Jerusalem
{eliors|oabend|arir}@cs.huji.ac.il

Abstract

Current measures for evaluating text simplification systems focus on evaluating lexical text aspects, neglecting its structural aspects. In this paper we propose the first measure to address structural aspects of text simplification, called SAMSA. It leverages recent advances in semantic parsing to assess simplification quality by decomposing the input based on its semantic structure and comparing it to the output. SAMSA provides a reference-less automatic evaluation procedure, avoiding the problems that reference-based methods face due to the vast space of valid simplifications for a given sentence. Our human evaluation experiments show both SAMSA's substantial correlation with human judgments, as well as the deficiency of existing reference-based measures in evaluating structural simplification.[1]

1 Introduction

Text simplification (*TS*) addresses the translation of an input sentence into one or more simpler sentences. It is a useful preprocessing step for several NLP tasks, such as machine translation (Chandrasekar et al., 1996; Mishra et al., 2014) and relation extraction (Niklaus et al., 2016), and has also been shown useful in the development of reading aids, e.g., for people with dyslexia (Rello et al., 2013) or non-native speakers (Siddharthan, 2002).

The task has attracted much attention in the past decade (Zhu et al., 2010; Woodsend and Lapata, 2011; Wubben et al., 2012; Siddharthan and Angrosh, 2014; Narayan and Gardent, 2014), but has yet to converge on an evaluation protocol that yields comparable results across different methods and strongly correlates with human judgments. This is in part due to the difficulty to combine the effects of different simplification operations (e.g., deletion, splitting and substitution). Xu et al. (2016) has recently made considerable progress towards that goal, and proposed to tackle it both by using an improved reference-based measure, named SARI, and by increasing the number of references. However, their research focused on lexical, rather than structural simplification, which provides a complementary view of TS quality as this paper will show.

This paper focuses on the evaluation of the structural aspects of the task. We introduce the semantic measure SAMSA (Simplification Automatic evaluation Measure through Semantic Annotation), the first structure-aware measure for TS in general, and the first to use semantic structure in this context in particular. SAMSA stipulates that an optimal split of the input is one where each predicate-argument structure is assigned its own sentence, and measures to what extent this assertion holds for the input-output pair in question, by using semantic structure. SAMSA focuses on the core semantic components of the sentence, and is tolerant towards the deletion of other units.[2]

For example, SAMSA will assign a high score to the output split "John got home. John gave Mary a call." for the input sentence "John got home and gave Mary a call.", as it splits each of its predicate-argument structures to a different sentence. Splits that alter predicate-argument relations such as "John got home and gave. Mary called." are penalized by SAMSA.

SAMSA's use of semantic structures for TS evaluation has several motivations. First, it provides means to measure the extent to which the meaning of the source is preserved in the output. Second, it provides means for measuring whether the input sentence was split to semantic units of

[1] All data and code are available in https://github.com/eliorsulem/SAMSA.

[2] We do not consider other structural operations, such as passive to active transformations (Canning, 2002), that are currently not treated by corpus-based simplification systems.

Proceedings of NAACL-HLT 2018, pages 685–696
New Orleans, Louisiana, June 1 - 6, 2018.

the right granularity. Third, defining a semantic measure that does not require references avoids the difficulties incurred by their non-uniqueness, and the difficulty in collecting high quality references, as reported by Xu et al. (2015) and by Narayan and Gardent (2014) with respect to the Parallel Wikipedia Corpus (PWKP; Zhu et al., 2010). SAMSA is further motivated by its use of semantic annotation only on the source side, which allows to evaluate multiple systems using same source-side annotation, and avoids the need to parse system outputs, which can be garbled.

In this paper we use the UCCA scheme for defining semantic structure (Abend and Rappoport, 2013). UCCA has been shown to be preserved remarkably well across translations (Sulem et al., 2015) and has also been successfully used for machine translation evaluation (Birch et al., 2016) (Section 2). We note, however, that SAMSA can be adapted to work with any semantic scheme that captures predicate-argument relations, such as AMR (Banarescu et al., 2013) or Discourse Representation Structures (Kamp, 1981), as used by Narayan and Gardent (2014).

We experiment with SAMSA both where semantic annotation is carried out manually, and where it is carried out by a parser. See Section 4. We conduct human rating experiments and compare the resulting system rankings with those predicted by SAMSA. We find that SAMSA's rankings obtain high correlations with human rankings, and compare favorably to existing reference-based measures for TS. Moreover, our results show that existing measures, which mainly target lexical simplification, are ill-suited to predict human judgments where structural simplification is involved. Finally, we apply SAMSA to the dataset of the QATS shared task on simplification evaluation (Štajner et al., 2016). We find that SAMSA obtains comparative correlation with human judgments on the task, despite operating in a more restricted setting, as it does not use human ratings as training data and focuses only on structural aspects of simplicity. Section 2 presents previous work. Section 3 discusses UCCA. Section 4 presents SAMSA. Section 5 details the collection of human judgments. Our experimental setup for comparing our human and automatic rankings is given in Section 6, and results are given in Section 7, showing superior results for SAMSA. A discussion on the results is presented in Section 8. Section 9 presents experiments with SAMSA on the QATS evaluation benchmark.

2 Related Work

Evaluation Metrics for Text Simplification. As pointed out by Xu et al. (2016), many of the existing measures for TS evaluation do not generalize across systems, because they fail to capture the combined effects of the different simplification operations. The two main directions pursued are direct human judgments and automatic measures borrowed from machine translation (MT) evaluation. Human judgments generally include grammaticality (or fluency), meaning preservation (or adequacy) and simplicity. Human evaluation is usually carried out with a small number of sentences (18 to 20), randomly selected from the test set (Wubben et al., 2012; Narayan and Gardent, 2014, 2016).

The most commonly used automatic measure for TS is BLEU (Papineni et al., 2002). Using 20 source sentences from the PWKP test corpus with 5 simplified sentences for each of them, Wubben et al. (2012) investigated the correlation of BLEU with human evaluation, reporting positive correlation for simplicity, but no correlation for adequacy. Štajner et al. (2014) explored the correlation with human judgments of six automatic metrics: cosine similarity with a bag-of-words representation, METEOR (Denkowski and Lavie, 2011), TERp (Snover et al., 2009), TINE (Rios et al., 2011) and two sub-components of TINE: T-BLEU (a variant of BLEU which uses lower n-grams when no 4-grams are found) and SRL (based on semantic role labeling). Using 280 pairs of a source sentence and a simplified output with only structural modifications, they found positive correlations for all the metrics except TERp with respect to meaning preservation and positive albeit lower correlations for METEOR, T-BLEU and TINE with respect to grammaticality. Human simplicity judgments were not considered in this experiment. In this paper we collect human judgments for grammaticality, meaning preservation and *structural* simplicity. To our knowledge, this is the first work to target structural simplicity evaluation, and it does so both through elicitation of human judgments and through the definition of SAMSA.

Xu et al. (2016) were the first to propose two evaluation measures tailored for simplification, focusing on lexical simplification. The first metric is FKBLEU, a combination of iBLEU (Sun

and Zhou, 2012), originally proposed for evaluating paraphrase generation by comparing the output both to the reference and to the input, and of the Flesch-Kincaid Index (FK), a measure of the readability of the text (Kincaid et al., 1975). The second one is SARI (System output Against References and against the Input sentence) which compares the n-grams of the system output with those of the input and the human references, separately evaluating the quality of words that are added, deleted and kept by the systems. They found that FKBLEU and even more so SARI correlate better with human simplicity judgments than BLEU. On the other hand, BLEU (with multiple references) outperforms the other metrics on the dimensions of grammaticality and meaning preservation.

As the Parallel Wikipedia Corpus (PWKP), usually used in simplification research, has been shown to contain a large portion of problematic simplifications (Xu et al., 2015; Hwang et al., 2015), Xu et al. (2016) further proposed to use multiple references (instead of a single reference) in the evaluation measures. SAMSA addresses this issue by directly comparing the input and the output of the simplification system, without requiring manually curated references.

Structural Measures for Text-to-text Generation. Other than measuring the number of splits (Narayan and Gardent, 2014, 2016), which only assesses the frequency of this operation and not its quality, no structural measures were previously proposed for the evaluation of structural simplification. The need for such a measure is pressing, given recent interest in structural simplification, e.g., in the Split and Rephrase task (Narayan et al., 2017), which focuses on sentence splitting.

In the task of sentence compression, which is similar to simplification in that they both involve deletion and paraphrasing, Clarke and Lapata (2006) showed that a metric that uses syntactic dependencies better correlates with human evaluation than a metric based on surface sub-strings. Toutanova et al. (2016) found that structure-aware metrics obtain higher correlation with human evaluation over bigram-based metrics, in particular with grammaticality judgments, but that they do not significantly outperform bigram-based metrics on any parameter. Both Clarke and Lapata (2006) and Toutanova et al. (2016) use reference-based metrics that use syntactic structure on both the output and the references. SAMSA on the other hand uses linguistic annotation only on the source side, with semantic structures instead of syntactic ones.

Semantic structures were used in MT evaluation, for example in the MEANT metric (Lo et al., 2012), which compares the output and the reference sentences, both annotated using SRL (Semantic Role Labeling). Lo et al. (2014) proposes the XMEANT variant, which compares the SRL structures of the source and output (without using references). As some frequent constructions like nominal argument structures are not addressed by the SRL annotation, Birch et al. (2016) proposed HUME, a human evaluation metric based on UCCA, using the semantic annotation only on the source side when comparing it to the output. We differ from HUME in proposing an automatic metric, tackling monolingual text simplification, rather than MT.

The UCCA annotation has also been recently used for the evaluation of Grammatical Error Correction (GEC). The USIM metric (Choshen and Abend, 2018) measures the semantic faithfulness of the output to the source by comparing their respective UCCA graphs.

Semantic Structures in Text Simplification. In most of the work investigating the structural operations involved in text simplification, both in rule-based systems (Siddharthan and Angrosh, 2014) and in statistical systems (Zhu et al., 2010; Woodsend and Lapata, 2011), the structures that were considered were syntactic. Narayan and Gardent (2014, 2016) proposed to use semantic structures in the simplification model, in particular in order to avoid splits and deletions which are inconsistent with the semantic structures. SAMSA identifies such incoherent splits, e.g., a split of a phrase describing a single event, and penalizes them.

Glavas and Štajner (2013) presented two simplification systems based on event extraction. One of them, named Event-wise Simplification, transforms each factual event motion into a separate sentence. This approach fits with SAMSA's stipulation, that an optimal structural simplification is one where each (UCCA-) event in the input sentence is assigned a separate output sentence. However, unlike in their model, SAMSA stipulates that not only should multiple events evoked by a verb in the same sentence be avoided in a simplification, but penalizes sentences containing multiple events evoked by a lexical item of any category. For example, the sentence "John's un-

expected kick towards the gate saved the game" which has two events, one evoked by "kick" (a noun) and another by "saving" (a verb) can be converted to "John kicked the ball towards the gate. It saved the game."

3 UCCA's Semantic Structures

In this section we will briefly describe the UCCA scheme, focusing on the concepts of Scenes and Centers which are key in the definition of SAMSA. UCCA (Universal Cognitive Conceptual Annotation; Abend and Rappoport, 2013) is a semantic annotation scheme based on typological (Dixon, 2010b,a, 2012) and cognitive (Langacker, 2008) theories which aims to represent the main semantic phenomena in the text, abstracting away from syntactic detail. UCCA structures are directed acyclic graphs whose nodes (or units) correspond either to the leaves of the graph (including the words of the text) or to several elements jointly viewed as a single entity according to some semantic or cognitive consideration. Unlike AMR, UCCA semantic units are directly anchored in the text (Abend and Rappoport, 2017; Birch et al., 2016), which allows easy inclusion of a word-to-word alignment in the metric model (Section 4).

UCCA Scenes. A Scene, which is the most basic notion of the foundational layer of UCCA considered here, describes a movement, an action or a state which persists in time. Every Scene contains one main relation, which can be either a Process or a State. The Scene may contain one or more Participants, which are interpreted in a broad sense, including locations and destinations. For example, the sentence "He ran into the park" has a single Scene whose Process is "ran". The two Participants are "He" and "into the park".

Scenes can have several roles in the text. First, they can provide additional information about an established entity (Elaborator Scenes) as for example the Scene "who entered the house" in the sentence "The man who entered the house is John". They can also be one of the Participants of another Scene, for example, "he will be late" in the sentence: "He said he will be late". In the other cases, the Scenes are annotated as parallel Scenes (H) which can be linked by a Linker (L): "When$_L$ [he will arrive at home]$_H$, [he will call them]$_H$".

Unit Centers. With regard to units which are not Scenes, the category Center denotes the semantic head of the unit. For example, "dogs" is the center of the expression "big brown dogs" and "box" is the center of "in the box". There could be more than one Center in a non-Scene unit, for example in the case of coordination, where all conjuncts are Centers.

4 The SAMSA Metric

SAMSA's main premise is that a structurally correct simplification is one where: (1) each sentence contains a single event from the input (UCCA Scene), (2) the main relation of each of the events and their participants are retained in the output.

For example, consider "John wrote a book. I read that book." as a simplification of "I read the book that John wrote.". Each output sentence contains one Scene, which has the same Scene elements as the source, and would thus be deemed correct by SAMSA. On the other hand, the output "John wrote. I read the book." is an incorrect split of that sentence, since a participant of the "writing" Scene, namely "the book" is absent in the split sentence. SAMSA would indeed penalize such a case.

Similarly, Scenes which have elements across several sentences receive a zero score by SAMSA. As an example, consider the sentence "The combination of new weapons and tactics marks this battle as the end of chivalry", and erroneous split "The combination of new weapons and tactics. It is the end of chivalry." (adapted from the output of a recent system on the PWKP corpus), which does not preserve the original meaning.

4.1 Matching Scenes to Sentences

SAMSA is based on two external linguistic resources. One is a semantic annotation (UCCA in our experiments) of the source side, which can be carried out either manually or automatically, using the TUPA parser[3] (Transition-based UCCA parser; Hershcovich et al., 2017) for UCCA. UCCA decomposes each sentence s into a set of Scenes $\{sc_1, sc_2, .., sc_n\}$, where each scene sc_i contains a main relation mr_i (sub-span of sc_i) and a set of zero or more participants A_i.

The second resource is a word-to-word alignment A between the words in the input and one or zero words in the output. The monolingual alignment thus permits SAMSA not to penalize outputs that involve lexical substitutions (e.g., "com-

[3] https://github.com/danielhers/tupa

mence" might be aligned with "start"). We denote by n_{inp} the number of UCCA Scenes in the input sentence and by n_{out} the number of sentences in the output.

Given an input sentence's UCCA Scenes $sc_1, \ldots, sc_{n_{inp}}$, a non-annotated output of a simplification system split into sentences $s_1, \ldots, s_{n_{out}}$, and their word alignment A, we distinguish between two cases:

1. $n_{inp} \geq n_{out}$: in this case, we compute the maximal Many-to-1 correspondence between Scenes and sentences. A Scene is matched to a sentence in the following way. We say that a leaf l in a Scene sc is *consistent* in a Scene-sentence mapping M which maps sc to a sentence s, if there is a word $w \in s$ which l aligns to (according to the word alignment A). The score of matching a Scene sc to a sentence s is then defined to be the total number of consistent leaves in sc. We traverse the Scenes in their order of occurrence in the text, selecting for each the sentence that maximizes the score. If $n_{inp} = n_{out}$, once a sentence is matched to a Scene, it cannot be matched to another one. Ties between sentences are broken towards the sentence that appeared first in the output.

$$\mathrm{M}^*(sc_i) = \mathrm{argmax}_s score(sc_i, s)$$
$$\text{s.t. } s \notin \{M^*(sc_1), \ldots, M^*(sc_{i-1})\} \text{ if } n_{inp} = n_{out}$$

2. $n_{inp} < n_{out}$: In this case, a Scene will necessarily be split across several sentences. As this is an undesired result, we assign this instance a score of zero.

4.2 Score Computation

Minimal Centers. The minimal center of a UCCA unit u is UCCA's notion of a semantic head word, defined through recursive rules not unlike the head propagation rules used for converting constituency structures to dependency structures. More formally, we define the minimal center of a UCCA unit u (here a Participant or a Main Relation) to be the UCCA graph's leaf reached by starting from u and iteratively selecting the child tagged as Center. If a Participant (or a Center inside a Participant) is a Scene, its center is the main relation (Process or State) of the Scene.

For example, the center of the unit "The previous president of the commission" (u_1) is "president of the commission". The center of the latter is "president", which is a leaf in the graph. So the minimal center of u_1 is "president".

Given the input sentence Scenes $\{sc_1, ..., sc_{n_{inp}}\}$, the output sentences $\{s_1, ..., s_{n_{out}}\}$, and a mapping between them M^*, SAMSA is defined as:

$$\frac{n_{out}}{n_{inp}} \frac{1}{2n_{inp}} \sum_{sc_i} [\mathbb{1}_{M^*(sc_i)}(MR_i) + \frac{1}{k_i} \sum_{j=1}^{k_i} \mathbb{1}_{M^*(sc_i)}(\mathrm{Par}_i^{(j)})]$$

where $\mathrm{MR_i}$ is the minimal center of the main relation (Process or State) of sc_i, and $\mathrm{Par_i^{(j)}}$ ($j = 1, \ldots, k_i$) are the minimal centers of the Participants of sc_i.

For an output sentence s, $\mathbb{1}_s(u)$ is a function from the input units to $\{0, 1\}$, which returns 1 iff u is aligned (according to A) with a word in s.[4]

The role of the non-splitting penalty term n_{out}/n_{inp} in the SAMSA formula is to penalize cases where the number of sentences in the output is smaller than the number of Scenes. In order to isolate the effect of the non-splitting penalty, we experiment with an additional metric SAMSA$_{abl}$ (reads "SAMSA ablated"), which is identical to SAMSA but does not take this term into account. Corpus-level SAMSA and SAMSA$_{abl}$ scores are obtained by averaging their sentence scores.

In the case of implicit units i.e. omitted units that do not appear explicitly in the text (Abend and Rappoport, 2013), since the unit preservation cannot be directly captured, the score t for the relevant unit will be set to 0.5. For example, in the Scene "traveling is fun", the people who are traveling correspond to an implicit Participant. As implicit units are not covered by TUPA, this will only be relevant for the semi-automatic implementation of the metric (see Section 6).

5 Human Evaluation Benchmark

5.1 Evaluation Protocol

For testing the automatic metric, we first build a human evaluation benchmark, using 100 sentences from the complex part of the PWKP corpus and the outputs of six recent simplification systems for these sentences:[5] (1) TSM (Zhu et al., 2010) using Tree-Based SMT, (2) RevILP (Woodsend and Lapata, 2011) using Quasi-Synchronous Grammars, (3) PBMT-R (Wubben et al., 2012) using Phrase-Based SMT, (4) Hybrid (Narayan and Gardent,

[4] In some cases, the unit u can be a sequence of centers (if there are several minimal centers). In these cases, $\mathbb{1}_s(u)$ returns 1 iff the condition holds for all centers.

[5] All the data can be found here: http://homepages.inf.ed.ac.uk/snaraya2/data/simplification-2016.tgz.

2014), a supervised system using DRS, (5) UNSUP (Narayan and Gardent, 2016), an unsupervised system using DRS, and (6) Split-Deletion (Narayan and Gardent, 2016), the unsupervised system with only structural operations.

All these systems explicitly address at least one type of structural simplification operation. The last system, Split-Deletion, performs only structural (i.e., no lexical) operations. It is thus an interesting test case for SAMSA since here the aligner can be replaced by a simple match between identical words. In total we obtain 600 system outputs from the six systems, as well as 100 sentences from the simple Wikipedia side of the corpus, which serve as references. Five in-house annotators with high proficiency in English evaluated the resulting 700 input-output pairs by answering the questions in Table 1.[6]

Qa addresses grammaticality, Qb and Qc capture two complementary aspects of meaning preservation (the addition and the removal of information) and Qd addresses structural simplicity. Possible answers are: 1 ("no"), 2 ("maybe") and 3 ("yes"). Following Glavas and Štajner (2013), we used a 3 point Likert scale, which has recently been shown to be preferable over a 5 point scale through human studies on sentence compression (Toutanova et al., 2016).

Question Qd was accompanied by a negative example [7] showing a case of lexical simplification, where a complex word is replaced by a simple one. A positive example was not included so as not to bias the annotators by revealing the nature of the operations our experiments focus on (i.e., splitting and deletion).

The PWKP test corpus (Zhu et al., 2010) was selected for our experiments over the development and test sets used in (Xu et al., 2016), as the latter's selection process was explicitly biased towards input-output pairs that mainly contain lexical simplifications.

Qa	Is the output grammatical?
Qb	Does the output add information, compared to the input?
Qc	Does the output remove important information, compared to the input?
Qd	Is the output simpler than the input, ignoring the complexity of the words?

Table 1: Questions for the human evaluation

[6]Each input-output pair was rated by all five annotators.
[7]Other questions appeared without any example.

5.2 Human Score Computation

Given the annotator's answers, we consider the following scores. First, the grammaticality score $\mathcal{G}$ is the answer to Qa. By inverting (changing 1 to 3 and 3 to 1) the answer for Qb, we obtain a Non-Addition score indicating to which extent no additional information has been added. Similarly, inverting the answer to Qc yields the Non-Removal score. Averaging these two scores, we obtain the meaning preservation score $\mathcal{P}$. Finally, the structural simplicity score $\mathcal{S}$ is the answer to Qd. Each of these scores is averaged over the five annotators. We further compute an average human score:

$$\text{AvgHuman} = \frac{1}{3}(\mathcal{G} + \mathcal{P} + \mathcal{S})$$

5.3 Inter-annotator Agreement

Inter-annotator agreement rates are computed in two ways. Table 2 presents the absolute agreement and Cohen's quadratic weighted κ (Cohen, 1968). Table 3 presents Spearman's correlation (ρ) between the human ratings of the input-output pairs (top row), and between the resulting system scores (bottom row). In both cases, the agreement between the five annotators is computed as the average agreement over the 10 annotator pairs.

	Qa	Qb	Qc	Qd
Total	0.58 (0.56)	0.74 (0.30)	0.53 (0.45)	0.57 (0.10)
TSM	0.59 (0.47)	0.75 (0.27)	0.50 (0.40)	0.43 (0.08)
RevILP	0.61 (0.59)	0.78 (0.27)	0.60 (0.43)	0.62 (0.11)
PBMT-R	0.47 (0.42)	0.70 (0.20)	0.58 (0.31)	0.76 (0.10)
Hybrid	0.59 (0.46)	0.77 (0.26)	0.52 (0.48)	0.72 (0.15)
UNSUP	0.51 (0.42)	0.59 (0.10)	0.45 (0.17)	0.52 (0.04)
Split-Deletion	0.59 (0.48)	0.93 (0.02)	0.45 (0.29)	0.55 (0.04)
Reference	0.70 (0.40)	0.66 (0.46)	0.52 (0.58)	0.41 (0.12)

Table 2: Inter-annotator absolute agreement (and quadratic weighted κ), averaged over the 10 annotator pairs. Rows correspond to systems, columns to questions. The top "Total" row refers to the concatenation of the outputs of all 6 systems together with the reference sentences.

	Qa	Qb	Qc	Qd	AvgHuman
Sen.	0.63^{*}	0.30^{*}	0.48^{*}	0.11^{**}	0.49^{*}
Sys.	0.92^{**}	0.54 (0.1)	0.64 (0.06)	0.14 (0.4)	0.64 (0.06)

Table 3: Spearman's correlation (and p-values) of the system-level (top row) and sentence-level (bottom row) ratings of the five annotators. $^{*}p < 10^{-5}$, $^{**}p = 0.002$.

6 Experimental Setup

We further compute SAMSA for the 100 sentences of the PWKP test set and the corresponding system outputs. Experiments are conducted in two settings: (1) a semi-automatic setting where

UCCA annotation was carried out manually by a single expert UCCA annotator using the UCCAApp annotation software (Abend et al., 2017), and according to the standard annotation guidelines;[8] (2) an automatic setting where the UCCA annotation was carried out by the TUPA parser (Hershcovich et al., 2017). Sentence segmentation of the outputs was carried out using the NLTK package (Loper and Bird, 2002). For word alignments, we used the aligner of Sultan et al. (2014).[9]

7 Correlation with Human Evaluation

We compare the system rankings obtained by SAMSA and by the four human parameters. We find that the two leading systems according to AvgHuman and SAMSA turn out to be the same: Split-Deletion and RevILP. This is the case both for the semi-automatic and the automatic implementations of the metric. A Spearman ρ correlation between the human and SAMSA scores (comparing their rankings) is presented in Table 4.

We compare SAMSA and SAMSA$_{abl}$ to the reference-based measures SARI[10] (Xu et al., 2016) and BLEU, as well as to the negative Levenshtein distance to the reference (-LD$_{\mathrm{SR}}$). We use the only available reference for this corpus, in accordance with the standard practice. SARI is a reference-based measure, based on n-gram overlap between the source, output and reference, and focuses on lexical (rather than structural) simplification. For completeness, we include the other two measures reported in Narayan and Gardent (2016), which are measures of similarity to the input (i.e., they quantify the tendency of the systems to introduce changes to the input): the negative Levenshtein distances between the output and input compared to the original complex corpus (-LD$_{\mathrm{SC}}$), and the number of sentences split by each of the systems.

The highest correlation with AvgHuman and grammaticality is obtained by semi-automatic SAMSA (0.58 and 0.54), a high correlation especially in comparison to the inter-annotator agreement on AvgHuman (0.64, Table 3). The automatic version obtains high correlation with human judgments in these settings, where for structural simplicity, it scores somewhat higher than the semi-automatic SAMSA. The highest correlation with structural simplicity is obtained by the number of sentences with splitting, where SAMSA (automatic and semi-automatic) is second and third highest, although when restricted to multi-Scene sentences, the correlation for SAMSA (semi-automatic) is higher (0.89, $p = 0.009$ and 0.77, $p = 0.04$).

The highest correlation for meaning preservation is obtained by SAMSA$_{abl}$ which provides further evidence that the retainment of semantic structures is a strong predictor of meaning preservation (Sulem et al., 2015). SAMSA in itself does not correlate with meaning preservation, probably due to its penalization of under-splitting sentences.

Note that the standard reference-based measures for simplification, BLEU and SARI, obtain low and often negative correlation with human ratings. We believe that this is the case because SARI and BLEU admittedly focus on lexical simplification, and are difficult to use to rank systems which also perform structural simplification.

Our results thus suggest that SAMSA provides additional value in predicting the quality of a simplification system and should be reported in tandem with more lexically-oriented measures.

8 Discussion

Human evaluation parameters. The fact that the highest correlations for structural simplicity and meaning preservation are obtained by different metrics (SAMSA and SAMSA$_{abl}$ respectively) highlights the complementarity of these two parameters for evaluating TS quality but also the difficulty of capturing them together. Indeed, a given sentence-level operation could both change the original meaning by adding or removing information (affecting the $\mathcal{P}$ score) and increase simplicity ($\mathcal{S}$). On the other hand, the identity transformation perfectly preserves the meaning of the original sentence without making it simpler.

For examining this phenomenon, we compute Spearman's correlation at the system-level between the simplicity and meaning preservation human scores. We obtain a correlation of -0.77 ($p = 0.04$) between $\mathcal{S}$ and $\mathcal{P}$. The correlation between $\mathcal{S}$ and the two sub-components of $\mathcal{P}$, the Non-Addition and the Non-Removal scores, are -0.43 ($p = 0.2$) and -0.77 ($p = 0.04$) respectively. These negative correlations support our use

Table 4: Spearman's correlation of system scores i.e. Pearson's correlation of system rankings (and p-values), between evaluation measures (columns) and human judgments (rows). The ranking is between the six simplification systems experimented with. The left block of columns corresponds to the SAMSA and SAMSA_{abl} measures, in their semi-automatic and automatic forms. The middle block of columns corresponds to the reference-based measures SARI and BLEU, as well as -LD_{SR}, which is the negative Levenshtein distances of the system output from the reference. The right block corresponds to measures of conservatism, and reflect how well the tendency of the systems to introduce changes to the input correlates with the human rankings. The block includes -LD_{SC}, the negative Levenshtein distance from the source sentence, and the number of input sentences split by each of the systems. Levenshtein distances are taken as negative in order to capture similarity between the output and source/reference. The measure with the highest correlation in each row is boldfaced.

of an average human score for assessing the overall quality of the simplification.

Distribution at the sentence level. In addition to the system-level analysis presented in Section 7, we also investigate the behavior of SAMSA at the sentence level by examining its joint distribution with the human evaluation scores. Focusing on the AvgHuman score and the automatic implementation of SAMSA and using the same data as in Section 7, we consider a single pair of scores $(\text{AvgHuman}_i, \text{SAMSA}_i)$, $1 \leq i \leq 100$, for each of the 100 source sentences, averaging over the SAMSA and human scores obtained for the 6 simplification systems (See Figure 1).

The joint distribution indicates a positive correlation between SAMSA and AvgHuman. The corresponding Pearson correlation is indeed 0.27 ($p = 0.03$).

9 Evaluation on the QATS Benchmark

In order to provide further validation for SAMSA predictive value for quality of simplification systems, we report SAMSA's correlation with a recently proposed benchmark, used for the QATS (Quality Assessment for Text Simplification) shared task (Štajner et al., 2016).

Setup. The test corpus contains 126 sentences taken from 3 datasets described in Štajner et al. (2016)[11]: (1) EventS: original sentences from the EMM News-Brief[12] and their syntactically simplified versions (with significant content reduction) by the EventSimplify TS system (Glavas and Štajner, 2013)[13] (the test corpus contains 54 pairs from this dataset), (2) EncBrit: original sentences from the Encyclopedia Britannica (Barzilay and Elhadad, 2003) and their automatic simplifications obtained using ATS systems based on several phrase-based statistical MT systems (Štajner et al., 2015) trained on Wikipedia TS corpus (Coster and Kauchak, 2011) (24 pairs), and (3) LSLight: sentences from English Wikipedia and their automatic simplifications (Glavaš and Štajner, 2015) by three different lexical simplification systems (Biran et al., 2011; Horn et al., 2014; Glavaš and Štajner, 2015) (48 pairs).

Human evaluation is also provided by this resource, with scores for overall quality, grammaticality, meaning preservation and simplicity. Importantly, the simplicity score does not explicitly refer to the output's structural simplicity, but rather to its readability. We focus on the overall human score, and compare it to SAMSA. Since different systems were used to simplify different portions of the input, correlation is taken at the sentence level.

We use the same implementations of SAMSA. Manual UCCA annotation is here performed by one of the authors of this paper.

Results. We follow Štajner et al. (2016) and report the Pearson correlations (at the sentence level) between the rankings of the metrics and the human evaluation scores. Results show that the semi-automatic/automatic SAMSA obtains a Pearson correlation of 0.32 and 0.28 with the human scores. This places these measures in the 3rd and 4th places in the shared task, where the only two systems that surpassed it are marginally better, with scores of 0.33 and 0.34, and where the next

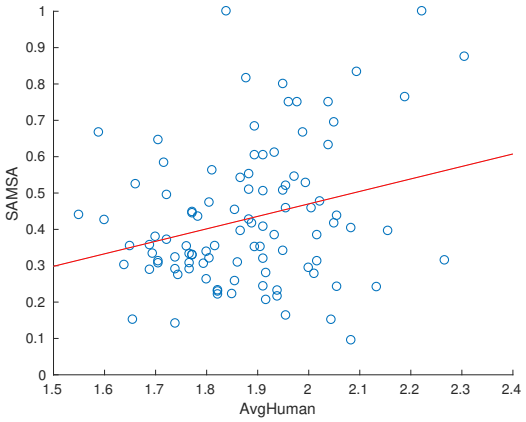

Figure 1: Joint distribution of the automatic SAMSA and the AvgHuman scores at the sentence level. Each point in the graph corresponds to a single source sentence. In addition to the scatter plot, a least-squares regression line is presented.

system in QATS obtained a correlation of 0.23.

This correlation by SAMSA was obtained in more restricted conditions, compared to the measures that competed in QATS. First, SAMSA computes its score by only considering the UCCA structure of the source, and an automatic word-to-word alignment between the source and output. Most QATS systems, including OSVCML and OSVCML2 (Nisioi and Nauze, 2016) which scored highest on the shared task, use an ensemble of classifiers based on bag-of-words, POS tags, sentiment information, negation, readability measures and other resources. Second, the systems participating in the shared task had training data available to them, annotated by the same annotators as the test data. This was used to train classifiers for predicting their score. This gives the QATS measures much predictive strength, but hampers their interpretability. SAMSA on the other hand is conceptually simple and interpretable. Third, the QATS shared task does not focus on structural simplification, but experiments on different types of systems. Indeed, some of the data was annotated by systems that exclusively perform lexical simplification, which is orthogonal to SAMSA's structural focus.

Given these factors, SAMSA's competitive correlation with the participating systems in QATS suggests that structural simplicity, as reflected by the correct splitting of UCCA Scenes, captures a major component in overall simplification quality, underscoring SAMSA's value. These promising results also motivate a future combination of SAMSA with classifier-based metrics.

10 Conclusion

We presented the first structure-aware metric for text simplification, SAMSA, and the first evaluation experiments that directly target the structural simplification component, separately from the lexical component. We argue that the structural and lexical dimensions of simplification are loosely related, and that TS evaluation protocols should assess both. We empirically demonstrate that strong measures that assess lexical simplification quality (notably SARI), fail to correlate with human judgments when structural simplification is performed by the evaluated systems. Our experiments show that SAMSA correlates well with human judgments in such settings, which demonstrates its usefulness for evaluating and tuning statistical simplification systems, and shows that structural evaluation provides a complementary perspective on simplification quality.

Acknowledgments

We would like to thank Zhemin Zhu and Sander Wubben for sharing their data, as well as the annotators for participating in our evaluation and UCCA annotation experiments. We also thank Daniel Hershcovich and the anonymous reviewers for their helpful comments. This work was partially supported by the Intel Collaborative Research Institute for Computational Intelligence (ICRI-CI) and by the Israel Science Foundation (grant No. 929/17), as well as by the HUJI Cyber Security Research Center in conjunction with the Israel National Cyber Bureau in the Prime Minister's Office.

Entity Commonsense Representation for Neural Abstractive Summarization

Reinald Kim Amplayo* and **Seonjae Lim*** and **Seung-won Hwang**
Yonsei University, Seoul, South Korea
{rktamplayo, sun.lim, seungwonh}@yonsei.ac.kr

Abstract

A major proportion of a text summary includes important entities found in the original text. These entities build up the topic of the summary. Moreover, they hold commonsense information once they are linked to a knowledge base. Based on these observations, this paper investigates the usage of linked entities to guide the decoder of a neural text summarizer to generate concise and better summaries. To this end, we leverage on an off-the-shelf entity linking system (ELS) to extract linked entities and propose **Entity2Topic (E2T)**, a module easily attachable to a sequence-to-sequence model that transforms a list of entities into a vector representation of the topic of the summary. Current available ELS's are still not sufficiently effective, possibly introducing unresolved ambiguities and irrelevant entities. We resolve the imperfections of the ELS by (a) encoding entities with selective disambiguation, and (b) pooling entity vectors using firm attention. By applying E2T to a simple sequence-to-sequence model with attention mechanism as base model, we see significant improvements of the performance in the Gigaword (sentence to title) and CNN (long document to multi-sentence highlights) summarization datasets by at least 2 ROUGE points.

1 Introduction

Text summarization is a task to generate a shorter and concise version of a text while preserving the meaning of the original text. The task can be divided into two subtask based on the approach: extractive and abstractive summarization. Extractive summarization is a task to create summaries by pulling out snippets of text form the original text and combining them to form a summary. Abstractive summarization asks to generate summaries from scratch without the restriction to use the available words from the original text. Due to the limitations of extractive summarization on incoherent texts and unnatural methodology (Yao et al., 2017), the research trend has shifted towards abstractive summarization.

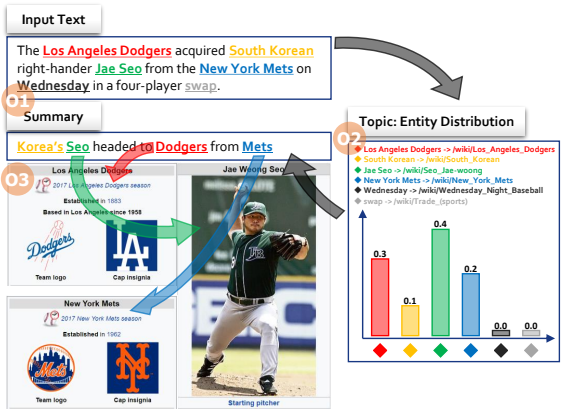

Figure 1: Observations on linked entities in summaries. **O1**: Summaries are mainly composed of entities. **O2**: Entities can be used to represent the topic of the summary. **O3**: Entity commonsense learned from a large corpus can be used.

Sequence-to-sequence models (Sutskever et al., 2014) with attention mechanism (Bahdanau et al., 2014) have found great success in generating abstractive summaries, both from a single sentence (Chopra et al., 2016) and from a long document with multiple sentences (Chen et al., 2016). However, when generating summaries, it is necessary to determine the main topic and to sift out unnecessary information that can be omitted. Sequence-to-sequence models have the tendency to include all the information, relevant or not, that are found in the original text. This may result to unconcise summaries that concentrates wrongly on irrelevant topics. The problem is especially severe when summarizing longer texts.

In this paper, we propose to use entities found in the original text to infer the summary topic, miti-

Proceedings of NAACL-HLT 2018, pages 697–707
New Orleans, Louisiana, June 1 - 6, 2018.

gating the aforementioned problem. Specifically, we leverage on linked entities extracted by employing a readily available entity linking system. The importance of using linked entities in summarization is intuitive and can be explained by looking at Figure 1 as an example. First (**O1** in the Figure), aside from auxiliary words to construct a sentence, a summary is mainly composed of linked entities extracted from the original text. Second (**O2**), we can depict the main topic of the summary as a probability distribution of relevant entities from the list of entities. Finally (**O3**), we can leverage on entity commonsense learned from a separate large knowledge base such as Wikipedia.

To this end, we present a method to effectively apply linked entities in sequence-to-sequence models, called **Entity2Topic (E2T)**. E2T is a module that can be easily attached to any sequence-to-sequence based summarization model. The module encodes the entities extracted from the original text by an entity linking system (ELS), constructs a vector representing the topic of the summary to be generated, and informs the decoder about the constructed topic vector. Due to the imperfections of current ELS's, the extracted linked entities may be too **ambiguous** and **coarse** to be considered relevant to the summary. We solve this issue by using entity encoders with **selective disambiguation** and by constructing topic vectors using **firm attention**.

We experiment on two datasets, Gigaword and CNN, with varying lengths. We show that applying our module to a sequence-to-sequence model with attention mechanism significantly increases its performance on both datasets. Moreover, when compared with the state-of-the-art models for each dataset, the model obtains a comparable performance on the Gigaword dataset where the texts are short, and outperforms all competing models on the CNN dataset where the texts are longer. Furthermore, we provide analysis on how our model effectively uses the extracted linked entities to produce concise and better summaries.

2 Usefulness of linked entities in summarization

In the next subsections, we present detailed arguments with empirical and previously examined evidences on the observations and possible issues when using linked entities extracted by an entity linking system (ELS) for generating abstractive summaries. For this purpose, we use the development sets of the Gigaword dataset provided in (Rush et al., 2015) and of the CNN dataset provided in (Hermann et al., 2015) as the experimental data for quantitative evidence and refer the readers to Figure 1 as the running example.

2.1 Observations

As discussed in Section 1, we find three observations that show the usefulness of linked entities for abstractive summarization.

First, summaries are mainly composed of linked entities extracted from the original text. In the example, it can be seen that the summary contains four words that refer to different entities. In fact, all noun phrases in the summary mention at least one linked entity. In our experimental data, we extract linked entities from the original text and compare them to the noun phrases found in the summary. We report that 77.1% and 75.1% of the noun phrases on the Gigaword and CNN datasets, respectively, contain at least one linked entity, which confirms our observation.

Second, linked entities can be used to represent the topic of the summary, defined as a multinomial distribution over entities, as graphically shown in the example, where the probabilities refer to the relevance of the entities. Entities have been previously used to represent topics (Newman et al., 2006), as they can be utilized as a controlled vocabulary of the main topics in a document (Hulpus et al., 2013). In the example, we see that the entity "*Jae Seo*" is the most relevant because it is the subject of the summary, while the entity "*South Korean*" is less relevant because it is less important when constructing the summary.

Third, we can make use of the entity commonsense that can be learned as a continuous vector representation from a separate larger corpus (Ni et al., 2016; Yamada et al., 2017). In the example, if we know that the entities "*Los Angeles Dodgers*" and "*New York Mets*" are American baseball teams and "*Jae Seo*" is a baseball player associated with the teams, then we can use this information to generate more coherent summaries. We find that 76.0% of the extracted linked entities are covered by the pre-trained vectors[1] in our experimental data, proving our third observation.

[1] https://github.com/idio/wiki2vec

2.2 Possible issues

Despite its usefulness, linked entities extracted from ELS's have issues because of low precision rates (Hasibi et al., 2016) and design challenges in training datasets (Ling et al., 2015). These issues can be summarized into two parts: ambiguity and coarseness.

First, the extracted entities may be ambiguous. In the example, the entity "*South Korean*" is ambiguous because it can refer to both the South Korean person and the South Korean language, among others[2]. In our experimental data, we extract (1) the top 100 entities based on frequency, and (2) the entities extracted from 100 randomly selected texts, and check whether they have disambiguation pages in Wikipedia or not. We discover that 71.0% of the top 100 entities and 53.6% of the entities picked at random have disambiguation pages, which shows that most entities are prone to ambiguity problems.

Second, the linked entities may also be too common to be considered an entity. This may introduce *errors* and *irrelevance* to the summary. In the example, "*Wednesday*" is erroneous because it is wrongly linked to the entity "*Wednesday Night Baseball*". Also, "*swap*" is irrelevant because although it is linked correctly to the entity "*Trade (Sports)*", it is too common and irrelevant when generating the summaries. In our experimental data, we randomly select 100 data instances and tag the correctness and relevance of extracted entities into one of four labels: A: correct and relevant, B: correct and somewhat relevant, C: correct but irrelevant, and D: incorrect. Results show that 29.4%, 13.7%, 30.0%, and 26.9% are tagged with A, B, C, and D, respectively, which shows that there is a large amount of incorrect and irrelevant entities.

3 Our model

To solve the issues described above, we present **Entity2Topic (E2T)**, a module that can be easily attached to any sequence-to-sequence based abstractive summarization model. E2T encodes the linked entities extracted from the text and transforms them into a single topic vector. This vector is ultimately concatenated to the decoder hidden state vectors. The module contains two submodules specifically for the issues presented by the entity linking systems: the entity encoding submodule with selective disambiguation and the pooling submodule with firm attention.

Overall, our full architecture can be illustrated as in Figure 2, which consists of an entity linking system (ELS), a sequence-to-sequence with attention mechanism model, and the E2T module. We note that our proposed module can be easily attached to more sophisticated abstractive summarization models (Zhou et al., 2017; Tan et al., 2017) that are based on the traditional encoder-decoder framework and consequently can produce better results. The code of the base model and the E2T are available online[3].

3.1 Base model

As our base model, we employ a basic encoder-decoder RNN used in most neural machine translation (Bahdanau et al., 2014) and text summarization (Nallapati et al., 2016) tasks. We employ a two-layer bidirectional GRU (BiGRU) as the recurrent unit of the encoder. The BiGRU consists of a forward and backward GRU, which results to sequences of forward and backward hidden states $(\overrightarrow{h}_1, \overrightarrow{h}_2, ..., \overrightarrow{h}_n)$ and $(\overleftarrow{h}_1, \overleftarrow{h}_2, ..., \overleftarrow{h}_n)$, respectively:

$$\overrightarrow{h}_i = GRU(x_i, \overrightarrow{h}_{i-1})$$
$$\overleftarrow{h}_i = GRU(x_i, \overleftarrow{h}_{i+1})$$

The forward and backward hidden states are concatenated to get the hidden state vectors of the tokens (i.e. $h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i]$). The final states of the forward and backward GRU are also concatenated to create the final text representation vector of the encoder $s = [\overrightarrow{h}_n; \overleftarrow{h}_1]$. These values are calculated per layer, where x_t of the second layer is h_t of the first layer. The final text representation vectors are projected by a fully connected layer and are passed to the decoder as the initial hidden states $s_0 = s$.

For the decoder, we use a two-layer unidirectional GRU with attention. At each time step t, the previous token y_{t-1}, the previous hidden state s_{t-1}, and the previous context vector c_{t-1} are passed to a GRU to calculate the new hidden state s_t, as shown in the equation below.

$$s_t = GRU(w_{t-1}, s_{t-1}, c_{t-1})$$

[2] https://en.wikipedia.org/wiki/South_Korean

[3] https://github.com/rktamplayo/Entity2Topic

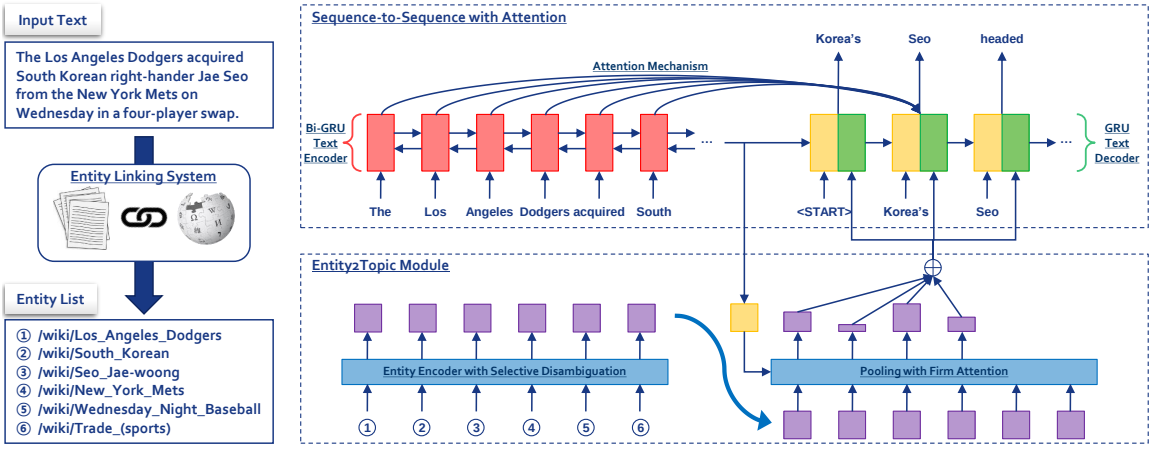

Figure 2: Full architecture of our proposed sequence-to-sequence model with Entity2Topic (E2T) module.

The context vector c_t is computed using the additive attention mechanism (Bahdanau et al., 2014), which matches the current decoder state s_t and each encoder state h_i to get an importance score. The scores are then passed to a softmax and are used to pool the encoder states using weighted sum. The final pooled vector is the context vector, as shown in the equations below.

$$g_{t,i} = v_a^\top tanh(W_a s_{t-1} + U_a h_i)$$
$$a_{t,i} = \frac{exp(g_{t,i})}{\sum_i exp(g_{t,i})}$$
$$c_t = \sum_i a_{t,i} h_i$$

Finally, the previous token y_{t-1}, the current context vector c_t, and the current decoder state s_t are used to generate the current word y_t with a softmax layer over the decoder vocabulary, as shown below.

$$o_t = W_w w_{t-1} + W_c c_t + W_s s_t$$
$$p(y_t|y_{<t}) = softmax(W_o o_t)$$

3.2 Entity encoding submodule

After performing entity linking to the input text using the ELS, we receive a sequential list of linked entities, arranged based on their location in the text. We embed these entities to d-dimensional vectors $E = \{e_1, e_2, ..., e_m\}$ where $e_i \in \mathbb{R}^d$. Since these entities may still contain ambiguity, it is necessary to resolve them before applying them to the base model. Based on the idea that an ambiguous entity can be disambiguated using its neighboring entities, we introduce two kinds of disambiguating encoders below.

Globally disambiguating encoder One way to disambiguate an entity is by using all the other entities, putting more importance to entities that are nearer. For this purpose, we employ an RNN-based model to globally disambiguate the entities. Specifically, we use BiGRU and concatenate the forward and backward hidden state vectors as the new entity vector:

$$\overrightarrow{h}_i = GRU(e_i, \overrightarrow{h}_{i-1})$$
$$\overleftarrow{h}_i = GRU(e_i, \overleftarrow{h}_{i+1})$$
$$e'_i = [\overrightarrow{h}_i; \overleftarrow{h}_i]$$

Locally disambiguating encoder Another way to disambiguate an entity is by using only the direct neighbors of the entity, putting no importance value to entities that are far. To do this, we employ a CNN-based model to locally disambiguate the entities. Specifically, we do the convolution operation using filter matrices $W_f \in \mathbb{R}^{h \times d}$ with filter size h to a window of h words. We do this for different sizes of h. This produces new feature vectors $c_{i,h}$ as shown below, where $f(.)$ is a non-linear function:

$$c_{i,h} = f([e_{i-(h-1)/2}; ...; e_{i+h(+1)/2}]^\top W_f + b_f)$$

The convolution operation reduces the number of entities differently depending on the filter size h. To prevent loss of information and to produce the same amount of feature vectors $c_{i,h}$, we pad the entity list dynamically such that when the filter size is h, the number of paddings on each side is $(h-1)/2$. The filter size h therefore refers to the number of entities used to disambiguate a middle entity. Finally, we concatenate all feature vectors

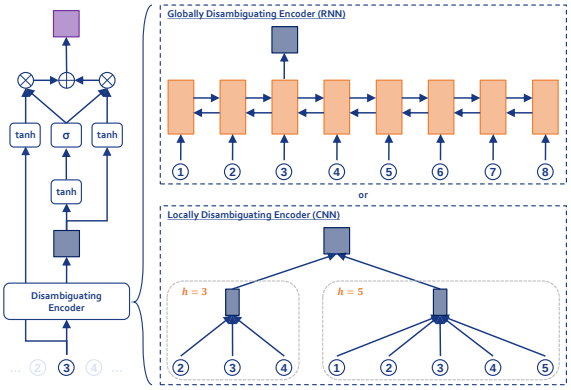

Figure 3: Entity encoding submodule with selective disambiguation applied to the entity ③. The left figure represents the full submodule while the right figure represents the two choices of disambiguating encoders.

of different h's for each i as the new entity vector:

$$e'_i = [c_{i,h_1}; c_{i,h_2}; ...]$$

The question on which disambiguating encoder is better has been a debate; some argued that using only the local context is appropriate (Lau et al., 2013) while some claimed that additionally using global context also helps (Wang et al., 2015). The RNN-based encoder is good as it smartly makes use of all entities, however it may perform bad when there are many entities as it introduces noise when using a far entity during disambiguation. The CNN-based encoder is good as it minimizes the noise by totally ignoring far entities when disambiguating, however determining the appropriate filter sizes h needs engineering. Overall, we argue that when the input text is short (e.g. a sentence), both encoders perform comparably, otherwise when the input text is long (e.g. a document), the CNN-based encoder performs better.

Selective disambiguation It is obvious that not all entities need to be disambiguated. When a correctly linked and already adequately disambiguated entity is disambiguated again, it would make the entity very context-specific and might not be suitable for the summarization task. Our entity encoding submodule therefore uses a selective mechanism that decides whether to use the disambiguating encoder or not. This is done by introducing a selective disambiguation gate d. The final entity vector $\tilde{e}_i$ is calculated as the linear transformation of e_i and e'_i:

$$\begin{aligned} e'_i &= encoder(e_i) \\ d &= \sigma(W_d e'_i + b_d) \\ \tilde{e}_i &= d \times f(W_x e_i + b_x) + \\ &\quad (1-d) \times f(W_y e'_i + b_y) \end{aligned}$$

The full entity encoding submodule is illustrated in Figure 3. Ultimately, the submodule outputs the disambiguated entity vectors $\tilde{E} = \{\tilde{e}_1, \tilde{e}_2, ..., \tilde{e}_m\}$.

3.3 Pooling submodule

The entity vectors $\tilde{E}$ are pooled to create a single topic vector t that represents the topic of the summary. One possible pooling technique is to use soft attention (Xu et al., 2015) on the vectors to determine the importance value of each vector, which can be done by matching each entity vector with the text vector s from the text encoder as the context vector. The entity vectors are then pooled using weighted sum. One problem with soft attention is that it considers *all* entity vectors when constructing the topic vector. However, not all entities are important and necessary when generating summaries. Moreover, a number of these entities may be erroneous and irrelevant, as reported in Section 2.2. Soft attention gives non-negligible important scores to these entities, thus adds unnecessary noise to the construction of the topic vector.

Our pooling submodule instead uses **firm attention** mechanism to consider only top k entities when constructing the topic vector. This is done in a differentiable way as follows:

$$\begin{aligned} G &= v_a^\top tanh(W_a \tilde{E} + U_a s) \\ K &= top\_k(G) \\ P &= sparse\_vector(K, 0, -\infty) \\ g'_i &= g_i + p_i \\ a_i &= \frac{exp(g'_i)}{\sum_i exp(g'_i)} \\ t &= \sum_i a_i \tilde{e}_i \end{aligned}$$

where the functions $K = top\_k(G)$ gets the indices of the top k vectors in G and $P = sparse\_vector(K, 0, -\infty)$ creates a sparse vector where the values of K is 0 and $-\infty$ otherwise[4]. The sparse vector P is added to the original importance score vector G to create a new importance

[4]We use -10^9 to represent $-\infty$.

score vector. In this new vector, important scores of non-top k entities are $-\infty$. When softmax is applied, this gives very small, negligible, and close-to-zero values to non-top k entities. The value k depends on the lengths of the input text and summary. Moreover, when k increases towards infinity, firm attention becomes soft attention. We decide k empirically (see Section 5).

3.4 Extending from the base model

Entity2Topic module extends the base model as follows. The final text representation vector s is used as a context vector when constructing the topic vector t in the pooling submodule. The topic vector t is then concatenated to the decoder hidden state vectors s_i, i.e. $s'_i = [s_i; t]$. The concatenated vector is finally used to create the output vector:

$$o_i = W_w w_{i-1} + W_c c_i + W_s s'_i$$

4 Related work

Due to its recent success, neural network models have been used with competitive results on abstractive summarization. A neural attention model was first applied to the task, easily achieving state-of-the-art performance on multiple datasets (Rush et al., 2015). The model has been extended to instead use recurrent neural network as decoder (Chopra et al., 2016). The model was further extended to use a full RNN encoder-decoder framework and further enhancements through lexical and statistical features (Nallapati et al., 2016). The current state-of-the-art performance is achieved by selectively encoding words as a process of distilling salient information (Zhou et al., 2017).

Neural abstractive summarization models have also been explored to summarize longer documents. Word extraction models have been previously explored, performing worse than sentence extraction models (Cheng and Lapata, 2016). Hierarchical attention-based recurrent neural networks have also been applied to the task, owing to the idea that there are multiple sentences in a document (Nallapati et al., 2016). Finally, distraction-based models were proposed to enable models to traverse the text content and grasp the overall meaning (Chen et al., 2016). The current state-of-the-art performance is achieved by a graph-based attentional neural model, considering the key factors of document summarization such as saliency, fluency and novelty (Tan et al., 2017).

Dataset	Gigaword	CNN

min(inputEntity)	1	1
max(inputEntity)	36	743
avg(inputEntity)	4.5	94.6

Table 1: Dataset statistics.

Previous studies on the summarization tasks have only used entities in the preprocessing stage to anonymize the dataset (Nallapati et al., 2016) and to mitigate out-of-vocabulary problems (Tan et al., 2017). Linked entities for summarization are still not properly explored and we are the first to use linked entities to improve the performance of the summarizer.

5 Experimental settings

Datasets We use two widely used summarization datasets with different text lengths. First, we use the Annotated English Gigaword dataset as used in (Rush et al., 2015). This dataset receives the first sentence of a news article as input and use the headline title as the gold standard summary. Since the development dataset is large, we randomly selected 2000 pairs as our development dataset. We use the same held-out test dataset used in (Rush et al., 2015) for comparison. Second, we use the CNN dataset released in (Hermann et al., 2015). This dataset receives the full news article as input and use the human-generated multiple sentence highlight as the gold standard summary. The original dataset has been modified and preprocessed specifically for the document summarization task (Nallapati et al., 2016). In addition to the previously provided datasets, we extract linked entities using Dexter[5] (Ceccarelli et al., 2013), an open source ELS that links text snippets found in a given text to entities contained in Wikipedia. We use the default recommended parameters stated in the website. We summarize the statistics of both datasets in Table 1.

Implementation For both datasets, we further reduce the size of the input, output, and entity vocabularies to at most 50K as suggested in (See et al., 2017) and replace less frequent words to

[5] http://dexter.isti.cnr.it/

"<unk>". We use 300D Glove[6] (Pennington et al., 2014) and 1000D wiki2vec[7] pre-trained vectors to initialize our word and entity vectors. For GRUs, we set the state size to 500. For CNN, we set $h = 3, 4, 5$ with $400, 300, 300$ feature maps, respectively. For firm attention, k is tuned by calculating the perplexity of the model starting with smaller values (i.e. $k = 1, 2, 5, 10, 20, ...$) and stopping when the perplexity of the model becomes worse than the previous model. Our preliminary tuning showed that $k = 5$ for Gigaword dataset and $k = 10$ for CNN dataset are the best choices. We use dropout (Srivastava et al., 2014) on all non-linear connections with a dropout rate of 0.5. We set the batch sizes of Gigaword and CNN datasets to 80 and 10, respectively. Training is done via stochastic gradient descent over shuffled mini-batches with the Adadelta update rule, with l_2 constraint (Hinton et al., 2012) of 3. We perform early stopping using a subset of the given development dataset. We use beam search of size 10 to generate the summary.

Baselines For the Gigaword dataset, we compare our models with the following abstractive baselines: **ABS+** (Rush et al., 2015) is a fine tuned version of ABS which uses an attentive CNN encoder and an NNLM decoder, **Feat2s** (Nallapati et al., 2016) is an RNN sequence-to-sequence model with lexical and statistical features in the encoder, **Luong-NMT** (Luong et al., 2015) is a two-layer LSTM encoder-decoder model, **RAS-Elman** (Chopra et al., 2016) uses an attentive CNN encoder and an Elman RNN decoder, and **SEASS** (Zhou et al., 2017) uses BiGRU encoders and GRU decoders with selective encoding. For the CNN dataset, we compare our models with the following extractive and abstractive baselines: **Lead-3** is a strong baseline that extracts the first three sentences of the document as summary, **LexRank** extracts texts using LexRank (Erkan and Radev, 2004), **Bi-GRU** is a non-hierarchical one-layer sequence-to-sequence abstractive baseline, **Distraction-M3** (Chen et al., 2016) uses a sequence-to-sequence abstractive model with distraction-based networks, and **GBA** (Tan et al., 2017) is a graph-based attentional neural abstractive model. All baseline results used beam search and are gathered from previous papers. Also, we compare our final model **BASE+E2T** with the base model **BASE** and some variants of our model (without selective disambiguation, using soft attention).

6 Results

We report the ROUGE F1 scores for both datasets of all the competing models using ROUGE F1 scores (Lin, 2004). We report the results on the Gigaword and the CNN dataset in Table 2 and Table 3, respectively. In Gigaword dataset where the texts are short, our best model achieves a comparable performance with the current state-of-the-art. In CNN dataset where the texts are longer, our best model outperforms all the previous models. We emphasize that E2T module is easily attachable to better models, and we expect E2T to improve

Model	1st	2nd	3rd	4th	mean
GOLD	0.27	0.34	0.21	0.18	2.38
BASE	0.14	0.15	0.28	0.43	3.00
BASE+E2T$_{rnn}$	0.12	0.24	0.39	0.25	2.77
BASE+E2T$_{cnn}$	**0.47**	0.27	0.12	0.14	**1.93**

Table 4: Human evaluations on the Gigaword dataset. Bold-faced values are the best while red-colored values are the worst among the values in the evaluation metric.

their performance as well. Overall, E2T achieves a significant improvement over the baseline model BASE, with at least 2 ROUGE-1 points increase in the Gigaword dataset and 6 ROUGE-1 points increase in the CNN dataset. In fact, all variants of E2T gain improvements over the baseline, implying that leveraging on linked entities improves the performance of the summarizer. Among the model variants, the CNN-based encoder with selective disambiguation and firm attention performs the best.

Automatic evaluation on the Gigaword dataset shows that the CNN and RNN variants of BASE+E2T have similar performance. To break the tie between both models, we also conduct human evaluation on the Gigaword dataset. We instruct two annotators to read the input sentence and rank the competing summaries from first to last according to their relevance and fluency: (a) the original summary GOLD, and from models (b) BASE, (c) BASE+E2T$_{cnn}$, and (d) BASE+E2T$_{rnn}$. We then compute (i) the proportion of every ranking of each model and (ii) the mean rank of each model. The results are reported in Table 4. The model with the best mean rank is BASE+E2T$_{cnn}$, followed by GOLD, then by BASE+E2T$_{rnn}$ and BASE, respectively. We also perform ANOVA and post-hoc Tukey tests to show that the CNN variant is significantly ($p < 0.01$) better than the RNN variant and the base model. The RNN variant does not perform as well as the CNN variant, contrary to the automatic ROUGE evaluation above. Interestingly, the CNN variant produces better (but with no significant difference) summaries than the gold summaries. We posit that this is due to the fact that the article title does not correspond to the summary of the first sentence.

Selective disambiguation of entities We show the effectiveness of the selective disambiguation gate d in selecting which entities to disambiguate or not. Table 6 shows a total of four different examples of two entities with the highest/lowest d values. In the first example, sentence **E1.1** contains the entity "*United States*" and is linked with the country entity of the same name, however the correct linked entity should be "*United States Davis Cup team*", and therefore is given a high d value. On the other hand, sentence **E1.2** is linked correctly to the country "*United States*", and thus is given a low d value.. The second example provides a similar scenario, where sentence **E2.1** is linked to the entity "*Gold*" but should be linked to the entity "*Gold medal*". Sentence **E2.2** is linked correctly to the chemical element. Hence, the former case received a high value d while the latter case received a low d value.

Entities as summary topic Finally, we provide one sample for each dataset in Table 5 for case study, comparing our final model that uses **firm** attention (BASE$_{cnn+sd}$), a variant that uses **soft** attention (BASE$_{cnn+soft}$), and the **baseline** model (BASE). We also show the attention weights of the **firm** and **soft** models.

In the Gigaword example, we find three observations. First, the base model generated a less informative summary, not mentioning "*mexico state*" and "*first edition*". Second, the soft model produced a factually wrong summary, saying that "*guadalajara*" is a mexican state, while actually it is a city. Third, the firm model is able to solve the problem by focusing only on the five most important entities, eliminating possible noise such as "*Unk*" and less crucial entities such as "*Country club*". We can also see the effectiveness of the selective disambiguation in this example, where the entity "*U.S. state*" is corrected to mean the entity "*Mexican state*" which becomes relevant and is therefore selected.

In the CNN example, we also find that the baseline model generated a very erroneous summary. We argue that this is because the length of the input text is long and the decoder is not guided as to which topics it should focus on. The soft model generated a much better summary, however it focuses on the wrong topics, specifically on "*Iran's nuclear program*", making the summary less general. A quick read of the original article tells us that the main topic of the article is all about the two political parties arguing over the deal with Iran. However, the entity "*nuclear*" appeared a lot in the article, which makes the soft model wrongly focus on the "*nuclear*" entity. The firm model produced the more relevant summary, focusing on the po-

litical entities (e.g. "*republicans*", "*democrats*"). This is due to the fact that only the $k = 10$ most important elements are attended to create the summary topic vector.

7 Conclusion

We proposed to leverage on linked entities to improve the performance of sequence-to-sequence models on neural abstractive summarization task. Linked entities are used to guide the decoding process based on the summary topic and commonsense learned from a knowledge base. We introduced Entity2Topic (E2T), a module that is easily attachable to any model using an encoder-decoder framework. E2T applies linked entities into the summarizer by encoding the entities with selective disambiguation and pooling them into one summary topic vector with firm attention mechanism. We showed that by applying E2T to a basic sequence-to-sequence model, we achieve significant improvements over the base model and consequently achieve a comparable performance with more complex summarization models.

NEWSROOM: A Dataset of 1.3 Million Summaries with Diverse Extractive Strategies

Max Grusky[1,2], **Mor Naaman**[2], **Yoav Artzi**[1,2]

Abstract

We present NEWSROOM, a summarization dataset of 1.3 million articles and summaries written by authors and editors in newsrooms of 38 major news publications. Extracted from search and social media metadata between 1998 and 2017, these high-quality summaries demonstrate high diversity of summarization styles. In particular, the summaries combine *abstractive* and *extractive* strategies, borrowing words and phrases from articles at varying rates. We analyze the extraction strategies used in NEWSROOM summaries against other datasets to quantify the diversity and difficulty of our new data, and train existing methods on the data to evaluate its utility and challenges. The dataset is available online at summari.es.

1 Introduction

The development of learning methods for automatic summarization is constrained by the limited high-quality data available for training and evaluation. Large datasets have driven rapid improvement in other natural language generation tasks, such as machine translation, where data size and diversity have proven critical for modeling the alignment between source and target texts (Tiedemann, 2012). Similar challenges exist in summarization, with the additional complications introduced by the length of source texts and the diversity of summarization strategies used by writers. Access to large-scale high-quality data is an essential prerequisite for making substantial progress in summarization. In this paper, we present NEWSROOM, a dataset with 1.3 million news articles and human-written summaries.

NEWSROOM's summaries were written by authors and editors in the newsrooms of news, sports, entertainment, financial, and other publications. The summaries were published with articles as HTML metadata for social media services and search engines page descriptions. NEWSROOM summaries are written by humans, for common readers, and with the explicit purpose of summarization. As a result, NEWSROOM is a nearly two decade-long snapshot representing how single-document summarization is used in practice across a variety of sources, writers, and topics.

Abstractive Summary: South African photographer Anton Hammerl, *missing* in Libya *since* April *4th*, was *killed* in Libya *more than* a *month ago*.

Mixed Summary: A major climate protest in New York on Sunday *could* mark a seminal *shift* in the *politics* of global warming, just *ahead* of the *U.N.* Climate Summit.

Extractive Summary: A person familiar with the search *tells* The Associated Press that Texas has *offered* its head coaching job to Louisvilles Charlie Strong and he is expected to accept.

Figure 1: NEWSROOM summaries showing different extraction strategies, from time.com, mashable.com, and foxsports.com. Multi-word phrases shared between article and summary are underlined. Novel words used only in the summary are italicized.

Identifying large, high-quality resources for summarization has called for creative solutions in the past. This includes using news headlines as summaries of article prefixes (Napoles et al., 2012; Rush et al., 2015), concatenating bullet points as summaries (Hermann et al., 2015; See et al., 2017), or using librarian archival summaries (Sandhaus, 2008). While these solutions provide large scale data, it comes at the cost of how well they reflect the summarization problem or their focus on very specific styles of summarizations, as we discuss in Section 4. NEWSROOM is distinguished from these resources in its combination of size and diversity. The summaries were written with the explicit goal of concisely summarizing news articles over almost two decades.

Proceedings of NAACL-HLT 2018, pages 708–719
New Orleans, Louisiana, June 1 - 6, 2018.

Rather than rely on a single source, the dataset includes summaries from 38 major publishers. This diversity of sources and time span translate into a diversity of summarization styles.

We explore NEWSROOM to better understand the dataset and how summarization is used in practice by newsrooms. Our analysis focuses on a key dimension, *extractivenss* and *abstractiveness*: extractive summaries frequently borrow words and phrases from their source text, while abstractive summaries describe the contents of articles primarily using new language. We develop measures designed to quantify extractiveness and use these measures to subdivide the data into extractive, mixed, and abstractive subsets, as shown in Figure 1, displaying the broad set of summarization techniques practiced by different publishers.

Finally, we analyze the performance of three summarization models as baselines for NEWSROOM to better understand the challenges the dataset poses. In addition to automated ROUGE evaluation (Lin, 2004a,b), we design and execute a benchmark human evaluation protocol to quantify the output summaries relevance and quality. Our experiments demonstrate that NEWSROOM presents an open challenge for summarization systems, while providing a large resource to enable data-intensive learning methods. The dataset and evaluation protocol are available online at summari.es.

2 Existing Datasets

There are a several frequently used summarization datasets. Listed in Figure 2 are examples from four datasets. The examples are chosen to be representative: they have scores within 5% of their dataset average across our analysis measures (Section 4). To illustrate the extractive and abstractive nature of summaries, we underline multi-word phrases shared between the article and summary, and italicize *words* used only in the summary.

2.1 Document Understanding Conference

Datasets produced for the Document Understanding Conference (DUC)[1] are small, high-quality datasets developed to evaluate summarization systems (Harman and Over, 2004; Dang, 2006).

DUC data consist of newswire articles paired with human summaries written specifically for DUC. One distinctive feature of the DUC datasets

Example Summary: Seve *gets* invite to US Open

Start of Article: Seve Ballesteros will be playing in next month's US Open after all. The USGA decided Tuesday to give the Spanish star a special exemption. American Ben Crenshaw was also given a special exemption by the United States Golf Association. Earlier this week [...]

New York Times Corpus

Example Summary: *Annual* New York City Toy Fair opens in Manhattan; feud between Toy Manufacturers of America and its landlord at International Toy Center *leads* to confusion and *turmoil* as registration *begins*; *dispute discussed.*

Start of Article: There was toylock when the Toy Fair opened in Manhattan yesterday. The reason? A family feud between the Toy Manufacturers of America and its landlord at Fifth Avenue and 23d Street. Toy buyers and exhibitors arriving to attend the kickoff of the [...]

CNN / Daily Mail

Example Summary:

- Eight Al Jazeera journalists are named on *an* Egyptian charge sheet, the network *says*
- The eight were *among* 20 people named 'Most are not employees of Al Jazeera," the network said
- The eight include three journalists jailed in Egypt

Start of Article: Egyptian authorities have served Al Jazeera with a charge sheet that identifies eight of its staff on a list of 20 people – all believed to be journalists – for allegedly conspiring with a terrorist group, the network said Wednesday. The 20 are wanted by Egyptian [...]

Figure 2: Example summaries for existing datasets.

is the availability of multiple reference summaries for each article. This is a major advantage of DUC compared to other datasets, especially when evaluating with ROUGE (Lin, 2004b,a), which was designed to be used with multiple references. However, DUC datasets are small, which makes it difficult to use them as training data.

DUC summaries are often used in conjunction with larger training datasets, including Gigaword (Rush et al., 2015; Chopra et al., 2016), CNN / Daily Mail (Nallapati et al., 2017; Paulus et al., 2017; See et al., 2017), or Daily Mail alone (Nallapati et al., 2016b; Cheng and Lapata, 2016). The data have also been used to evaluate

unsupervised methods (Dorr et al., 2003; Mihalcea and Tarau, 2004; Barrios et al., 2016).

2.2 Gigaword

The Gigaword Corpus (Napoles et al., 2012) contains nearly 10 million documents from seven newswire sources, including the Associated Press, New York Times Newswire Service, and Washington Post Newswire Service. Compared to other existing datasets used for summarization, the Gigaword corpus is the largest and most diverse in its sources. While Gigaword does not contain summaries, prior work uses Gigaword headlines as simulated summaries (Rush et al., 2015; Chopra et al., 2016). These systems are trained on Gigaword to recreate headlines given the first sentence of an article. When used this way, Gigaword's simulated summaries are shorter than most natural summary text. Gigaword, along with similar text-headline datasets (Filippova and Altun, 2013), are also used for the related sentence compression task (Dorr et al., 2003; Filippova et al., 2015).

2.3 New York Times Corpus

The New York Times Annotated Corpus (Sandhaus, 2008) is the largest summarization dataset currently available. It consists of carefully curated articles from a single source, The New York Times. The corpus contains several hundred thousand articles written between 1987–2007 that have paired summaries. The summaries were written for the corpus by library scientists, rather than at the time of publication. Our analysis in Section 4 reveals that the data are somewhat biased toward extractive strategies, making it particularly useful as an extractive summarization dataset. Despite this, limited work has used this dataset for summarization (Hong and Nenkova, 2014; Durrett et al., 2016; Paulus et al., 2017).

2.4 CNN / Daily Mail

The CNN / Daily Mail question answering dataset (Hermann et al., 2015) is frequently used for summarization. The dataset includes CNN and Daily Mail articles, each associated with several bullet point descriptions. When used in summarization, the bullet points are typically concatenated into a single summary.[2] The dataset has been used for summarization as is (See et al., 2017), or after pre-processing for entity anonymization (Nallapati et al., 2017). This different usage makes comparisons between systems using these data challenging. Additionally, some systems use both CNN and Daily Mail for training (Nallapati et al., 2017; Paulus et al., 2017; See et al., 2017), whereas others use only Daily Mail articles (Nallapati et al., 2016b; Cheng and Lapata, 2016). Our analysis shows that the CNN / Daily Mail summaries have strong bias toward extraction (Section 4). Similar observations about the data were made by Chen et al. (2016) with respect to the question answering task.

3 Collecting NEWSROOM Summaries

The NEWSROOM dataset was collected using social media and search engine metadata. To create the dataset, we performed a Web-scale crawling of over 100 million pages from a set of online publishers. We identify newswire articles and use the summaries provided in the HTML metadata. These summaries were created to be used in search engines and social media.

We collected HTML pages and metadata using the Internet Archive (Archive.org), accessing archived pages of a large number of popular news, sports, and entertainment sites. Using Archive.org provides two key benefits. First, the archive provides an API that allows for collection of data across time, not limited to recently available articles. Second, the archived URLs of the dataset articles are immutable, allowing distribution of this dataset using a thin, URL-only list.

The publisher sites we crawled were selected using a combination of Alexa.com top overall sites, as well as Alexa's top news sites.[3] We supplemented the lists with older lists published by Google of the highest-traffic sites on the Web.[4] We excluded sites such as Reddit that primarily aggregate rather than produce content, as well as publisher sites that proved to have few or no articles with summary metadata available, or have articles primarily in languages other than English. This process resulted in a set of 38 publishers that were included in the dataset.

[2] https://github.com/abisee/cnn-dailymail

[3] Alexa removed the extended public list in 2017, see: https://web.archive.org/web/2016/https://www.alexa.com/topsites/category/News

[4] Google removed this list in 2013, see: https://web.archive.org/web/2012/http://www.google.com/adplanner/static/top1000

3.1 Content Scraping

We used two techniques to identify article pages from the selected publishers on Archive.org: the search API and index-page crawl. The API allows queries using URL pattern matching, which focuses article crawling on high-precision subdomains or paths. We used the API to search for content from the publisher domains, using specific patterns or post-processing filtering to ensure article content. In addition, we used Archive.org to retrieve the historical versions of the home page for all publisher domains. The archive has content from 1998 to 2017 with varying degrees of time resolution. We obtained at least one snapshot of each page for every available day. For each snapshot, we retrieved all articles listed on the page.

For both search and crawled URLs, we performed article de-duplication using URLs to control for varying URL fragments, query parameters, protocols, and ports. When performing the merge, we retained only the earliest article version available to prevent the collection of stale summaries that are not updated when articles are changed.

3.2 Content Extraction

Following identification and de-duplication, we extracted the article texts and summaries and further cleaned and filtered the dataset.

Article Text We used Readability[5] to extract HTML body content. Readability uses HTML heuristics to extract the main content and title of a page, producing article text without extraneous HTML markup and images. Our preliminary testing, as well as comparison by Peters (2015), found Readability to be one of the highest accuracy content extraction algorithms available. To exclude inline advertising and image captions sometimes present in extractions, we applied additional filtering of paragraphs with fewer than five words. We excluded articles with no body text extracted.

Summary Metadata We extracted the article summaries from the metadata available in the HTML pages of articles. These summaries are often written by newsroom editors and journalists to appear in social media distribution and search results. While there is no standard metadata format for summaries online, common fields are often present in the page's HTML. Popular metadata field types include: *og:description*, *twitter:description*, and *description*. In cases where different metadata summaries were available, and were different, we used the first field available according to the order above. We excluded articles with no summary text of any type. We also removed article-summary pairs with a high amount of precisely-overlapping text to remove rule-based automatically-generated summaries fully copied from the article (e.g., the first paragraph).

Dataset Size	1,321,995 articles
Training Set Size	995,041 articles
Mean Article Length	658.6 words
Mean Summary Length	26.7 words
Total Vocabulary Size	6,925,712 words
Occurring 10+ Times	784,884 words

Table 1: Dataset Statistics

3.3 Building the Dataset

Our scraping and extraction process resulted in a set of 1,321,995 article-summary pairs. Simple dataset statistics are shown in Table 1. The data are divided into training (76%), development (8%), test (8%), and unreleased test (8%) datasets using a hash function of the article URL. We use the articles' Archive.org URLs for lightweight distribution of the data. Archive.org is an ideal platform for distributing the data, encouraging its users to scrape its resources. We provide the extraction and analysis scripts used during data collection for reproducing the full dataset from the URL list.

4 Data Analysis

NEWSROOM contains summaries from different topic domains, written by many authors, over the span of more than two decades. This diversity is an important aspect of the dataset. We analyze the data to quantify the differences in summarization styles and techniques between the different publications to show the importance of reflecting this diversity. In Sections 6 and 7, we examine the effect of the dataset diversity on the performance of a variety of summarization systems.

4.1 Characterizing Summarization Strategies

We examine summarization strategies using three measures that capture the degree of text overlap between the summary and article, and the rate of compression of the information conveyed.

Given an article text $A = \langle a_1, a_2, \ldots, a_n \rangle$ consisting of a sequence of tokens a_i and the corresponding article summary $S = \langle s_1, s_2, \cdots, s_m \rangle$ consisting of tokens s_i, the set of extractive frag-

```
function F(A, S)
    F ← ∅, ⟨i, j⟩ ← ⟨1, 1⟩
    while i ≤ |S| do
        f ← ⟨ ⟩
        while j ≤ |A| do
            if s_i = a_j then
                ⟨i', j'⟩ ← ⟨i, j⟩
                while s_{i'} = a_{j'} do
                    ⟨i', j'⟩ ← ⟨i' + 1, j' + 1⟩
                if |f| < (i' − i − 1) then
                    f ← ⟨s_i ··· s_{i'−1}⟩
                j ← j'
            else
                j ← j + 1
        ⟨i, j⟩ ← ⟨i + max{|f|, 1}, 1⟩
        F ← F ∪ {f}
    return F
```

Figure 3: Procedure to compute the set $\mathcal{F}(A, S)$ of extractive phrases in summary S extracted from article A. For each sequential token of the summary, s_i, the procedure iterates through tokens of the text, a_j. If tokens s_i and a_j match, the longest shared token sequence after s_i and a_j is marked as the extraction starting at s_i.

ments $\mathcal{F}(A, S)$ is the set of shared sequences of tokens in A and S. We identify these extractive fragments of an article-summary pair using a greedy process. We process the tokens in the summary in order. At each position, if there is a sequence of tokens in the source text that is prefix of the remainder of the summary, we mark this prefix as extractive and continue. We prefer to mark the longest prefix possible at each step. Otherwise, we mark the current summary token as abstractive. The set $\mathcal{F}(A, S)$ includes all the tokens sequences identified as extractive. Figure 3 formally describes this procedure. Underlined phrases of Figures 1 and 2 are examples of fragments identified as extractive. Using $\mathcal{F}(A, S)$, we compute two measures: *extractive fragment coverage* and *extractive fragment density*.

Extractive Fragment Coverage The coverage measure quantifies the extent to which a summary is derivative of a text. $\textsc{Coverage}(A, S)$ measures the percentage of words in the summary that are part of an extractive fragment with the article:

$$\textsc{Coverage}(A, S) = \frac{1}{|S|} \sum_{f \in \mathcal{F}(A,S)} |f| \ .$$

For example, a summary with 10 words that borrows 7 words from its article text and includes 3 new words will have $\textsc{Coverage}(A, S) = 0.7$.

Extractive Fragment Density The density measure quantifies how well the word sequence of a summary can be described as a series of extractions. For instance, a summary might contain many individual words from the article and therefore have a high coverage. However, if arranged in a new order, the words of the summary could still be used to convey ideas not present in the article. We define $\textsc{Density}(A, S)$ as the average length of the extractive fragment to which each word in the summary belongs. The density formulation is similar to the coverage definition but uses a square of the fragment length:

$$\textsc{Density}(A, S) = \frac{1}{|S|} \sum_{f \in \mathcal{F}(A,S)} |f|^2 \ .$$

For example, an article with a 10-word summary made of two extractive fragments of lengths 3 and 4 would have $\textsc{Coverage}(A, S) = 0.7$ and $\textsc{Density}(A, S) = 2.5$.

Compression Ratio We use a simple dimension of summarization, *compression ratio*, to further characterize summarization strategies. We define $\textsc{Compression}$ as the word ratio between the article and summary:

$$\textsc{Compression}(A, S) = |A| \ / \ |S| \ .$$

Summarizing with higher compression is challenging as it requires capturing more precisely the critical aspects of the article text.

4.2 Analysis of Dataset Diversity

We use density, coverage, and compression to understand the distribution of human summarization techniques across different sources. Figure 4 shows the distributions of summaries for different domains in the $\textsc{Newsroom}$ dataset, along with three major existing summarization datasets: DUC 2003-2004 (combined), CNN / Daily Mail, and the New York Times Corpus.

Publication Diversity Each $\textsc{Newsroom}$ publication shows a unique distribution of summaries mixing extractive and abstractive strategies in varying amounts. For example, the third entry on the top row shows the summarization strategy used by BuzzFeed. The density (y-axis) is relatively low, meaning BuzzFeed summaries are unlikely to include long extractive fragments. While the coverage (x-axis) is more varied, BuzzFeed's coverage tends to be lower, indicating that it frequently uses novel words in summaries. The publication plots in the figure are sorted by median compression ratio. We observe that publications with lower compression ratio (top-left of the figure) exhibit higher diversity along both dimensions of extractiveness. However, as the median compression ratio increases, the distributions become more con-

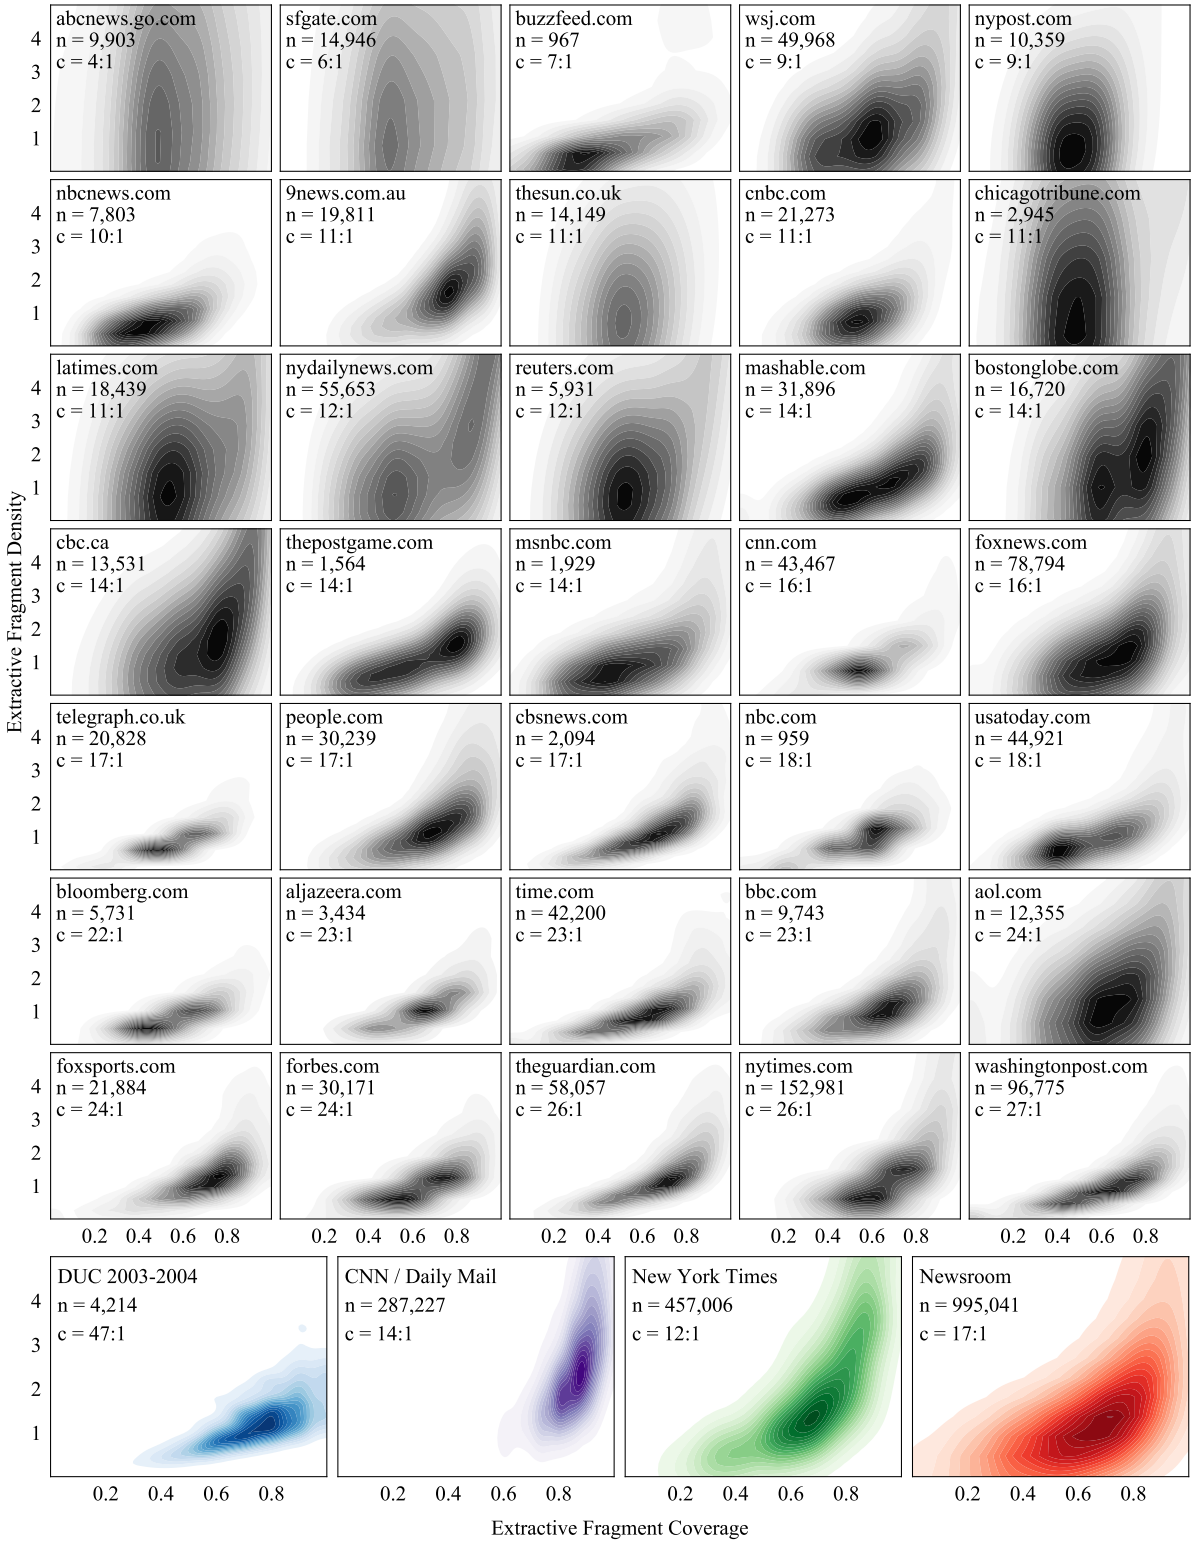

Figure 4: Density and coverage distributions across the different domains and existing datasets. NEWSROOM contains diverse summaries that exhibit a variety of summarization strategies. Each box is a normalized bivariate density plot of extractive fragment coverage (x-axis) and density (y-axis), the two measures of extraction described in Section 4.1. The top left corner of each plot shows the number of training set articles n and the median compression ratio c of the articles. For DUC and New York Times, which have no standard data splits, n is the total number of articles. *Above, top left to bottom right:* Plots for each publication in the NEWSROOM dataset. We omit TMZ, Economist, and ABC for presentation. *Below, left to right:* Plots for each summarization dataset showing increasing diversity of summaries along both dimensions of extraction in NEWSROOM.

centrated, indicating that summarization strategies become more rigid.

Dataset Diversity Figure 4 demonstrates how DUC, CNN / Daily Mail, and the New York Times exhibit different human summarization strategies. DUC summarization is fairly similar to the high-compression newsrooms shown in the lower publication plots in Figure 4. However, DUC's median compression ratio is much higher than all other datasets and NEWSROOM publications. The figure shows that CNN / Daily Mail and New York Times are skewed toward extractive summaries with lower compression ratios. CNN / Daily Mail shows higher coverage and density than all other datasets and publishers in our data. Compared to existing datasets, NEWSROOM covers a much larger range of summarization styles, ranging from both highly extractive to highly abstractive.

5 Performance of Existing Systems

We train and evaluate several summarization systems to understand the challenges of NEWSROOM and its usefulness for training systems. We evaluate three systems, each using a different summarization strategy with respect to extractiveness: fully extractive (TextRank), fully abstractive (Seq2Seq), and mixed (pointer-generator). We further study the performance of the pointer-generator model on NEWSROOM by training three systems using different dataset configurations. We compare these systems to two rule-based systems that provide baseline (Lede-3) and an extractive oracle (Fragments).

Extractive: TextRank TextRank is a sentence-level extractive summarization system. The system was originally developed by Mihalcea and Tarau (2004) and was later further developed and improved by Barrios et al. (2016). TextRank uses an unsupervised sentence-ranking approach similar to Google PageRank (Page et al., 1999). TextRank picks a sequence of sentences from a text for the summary up to a maximum allowable length. While this maximum length is typically preset by the user, in order to optimize ROUGE scoring, we tune this parameter to optimize ROUGE-1 F_1-score on the NEWSROOM training data. We experimented with values between 1–200, and found the optimal value to be 50 words. We use tuned TextRank of in Tables 2, 3, and in the supplementary material.

Abstractive: Seq2Seq / Attention Sequence-to-sequence models with attention (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014) have been applied to various language tasks, including summarization (Chopra et al., 2016; Nallapati et al., 2016a). The process by which the model produces tokens is abstractive, as there is no explicit mechanism to copy tokens from the input text. We train a TensorFlow implementation[6] of the Rush et al. (2015) model using NEWSROOM.

Mixed: Pointer-Generator The pointer-generator model (See et al., 2017) uses abstractive token generation and extractive token copying using a pointer mechanism (Vinyals et al., 2015; Gülçehre et al., 2016), keeping track of extractions using coverage (Tu et al., 2016). We evaluate three instances of this model by varying the training data: (1) Pointer-C: trained on the CNN / Daily Mail dataset; (2) Pointer-N: trained on the NEWSROOM dataset; and (3) Pointer-S: trained on a random subset of NEWSROOM training data the same size as the CNN / Daily Mail training. The last instance aims to understand the effects of dataset size and summary diversity.

Lower Bound: Lede-3 A common automatic summarization strategy of online publications is to copy the first sentence, first paragraph, or first k words of the text and treat this as the summary. Following prior work (See et al., 2017; Nallapati et al., 2017), we use the Lede-3 baseline, in which the first three sentences of the text are returned as the summary. Though simple, this baseline is competitive with state-of-the-art systems.

Extractive Oracle: Fragments This system has access to the reference summary. Given an article A and its summary S, the system computes $\mathcal{F}(A, S)$ (Section 4). Fragments concatenates the fragments in $\mathcal{F}(A, S)$ in the order they appear in the summary, representing the best possible performance of an ideal extractive system. Only systems that are capable of abstractive reasoning can outperform the ROUGE scores of Fragments.

6 Automatic Evaluation

We study model performance of NEWSROOM, CNN / Daily Mail, and the combined DUC 2003 and 2004 datasets. We use the five systems described in Section 5, including the extractive oracle. We also evaluate the systems using subsets of

Table 3: Performance of the baselines and systems on the three extractiveness subsets of the NEWSROOM development set, and the overall scores of systems on the full development set (D). The best results for non-baseline systems in the lower parts of the table are in **bold**.

NEWSROOM to characterize the sensitivity of systems to different levels of extractiveness in reference summaries. We use the F_1-score variants of ROUGE-1, ROUGE-2, and ROUGE-L to account for different summary lengths. ROUGE scores are computed with the default configuration of the Lin (2004b) ROUGE v1.5.5 reference implementation. Input article text and reference summaries for all systems are tokenized using the Stanford CoreNLP tokenizer (Manning et al., 2014).

Table 2 shows results for summarization systems on DUC, CNN / Daily Mail, and NEWSROOM. In nearly all cases, the fully extractive Lede-3 baseline produces the most successful summaries, with the exception of the relatively extractive DUC. Among models, NEWSROOM-trained Pointer-N performs best on all datasets other than CNN / Daily Mail, an out-of-domain dataset. Pointer-C, which has access to only a limited subset of NEWSROOM, performs worse than Pointer-N on average. However, despite not being trained on CNN / Daily Mail, Pointer-S outperforms Pointer-C on its own data under ROUGE-N and is competitive under ROUGE-L. Finally, both Pointer-N and Pointer-S outperform other systems and baselines on DUC, whereas Pointer-C does not outperform Lede-3.

Table 3 shows development results on the NEWSROOM data for different level of extractiveness. Pointer-N outperforms the remaining models across all extractive subsets of NEWSROOM and, in the case of the abstractive subset, exceeds the performance of Lede-3. The success of Pointer-N and Pointer-S in generalizing and outperforming models on DUC and CNN / Daily Mail indicates the usefulness of NEWSROOM in generalizing to out-of-domain data. Similar subset analysis for our other two measures, coverage and compression, are included in the supplementary material.

7 Human Evaluation

ROUGE scores systems using frequencies of shared n-grams. Evaluating systems with ROUGE alone biases scoring against abstractive systems, which rely more on paraphrasing. To overcome this limitation, we provide human evaluation of the different systems on NEWSROOM. While human evaluation is still uncommon in summarization work, developing a benchmark dataset presents an opportunity for developing an accompanying protocol for human evaluation.

Our evaluation method is centered around three objectives: (1) distinguishing between syntactic and semantic summarization quality, (2) providing a reliable (consistent and replicable) measurement, and (3) allowing for portability such that the

DIMENSION	PROMPT
Informativeness	How well does the summary capture the key points of the article?
Relevance	Are the details provided by the summary consistent with details in the article?
Fluency	Are the individual sentences of the summary well-written and grammatical?
Coherence	Do phrases and sentences of the summary fit together and make sense collectively?

Table 4: The prompts given to Amazon Mechanical Turk crowdworkers for evaluating each summary.

Abs-N	2.09	2.35	2.66	2.50	2.40
Pointer-C	3.55	3.78	3.22	3.30	3.46
Pointer-S	**3.77**	**4.02**	3.56	3.56	3.73
Pointer-N	3.36	3.82	3.43	3.39	3.50

Table 5: Average performance of systems as scored by human evaluators. Each summary was scored by three different evaluators. *Dimensions, from left to right:* informativeness, relevance, fluency, and coherence, and a mean of the four dimensions for each system.

measure can be applied to other models or summarization datasets.

We select two semantic and two syntactic dimensions for evaluation based on experiments with evaluation tasks by Paulus et al. (2017) and Tan et al. (2017). The two semantic dimensions, summary *informativeness* (INF) and *relevance* (REL), measure whether the system-generated text is useful as a summary, and appropriate for the source text, respectively. The two syntactic dimensions, *fluency* (FLU) and *coherence* (COH), measure whether individual sentences or phrases of the summary are well-written and whether the summary as a whole makes sense respectively. Evaluation was performed on 60 summaries, 20 from each extractive NEWSROOM subset. Each system-article pair was evaluated by three unique raters. Exact prompts given to raters for each dimension are shown in Table 4.

Table 5 shows the mean score given to each system under each of the four dimensions, as well as the mean overall score (rightmost column). No summarization system exceeded the scores given to the Lede-3 baseline. However, the extractive oracle designed to maximize n-gram based evaluation performed worse than the majority of systems under human evaluation. While the fully abstractive Abs-N model performed very poorly under automatic evaluation, it fared slightly better when scored by humans. TextRank received the highest overall score. TextRank generates full sentences extracted from the article, and raters preferred TextRank primarily for its fluency and coherence. The pointer-generator models do not have this advantage, and raters did not find the pointer-generator models to be as syntactically sound as TextRank. However, raters preferred the informativeness and relevance of the Pointer-S and Pointer-N models, though not the Pointer-C model, over TextRank.

8 Conclusion

We present NEWSROOM, a dataset of articles and their summaries written in the newsrooms of online publications. NEWSROOM is the largest summarization dataset available to date, and exhibits a wide variety of human summarization strategies. Our proposed measures and the analysis of strategies used by different publications and articles propose new directions for evaluating the difficulty of summarization tasks and for developing future summarization models. We show that the dataset's diversity of summaries presents a new challenge to summarization systems. Finally, we find that using NEWSROOM to train an existing state-of-art mixed-strategy summarization model results in performance improvements on out-of-domain data. The NEWSROOM dataset is available online at summari.es.

Additional Evaluation

In Section 4, we discuss three measures of summarization diversity: coverage, density, and compression. In addition to quantifying diversity of summarization strategies, these measures are helpful for system error analysis. We use the density measurement to understand how system performance varies when compared against references using different extractive strategies by subdividing NEWSROOM into three subsets by extractiveness and evaluating using ROUGE on each. We show here a similar analysis using the remaining two measures, coverage and compression. Results for subsets based on coverage and compression are shown in Tables 6 and 7.

	LOW COVERAGE			MEDIUM			HIGH COVERAGE		
	R-1	R-2	R-L	R-1	R-2	R-L	R-1	R-2	R-L
Lede-3	15.07	4.02	12.66	29.66	18.69	26.98	46.89	41.25	45.77
Fragments	72.45	46.16	72.45	93.41	83.08	93.41	99.13	98.16	99.13
TextRank	14.43	2.80	11.36	23.62	9.48	19.27	30.15	17.04	26.18
Abs-N	6.25	1.09	5.72	5.61	0.15	5.05	6.10	0.19	5.40

Table 7: Performance of the baselines and systems on the three compression subsets of the NEWSROOM development set. Article-summary pairs with low compression have longer reference summaries with respect to their texts. Article-summary pairs with high compression have shorter reference summaries with respect to their texts.

Polyglot Semantic Parsing in APIs

[†]Institute for Natural Language Processing, University of Stuttgart, Germany
{kyle,jonas}@ims.uni-stuttgart.de
[‡]Tel-Aviv University, Israel
joberant@cs.tau.ac.il

Abstract

Traditional approaches to semantic parsing (SP) work by training individual models for each available parallel dataset of text-meaning pairs. In this paper, we explore the idea of polyglot semantic translation, or learning semantic parsing models that are trained on multiple datasets and natural languages. In particular, we focus on translating text to code signature representations using the software component datasets of Richardson and Kuhn (2017a,b). The advantage of such models is that they can be used for parsing a wide variety of input natural languages and output programming languages, or mixed input languages, using a single unified model. To facilitate modeling of this type, we develop a novel graph-based decoding framework that achieves state-of-the-art performance on the above datasets, and apply this method to two other benchmark SP tasks.

1 Introduction

Recent work by Richardson and Kuhn (2017a,b); Miceli Barone and Sennrich (2017) considers the problem of translating source code documentation to lower-level code template representations as part of an effort to model the meaning of such documentation. Example documentation for a number of programming languages is shown in Figure 1, where each *docstring* description in red describes a given function (blue) in the library. While capturing the semantics of docstrings is in general a difficult task, learning the translation from descriptions to formal code representations (e.g., formal representations of functions) is proposed as a reasonable first step towards learning more general natural language understanding models in the software domain. Under this approach, one can view a software library, or API, as a kind of parallel translation corpus for studying *text* → `code` or `code` → *text* translation.

1. (*en*, `Java`) Documentation

```
*Returns the greater of two long values
public static long max(long a, long b)
```

2. (*en*, `Python`) Documentation

```
max(self, a, b):
    """Compares two values numerically
    and returns the maximum"""
```

3. (*en*, `Haskell`) Documentation

```
--| "The largest element of a non-empty structure"
maximum :: forall z. Ord a a => t a -> a
```

4. (*de*, `PHP`) Documentation

```
*gibt den größeren dieser Werte zurück.
max (mixed $value1, mixed $value2)
```

Figure 1: Example source code documentation.

Richardson and Kuhn (2017b) extracted the standard library documentation for 10 popular programming languages across a number of natural languages to study the problem of text to function signature translation. Initially, these datasets were proposed as a resource for studying semantic parser induction (Mooney, 2007), or for building models that learn to translate text to formal meaning representations from parallel data. In follow-up work (Richardson and Kuhn, 2017a), they proposed using the resulting models to do automated question-answering (QA) and code retrieval on target APIs, and experimented with an additional set of software datasets built from 27 open-source Python projects.

As traditionally done in SP (Zettlemoyer and Collins, 2012), their approach involves learning individual models for each parallel dataset or language pair, e.g., (*en*, `Java`), (*de*, `PHP`), and (*en*, `Haskell`). Looking again at Figure 1, we notice that while programming languages differ in terms of representation conventions, there is often overlap between the functionality implemented and naming in these different languages (e.g., the `max`

Proceedings of NAACL-HLT 2018, pages 720–730
New Orleans, Louisiana, June 1 - 6, 2018.

function), and redundancy in the associated linguistic descriptions. In addition, each English description (Figure 1.1-1.3) describes `max` differently using the synonyms *greater, maximum, largest*. In this case, it would seem that training models on multiple datasets, as opposed to single language pairs, might make learning more robust, and help to capture various linguistic alternatives.

With the software QA application in mind, an additional limitation is that their approach does not allow one to freely translate a given description to multiple output languages, which would be useful for comparing how different programming languages represent the same functionality. The model also cannot translate between natural languages and programming languages that are not observed during training. While software documentation is easy to find in bulk, if a particular API is not already documented in a language other than English (e.g., `Haskell` in *de*), it is unlikely that such a translation will appear without considerable effort by experienced translators. Similarly, many individual APIs may be too small or poorly documented to build individual models or QA applications, and will in some way need to bootstrap off of more general models or resources.

To deal with these issues, we aim to learn more general text-to-code translation models that are trained on multiple datasets simultaneously. Our ultimate goal is to build *polyglot* translation models (cf. Johnson et al. (2016)), or models with shared representations that can translate any input text to any output programming language, regardless of whether such language pairs were encountered explicitly during training. Inherent in this task is the challenge of building an efficient polyglot decoder, or a translation mechanism that allows such crossing between input and output languages. A key challenge is ensuring that such a decoder generates well-formed code representations, which is not guaranteed when one simply applies standard decoding strategies from SMT and neural MT (cf. Cheng et al. (2017)). Given our ultimate interest in API QA, such a decoder must also facilitate monolingual translation, or being able to translate to specific output languages as needed.

To solve the decoding problem, we introduce a new graph-based decoding and representation framework that reduces to solving shortest path problems in directed graphs. We investigate several translation models that work within this framework, including traditional SMT models and models based on neural networks, and report state-of-the-art results on the technical documentation task of Richardson and Kuhn (2017b,a). To show the applicability of our approach to more conventional SP tasks, we apply our methods to the GeoQuery domain (Zelle and Mooney, 1996) and the Sportscaster corpus (Chen et al., 2010). These experiments also provide insight into the main technical documentation task and highlight the strengths and weaknesses of the various translation models being investigated.

2 Related Work

Our approach builds on the baseline models introduced in Richardson and Kuhn (2017b) (see also Deng and Chrupała (2014)). Their work is positioned within the broader SP literature, where traditionally SMT (Wong and Mooney, 2006a) and parsing (Zettlemoyer and Collins, 2009) methods are used to study the problem of translating text to formal meaning representations, usually centering around QA applications (Berant et al., 2013). More recently, there has been interest in using neural network approaches either in place of (Dong and Lapata, 2016; Kočiský et al., 2016) or in combination with (Misra and Artzi, 2016; Jia and Liang, 2016; Cheng et al., 2017) these traditional models, the latter idea we look at in this paper.

Work in NLP on software documentation has accelerated in recent years due in large part to the availability of new data resources through websites such as StackOverflow and Github (cf. Allamanis et al. (2017)). Most of this recent work focuses on processing large amounts of API data in bulk (Gu et al., 2016; Miceli Barone and Sennrich, 2017), either for learning longer executable programs from text (Yin and Neubig, 2017; Rabinovich et al., 2017), or solving the inverse problem of code to text generation (Iyer et al., 2016; Richardson et al., 2017). In contrast to our work, these studies do not look explicitly at translating to target APIs, or at non-English documentation.

The idea of polyglot modeling has gained some traction in recent years for a variety of problems (Tsvetkov et al., 2016) and has appeared within work in SP under the heading of *multilingual SP* (Jie and Lu, 2014; Duong et al., 2017). A related topic is learning from multiple knowledge sources or domains (Herzig and Berant, 2017), which is related to our idea of learning from multiple APIs.

When building models that can translate between unobserved language pairs, we use the term *zero-shot translation* from Johnson et al. (2016).

3 Baseline Semantic Translator

Problem Formulation Throughout the paper, we refer to target code representations as API *components*. In all cases, components will consist of formal representations of functions, or function signatures (e.g., `long max(int a, int b)`), which include a function name (`max`), a sequence of arguments (`int a, int b`), and other information such as a return value (`long`) and namespace (for more details, see Richardson (2018)). For a given API dataset $D = \{(\mathbf{x}_i, \mathbf{z}_i)\}_{i=1}^{n}$ of size n, the goal is to learn a model that can generate *exactly* a correct component sequence $\mathbf{z} = (z_1, .., z_{|\mathbf{z}|})$, within a finite space $\mathcal{C}$ of signatures (i.e., the space of all defined functions), for each input text sequence $\mathbf{x} = (x_1, ..., x_{|\mathbf{x}|})$. This involves learning a probability distribution $p(\mathbf{z} \mid \mathbf{x})$. As such, one can think of this underlying problem as a *constrained* MT task.

In this section, we describe the baseline approach of Richardson and Kuhn (2017b). Technically, their approach has two components: a simple word-based translation model and task specific decoder, which is used to generate a k-best list of candidate component representations for a given input $\mathbf{x}$. They then use a discriminative model to rerank the translation output using additional non-world level features. The goal in this section is to provide the technical details of their translation approach, which we improve in Section 4.

3.1 Word-based Translation Model

The translation models investigated in Richardson and Kuhn (2017b) use a noisy-channel formulation where $p(\mathbf{z} \mid \mathbf{x}) \propto p(\mathbf{x} \mid \mathbf{z})p(\mathbf{z})$ via Bayes rule. By assuming a uniform prior on output components, $p(\mathbf{z})$, the model therefore involves estimating $p(\mathbf{x} \mid \mathbf{z})$, which under a word-translation model is computed using the following formula: $p(\mathbf{x} \mid \mathbf{z}) = \sum_{a \in \mathcal{A}} p(\mathbf{x}, a \mid \mathbf{z})$, where the summation ranges over the set of all many-to-one word alignments $\mathcal{A}$ from $\mathbf{x} \rightarrow \mathbf{z}$, with $|\mathcal{A}|$ equal to $(|\mathbf{z}| + 1)^{|\mathbf{x}|}$. They investigate various types of sequence-based alignment models (Och and Ney, 2003), and find that the classic IBM Model 1 outperforms more complex word models. This model factors in the following way and assumes an *independent word generation* process:

$$p(\mathbf{x} \mid \mathbf{z}) = \frac{1}{|\mathcal{A}|} \prod_{j=1}^{|\mathbf{x}|} \sum_{i=0}^{|\mathbf{z}|} p_t(x_j \mid z_i) \qquad (1)$$

where each p_t defines a multinomial distribution over a given component term z for all words x.

The decoding problem for the above translation model involves finding the most likely output $\hat{z}$, which requires solving an $\arg\max_{\mathbf{z}}$ over Equation 1. In the general case, this problem is known to be $\mathcal{NP}$-complete for the models under consideration (Knight, 1999) largely due to the large space of possible predictions $\mathbf{z}$. Richardson and Kuhn (2017b) avoid these issues by exploiting the finiteness of the target component search space (an idea we also pursue here and discuss more below), and describe a constrained decoding algorithm that runs in time $O(|\mathcal{C}| \log |\mathcal{C}|)$. While this works well for small APIs, it becomes less feasible when dealing with large sets of APIs, as in the polyglot case, or with more complex semantic languages typically used in SP (Liang, 2013).

4 Shortest Path Framework

To improve the baseline translation approach used previously (Section 3.1), we pursue a graph based approach. Given the formulation above and the finiteness of our prediction space $\mathcal{C}$, our approach exploits the fact that we can represent the complete component search space for any set of APIs as a directed acyclic finite-state automaton (`DAFSA`), such as the one shown graphically in Figure 2. The underlying graph is constructed by concatenating all of the component representations for each API of interest and applying standard finite-state construction and minimization techniques (Mohri, 1996). Each path in the resulting compact automaton is therefore a well-formed component representation.

Using an idea from Johnson et al. (2016), we add to each component representation an *artificial* token that identifies the output programming language or library. For example, the two edges from the initial state 0 in Figure 2 are labeled as *2C* and *2Clojure*, which identify the C and Clojure programming languages respectively. All paths starting from the right of these edges are therefore valid paths in each respective programming language. The paths starting from the initial state 0, in contrast, correspond to all valid component representations in all languages.

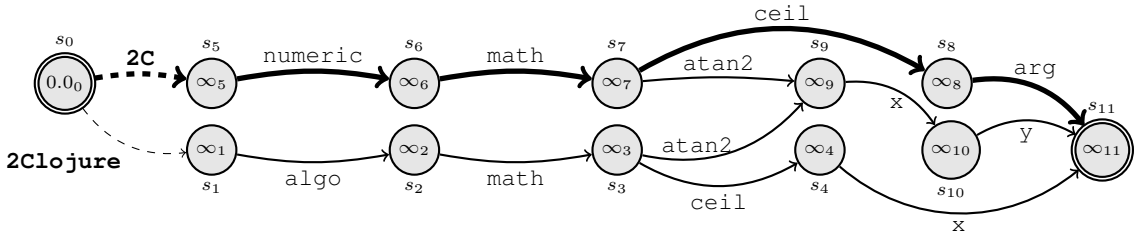

Figure 2: A DAFSA representation for a portion of the component sequence search space $\mathcal{C}$ that includes math functions in **C** and **Clojure**, and an example path/translation (in **bold**): **2C** `numeric math ceil arg`.

Decoding reduces to the problem of finding a path for a given text input **x**. For example, given the input *the ceiling of a number*, we would want to find the paths corresponding to the component translations `numeric math ceil arg` (in C) and `algo math ceil x` (in Clojure) in the graph shown in Figure 2. Using the trick above, our setup facilitates both monolingual decoding, i.e., generating components specific to a particular output language (e.g., the C language via the path shown in bold), and polyglot decoding, i.e., generating any output language by starting at the initial state 0 (e.g., C and Clojure).

We formulate the decoding problem using a variant of the well-known single source shortest path (SSSP) algorithm for directed acyclic graphs (DAGs) (Johnson (1977)). This involves a graph $\mathcal{G} = (V, E)$ (nodes V and labeled edges E, see graph in Figure 2), and taking an off-line topological sort of the graph's vertices. Using a data structure $d \in \mathbb{R}^{|V|}$ (initialized as $\infty^{|V|}$, as shown in Figure 2), the standard SSSP algorithm (which is the *forward update* variant of the Viterbi algorithm (Huang, 2008)) works by searching forward through the graph in sorted order and finding for each node v an incoming labeled edge u, with label z, that solves the following recurrence:

$$d(v) = \min_{(u,z):(u,v,z)\in E} \Big\{ d(u) + w(u, v, z) \Big\} \quad (2)$$

where $d(u)$ is shortest path score from a unique source node b to the incoming node u (computed recursively) and $w(u, v, z)$ is the weight of the particular labeled edge. The weight of the resulting shortest path is commonly taken to be the sum of the path edge weights as given by w, and the output translation is the sequence of labels associated with each edge. This algorithm runs in linear time over the size of the graph's adjacency matrix (`Adj`) and can be extended to find k SSSPs. In the standard case, a weighting function w is provided by assuming a static weighted graph. In our translation context, we replace w with a translation model, which is used to dynamically generate edge weights during the SSSP search for each input **x** by scoring the translation between **x** and each edge label z encountered.

Algorithm 1 Lexical Shortest Path Search

Input: Input **x** of size n, DAG $\mathcal{G} = (V, E)$, lexical translation function p_t, source node b with initial score o.
Output: Shortest component path

$d[V[\mathcal{G}]] \leftarrow \infty, \pi[V[\mathcal{G}]] \leftarrow Nil, d[b] \leftarrow o$
$s[V[\mathcal{G}], n] \leftarrow 0.0$ ▷ Shortest path sums at each node
for each vertex $u \geq b \in V[\mathcal{G}]$ in sorted order **do**
  for each vertex and label $(v, z) \in \mathtt{Adj}[u]$ **do**
    $\mathtt{score} \leftarrow -log\big[\ \prod_i^n p_t(x_i \mid z) + s[u, i]\ \big]$
    if $d[v] > \mathtt{score}$ **then**
      $d[v] \leftarrow \mathtt{score}, \pi[v] \leftarrow u$
      for i in $1, .., n$ **do** ▷ Update scores
        $s[v, i] \leftarrow p_t(x_i \mid z) + s[u, i]$
return FINDPATH$(\pi, |V|, b)$

Given this general framework, many different translation models can be used for scoring. In what follows, we describe two types of decoders based on lexical translation (or unigram) and neural sequence models. Technically, each decoding algorithm involves modifying the standard SSSP search procedure by adding an additional data structure s to each node (see Figure 2), which is used to store information about translations (e.g., running lexical translation scores, RNN state information) associated with particular shortest paths. By using these two very different models, we can get insight into the challenges associated with the technical documentation translation task. As we show in Section 6, each model achieves varying levels of success when subjected to a wider range of SP tasks, which reveals differences between our task and other SP tasks.

4.1 Lexical Translation Shortest Path

In our first model, we use the lexical translation model and probability function p_t in Equation 1 as

the weighting function, which can be learned efficiently off-line using the EM algorithm. When attempting to use the SSSP procedure to compute this equation for a given source input $\mathbf{x}$, we immediately have the problem that such a computation requires a complete component representation $\mathbf{z}$ (Knight and Al-Onaizan, 1998). We use an approximation[1] that involves ignoring the normalizer $|\mathcal{A}|$ and exploiting the word independence assumption of the model, which allows us to incrementally compute translation scores for individual source words given output translations corresponding to shortest paths during the SSSP search.

The full decoding algorithm in shown in Algorithm 1, where the red highlights the adjustments made to the standard SSSP search as presented in Cormen et al. (2009). The main modification involves adding a data structure $s \in \mathbb{R}^{|V| \times |\mathbf{x}|}$ (initialized as $0.0^{|V| \times |\mathbf{x}|}$ at line 2) that stores a running sum of source word scores given the best translations at each node, which can be used for computing the inner sum in Equation 1. For example, given an input utterance *ceiling function*, s_6 in Figure 2 contains the *independent* translation scores for words *ceiling* and *function* given the edge label `numeric` and p_t. Later on in the search, these scores are used to compute s_7, which will provide translation scores for each word given the edge sequence *numeric math*. Taking the product over any given s_j (as done in line 7 to get `score`) will give the probability of the shortest path translation at the particular point j. Here, the transformation into $-\log$ space is used to find the *minimum* incoming path. Standardly, the data structure π can be used to retrieve the shortest path back to the source node b (done via the FINDPATH method).

4.2 Neural Shortest Path

Our second set of models use neural networks to compute the weighting function in Equation 2. We use an encoder-decoder model with global attention (Bahdanau et al., 2014; Luong et al., 2015), which has the following two components:

Encoder Model The first is an *encoder* network, which uses a bi-directional recurrent neural network architecture with LSTM units (Hochreiter and Schmidhuber, 1997) to compute a sequence of forward annotations or hidden states $(\overrightarrow{h}_1, ..., \overrightarrow{h}_{|\mathbf{x}|})$ and a sequence of backward hidden states $(\overleftarrow{h}_1, ..., \overleftarrow{h}_{|\mathbf{x}|})$ for the input sequence $(x_1, ..., x_{|\mathbf{x}|})$. Standardly, each word is then represented as the concatenation of its forward and backward states: $h_j = [\overrightarrow{h}_j, \overleftarrow{h}_j]$.

Decoder Model The second component is a *decoder* network, which directly computes the conditional distribution $p(\mathbf{z} \mid \mathbf{x})$ as follows:

$$p(\mathbf{z} \mid \mathbf{x}) = \sum_{i=1}^{|\mathbf{z}|} \log p_\Theta(z_i \mid z_{<i}, \mathbf{x}) \quad (3)$$

$$p_\Theta(z_i \mid z_{<i}, \mathbf{x}) \sim \texttt{softmax}(f(\Theta, z_{<i}, \mathbf{x})) \quad (4)$$

where f is a non-linear function that encodes information about the sequence $z_{<i}$ and the input $\mathbf{x}$ given the model parameters Θ. We can think of this model as an ordinary recurrent language model that is additionally conditioned on the input $\mathbf{x}$ using information from our encoder. We implement the function f in the following way:

$$f(\Theta, z_{<i}, \mathbf{x}) = \mathbf{W}_o \eta_i + \mathbf{b}_o \quad (5)$$

$$\eta_i = \texttt{MLP}(c_i, g_i) \quad (6)$$

$$g_i = \texttt{LSTM}_{dec}(g_{i-1}, \mathbf{E}^{out}_{z_{i-1}}, c_i) \quad (7)$$

where `MLP` is a multi-layer perceptron model with a single hidden layer, $\mathbf{E}^{out} \in \mathbb{R}^{|\Sigma_{dec}| \times e}$ is a randomly initialized embedding matrix, g_i is the decoder's hidden state at step i, and c_i is a context-vector that encodes information about the input $\mathbf{x}$ and the encoder annotations. Each context vector c_i in turn is a weighted sum of each annotation h_j against an attention vector $\alpha_{i,j}$, or $c_i = \sum_{j=1}^{|\mathbf{x}|} \alpha_{i,j} h_j$, which is jointly learned using an additional single layered multi-layer perceptron defined in the following way:

$$\alpha_{i,j} \propto \exp(e_{i,j}); \quad e_{i,j} = \texttt{MLP}(g_{i-1}, h_j) \quad (8)$$

Lexical Bias and Copying In contrast to standard MT tasks, we are dealing with a relatively low-resource setting where the sparseness of the target vocabulary is an issue. For this reason, we experimented with integrating lexical translation scores using a biasing technique from Arthur et al. (2016). Their method is based on the following computation for each token z_i:

$$\texttt{bias}_i = \begin{bmatrix} p_{t'}(z_1 \mid x_1) & \dots & p_{t'}(z_1 \mid x_{|\mathbf{x}|}) \\ \vdots & \ddots & \vdots \\ p_{t'}(z_{|\Sigma_{dec}|} \mid x_1) & \dots & p_{t'}(z_{|\Sigma_{dec}|} \mid x_{|\mathbf{x}|}) \end{bmatrix} \begin{bmatrix} \alpha_{i,1} \\ \vdots \\ \alpha_{i,|\mathbf{x}|} \end{bmatrix}$$

[1] Details about the approx. are provided as supp. material.

Algorithm 2 Neural Shortest Path Search

Input: Input $\mathbf{x}$, DAG $\mathcal{G}$, neural parameters Θ and non-linear function f, beam size l, source node b with init. score o.
Output: Shortest component path

1: $d[V[\mathcal{G}]] \leftarrow \infty, d[b] \leftarrow o, \pi[V[\mathcal{G}]] \leftarrow Nil$
2: $s[V[\mathcal{G}]] \leftarrow Nil$ ▷ Path state information
3: $s[b] \leftarrow \texttt{InitState()}$ ▷ Initialize source state
4: **for** each vertex $u \geq b \in V[\mathcal{G}]$ in sorted order **do**
5: **if** $\texttt{isinf}(d[u])$ **then** continue
6: $p \leftarrow s[u]$ ▷ Current state at node u, or $z_{<i}$
7: $L^1_{[l]} \leftarrow \underset{(v_1,\ldots,v_k)\in \texttt{Adj}[u]}{\arg\max} \texttt{softmax}(f(\Theta, p, \mathbf{x}))$
8: **for** each vertex and label $(v, z) \in L$ **do**
9: $\texttt{score} \leftarrow -\log p_\Theta(z \mid p, \mathbf{x}) + d[u]$
10: **if** $d[v] > \texttt{score}$ **then**
11: $d[v] \leftarrow \texttt{score}, \pi[v] \leftarrow u$
12: $s[v] \leftarrow \texttt{UpdateState}(p, z)$
13: **return** FINDPATH$(\pi, |V|, b)$

The first matrix uses the inverse ($p_{t'}$) of the lexical translation function p_t already introduced to compute the probability of each word in the target vocabulary Σ_{dec} (the columns) with each word in the input $\mathbf{x}$ (the rows), which is then weighted by the attention vector from Equation 8. $bias_i$ is then used to modify Equation 5 in the following way:

$$f_{bias}(\Theta, z_{<i}, \mathbf{x}) = \mathbf{W}_o \eta_i + \mathbf{b}_o + \log(\texttt{bias}_i + \epsilon)$$

where ϵ is a hyper-parameter that helps to preserve numerical stability and biases more heavily on the lexical model when set lower.

We also experiment with the *copying* mechanism from Jia and Liang (2016), which works by allowing the decoder to choose from a set of latent actions, a_j, that includes writing target words according to Equation 5, as done standardly, or copying source words from $\mathbf{x}$, or $\texttt{copy}[x_i]$ according to the attention scores in Equation 8. A distribution is then computed over these actions using a $\texttt{softmax}$ function and particular actions are chosen accordingly during training and decoding.

Decoding and Learning The full decoding procedure is shown in Algorithm 2, where the differences with the standard SSSP are again shown in red. We change the data structure s to contain the decoder's RNN state at each node. We also modify the scoring (line 7, which uses Equation 4) to consider only the top l edges or translations at that point, as opposed to imposing a full search. When l is set to 1, for example, the procedure does a greedy search through the graph, whereas when l is large the procedure is closer to a full search.

In general terms, the decoder described above works like an ordinary neural decoder with the difference that each decision (i.e., new target-side word translation) is constrained (in line 7) by the transitions allowed in the underlying graph in order to ensure wellformedness of each component output. Standardly, we optimize these models using stochastic gradient descent with the objective of finding parameters $\hat{\Theta}$ that minimize the negative conditional log-likelihood of the training dataset.

4.3 Monolingual vs. Polyglot Decoding

Our framework facilitates both monolingual and polyglot decoding. In the first case, the decoder requires a graph associated with the output semantic language (more details in next section) and a trained translation model. The latter case requires taking the union of all datasets and graphs (with artificial identifier tokens) for a collection of target datasets and training a single model over this global dataset. In this setting, we can then decode to a particular language using the language identifiers or decode without specifying the output language. The main focus in this paper is investigating polyglot decoding, and in particular the effect of training models on multiple datasets when translating to individuals APIs or SP datasets.

When evaluating our models and building QA applications, it is important to be able to generate the k best translations. This can easily be done in our framework by applying standard k SSSP algorithms (Brander and Sinclair, 1995). We use an implementation of the algorithm of Yen (1971), which works on top of the SSSP algorithms introduced above by iteratively finding deviating or branching paths from an initial SSSP (more details provided in supplementary materials).

5 Experiments

We experimented with two main types of resources: 45 API documentation datasets and two multilingual benchmark SP datasets. In the former case, our main objective is to test whether training polyglot models (shown as **polyglot** in Tables 1-2) on multiple datasets leads to an improvement when compared to training individual monolingual models (shown as **monolingual** in Tables 1-2). Experiments involving the latter datasets are meant to test the applicability of our general graph and polyglot method to related SP tasks, and are also used for comparison against our main technical documentation task.

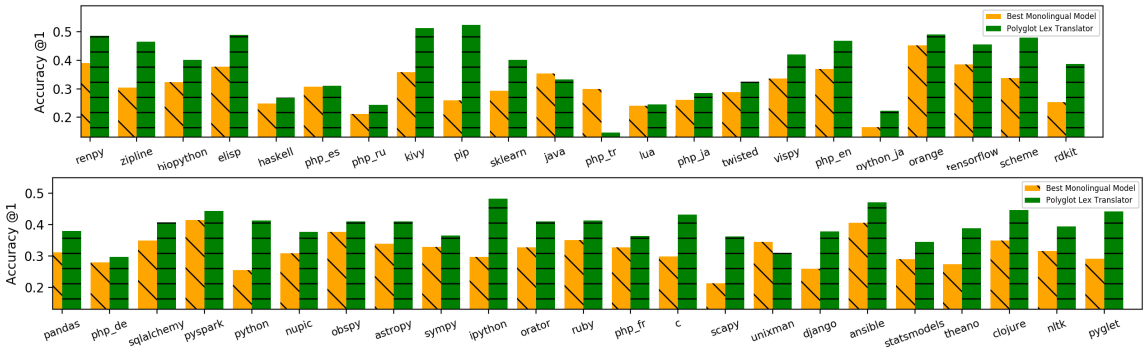

Figure 3: Test **Acc@1** for the best monolingual models (in yellow/left) compared with the best lexical polyglot model (green/right) across all 45 technical documentation datasets.

5.1 Datasets

Technical API Docs The first dataset includes the Stdlib and Py27 datasets of Richardson and Kuhn (2017b,a), which are publicly available via Richardson (2017). Stdlib consists of short description and function signature pairs for 10 programming languages in 7 languages, and Py27 contains the same type of data for 27 popular Python projects in English mined from Github. We also built new datasets from the Japanese translation of the Python 2.7 standard library, as well as the Lua stdlib documentation in a mixture of Russian, Portuguese, German, Spanish and English.

Taken together, these resources consist of 79,885 training pairs, and we experiment with training models on Stdlib and Py27 separately as well as together (shown as **+ more** in Table 1). We use a BPE subword encoding (Sennrich et al., 2015) of both input and output words to make the representations more similar and transliterated all datasets (excluding Japanese datasets) to an 8-bit latin encoding. Graphs were built by concatenating all function representations into a single word list and compiling this list into a minimized DAFSA. For our global polyglot dataset, this resulted in a graph with 218,505 nodes, 313,288 edges, and 112,107 paths or component representations over an output vocabulary of 9,324 words.

Mixed GeoQuery and Sportscaster We run experiments on the GeoQuery 880 corpus using the splits from Andreas et al. (2013), which includes geography queries for English, Greek, Thai, and German paired with formal database queries, as well as a seed lexicon or *NP list* for each language. In addition to training models on each individual dataset, we also learn polyglot models trained on all datasets concatenated together. We also created a new mixed language test set that was built by replacing NPs in 803 test examples with one or more NPs from a different language using the NP lists mentioned above (see examples in Figure 4). The goal in the last case is to test our model's ability to handle mixed language input. We also ran monolingual experiments on the English Sportscaster corpus, which contains human generated soccer commentary paired with symbolic meaning representation produced by a simulation of four games.

For GeoQuery graph construction, we built a single graph for all languages by extracting general rule templates from all representations in the dataset, and exploited additional information and patterns using the Geobase database and the semantic grammars used in (Wong and Mooney, 2006b). This resulted in a graph with 2,419 nodes, 4,936 edges and 39,482 paths over an output vocabulary of 164. For Sportscaster, we directly translated the semantic grammar provided in Chen and Mooney (2008) to a DAFSA, which resulted in a graph with 98 nodes, 86 edges and 830 paths.

5.2 Experimental Setup

For the technical datasets, the goal is to see if our model generates correct signature representations from unobserved descriptions using exact match. We follow exactly the experimental setup and data splits from Richardson and Kuhn (2017b), and measure the accuracy at 1 (**Acc@1**), accuracy in top 10 (**Acc@10**), and **MRR**.

For the GeoQuery and Sportscaster experiments, the goal is to see if our models can generate correct meaning representations for unseen input. For GeoQuery, we follow Andreas et al. (2013) in evaluating extrinsically by checking that each representation evaluates to the same answer as the gold representation when executed against the Geobase database. For Sportscaster, we evaluate by exact match to a gold representation.

		Method	Acc@1	Acc@10	MRR
stdlib	mono.	RK Trans + *rerank*	29.9	69.2	43.1
		Lexical SP	**33.2**	70.7	45.9

Table 1: Test results on the Stdlib and Py27 tasks averaged over all datasets and compared against the best monolingual results from Richardson and Kuhn (2017b,a), or RK

5.3 Implementation and Model Details

We use the Foma finite-state toolkit of Hulden (2009) to construct all graphs used in our experiments. We also use the Cython version of Dynet (Neubig et al., 2017) to implement all the neural models (see supp. materials for more details).

In the results tables, we refer to the lexical and neural models introduced in Section 4 as *Lexical Shortest Path* and *Neural Shortest Path*, where models that use copying (+ *copy*) and lexical biasing (+ *bias*) are marked accordingly. We also experimented with adding a discriminative reranker to our lexical models (+ *rerank*), using the approach from Richardson and Kuhn (2017b), which uses additional lexical (e.g., word match and alignment) features and other phrase-level and syntax features. The goal here is to see if these additional (mostly non-word level) features help improve on the baseline lexical models.

6 Results and Discussion

Technical Documentation Results Table 1 shows the results for Stdlib and Py27. In the monolingual case, we compare against the best performing models in Richardson and Kuhn (2017b,a). As summarized in Figure 3, our experiments show that training polyglot models on multiple datasets can lead to large improvements over training individual models, especially on the Py27 datasets where using a polyglot model resulted in a nearly 9% average increase in accuracy @1. In both cases, however, the best performing lexical models are those trained only on the datasets they are evaluated on, as opposed to training on all datasets (i.e., + *more*). This is surprising given that training on all datasets doubles the size of the training data, and shows that adding more data does not necessarily boost performance when the additional data is from another distribution.

		Method	Acc@1	Acc@10
Standard Geoquery	monolingual	UBL (Kwiatkowski et al., 2010)	74.2	–

Table 2: Test results for the standard (above) and mixed (middle) GeoQuery tasks averaged over all languages, and results for the English Sportscaster task (below).

The neural models are strongly outperformed by all other models both in the monolingual and polyglot case (only the latter results shown), even when lexical biasing is applied. While surprising, this is consistent with other studies on *low-resource* neural MT (Zoph et al., 2016; Östling and Tiedemann, 2017), where datasets of comparable size to ours (e.g., 1 million tokens or less) typically fail against classical SMT models. This result has also been found in relation to neural AMR semantic parsing, where similar issues of sparsity are encountered (Peng et al., 2017). Even by doubling the amount of training data by training on all datasets (results not shown), this did not improve the accuracy, suggesting that much more data is needed (more discussion below).

Beyond increases in accuracy, our polyglot models support zero-shot translation as shown in Figure 4, which can be used for translating between unobserved language pairs (e.g., (*es*,`Clojure`), (*ru*,`Haskell`) as shown in 1-2), or for finding related functionality across different software projects (as shown in 3). These results were obtained by running our decoder model without specifying the output language. We note, however, that the decoder can be constrained to selectively translate to any specific programming language or project (e.g., in a QA setting). Future work will further investigate the decoder's polyglot capabilities, which is currently hard to evaluate since we do not have an annotated set of function equivalences between different APIs.

1.	Source API (stdlib): (***es***, **PHP**)	**Input**: Devuelve el mensaje asociado al objeto lanzado.
Output	Language: **PHP**	Function Translation: `public string Throwable::getMessage ( void )`
	Language: **Java**	Function Translation: `public String lang.getMessage( void )`
	Language: **Clojure**	Function Translation: `(tools.logging.fatal throwable message & more)`
2.	Source API (stdlib): (***ru***, **PHP**)	**Input**: конвертирует строку из формата UTF-32 в формат UTF-16.
Output	Language: **PHP**	Function Translation: `string PDF_utf32_to_utf16 ( ... )`
	Language: **Ruby**	Function Translation: `String#toutf16 => string`
	Language: **Haskell**	Function Translation: `Encoding.encodeUtf16LE :: Text -> ByteString`

	Project: **stats**	Function Translation: `tools.pinv2( a,cond=None,rcond=None )`
4.	Mixed GeoQuery (de/gr)	**Input**: Wie hoch liegt der höchstgelegene punkt in Αλαμπάμα?
	Logical Form Translation: `answer(elevation_1(highest(place(loc_2(stateid('alabama'))))))`	

Figure 4: Examples of zero-shot translation when running in polyglot mode (1-3, function representations shown in a conventionalized format), and mixed language parsing (4).

Semantic Parsing Results SP results are summarized in Table 2. In contrast, the neural models, especially those with biasing and copying, strongly outperform all other models and are competitive with related work. In the GeoQuery case, we compare against two classic grammar-based models, UBL and TreeTrans, as well as a feature rich, neural hybrid tree model (nHT). We also see that the polyglot Geo achieves the best performance, demonstrating that training on multiple datasets helps in this domain as well. In the Sportscaster case we compare against two PCFG learning approaches, where the second model (wo-PCFG) involves a grammar with complex word-order constraints.

The advantage of training a polyglot model is shown on the results related to mixed language parsing (i.e., the middle set of results). Here we compared against the best performing monolingual English model (**Best Mono. Model**), which does not have a way to deal with multilingual NPs. We also find the neural model to be more robust than the lexical models with reranking.

While the lexical models overall perform poorly on both tasks, the weakness of this model is particularly acute in the Sportscaster case. We found that mistakes are largely related to the ordering of arguments, which these lexical (unigram) models are blind to. That these models still perform reasonably well on the Geo task shows that such ordering issues are less of a factor in this domain.

Discussion Having results across related SP tasks allows us to reflect on the nature of the main technical documentation task. Consistent with recent findings (Dong and Lapata, 2016), we show that relatively simple neural sequence models are competitive with, and in some cases outperform, traditional grammar-based SP methods on benchmark SP tasks. However, this result is not observed in our technical documentation task, in part because this problem is much harder for neural learners given the sparseness of the target data and lack of redundancy. For this reason, we believe our datasets provide new challenges for neural-based SP, and serve as a cautionary tale about the scalability and applicability of commonly used neural models to lower-resource SP problems.

In general, we believe that focusing on polyglot and mixed language decoding is not only of interest to applications (e.g, mixed language API QA) but also allows for new forms of SP evaluation that are more revealing than only translation accuracy. When comparing the accuracy of the best monolingual Geo model and the worst performing neural polyglot model, one could mistakingly think that these models have equal abilities, though the polyglot model is much more robust and general. Moving forward, we hope that our work helps to motivate more diverse evaluations of this type.

7 Conclusion

We look at learning from multiple API libraries and datasets in the context of learning to translate text to code representations and other SP tasks. To support *polyglot* modeling of this type, we developed a novel graph based decoding method and experimented with various SMT and neural MT models that work in this framework. We report a mixture of positive results specific to each task and set of models, some of which reveal interesting limitations of different approaches to SP. We also introduced new API and mixed language datasets to facilitate further work on polyglot SP.

Neural models of factuality

Rachel Rudinger

Abstract

We present two neural models for event factuality prediction, which yield significant performance gains over previous models on three event factuality datasets: FactBank, UW, and MEANTIME. We also present a substantial expansion of the It Happened portion of the Universal Decompositional Semantics dataset, yielding the largest event factuality dataset to date. We report model results on this extended factuality dataset as well.

1 Introduction

A central function of natural language is to convey information about the properties of events. Perhaps the most fundamental of these properties is *factuality*: whether an event happened or not.

A natural language understanding system's ability to accurately predict event factuality is important for supporting downstream inferences that are based on those events. For instance, if we aim to construct a knowledge base of events and their participants, it is crucial that we know which events to include and which ones not to.

The *event factuality prediction* task (EFP) involves labeling event-denoting phrases (or their heads) with the (non)factuality of the events denoted by those phrases (Saurí and Pustejovsky, 2009, 2012; de Marneffe et al., 2012). Figure 1 exemplifies such an annotation for the phrase headed by *leave* in (1), which denotes a factual event (⊕=factual, ⊖=nonfactual).

(1) Jo failed to **leave** no trace. ⊕

In this paper, we present two neural models of event factuality (and several variants thereof). We show that these models significantly outperform previous systems on four existing event factuality datasets – FactBank (Saurí and Pustejovsky, 2009), the UW dataset (Lee et al., 2015), MEANTIME (Minard et al., 2016), and Universal Decompositional Semantics It Happened v1 (UDS-IH1; White et al., 2016) – and we demonstrate the efficacy of multi-task training and ensembling in this setting. In addition, we collect and release an extension of the UDS-IH1 dataset, which we refer to as UDS-IH2, to cover the entirety of the English Universal Dependencies v1.2 (EUD1.2) treebank (Nivre et al., 2015), thereby yielding the largest event factuality dataset to date.[1]

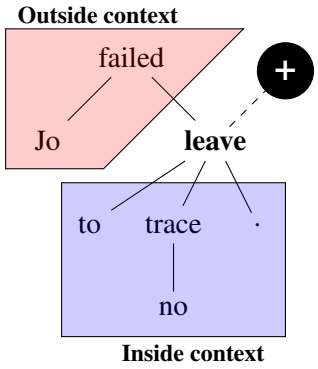

Figure 1: Event factuality (⊕=factual) and inside v. outside context for *leave* in the dependency tree.

We begin with theoretical motivation for the models we propose as well as discussion of prior EFP datasets and systems (§2). We then describe our own extension of the UDS-IH1 dataset (§3), followed by our neural models (§4). Using the data we collect, along with the existing datasets, we evaluate our models (§6) in five experimental settings (§5) and analyze the results (§7).

2 Background

2.1 Linguistic description

Words from effectively every syntactic category can convey information about the factuality of an event. For instance, negation (2a), modal auxiliaries (2b), determiners (2c), adverbs (2d), verbs (2e), adjectives (2f), and nouns (2g) can all con-

[1] Data available at decomp.net.

Proceedings of NAACL-HLT 2018, pages 731–744
New Orleans, Louisiana, June 1 - 6, 2018.

vey that a particular event – in the case of (2), a leaving event – did not happen.

(2) a. Jo didn't **leave**.
b. Jo might **leave**.
c. Jo **left** no trace.
d. Jo never **left**.
e. Jo failed to **leave**.
f. Jo's **leaving** was fake.
g. Jo's **leaving** was a hallucination.

Further, such words can interact to yield nontrivial effects on factuality inferences: (3a) conveys that the leaving didn't happen, while the superficially similar (3b) does not.

(3) a. Jo didn't remember to **leave**. ⊖
b. Jo didn't remember **leaving**. ⊕

A main goal of many theoretical treatments of factuality is to explain why these sorts of interactions occur and how to predict them. It is not possible to cover all the relevant literature in depth, and so we focus instead on the broader kind of interactions our models need to be able to capture in order to correctly predict the factuality of an event denoted by a particular predicate—namely, interactions between that predicate's *outside* and *inside* context, exemplified in Figure 1.

Outside context Factuality information coming from the outside context is well-studied in the domain of clause-embedding predicates, which break into at least four categories: factives, like *know* and *love* (Kiparsky and Kiparsky, 1970; Karttunen, 1971b; Hintikka, 1975); implicatives, like *manage* and *fail* (Karttunen, 1971a, 2012, 2013; Karttunen et al., 2014), veridicals, like *prove* and *verify* (Egré, 2008; Spector and Egré, 2015), and non-veridicals, like *hope* and *want*.

Consider the factive-implicative verb *forget* (Karttunen, 1971a; White, 2014).

(4) a. Jo forgot that Bo **left**. ⊕
b. Jo forgot to **leave**. ⊖

(5) a. Jo didn't forget that Bo **left**. ⊕
b. Jo didn't forget to **leave**. ⊕

When a predicate directly embedded by *forget* is tensed, as in (4a) and (5a), we infer that that predicate denotes a factual event, regardless of whether *forget* is negated. In contrast, when a predicate directly embedded by *forget* is untensed, as in (4b) and (5b), our inference is dependent on whether *forget* is negated. Thus, any model that correctly predicts factuality will need to not only be able to represent the effect of individual words in the outside context on factuality inferences, it will furthermore need to represent their interaction.

Inside context Knowledge of the inside context is important for integrating factuality information coming from a predicate's arguments—e.g. from determiners, like *some* and *no*.

(6) a. Some girl **ate** some dessert. ⊕
b. Some girl **ate** no dessert. ⊖
c. No girl **ate** no dessert. ⊕

In simple monoclausal sentences like those in (6), the number of arguments that contain a negative quantifier, like *no*, determine the factuality of the event denoted by the verb. An even number (or zero) will yield a factuality inference and an odd number will yield a nonfactuality inference. Thus, as for outside context, any model that correctly predicts factuality will need to integrate interactions between words in the inside context.

The (non)necessity of syntactic information One question that arises in the context of inside and outside information is whether syntactic information is strictly necessary for capturing the relevant interactions between the two. To what extent is linear precedence sufficient for accurately computing factuality?

We address these questions using two bidirectional LSTMs—one that has a linear chain topology and another that has a dependency tree topology. Both networks capture context on either side of an event-denoting word, but each does it in a different way, depending on its topology. We show below that, while both networks outperform previous models that rely on deterministic rules and/or hand-engineered features, the linear chain-structured network reliably outperforms the tree-structured network.

2.2 Event factuality datasets

Saurí and Pustejovsky (2009) present the FactBank corpus of event factuality annotations, built on top of the TimeBank corpus (Pustejovsky et al., 2006). These annotations (performed by trained annotators) are discrete, consisting of an epistemic modal $\{$*certain*, *probable*, *possible*$\}$ and a polarity $\{+,-\}$. In FactBank, factuality judgments are with respect to a *source*; following recent work, here we consider only judgments with respect to a single source: the author. The smaller MEANTIME corpus (Minard et al., 2016) includes sim-

Dataset	Train	Dev	Test	Total
FactBank	6636	2462	663	9761
MEANTIME	967	210	218	1395
UW	9422	3358	864	13644
UDS-IH2	22108	2642	2539	27289

Table 1: Number of annotated predicates.

ilar discrete factuality annotations. de Marneffe et al. (2012) re-annotate a portion of FactBank using crowd-sourced ordinal judgments to capture pragmatic effects on readers' factuality judgments.

Lee et al. (2015) construct an event factuality dataset – henceforth, UW – on the TempEval-3 data (UzZaman et al., 2013) using crowdsourced annotations on a $[-3, 3]$ scale (*certainly did not happen* to *certainly did*), with over 13,000 predicates. Adopting the $[-3, 3]$ scale of Lee et al. (2015), Stanovsky et al. (2017) assemble a Unified Factuality dataset, mapping the discrete annotations of both FactBank and MEANTIME onto the UW scale. Each scalar annotation corresponds to a token representing the event, and each sentence may have more than one annotated token.

The UDS-IH1 dataset (White et al., 2016) consists of factuality annotations over 6,920 event tokens, obtained with another crowdsourcing protocol. We adopt this protocol, described in §3, to collect roughly triple this number of annotations. We train and evaluate our factuality prediction models on this new dataset, UDS-IH2, as well as the unified versions of UW, FactBank, and MEANTIME.

Table 1 shows the number of annotated predicates in each split of each factuality dataset used in this paper. Annotations relevant to event factuality and polarity appear in a number of other resources, including the Penn Discourse Treebank (Prasad et al., 2008), MPQA Opinion Corpus (Wiebe and Riloff, 2005), the LU corpus of author belief commitments (Diab et al., 2009), and the ACE and ERE formalisms. Soni et al. (2014) annotate Twitter data for factuality.

2.3 Event factuality systems

Nairn et al. (2006) propose a deterministic algorithm based on hand-engineered lexical features for determining event factuality. They associate certain clause-embedding verbs with *implication signatures* (Table 2), which are used in a recursive polarity propagation algorithm. TruthTeller is also a recursive rule-based system for factuality ("predicate truth") prediction using implication signatures, as well as other lexical- and dependency tree-based features (Lotan et al., 2013).

Several systems use supervised models trained over rule-based features. Diab et al. (2009) and Prabhakaran et al. (2010) use SVMs and CRFs over lexical and dependency features for predicting author belief commitments, which they treat as a sequence tagging problem. Lee et al. (2015) train an SVM on lexical and dependency path features for their factuality dataset. Saurí and Pustejovsky (2012) and Stanovsky et al. (2017) train support vector models over the outputs of rule-based systems, the latter with TruthTeller.

3 Data collection

Even the largest currently existing event factuality datasets are extremely small from the perspective of related tasks, like natural language inference (NLI). Where FactBank, UW, MEANTIME, and the original UDS-IH1 dataset have on the order of 30,000 labeled examples combined, standard NLI datasets, like the Stanford Natural Language Inference (SNLI; Bowman et al. 2015) dataset, have on the order of 500,000.

To begin to remedy this situation, we collect an extension of the UDS-IH1 dataset. The resulting UDS-IH2 dataset covers all predicates in EUD1.2. Beyond substantially expanding the amount of publicly available event factuality annotations, another major benefit is that EUD1.2 consists entirely of gold parses and has a variety of other annotations built on top of it, making future multitask modeling possible.

We use the protocol described by White et al. (2016) to construct UDS-IH2. This protocol involves four kinds of questions for a particular predicate candidate:

1. UNDERSTANDABLE: whether the sentence is understandable
2. PREDICATE: whether or not a particular word refers to an eventuality (event or state)
3. HAPPENED: whether or not, according to the author, the event has already happened or is currently happening
4. CONFIDENCE: how confident the annotator is about their answer to HAPPENED from 0-4

If an annotator answers *no* to either UNDERSTANDABLE or PREDICATE, HAPPENED and CONFIDENCE do not appear.

The main differences between this protocol and the others discussed above are: (i) instead of asking about annotator confidence, the other proto-

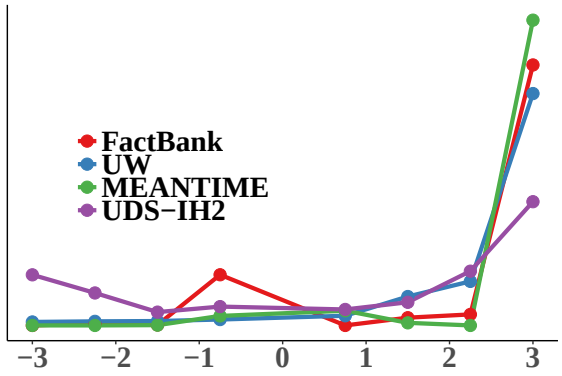

Figure 2: Relative frequency of factuality ratings in training and development sets.

cols ask the annotator to judge either source confidence or likelihood; and (ii) factuality and confidence are separated into two questions. We choose to retain White et al.'s protocol to maintain consistency with the portions of EUD1.2 that were already annotated in UDS-IH1.

Annotators We recruited 32 unique annotators through Amazon's Mechanical Turk to annotate 20,580 total predicates in groups of 10. Each predicate was annotated by two distinct annotators. Including UDS-IH1, this brings the total number of annotated predicates to 27,289.

Raw inter-annotator agreement for the HAPPENED question was 0.84 (Cohen's κ=0.66) among the predicates annotated only for UDS-IH2. This compares to the raw agreement score of 0.82 reported by White et al. (2016) for UDS-IH1.

To improve the overall quality of the annotations, we filter annotations from annotators that display particularly low agreement with other annotators on HAPPENED and CONFIDENCE. (See the Supplementary Materials for details.)

Pre-processing To compare model results on UDS-IH2 to those found in the unified datasets of Stanovsky et al. (2017), we map the HAPPENED and CONFIDENCE ratings to a single FACTUALITY value in [-3,3] by first taking the mean confidence rating for each predicate and mapping FACTUALITY to $\frac{3}{4}$CONFIDENCE if HAPPENED and -$\frac{3}{4}$CONFIDENCE otherwise.

Response distribution Figure 2 plots the distribution of factuality ratings in the train and dev splits for UDS-IH2, alongside those of FactBank, UW, and MEANTIME. One striking feature of these distributions is that UDS-IH2 displays a much more entropic distribution than the other datasets. This may be due to the fact that, unlike the newswire-heavy corpora that the other datasets annotate, EUD1.2 contains text from genres – weblogs, newsgroups, email, reviews, and question-answers – that tend to involve less reporting of raw facts. One consequence of this more entropic distribution is that, unlike the datasets discussed above, it is much harder for systems that always guess 3 – i.e. factual with high confidence/likelihood – to perform well.

4 Models

We consider two neural models of factuality: a stacked bidirectional linear chain LSTM (§4.1) and a stacked bidirectional child-sum dependency tree LSTM (§4.2). To predict the factuality v_t for the event referred to by a word w_t, we use the hidden state at t from the final layer of the stack as the input to a two-layer regression model (§4.3).

4.1 Stacked bidirectional linear LSTM

We use a standard stacked bidirectional linear chain LSTM (stacked L-biLSTM), which extends the unidirectional linear chain LSTM (Hochreiter and Schmidhuber, 1997) by adding the notion of a layer $l \in \{1, \ldots, L\}$ and a direction $d \in \{\rightarrow, \leftarrow\}$ (Graves et al., 2013; Sutskever et al., 2014; Zaremba and Sutskever, 2014).

$$\mathbf{f}_t^{(l,d)} = \sigma\left(\mathbf{W}_{\text{f}}^{(l,d)}\left[\mathbf{h}_{\mathbf{prev}_d(t)}^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\text{f}}^{(l,d)}\right)$$
$$\mathbf{i}_t^{(l,d)} = \sigma\left(\mathbf{W}_{\text{i}}^{(l,d)}\left[\mathbf{h}_{\mathbf{prev}_d(t)}^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\text{i}}^{(l,d)}\right)$$
$$\mathbf{o}_t^{(l,d)} = \sigma\left(\mathbf{W}_{\text{o}}^{(l,d)}\left[\mathbf{h}_{\mathbf{prev}_d(t)}^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\text{o}}^{(l,d)}\right)$$
$$\hat{\mathbf{c}}_t^{(l,d)} = g\left(\mathbf{W}_{\text{c}}^{(l,d)}\left[\mathbf{h}_{\mathbf{prev}_d(t)}^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\text{c}}^{(l,d)}\right)$$
$$\mathbf{c}_t^{(l,d)} = \mathbf{i}_t^{(l,d)} \circ \hat{\mathbf{c}}_t^{(l,d)} + \mathbf{f}_t^{(l,d)} \circ \mathbf{c}_{\mathbf{prev}_d(t)}^{(l,d)}$$
$$\mathbf{h}_t^{(l,d)} = \mathbf{o}_t^{(l,d)} \circ g\left(\mathbf{c}_t^{(l,d)}\right)$$

where $\circ$ is the Hadamard product; $\mathbf{prev}_{\rightarrow}(t) = t-1$ and $\mathbf{prev}_{\leftarrow}(t) = t+1$, and $\mathbf{x}_t^{(l,d)} = \mathbf{x}_t$ if $l = 1$; and $\mathbf{x}_t^{(l,d)} = [\mathbf{h}_t^{(l-1,\rightarrow)}; \mathbf{h}_t^{(l-1,\leftarrow)}]$ otherwise. We set g to the pointwise nonlinearity tanh.

4.2 Stacked bidirectional tree LSTM

We use a stacked bidirectional extension to the child-sum dependency tree LSTM (T-LSTM; Tai et al., 2015), which is itself an extension of a standard unidirectional linear chain LSTM (L-LSTM). One way to view the difference between the L-LSTM and the T-LSTM is that the T-LSTM redefines $\mathbf{prev}_{\rightarrow}(t)$ to return the set of indices that

correspond to the children of w_t in some dependency tree. Because the cardinality of these sets varies with t, it is necessary to specify how multiple children are combined. The basic idea, which we make explicit in the equations for our extension, is to define $\mathbf{f}_{tk}$ for each child index $k \in \mathbf{prev}_{\rightarrow}(t)$ in a way analogous to the equations in §4.1 – i.e. as though each child were the only child – and then sum across k within the equations for $\mathbf{i}_t$, $\mathbf{o}_t$, $\hat{\mathbf{c}}_t$, $\mathbf{c}_t$, and $\mathbf{h}_t$.

Our stacked bidirectional extension (stacked T-biLSTM) is a minimal extension to the T-LSTM in the sense that we merely define the *downward* computation in terms of a $\mathbf{prev}_{\leftarrow}(t)$ that returns the set of indices that correspond to the *parents* of w_t in some dependency tree (cf. Miwa and Bansal 2016, who propose a similar, but less minimal, model for relation extraction). The same method for combining children in the upward computation can then be used for combining parents in the downward computation. This yields a minimal change to the stacked L-biLSTM equations.

$$\mathbf{f}_{tk}^{(l,d)} = \sigma\left(\mathbf{W}_{\mathrm{f}}^{(l,d)}\left[\mathbf{h}_k^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\mathrm{f}}^{(l,d)}\right)$$
$$\hat{\mathbf{h}}_t^{(l,d)} = \sum_{k \in \mathbf{prev}_d(t)} \mathbf{h}_k^{(l,d)}$$
$$\mathbf{i}_t^{(l,d)} = \sigma\left(\mathbf{W}_{\mathrm{i}}^{(l,d)}\left[\hat{\mathbf{h}}_t^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\mathrm{i}}^{(l,d)}\right)$$
$$\mathbf{o}_t^{(l,d)} = \sigma\left(\mathbf{W}_{\mathrm{o}}^{(l,d)}\left[\hat{\mathbf{h}}_t^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\mathrm{o}}^{(l,d)}\right)$$
$$\hat{\mathbf{c}}_t^{(l,d)} = g\left(\mathbf{W}_{\mathrm{c}}^{(l,d)}\left[\hat{\mathbf{h}}_t^{(l,d)}; \mathbf{x}_t^{(l,d)}\right] + \mathbf{b}_{\mathrm{c}}^{(l,d)}\right)$$
$$\mathbf{c}_t^{(l,d)} = \mathbf{i}_t^{(l,d)} \circ \hat{\mathbf{c}}_t^{(l,d)} + \sum_{k \in \mathbf{prev}_d(t)} \mathbf{f}_{tk}^{(l,d)} \circ \mathbf{c}_k^{(l,d)}$$
$$\mathbf{h}_t^{(l,d)} = \mathbf{o}_t^{(l,d)} \circ g\left(\mathbf{c}_t^{(l,d)}\right)$$

We use a ReLU pointwise nonlinearity for g. These minimal changes allow us to represent the inside and the outside contexts of word t (at layer l) as single vectors: $\hat{\mathbf{h}}_t^{(l,\rightarrow)}$ and $\hat{\mathbf{h}}_t^{(l,\leftarrow)}$.

An important thing to note here is that – in contrast to other dependency tree-structured T-LSTMs (Socher et al., 2014; Iyyer et al., 2014) – this T-biLSTM definition does not use the dependency labels in any way. Such labels could be straightforwardly incorporated to determine which parameters are used in a particular cell, but for current purposes, we retain the simpler structure (i) to more directly compare the L- and T-biLSTMs and (ii) because a model that uses dependency labels substantially increases the number of trainable parameters, relative to the size of our datasets.

4.3 Regression model

To predict the factuality v_t for the event referred to by a word w_t, we use the hidden states from the final layer of the stacked L- or T-biLSTM as the input to a two-layer regression model.

$$\mathbf{h}_t^{(L)} = [\mathbf{h}_t^{(L,\rightarrow)}; \mathbf{h}_t^{(L,\leftarrow)}]$$
$$\hat{v_t} = \mathbf{V}_2\, g\left(\mathbf{V}_1 \mathbf{h}_t^{(L)} + \mathbf{b}_1\right) + \mathbf{b}_2$$

where $\hat{v_t}$ is passed to a loss function $\mathbb{L}(\hat{v_t}, v_t)$: in this case, smooth L1 – i.e. Huber loss with $\delta = 1$. This loss function is effectively a smooth variant of the hinge loss used by Lee et al. (2015) and Stanovsky et al. (2017).

We also consider a simple ensemble method, wherein the hidden states from the final layers of both the stacked L-biLSTM and the stacked T-biLSTM are concatenated and passed through the same two-layer regression model. We refer to this as the H(ybrid)-biLSTM.[2]

5 Experiments

Implementation We implement both the L-biLSTM and T-biLSTM models using `pytorch 0.2.0`. The L-biLSTM model uses the stock implementation of the stacked bidirectional linear chain LSTM found in `pytorch`, and the T-biLSTM model uses a custom implementation, which we make available at decomp.net.

Word embeddings We use the 300-dimensional GloVe 42B uncased word embeddings (Pennington et al., 2014) with an UNK embedding whose dimensions are sampled iid from a Uniform[-1,1]. We do not tune these embeddings during training.

Hidden state sizes We set the dimension of the hidden states $\mathbf{h}_t^{(l,d)}$ and cell states $\mathbf{c}_t^{(l,d)}$ to 300 for all layers of the stacked L- and stacked T-biLSTMs – the same size as the input word embeddings. This means that the input to the regression model is 600-dimensional, for the stacked L- and T-biLSTMs, and 1200-dimensional, for the stacked H-biLSTM. For the hidden layer of the regression component, we set the dimension to half the size of the input hidden state: 300, for

[2] See Miwa and Bansal 2016; Bowman et al. 2016 for alternative ways of hybridizing linear and tree LSTMs for semantic tasks. We use the current method since it allows us to make minimal changes to the architectures of each model, which in turn allows us to assess the two models' ability to capture different aspects of factuality.

Verb	Signature	Type	Example
know	$+\|+$	fact.	Jo knew that Bo ate.
manage	$+\|-$	impl.	Jo managed to go.
neglect	$-\|+$	impl.	Jo neglected to call Bo.
hesitate	$\circ\|+$	impl.	Jo didn't hesitate to go.
attempt	$\circ\|-$	impl.	Jo didn't attempt to go.

Table 2: Implication signature features from Nairn et al. (2006). As an example, a signature of $-|+$ indicates negative implication under positive polarity (left side) and positive implication under negative polarity (right side); $\circ$ indicates neither positive nor negative implication.

the stacked L- and T-biLSTMs, and 600, for the stacked H-biLSTM.

Bidirectional layers We consider stacked L-, T-, and H-biLSTMs with either one or two layers. In preliminary experiments, we found that networks with three layers badly overfit the training data.

Dependency parses For the T- and H-biLSTMs, we use the gold dependency parses provided in EUD1.2 when training and testing on UDS-IH2. On FactBank, MEANTIME, and UW, we follow Stanovsky et al. (2017) in using the automatic dependency parses generated by the parser in `spaCy` (Honnibal and Johnson, 2015).[3]

Lexical features Recent work on neural models in the closely related domain of genericity/habituality prediction suggests that inclusion of hand-annotated lexical features can improve classification performance (Becker et al., 2017). To assess whether similar performance gains can be obtained here, we experiment with lexical features for simple factive and implicative verbs (Kiparsky and Kiparsky, 1970; Karttunen, 1971a). When in use, these features are concatenated to the network's input word embeddings so that, in principle, they may interact with one another and inform other hidden states in the biLSTM, akin to how verbal implicatives and factives are observed to influence the factuality of their complements. The hidden state size is increased to match the input embedding size. We consider two types:

Signature features We compute binary features based on a curated list of 92 simple implicative and 95 factive verbs including their their type-level "implication signatures," as compiled by Nairn et al. (2006).[4] These signatures characterize the implicative or factive behavior of a verb with respect to its complement clause, how this behavior changes (or does not change) under negation, and how it composes with other such verbs under nested recursion. We create one indicator feature for each signature type.

Mined features Using a simplified set of pattern matching rules over Common Crawl data (Buck et al., 2014), we follow the insights of Pavlick and Callison-Burch (2016) – henceforth, PC – and use corpus mining to automatically score verbs for implicativeness. The insight of PC lies in Karttunen's (1971a) observation that "the main sentence containing an implicative predicate and the complement sentence necessarily agree in tense."

Accordingly, PC devise a *tense agreement score* – effectively, the ratio of times an embedding predicate's tense matches the tense of the predicate it embeds – to predict implicativeness in English verbs. Their scoring method involves the use of fine-grained POS tags, the Stanford Temporal Tagger (Chang and Manning, 2012), and a number of heuristic rules, which resulted in a confirmation that tense agreement statistics are predictive of implicativeness, illustrated in part by observing a near perfect separation of a list of implicative and non-implicative verbs from Karttunen (1971a).

dare to	1.00	intend to	0.83
bother to	1.00	want to	0.77
happen to	0.99	decide to	0.75
forget to	0.99	promise to	0.75
manage to	0.97	agree to	0.35
try to	0.96	plan to	0.20
get to	0.90	hope to	0.05
venture to	0.85		

Table 3: Implicative (bold) and non-implicative (not bold) verbs from Karttunen (1971a) are nearly separable by our tense agreement scores, replicating the results of PC.

We replicate this finding by employing a simplified pattern matching method over 3B sentences of raw Common Crawl text. We efficiently search for instances of any pattern of the form: `I $VERB to * $TIME`, where `$VERB` and `$TIME` are pre-instantiated variables so their corresponding tenses are known, and '`*`' matches any one to three whitespace-separated tokens at runtime (not pre-instantiated).[5] Our results in Table 3 are a close

[3] In rebuilding the Unified Factuality dataset (Stanovsky et al., 2017), we found that sentence splitting was potentially sensitive to the version of `spaCy` used. We used v1.9.0.

[4] `http://web.stanford.edu/group/csli_lnr/Lexical_Resources`

[5] To instantiate `$VERB`, we use a list of 1K clause-embedding verbs compiled by (White and Rawlins, 2016) as well as the python package `pattern-en` to conjugate each verb in past, present progressive, and future tenses; all conjugations are first-person singular. `$TIME` is instantiated

replication of PC's findings. Prior work such as by PC is motivated in part by the potential for corpus-linguistic findings to be used as fodder in downstream predictive tasks: we include these agreement scores as potential input features to our networks to test whether contemporary models do in fact benefit from this information.

Training For all experiments, we use stochastic gradient descent to train the LSTM parameters and regression parameters end-to-end with the Adam optimizer (Kingma and Ba, 2015), using the default learning rate in `pytorch` (`1e-3`). We consider five training regimes:[6]

1. SINGLE-TASK SPECIFIC (-S) Train a separate instance of the network for each dataset, training only on that dataset.
2. SINGLE-TASK GENERAL (-G) Train one instance of the network on the simple concatenation of all unified factuality datasets, {FactBank, UW, MEANTIME}.
3. MULTI-TASK SIMPLE (-MULTISIMP) Same as SINGLE-TASK GENERAL, except the network maintains a distinct set of regression parameters for each dataset; all other parameters (LSTM) remain tied. "w/UDS-IH2" is specified if UDS-IH2 is included in training.
4. MULTI-TASK BALANCED (-MULTIBAL) Same as MULTI-TASK SIMPLE but upsampling examples from the smaller datasets to ensure that examples from those datasets are seen at the same rate.
5. MULTI-TASK FOCUSED (-MULTIFOC) Same as MULTI-TASK SIMPLE but upsampling examples from a particular target dataset to ensure that examples from that dataset are seen 50% of the time and examples from the other datasets are seen 50% (evenly distributed across the other datasets).

Calibration Post-training, network predictions are monotonically re-adjusted to a specific dataset using isotonic regression (fit on train split only).

Evaluation Following Lee et al. (2015) and Stanovsky et al. (2017), we report two evaluation measures: mean absolute error (MAE) and Pearson correlation (r). We would like to note, however, that we believe correlation to be a better indicator of performance for two reasons: (i) for datasets with a high degree of label imbalance

with each of five past tense phrases ("yesterday," "last week," etc.) and five corresponding future tense phrases ("tomorrow," "next week," etc). See Supplement for further details.

[6] *Multi-task* can have subtly different meanings in the NLP community; following terminology from Mou et al. (2016), our use is best described as "semantically equivalent transfer" with simultaneous (MULT) network training.

Table 5: Mean gold labels, counts, and MAE for L-biLSTM(2)-S and T-biLSTM(2)-S model predictions on UDS-IH2-dev, grouped by modals and negation.

(Figure 2), a baseline that always guesses the mean or mode label can be difficult to beat in terms of MAE but not correlation, and (ii) MAE is harder to meaningfully compare across datasets with different label mean and variance.

Development Under all regimes, we train the model for 20 epochs – by which time all models appear to converge. We save the parameter values after the completion of each epoch and then score each set of saved parameter values on the development set for each dataset. The set of parameter values that performed best on dev in terms of Pearson correlation for a particular dataset were then used to score the test set for that dataset.

6 Results

Table 4 reports the results for all of the 2-layer L-, T-, and H-biLSTMs.[7] The best-performing system for each dataset and metric are highlighted in purple, and when the best-performing system for a particular dataset was a 1-layer model, that system is included in Table 4.

New state of the art For each dataset and metric, with the exception of MAE on UW, we achieve state of the art results with multiple systems. The highest-performing system for each is reported in Table 4. Our results on UDS-IH2 are the first reported numbers for this new factuality resource.

Linear v. tree topology On its own, the biLSTM with linear topology (L-biLSTM) performs consistently better than the biLSTM with tree topology (T-biLSTM). However, the hybrid topology (H-biLSTM), consisting of both a L- and T-biLSTM is the top-performing system on UW for correlation (Table 4). This suggests that the T-biLSTM may be contributing something complementary to the L-biLSTM.

[7] Full results are reported in the Supplementary Materials. Note that the 2-layer networks do not strictly dominate the 1-layer networks in terms of MAE and correlation.

Table 6: Mean predictions for linear (L-biLSTM-S(2)) and tree models (T-biLSTM-S(2)) on UDS-IH2-dev, grouped by governing dependency relation. Only the 10 most frequent governing dependency relations in UDS-IH2-dev are shown.

Evidence of this complementarity can be seen in Table 6, which contains a breakdown of system performance by governing dependency relation, for both linear and tree models, on UDS-IH2-dev. In most cases, the L-biLSTM's mean prediction is closer to the true mean. This appears to arise in part because the T-biLSTM is less confident in its predictions – i.e. its mean prediction tends to be closer to 0. This results in the L-biLSTM being too confident in certain cases – e.g. in the case of the `xcomp` governing relation, where the T-biLSTM mean prediction is closer to the true mean.

Lexical features have minimal impact Adding all lexical features (both SIGNATURE and MINED) yields mixed results. We see slight improvements on UW, while performance on the other datasets mostly declines (compare with SINGLE-TASK SPECIFIC). Factuality prediction is precisely the kind of NLP task one would expect these types of features to assist with, so it is notable that, in our experiments, they do not.

Multi-task helps Though our methods achieve state of the art in the single-task setting, the best performing systems are mostly multi-task (Table 4 and Supplementary Materials). This is an ideal setting for multi-task training: each dataset is relatively small, and their labels capture closely-related (if not identical) linguistic phenomena. UDS-IH2, the largest by a factor of two, reaps the smallest gains from multi-task.

7 Analysis

As discussed in §2, many discrete linguistic phenomena interact with event factuality. Here we provide a brief analysis of some of those interactions, both as they manifest in the UDS-IH2 dataset, as well as in the behavior of our models. This analysis employs the gold dependency parses present in EUD1.2.

Table 5 illustrates the influence of modals and negation on the factuality of the events they have direct scope over. The context with the highest factuality on average is *no direct modal* and *no negation* (first row); all other modal contexts have varying degrees of negative mean factuality scores, with *will* as the most negative. This is likely a result of UDS-IH2 annotation instructions to mark future events as not having happened.

Table 7 shows results from a manual error analysis on 50 events from UDS-IH2-dev with highest absolute prediction error (using H-biLSTM(2)-MultiSim w/UDS-IH2). Grammatical errors (such as run-on sentences) in the underlying text of UDS-IH2 appear to pose a particular challenge for these models; informal language and grammatical errors in UDS-IH2 is a substantial distinction from the other factuality datasets used here.

In §6 we observe that the linguistically-motivated lexical features that we test (+lexfeats) do not have a big impact on overall performance. Tables 8 and 9 help nuance this observation.

Table 8 shows that we can achieve similar separation between implicatives and non-implicatives as the feature mining strategy presented in §5. That is, those features may be redundant with information already learnable from factuality datasets (UDS-IH2). Despite the underperformance of these features overall, Table 9 shows that they may still improve performance in the subset of instances where they appear.

8 Conclusion

We have proposed two neural models of event factuality prediction – a bidirectional linear-chain LSTM (L-biLSTM) and a bidirectional child-sum dependency tree LSTM (T-biLSTM) – which yield substantial gains over previous models based on deterministic rules and hand-engineered features. We found that both models yield such gains, though the L-biLSTM outperforms the T-biLSTM; for some datasets, an ensemble of the two (H-biLSTM) improves over either alone.

We have also extended the UDS-IH1 dataset, yielding the largest publicly-available factuality dataset to date: UDS-IH2. In experiments, we see substantial gains from multi-task training over the three factuality datasets unified by Stanovsky et al. (2017), as well as UDS-IH2. Future work will further probe the behavior of these models, or extend them to learn other aspects of event semantics.

A Appendix

A.1 Dataset filtering

We filter our dataset to remove annotators with very low agreement in two ways: (i) based on the their agreement with other annotators on the HAPPENED question; and (ii) based on the their agreement with other annotators on the CONFIDENCE question.

For the HAPPENED question, we computed, for each pair of annotators and each item that both of those annotators annotated, whether the two responses were equal. We then fit a random effects logistic regression to response equality with random intercepts for annotator. The Best Linear Unbiased Predictors (BLUPs) for each annotator were then extracted and z-scored. Annotators were removed if their z-scored BLUP was less than -2.

For the CONFIDENCE question, we first ridit-scored the ratings by annotator; and for each pair of annotators and each item that both of those annotators annotated, we computed the difference between the two ridit-scored confidences. We then fit a random effects linear regression to the resulting difference after logit-transformation with random intercepts for annotator. The same BLUP-based exclusion procedure was then used.

This filtering results in the exclusion of one annotator, who is excluded for low agreement on HAPPENED. 4,179 annotations are removed in the filtering, but because we remove only a single annotator, there remains at least one annotation for every predicate.

A.2 Mining Implicatives

All options for instantiating the `$TIME` pattern variable, described in §5, are listed here.

- Past Tense Phrases: *earlier today*, *yesterday*, *last week*, *last month*, *last year*
- Future Tense Phrases: *later today*, *tomorrow*, *next week*, *next month*, *next year*

Abstract

Previous representation learning techniques for knowledge graph representation usually represent the same entity or relation in different triples with the same representation, without considering the ambiguity of relations and entities. To appropriately handle the semantic variety of entities/relations in distinct triples, we propose an accurate text-enhanced knowledge graph representation learning method, which can represent a relation/entity with different representations in different triples by exploiting additional textual information. Specifically, our method enhances representations by exploiting the entity descriptions and triple-specific relation mention. And a mutual attention mechanism between relation mention and entity description is proposed to learn more accurate textual representations for further improving knowledge graph representation. Experimental results show that our method achieves the state-of-the-art performance on both link prediction and triple classification tasks, and significantly outperforms previous text-enhanced knowledge representation models.

1 Introduction

Knowledge graphs such as Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007) and WordNet (Miller, 1995) are among the most widely used resources in NLP applications. Typically, a knowledge graph consists of a set of triples $\{(h, r, t)\}$, where h, r, t stand for head entity, relation and tail entity respectively.

Learning distributional representation of knowledge graph has attracted many research attentions in recent years. By projecting all elements in a knowledge graph into a dense vector space, the semantic distance between all elements can be easily calculated, and thus enables many applications

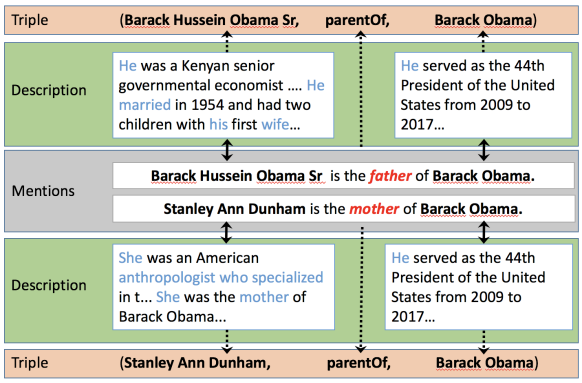

Figure 1: A demonstration of our accurate text-enhanced model. The meanings of relation `parentOf` in different triples are distinguished by their entity descriptions, and the relation `parentOf` emphasizes words which describe its social relationship in entity descriptions.

such as link prediction and triple classification (Socher et al., 2013).

Recently, translation-based models, including TransE (Bordes et al., 2013), TransH (Wang et al., 2014), TransD (Ji et al., 2015) and TransR (Lin et al., 2015b), have achieved promising results in distributional representation learning of knowledge graph. ComplEx (Trouillon et al., 2016) has achieved the state-of-the-art performance on multiple tasks, such as triple classification and link prediction. Unfortunately, all of these methods only utilize the structure information of knowledge graph, which inevitably suffer from the sparseness and incompleteness of knowledge graph. Even worse, structure information usually cannot distinguish the different meanings of relations and entities in different triples.

To address the above problem, additional information is introduced to enrich the knowledge representations, including entity types and logic rules. However, most researches of this line are limited by manually constructed logic rules, which

Proceedings of NAACL-HLT 2018, pages 745–755
New Orleans, Louisiana, June 1 - 6, 2018.

are knowledge graph sensitive and require the expert knowledge. Another type of widely used resources is textual information, such as entity descriptions and words co-occurrence with entities (Socher et al., 2013; Wang et al., 2014; Zhong et al., 2015).

The main drawback of the above methods is that they represent the same entity/relation in different triples with a unique representation. Unfortunately, by detailed analyzing the triples in knowledge graph, we find two problems of the unique representation: (1) Relations are ambiguous, i.e., the accurate semantic meaning of a relation in a specific triple is related to the entities in the same triple. For example, the relation "`parentOf`" may refer to two different meanings of (i.e., "*father*" and "*mother*"), depending on the entities in triples. (2) Because different relations may concern different attributes of an entity, the same entity may express different aspects in different triples. For example, different words in the description of "*Barack Obama*" should be emphasized by relations "`parentOf`" and "`professionOf`". The ambiguity of entity/relation has been considered as one of the primary reasons why translation-based models cannot handle 1-to-N, N-to-1 and N-to-N categories of relations (Wang et al., 2014). Wang et al. (2016) tried to solve the two issues using words co-occurrence with the entities in the same sentences. Despite its apparent success, there remains a major drawback: this method suffers from noisy text, which reduces the value of textual information.

To solve above problems, this paper proposes an accurate text-enhanced knowledge representation model, which can enhance the representations of entities and relations by incorporating accurate textual information for each triple. To learn the representation of a given triple, we first extract its accurate relation mentions from text corpus, which reflect the specific relationship between its head entity and tail entity. Then a mutual attention mechanism between relation mention and entity descriptions (extracted from knowledge graph), is introduced to enhance the representations of entities and relations. For example, the two triples in Figure 1 have the same "`parentOf`" relationship, but have different underlying semantics "*was the father of*" and "*was the mother of*" respectively. Besides, our mutual attention mechanism enables knowledge representation focusing more on related information from text information. For example, the "`parentOf`" relation will concern more about the social relations and gender attributes of a person, rather than his/her jobs, which are also contained in its descriptions. And such a relation-specific entity description will make an entity has more appropriate, relation-specific representations in different triples.

Concretely, we employ BiLSTM model (Schuster and Paliwal, 1997; Graves and Schmidhuber, 2005) with mutual attention mechanism (Zhou et al., 2016) to learn representations for relation mentions and entity descriptions. Specifically, in order to generate triple-specific textual representation of entities and relation, a mutual attention mechanism is proposed to model relation between entity descriptions and relation mention of one triple. Then the learned textual representations are incorporated with previous traditional transition-based representations, which are, learned from structural information of knowledge graph, directly to obtain enhanced triple specific representations of elements.

We evaluate our method on both link prediction task and triple classification task, using benchmark datasets from Freebase[1] and WordNet[2] with the text corpus. Experimental results show that, our model achieves the state-of-the-art performance, and significantly outperforms previous text-enhanced models.

The main contributions are threefold: (i) To the best of our knowledge, this is the first work which simultaneously exploits both relation mention and entity description to handle the ambiguity of relations and entities (Section 3). (ii) We propose a mutual attention mechanism which exploits the textual representations of relation and entity to enhance each other (Section 3.2). (iii) This paper achieves new state-of-the-art performances on triple classification tasks over two most widely used benchmarks (Section 4).

2 Related Work

Currently, a lot of structural-based knowledge representation learning methods have been proposed for knowledge graph completion, including Bilinear Model (Sutskever, 2009), Distance Model (Bordes et al., 2011), Unstructured Model (Bordes et al., 2012), Neural Tensor Network (Socher

[1] http://www.freebase.com
[2] http://www.princeton.edu/wordnet

et al., 2013), Single Layer Model (Socher et al., 2013). And many translation-based methods are introduced, including TransE (Bordes et al., 2013) and its extensions like TransH (Wang et al., 2014), TransD (Ji et al., 2015), TransR (Lin et al., 2015b). Xiao et al. (2016a) proposed a manifold-based embedding principle to deal with the overstrict geometric form of translation-based assumption. Trouillon et al. (2016) employed complex value embeddings to understand the structural information.

In recent years, many methods improve the knowledge representation by exploiting additional information. For example, both the path information and logic rules have been proved to be beneficial for knowledge representation (Lin et al., 2015a; Toutanova et al., 2016; Xiong et al., 2017; Xie et al., 2016; Xu et al., 2016).

One other direction to enhance knowledge representation is to utilize entity descriptions of entities and relations. Socher et al. (2013) proposed a neural tensor network model which enhances an entity's representation using the average of the word embeddings in its name. Wang et al. (2014) proposed a model which combines entity embeddings with word embeddings using its names and Wikipedia anchors. Zhong et al. (2015) further improved the model of Wang et al. (2014) by aligning entity and text using entity descriptions. Zhang et al. (2015) proposed to model entities with word embeddings of entity names or entity descriptions. Xie et al. (2016) proposed a model to learn the embeddings of a knowledge graph by modelling both knowledge triples and entity descriptions. Xu et al. (2016) learns different representations for entities based on the attention from relation. The textual mentions of relations are also explored by Fan et al. (2014). The universal schema based models (Riedel et al., 2013; Toutanova et al., 2015) enhance knowledge representation by incorporating textual triples, which assume that all the extracted triples express a relationship between the entities and they treat each pattern as a separate relation. The main drawback of these methods is that they assume all the relation mentions will express relationship between entity pairs, which inevitably introduces a lot of noisy information. For example, the sentence "`Miami Dolphins in 1966 and the Cincinnati Bengals in 1968`" does not express any relationship between "`miami_dolphins`" and "`cincinnati_bengals`". Even worse, the diversity of language often leads to the data sparsity problem.

To resolve the ambiguity of entities and relations in different triples (i.e., a relation/entity may have different meanings in different triples), Xiao et al. (2016b) proposed a generative model to handle the ambiguous relations. Wang et al. (2016) extended the translation-based models by textual information, which assigns a relation with different representations for different entity pairs, using words co-occurred with both entities in a triple. However, the words co-occur with an entity pair nay also not express the meanings of the relation between them, which will inevitably introduce noisy information for the specific triple. Compared with these methods the main advantages of our methods are: (i) We filters out noisy textual information for accurate enrich knowledge representation. (ii) We simultaneously take the ambiguity of entities and relations in various triples into consideration.

3 Accurate Text-enhanced Knowledge Graph Representation

This section presents our accurate text-enhanced knowledge graph representation learning framework. We first describe how to extract accurate textual information for a given triple, and then we propose a textual representation learning model, which generates textual representations for both entities and relation in a specific triple. Finally, we describe how to enhance knowledge representations based on the textual representations.

The framework of the proposed approach is illustrated in Figure 2.

3.1 Text Information Extraction

Given a triple, our method will first extract accurate textual mentions of its relation from a text corpus. For example, we will extract the relation mention "*Barack Hussein Obama Sr was the father of Barack Obama.*" for the triple *(Barack Hussein Obama Sr, parentOf, Barack Obama)*]]. We collect relation mentions by two steps: (1) Entity linking: linking entity names in a text corpus to entities in a knowledge graph. (2) Relation mention extraction: collecting accurate relation mentions which express the meanings of the relation in a given triple.

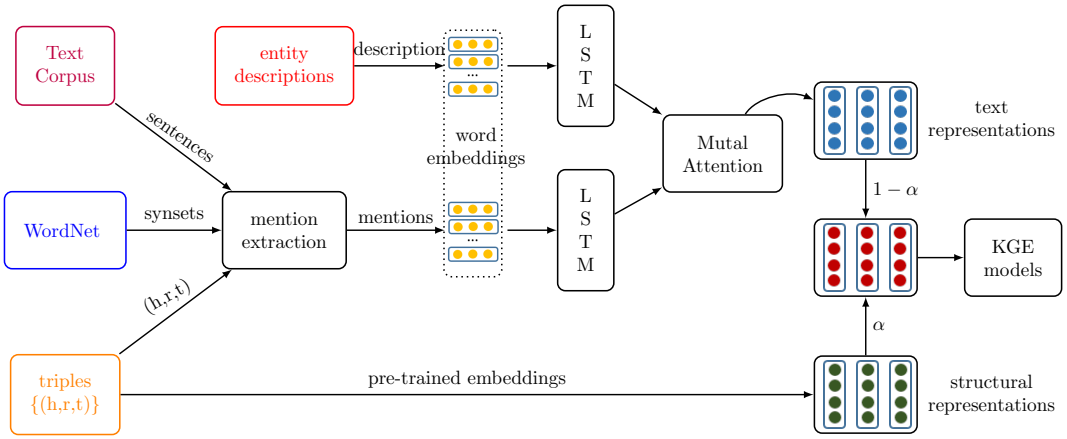

Figure 2: Framework of the proposed approach.

Entity Linking. Given a sentence $D = (w_1, w_2, ..., w_n)$, and an entity set $E = (e_1, e_2, ..., e_m)$, we first recognize entities of E in D to construct a new sentence $D' = (w_1, ..., e_1, ..., e_m, ..., w_n)$, where w_i represents the ith word in D and e_j corresponds to the jth entity in E. There are many general entity linking tools can be used for this purpose. The proposed method employs a simple and precise method to link entities of Freebase and WordNet as Wang et al. (2016). Concretely, we link a Wikipedia inner-link as an entity of Freebase if they have the same titles, and link a word in the corpus as a WordNet entity if the word belongs to one of its synsets.

Relation Mention Extraction. To extract accurate relation text mentions for a specific triple, we first collect all sentences containing both entities of the triple as candidate text mentions. And then, we calculate the similarity between a text mention and the relation based on WordNet. For example, for the triple of *(Steve Jobs, /people/person/parents, Paul Jobs)*, we treat a sentence as its accurate relation mention only if the sentence contains both of its entities and at least one hyponym/synonyms word of the relation. We collect accurate relation mentions for triples in WordNet in a similar way.

In this way, we can extract accurate relation mentions for triples with high precision. However, if a relation mention doesn't contain any hyponym/synonym words of the relation, our method would be unable to identify it. For example, the sentence "*In 1961 Obama was born in Hawaii, US*" expresses the meanings of `/people/person/nationality` in the triple `(Barack Obama,/people/person/nationality, USA )` but without any words belonging to the hyponym or synonyms of "*nationality*". For this, we further employ word embeddings to compute the similarity. Concretely, we represent a relation by averaging the pre-trained word embeddings of its last two words. Then we extract a sentence as an accurate relation mention of a given triple if the similarity between a word in the sentence and the relation representation is above a threshold, with the similarity between a word and a relation is calculated by the cosine similarity of their representations.

3.2 Learning Textual Representation

As mentioned above, the underlying semantics of entities and relations vary from different triples, and different attributes of an entity are concerned by different relations. In this section, we first utilize BiLSTM to encode relation mentions and entity descriptions. And then, we propose a mutual attention mechanism to learn more accurate text representations of relations and entities. Our model contains four layers including Embedding layer, BiLSTM layer and Mutual Attention Layer, and the details of these layers are described as follows.

Embedding Layer. To learn the distributional representation of relation mentions and entity descriptions, we convert words into distributional representations based on lookup word embeddings matrix (Mikolov et al., 2013). Concretely, given a relation mention $m = \{w_1, w_2, w_3, ..., w_n\}$, we transform the word w_i into its distributional representation $\vec{e_i} \in d^w$ using a word embeddings ma-

trix. We use the same pre-trained word embeddings as input for the BiLSTM networks of relation mentions and entity descriptions.

BiLSTM Layer. To learn the representation of text mentions, we utilize a BiLSTM (Long Short-Term Memory) (Hochreiter and Schmidhuber, 1997; Le and Zuidema, 2015; Zhou et al., 2016) model to compose the words in a sequence into the distributional representation. Concretely, we employ a two layer Bidirectional LSTM network to generate text representations. The detailed description of LSTM is presented in (Hochreiter and Schmidhuber, 1997). Two different BiLSTM networks are employed to encode relation mentions and entity descriptions respectively.

Mutual Attention Layer. Attention based neural networks have recently achieved success in a wide range of tasks, including machine translation, speech recognition and paraphrase detection (Luong et al., 2015; Yang et al., 2016; Yin et al., 2016; Vaswani et al., 2017). In this paper, we introduce a mutual attention to improve text representations. Given a triple, the goal of our mutual attention mechanism is two-fold. On one hand, our model wants to identify words in relation mention associated with the entity descriptions in the same triple. On the other hand, our model wants to recognize words in entity descriptions which are emphasized by its relation. To achieve the above goal, we first infer the representations of entity descriptions using relation representation as attention:

$$a_i(e) = \frac{exp(score(\vec{h_i}, \vec{r'}))}{\sum_{i'} exp(score(\vec{h_{i'}}, \vec{r'}))} \quad (1)$$

$$score(\vec{h_i}, \vec{r'}) = \vec{h_i}^T W_e \vec{r'} \quad (2)$$

where $\vec{r'} \in d^w$ is the representation of the relation mention by averaging all the hidden vectors of BiLSTM, $\vec{h_i}$ is the hidden representation of w_i, and $W_e \in d^{w \times 2 \times h}$ is a trained parameter matrix. The relation-sensitive representation of the entity description is generated as follows:

$$\vec{e^*} = tanh(\vec{a_e}^T H_e) \quad (3)$$

where $\vec{a_e} \in d^m$ is the relation-specific attention vector over the words in the entity description, d^m is the length of the description, $H_e \in d^{m \times h}$ is the hidden representation matrix generated by BiLSTM, and $\vec{e^*} \in d^h$ is the representation of the description. In this way, we learn the representations of entity descriptions of head entity $\vec{e_h^*} \in d^h$ and tail entity $\vec{e_t^*} \in d^h$ with the attention from relation representation.

The above two entity description representations are utilized as the attention for learning the triple-sensitive relation mention representation as follows:

$$\vec{e} = \vec{e_h^*} + \vec{e_t^*} \quad (4)$$

$$a_i(r) = \frac{exp(score(\vec{h_i}, \vec{e}))}{\sum_{i'} exp(score(\vec{h_{i'}}, \vec{e}))} \quad (5)$$

$$score(\vec{h_i}, \vec{e}) = \vec{h_i}^T W_r \vec{e} \quad (6)$$

where $\vec{e_h^*}$ and $\vec{e_t^*}$ are representations of head entity description and tail entity description respectively, $\vec{h_i}$ is the hidden vector of w_i for each word in the text mention, and $W_r \in d^{w \times 2 \times h}$ is a trained parameter matrix. The representation of the triple-sensitive relation mention is generated as Formula (7):

$$\vec{r^*} = tanh(\vec{a_r}^T H_r) \quad (7)$$

where $\vec{a_r}^T \in d^n$ is the triple-sensitive attention vector over the words in the relation mention, d^n is the length of the relation mention, $H_r \in d^{n \times h}$ is the hidden representation matrix generated by BiLSTM, and $\vec{r^*} \in d^h$ is the representation of the mention. In this way, we learn the triple-attention representation of all text mentions.

3.3 Text-Enhanced Representation Learning

In this section, we introduce how to incorporate the learned textual representations with representations learned from knowledge graph structure using previous methods.

For each given triple and its accurate textual information, we enhance the representations of the relation and entities based on the text representations of entities $\vec{e_h^*} \in d^h$, $\vec{e_t^*} \in d^h$ and relation $\vec{r^*} \in d^h$. Specifically, we enhance the relation and entity representations as follows:

$$Re(\vec{r_{ate}}) = \alpha \cdot Re(\vec{r_{kg}}) + (1-\alpha) \cdot \vec{r^*}, 0 \leq \alpha \leq 1 \quad (8)$$

$$Re(\vec{h_{ate}}) = \alpha \cdot Re(\vec{h_{kg}}) + (1-\alpha) \cdot \vec{e_h^*}, 0 \leq \alpha \leq 1 \quad (9)$$

$$Re(\vec{t_{ate}}) = \alpha \cdot Re(\vec{t_{kg}}) + (1-\alpha) \cdot \vec{e_t^*}, 0 \leq \alpha \leq 1 \quad (10)$$

where α represents the weight factor for the structural representations, $\vec{r_{kg}} \in d^h$, $\vec{h_{kg}} \in d^h$ and $\vec{t_{kg}} \in d^h$ represent the distributional representations of relation r head entity h and tail entity t

learned from structural information of knowledge graph, $\vec{r^*} \in d^h$, $\vec{e_h^*} \in d^h$ and $\vec{e_t^*} \in d^h$ represent the vectors of the text mention, head and tail entity descriptions for the triple, $\vec{r}_{ate} \in d^h$, $\vec{h}_{ate}$ and $\vec{t}_{ate}$ are the accurate text-enhanced representations of relation, head and tail entity, respectively. Note that, we enhance the real part vector of an entity with the textual representation of the entity as Formula (9) and (10), and treat the matrix representation of a relation as a vector with each element the same as the element in diagonal matrix, and then enhance its real part as Formula (8). In this way, we enhance the representation of knowledge graph, and calculate the plausibility of a triple based on their score functions.

If there is no accurate relation mention extracted for a triple, we only utilize the knowledge embeddings to estimate the plausibility of the triple, and the weight factor α is set to 1 in this case. For example, if there is no accurate relation mention extracted for triple `(Su Shi, /people/person/profession, Artist)`, then only its structural representations will be utilized to compute the plausibility of the triple. And α is set to 1 for the triples if none of the entities in it is linked.

3.4 Model Training

In the training process, the *(h, r, t, h_t, r_t, t_t)* tuples are used as supervision, where h_t, r_t and t_t are the description of head entity, relation text mention and the description of tail entity, respectively. Since there are only correct triples in the knowledge graph, following Lin et al. (2015a), we construct the corrupted tuples $(h', r, t', h_t, r_t, t_t) \in KG'$ for a $(h, r, t, h_t, r_t, t_t) \in KG$ by randomly replacing head/tail entity with entities from knowledge graph using Bernoulli Sampling Method (Wang et al., 2014). Furthermore, to train the model of text representation model, we construct the corrupted tuples $(h, r, t, h_t', r_t', t_t') \in KG'$ for a $(h, r, t, h_t, r_t, t_t) \in KG$ by random replacing the text information. We use the following margin-based ranking loss:

$$L = \sum_{q \in KG} \sum_{q' \in KG'} max(0, \gamma + f(q) - f(q')) \quad (11)$$

where f is the score function of our model, and $\gamma > 0$ is the margin between golden tuples and negative tuples, KG is the set of tuples in training dataset, and KG' is the corrupted set of tuples. The parameters of our model are optimized using the stochastic gradient descent (SGD) algorithm. To accelerate the training process and avoid overfitting, we initialize the representations of entities and relations using base models and initialize word representations with the pre-trained word embeddings, and all these embeddings are fine-tuned during training.

4 Experiments

In this section, we first describe the settings in our experiments, and then we conduct experiments of link prediction and triple classification tasks and compare our method with base models and the state-of-the-art baselines.

4.1 Experiment Settings

In this paper, we evaluate our model on four benchmark datasets: WN11, WN18, FB13 and FB15k (Bordes et al., 2013; Socher et al., 2013; Wang et al., 2014). For the text corpus, we use a snapshot of the English Wikipedia (Wiki) (Shaoul and Westbury, 2010) [3] dump in April 2016, which contains more than 1.2 billion tokens. We link entities in the text corpus to entities in Freebase and synsets in WordNet as described above, and replace entities with HEAD_TAG and TAIL_TAG. The text descriptions of entities are freely available[4]. In addition, we pre-process the word-entity corpus, including stemming, lowercasing and removing words with fewer than 5 occurrences. The statistics of the datasets and linked-entities in text corpus are shown in Table 1.

Dataset	WN11	WN18	FB13	FB15K
#Train	112,581	141,442	316,232	483,142
#Valid	2,609	5,000	5,908	50,000
#Test	10,544	5,000	23,733	59,071
# Entities	38,696	40,943	75,043	14,951
# Relations	11	18	13	1,345
#1-to-1	0	0	0	247
#1-to-N	0	0	0	179
#N-to-1	0	0	1	225
#N-to-N	11	18	12	694
#Linked	31,432	34,159	66,328	13,567

Table 1: Statistics of different datasets and the number of entities linked in Wikipedia, *#Linked* represents the number of entities linked in the text corpus. *#N-to-1* is the number of N-to-1 type of relations.

As introduced above, we implement our framework using TransE, TransH, TransR and ComplEx as base models, and evaluate on two classi-

[3] https://www.wikipedia.org/

[4] https://github.com/xrb92/DKRL

cal tasks: link prediction and triple classification. We refer $AATE\_E$ as the proposed model which enhances TransE with accurate textual informations and mutual attention mechanism, and refer ATE_E as the proposed model without mutual attention mechanism to reveal the effect of our attention mechanism.

To speed up training and reduce overfitting, we employ the SkipGram model of word2vec (Mikolov et al., 2013) to pre-train the word embeddings with the dimension of word embeddings is $d^w = 200$, the windows size is 5, the number of iterations is 5, and the number of negative samples is 10. And we pre-train the representations of entities and relations of knowledge graph using the mentioned base models, and the parameters are empirically tuned as follows: the dimension of vectors is $d^{kg} = 200$, the number of epochs is 2000 and the margin is 1.0. We implement our model based on the OpenKE [5] framework.

In our experiments, the hyper-parameters of BiLSTM are empirically set as follows: the number of hidden units is $d^h = 200$, the learning rates for SGD are among $\{0.1, 0.001, 0.0001\}$, the margin λ values are among $\{0.5, 1.0, 2.0\}$ and the batch sizes are among $\{100, 500, 2000\}$. We employ two different BiLSTM networks with the same hyper-parameters to learn the representations of text mentions and entity descriptions. And all the parameters are learned jointly, including BiLSTM networks and knowledge representations.

4.2 Link Prediction

Link prediction aims to predict missing head or tail entity of a triple, which is a widely employed evaluation task for knowledge graph completion models (Bordes et al., 2011; Wang et al., 2016). Concretely, given a head entity `h` (or tail entity `t`) and a relation `r`, the system will return a rank list of candidate entities for tail entity. Following (Bordes et al., 2013; Lin et al., 2015b), we conduct the link prediction task on WN18 and FB15k datasets.

In the testing phase, for each triple (h, r, t), we replace its head/tail entity with all entities to construct candidate triples, and extract text mentions from the text corpus for each candidate triple. Then we rank all these entities in descending order of the scores, which are calculated by our score function. Based on the entity ranking list, we employ two evaluation metrics from (Bordes et al., 2013): (1) mean rank of correct entities (MR); and (2) proportion of correct entities in top-10 rank entities Hit@10 ($Hit10$). A good link predictor should achieve low MR and high $Hit@10$. We tuned model parameters using validate datasets. We implement our framework using TransE, TransH, TransR and ComplEx as base models, and treat these base models as baselines. Furthermore, we also compare our method with the state-of-the-art results from Unstructured, SME, TransD, TEKE , Jointly (Xu et al., 2016), TransG and Mainifold, and we report the results from their original papers. The overall results are presented in Table 2.

Models		WN18		FB15K	
		MR	Hit10	MR	Hit10
Others	UnS	304	38.2	154	40.8
	SME	533	74.1	979	6.3
	TransD	212	92.2	91	77.3
	TransG	345	94.7	**50**	**88.2**
	Mainifold	-	**94.9**	-	88.1
Jointly	LSTM	**95**	91.6	90	69.7
	A-LSTM	123	90.9	73	75.5
TransE	TransE	251	89.2	125	47.1
	TEKE_E	127	93.8	79	67.6
	ATE_E	158	91.7	89	57.1
	AATE_E	123	94.1	76	76.1
TransH	TransH	303	86.7	84	58.5
	TEKE_H	128	93.6	75	70.4
	ATE_H	167	92.5	80	68.2
	AATE_H	132	94.0	73	74.6
TransR	TransR	219	91.7	78	65.5
	TEKE_R	203	92.3	79	68.5
	ATE_R	210	92.1	80	67.2
	AATE_R	185	93.7	77	69.4
ComplEx	ComplEx	219	94.7	78	84.0
	ATE_C	217	94.7	61	86.2
	AATE_C	**179**	**94.9**	**52**	**88.0**

Table 2: Evaluation results of link prediction.

From Table 2, we can see that both ATE and AATE models surpass all base models (TransE, TransH, TransR and ComplEx) on all metrics. This result verifies that the textual information is beneficial for structure-based knowledge graph representation learning models. Compared with the ATE models, the AATE models achieve better results on link prediction task, which verifies that the mutual attention between entity description and relation mention is effect for selecting meaningful words and enhancing the learning of knowledge graph representation.

For translation-based models, the proposed method achieves the best result based on TransE.

[5] http://openke.thunlp.org/

This is probably because TransH and TransR have tried to project the entity embeddings into the space of relation space, which may lead to the fact that the text information could not enhance the entity representation directly. In addition, our method implemented based on ComplEx has achieve better performances w.r.t TEKE (Wang et al., 2016) on all metrics, that verifies the importance of filtering out the noisy information.

4.2.1 Analysis on 1-to-N, N-to-1 and N-to-N Relations

To better analyse the effect of textual information for knowledge graph representation learning, this section presents the results of our model on different categories of relations including 1-N, N-1 and N-N on link prediction task. We present the results of our models based on TransE and of all baselines.

From Table 3, we can see that, both of our proposed methods have achieved higher performance over the base model on all types of relations (1-to-N, N-to-1 and N-to-N). In addition, our AATE model achieves better results than the Jointly(A-LSTM) model. Since both of AATE and Joint (A-LSTM) are implemented based on TransE, we verify that the triple-specific relation mention is valuable to improving the knowledge representation. Another reason why our proposed model achieves better results is that the attention from textual representation of relation and entity is more effective than the attention using structural representation for textual representation.

4.2.2 Fault Analysis

To gain more insight, we present a failure analysis to explore possible limitations and weaknesses of our model. In particular, several illustrative triples from the test set of FB15K are listed in Table 4. The tail entities of those triples are failed to be ranked in the top-10 candidates.

It can be seen from Table 4 that, the failures are mostly caused by the data sparsity problem, which results in relatively limited occurrences of entities and relations. All of "`Elementary school`", "`Abugida`", "`interests/collection_category /sub_categories`" and "`martial_arts/ martial_artist/martial_art`" appear less than 4 times in training data. It must also be mentioned that the triple "`(Abugida, language /language_writing_system/ languages, Khmer language)`" is included in the training data. Therefore, we can infer the first triple in Table 4 based on the above triple due to the general logic that "`language/human_language/writing _system`" and "`/language/language _writing_system/languages`" are a pair of inverse relations. Consequently, we believe it is important to incorporate the logic rules into knowledge embeddings, especially for the entities and relations with limited occurrences.

4.3 Triple Classification

In this section, we assess different models on the triple classification task. Triple classification aims to judge whether a given triple (h, r, t) is true fact or not, and it is usually modeled as a binary classification task (Socher et al., 2013; Bordes et al., 2013; Wang et al., 2016). Following Socher et al. (2013) we evaluate different systems on WN11 and FB13 datasets.

Given a triple (h, r, t) and all its accurate relation mentions and entity descriptions of this triple, In our experiments, a triple will be classified as a true fact if the score obtained by function f is below the relation-specific threshold δ_r, otherwise it will be classified as a false fact. The δ_r and the weight factor of α are optimized by maximizing classification accuracy on validation dataset, and different values of δ_r will be set for different relations. We use the same settings as link prediction task, all parameters are optimized on the validation datasets to obtain the best accuracies. We compare our method with all base models and the state-of-the-art performances from TransD, TEKE (Wang et al., 2016), TransG, Mainfold, and we report the best results from their original papers. The results are listed in Table 5.

From Table 5, we can see that: (1) The accurate textual information can consistently increase the accuracies on triple classification task. In all of the four base models, our model achieves significant improvements over TransE, TransH, TransR and ComplEx. This results verify that our method is a useful framework for exploiting textual information to enhance structure-based models; (2) Our method achieves better results on all datasets than TEKE. This result reveals that it is important to filter out the noisy data for knowledge graph representation learning. (3) Compared with the ATE model, our relation-sensitive attention

	Prediction Head (Hits@10)			Prediction Tail (Hits@10)		
Relation Category	1-to-N	N-to-1	N-to-N	1-to-N	N-to-1	N-to-N

Table 5: Evaluation results of triple classification.

model improves the accuracies on all the datasets. We believe this is because mutual attention mechanism can better identify the relation-sensitive words from entity descriptions and extract entity-sensitive words from relation mention.

The results demonstrate that, our method has achieved the best performances on the triple classification task, which verifies that it is critical to filter out noisy text information to determine whether a triple should be added into knowledge graph or not.

5 Conclusions

In this paper, we propose an accurate text-enhanced knowledge graph representation framework, which can utilize accurate textual information enhance the knowledge representations of a triple, and can effectively handle the ambiguity of relations and entities through a mutual attention model between relation mentions and entity descriptions. Experiment results show that our method can achieve the state-of-the-art performance, and significantly outperforms previous text-enhanced knowledge representation models. And the mutual attention between relation mentions and entity descriptions can significantly improve the performance of knowledge representation. For future work, we want to further exploit entity types and logic rules as constraints to further improve knowledge representations.

Abstract

How to identify, extract, and use phrasal knowledge is a crucial problem for the task of Recognizing Textual Entailment (RTE). To solve this problem, we propose a method for detecting paraphrases via natural deduction proofs of semantic relations between sentence pairs. Our solution relies on a graph reformulation of partial variable unifications and an algorithm that induces subgraph alignments between meaning representations. Experiments show that our method can automatically detect various paraphrases that are absent from existing paraphrase databases. In addition, the detection of paraphrases using proof information improves the accuracy of RTE tasks.

1 Introduction

Recognizing Textual Entailment (RTE) is a challenging natural language processing task that aims to judge whether one text fragment logically follows from another text fragment (Dagan et al., 2013). Logic-based approaches have been successful in representing the meanings of complex sentences, ultimately having a positive impact on RTE (Bjerva et al., 2014; Beltagy et al., 2014; Mineshima et al., 2015, 2016; Abzianidze, 2015, 2016). Although logic-based approaches succeed in capturing the meanings of functional or logical words, it is difficult to capture the meanings of content words or phrases using genuine logical inference alone. This remains a crucial problem in accounting for lexical relations between content words or phrases via logical inference. To solve this problem, previous logic-based approaches use knowledge databases such as WordNet (Miller, 1995) to identify lexical relations within a sentence pair. While this solution has been successful in handling word-level paraphrases, its extension to phrase-level semantic relations is still an unsolved problem. There are three main difficulties that prevent an effective identification and use of phrasal linguistic knowledge.

The first difficulty is the presence of out-of-context phrase relations in popular databases such as the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013). PPDB may suggest paraphrases that do not adhere to the context of our relevant text segments nor to their semantic structure, which might be problematic.

The second difficulty is finding semantic phrase correspondences between the relevant text segments. Typical approaches only rely on surface (Beltagy et al., 2013) or syntactic correspondences (Arase and Tsujii, 2017), often producing inaccurate alignments that significantly impact our inference capabilities. Instead, a mechanism to compute semantic phrase correspondences could potentially produce, if available, more coherent phrase pairs and solve the recurring issue of discontinuity.

The third difficulty is the intrinsic lack of coverage of databases for logical inference despite their large size. Whereas there is a relatively small number of possible word-to-word correspondences and thus their semantic relations can be enumerated, the same is not true for all phrase pairs that might be of interest. One alternative is to use functions of infinite domain (e.g., cosine similarity) between phrase representations (Tian et al., 2016), but these techniques are still under development, and we have not seen definitive successful applications when combined with logic systems.

In this study, we tackle these three problems. The contributions of this paper are summarized as follows: First, we propose a new method of detecting phrase correspondences through natu-

Proceedings of NAACL-HLT 2018, pages 756–766
New Orleans, Louisiana, June 1 - 6, 2018.

ral deduction proofs of semantic relations for a given sentence pair. Second, we show that our method automatically extracts various paraphrases that compensate for a shortage in previous paraphrase databases. Experiments show that extracted paraphrases using proof information improve the accuracy of RTE tasks.

2 Related Work

In this section, we review previous logical inference systems that are combined with lexical knowledge. The RTE system developed by Abzianidze (2016) uses WordNet as axioms and adds missing knowledge manually from the training dataset; however, this technique requires considerable human effort and is not extended to handle phrasal knowledge.

Martínez-Gómez et al. (2017) proposed an RTE system with an on-the-fly axiom injection mechanism guided by a natural deduction theorem prover. Pairs of unprovable sub-goals and plausible single premises are identified by means of a variable unification routine and then linguistic relations between their logical predicates are checked using lexical knowledge such as WordNet and VerbOcean (Chklovski and Pantel, 2004). However, this mechanism is limited to capturing word-to-word relations within a sentence pair.

Bjerva et al. (2014) proposes an RTE system where WordNet relations are used as axioms for word-to-word knowledge in theorem proving. For phrasal knowledge, PPDB is used to rephrase an input sentence pair instead of translating paraphrases into axioms. However, this solution ignores logical contexts that might be necessary when applying phrasal knowledge. Moreover, it does not apply to discontinuous phrases.

Beltagy et al. (2016) uses WordNet and PPDB as lexical knowledge in the RTE system. To increase their coverage of phrasal knowledge, the system combines a resolution strategy to align clauses and literals in a sentence pair and a statistical classifier to identify their semantic relation. However, this strategy only considers one possible set of alignments between fragments of a sentence pair, possibly causing inaccuracies when there are repetitions of content words and meta-predicates.

In our research, we propose an automatic phrase abduction mechanism to inject phrasal knowledge during the proof construction process. In addition, we consider multiple alignments by backtracking the decisions on variable and predicate unifications, which is a more flexible strategy. We represent logical formulas using graphs, since this is a general formalism that is easy to visualize and analyze. However, we use *natural deduction* (see Section 3.2) as a proof system instead of Markov Logic Networks for inference. Some research has investigated graph operations for semantic parsing (Reddy et al., 2014, 2016) and abstractive summarization (Liu et al., 2015); we contribute to these ideas by proposing a subgraph mapping algorithm that is useful for performing natural language inferences.

Considerable research efforts have been focused on the identification and extraction of paraphrases. One successful technique is associated with bilingual pivoting (Bannard and Callison-Burch, 2005; Zhao et al., 2008), in which alternative phrase translations are used as paraphrases at a certain probability. However, this technique requires large bilingual parallel corpora; moreover, word alignment errors likely cause noisy paraphrases. Another strategy is to extract phrase pairs from a monolingual paraphrase corpus using alignments between syntactic trees, guided by a linguistically motivated grammar (Arase and Tsujii, 2017). The main difference between these studies and ours is that they typically attempt alignment between words or syntactic trees, whereas we perform alignments between meaning representations, which enables the acquisition of more general paraphrases by distinguishing functional words from content words. This point is important in distinguishing among different semantic relations (e.g., antonyms and synonyms). In addition, word and syntactic alignments potentially ignore coreferences, making it difficult to find relations between many-to-many sentences. Semantic alignments enable this because coreferences must refer to the same variable as the original entity.

3 Logic-based Approach to RTE

3.1 Meaning representation

In logic-based approaches to RTE, a text T and a hypothesis H are mapped onto logical formulas T' and H'. To judge whether T entails H, we check whether $T' \Rightarrow H'$ is a theorem in a logical system.

For meaning representations, we use Neo-Davidsonian event semantics (Parsons, 1990). In this approach, a verb is analyzed as a one-place predicate over events. Both the arguments of a

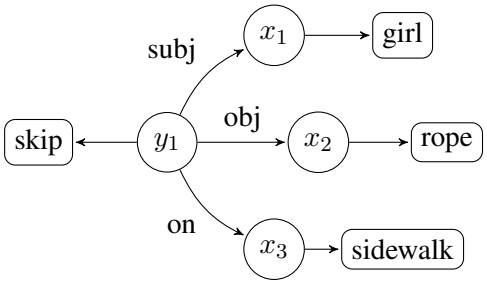

Figure 1: A graph for the basic formula (2).

verb and modifiers are linked to events by semantic roles, and the entire sentence is closed by existential quantification over events. For example, (1) is mapped onto (2).

(1) A girl is skipping rope on a sidewalk.

(2) $\exists x_1 \exists x_2 \exists x_3 \exists y_1 \, (\mathbf{girl}(x_1) \wedge \mathbf{rope}(x_2) \wedge \mathbf{sidewalk}(x_3) \wedge \mathbf{skip}(y_1) \wedge (\mathbf{subj}(y_1) = x_1) \wedge (\mathbf{obj}(y_1) = x_2) \wedge \mathbf{on}(y_1, x_3))$

We use x_i as a variable for entities and y_j for events. In this semantics, we represent all content words (e.g., *girl* and *skip*) as one-place predicates. Regarding functional words, we represent a preposition like *on* as a two-place predicate, e.g., $\mathbf{on}(y_1, x_3)$. We also use a small set of semantic roles such as $\mathbf{subj}$ and $\mathbf{obj}$ as a functional term and use equality ($=$) to connect an event and its participant, as in $\mathbf{subj}(y_1) = x_1$.

To be precise, the set of *atomic formulas* $\mathcal{A}$ in this event semantics is defined by the rule

$$\mathcal{A} ::= \mathbf{F}(t) \mid \mathbf{G}(t, u) \mid t = u$$

where $\mathbf{F}(t)$ is a one-place predicate (for content words), $\mathbf{G}(t, u)$ is a two-place predicate (for prepositions), t and u are a term. A term is defined as a constant, a variable, or a functional term of the form $f(t)$ where f is a semantic role and t is a term.

We call a formula constructed by conjunctions and existential quantifiers a *basic formula* in event semantics. Thus, a set of basic formulas φ in event semantics is defined as:

$$\varphi ::= \mathcal{A} \mid \varphi \wedge \varphi \mid \exists t \, \varphi$$

The formula in (2) is an instance of a basic formula, which captures the predicate-argument structure of a sentence.

On top of the system of basic formulas, we have a full language of event semantics with negation ($\neg$), disjunction ($\vee$), implication ($\rightarrow$), and a universal quantifier ($\forall$). These operators are used to represent additional logical features.

There is a natural correspondence between basic formulas and directed acyclic graphs (DAGs). Figure 1 shows an example[1]. In the graph representation, constants and variables correspond to vertices; both two-place predicates for prepositions (e.g., $\mathbf{on}(y_1, x_1)$) and functional terms for semantic roles (e.g., $\mathbf{subj}(y_1) = x_1$) are represented as edges. A one-place predicate $\mathbf{F}(t)$ in a logical formula can be represented as a functional relation $\mathbf{isa}(t, \mathbf{F})$, where $\mathbf{isa}$ is an expression relating a term t and a predicate $\mathbf{F}$ represented as a vertex. The $\mathbf{isa}$ edges are unlabeled for simplicity.

3.2 Natural deduction and word abduction

We use the system of natural deduction (Prawitz, 1965; Troelstra and Schwichtenberg, 2000) to capture phrase correspondences from a sentence pair (T, H), following the strategies for word axiom injection developed by Martínez-Gómez et al. (2017) and Yanaka et al. (2017). The sentence pair (T, H) is first mapped to a pair of formulas (T', H'). T' is initially set to the premise P, and H' is set to the goal G to be proved.

If formulas P and G are basic formulas, then the proving strategy is to decompose them into a set of atomic formulas using inference rules for conjunctions and existential quantifiers. The premise P is decomposed into a pool of premises $\mathcal{P} = \{\mathbf{p}_i(\theta_i) \mid i \in \{1, \ldots, m\}\}$, where each $\mathbf{p}_i(\theta_i)$ is an atomic formula and θ_i is a list of terms appearing in $\mathbf{p}_i(\theta_i)$. The goal G is also decomposed into a set of sub-goals $\mathcal{G} = \{\mathbf{g}_j(\theta'_j) \mid j \in \{1, \ldots, n\}\}$, where θ'_j is a list of terms appearing in $\mathbf{g}_j(\theta'_j)$.

The proof is performed by searching for a premise $\mathbf{p}_i(\theta_i)$ whose predicate matches that of a sub-goal $\mathbf{g}_j(\theta'_j)$. If such a premise is found, then variables in θ'_j are unified to those in θ_i and the sub-goal $\mathbf{g}_j(\theta'_j)$ can be removed from $\mathcal{G}$. If all the sub-goals can be removed, we prove $T' \rightarrow H'$. In the presence of two or more variables with the same predicate, there might be multiple possible variable unifications. Modern theorem provers explore these multiple possibilities in search of a configuration that proves a theorem.

Sub-goals may remain unproved when T logically does not entail H i.e., when there are no premise predicates $\mathbf{p}_i$ that are matched with $\mathbf{g}_j$. In this case, the system tries word axiom injection, called *word abduction*. More specifically, if there

[1] See Jones (2016) for some variants of graphical representations of logical formulas.

is a premise $\mathbf{p}_i(\theta_i)$ whose predicate has a linguistic relation (according to linguistic knowledge[2]) with that of a sub-goal $\mathbf{g}_j(\theta'_j)$, then variables in θ'_j are unified with those in θ_i and the sub-goal $\mathbf{g}_j(\theta'_j)$ can be removed from $\mathcal{G}$.

3.3 Graph illustration

Figure 2 shows an example to illustrate how the system works. To begin with, the input sentence pair (T, H) is mapped onto a pair of formulas, (T', H'). T' is initially placed to the premise P, and H' to the goal G. Note that these are basic formulas, and they are thus decomposed to the following sets of formulas $\mathcal{P}$ and $\mathcal{G}$, respectively:

$\mathcal{P} = \{\mathbf{lady}(x_1), \mathbf{meat}(x_2), \mathbf{cut}(y_1), \mathbf{up}(y_1),$
$\mathbf{precisely}(y_1), \mathbf{subj}(y_1)=x_1, \mathbf{obj}(y_1)=x_2\}$
$\mathcal{G} = \{\mathbf{woman}(x_3), \mathbf{meat}(x_4), \mathbf{cut}(y_2), \mathbf{piece}(x_5),$
$\mathbf{into}(y_2, x_5), \mathbf{subj}(y_2)=x_3, \mathbf{obj}(y_2)=x_4\}$

Steps 1 to 3 in Figure 2 demonstrate the variable unification routine and word axiom injection using graphs. Note that in step 1, all variables in formulas in $\mathcal{P}$ or $\mathcal{G}$ are initially different.

In step 2, we run a theorem proving mechanism that uses graph terminal vertices as anchors to unify variables between formulas in $\mathcal{P}$ and those in $\mathcal{G}$. The premise $\mathbf{meat}(x_2)$ in $\mathcal{P}$ matches the predicate $\mathbf{meat}$ of the sub-goal $\mathbf{meat}(x_4)$ in $\mathcal{G}$ and the variable unification $x_4 := x_2$ is applied (and similarly for the sub-goal $\mathbf{cut}(y_2)$ in $\mathcal{G}$ with the variable unification $y_2 := y_1$).

In step 3, we use the previous variable unification on y_1, the $\mathbf{subj}$ edge in $\mathcal{P}$ and $\mathcal{G}$ and the axiom $\forall x.\mathbf{lady}(x) \rightarrow \mathbf{woman}(x)$ from external knowledge to infer that $x_3 := x_1$.

4 Phrase Abduction

There is one critical reason that the word-to-word axiom injection described in Section 3.2 fails to detect phrase-to-phrase correspondences. That is, the natural deduction mechanism decomposes the goal G into atomic sub-goals that are then proved *one-by-one* (word-by-word), independently of each other except for the variable unification effect. This mechanism is particularly problematic when we attempt to prove phrases that resist decomposition, two-place predicates (e.g., $\mathbf{into}(x, y)$), or failures in variable unification (e.g., due to inaccurate semantics). Thus, we propose a method to detect phrase-to-phrase correspondence through natural deduction proofs.

[2]As given in a linguistic ontology or database such as WordNet or VerbOcean.

4.1 Phrase pair detection

We detect phrase-to-phrase entailing relations between T' and H' by finding alignments between the subgraphs of their meaning representations when $T' \Rightarrow H'$ or $T' \Rightarrow \neg H'$ hold. Finding subgraph alignments is a generalization of the subgraph isomorphism problem, which is NP-complete[3]. In this paper, we approximate a solution to this problem by using a combination of a backtracking variable unification and a deterministic graph search on the neighborhood of non-unified variables.

Using our running example in Figure 2, step 4 displays our proposed subgraph alignment. The variable x_5 in the graph of $\mathcal{G}$ cannot be unified with any variable in the graph of $\mathcal{P}$. This is a very common case in natural language inferences, as there might be concepts in H that are not directly supported by concepts in T. In this research, we propose spanning a subgraph starting at non-unified variables (e.g., x_5 in $\mathcal{G}$) whose boundaries are semantic roles (e.g., $\mathbf{subj}$, $\mathbf{obj}$). Its candidate semantics from $\mathcal{P}$ are then the attributes of its corresponding unified variables from $\mathcal{G}$ (e.g. *cut up precisely* $\rightarrow$ *cut into pieces*).

4.2 Graph alignments

To formalize this solution we introduce some graph notation. Let $V = \mathcal{V}^u \cup \mathcal{V}^{\bar{u}} \cup \mathcal{L}$ be the set of vertices, where $\mathcal{V}^u$ is the set of unified variables (e.g. x_1, x_2, y_1), $\mathcal{V}^{\bar{u}}$ is the set of non-unified variables (e.g. x_5), and $\mathcal{L}$ is a set of predicates (e.g., *lady*, *woman*). Let E be the set of labeled, directed edges $\langle v, l, v' \rangle$ where $v, v' \in V$ and l are labels that may represent a functional relation $\mathbf{isa}$, a preposition or a semantic role. We denote a set of two-place predicates for prepositions as PREP and a set of functional terms for semantic roles as ARGS; e.g., ARGS $= \{\mathbf{subj}, \mathbf{obj}\}$. A graph that represents $\mathcal{P}$ is then a tuple $G_\mathcal{P} = \langle V_\mathcal{P}, E_\mathcal{P} \rangle$, and similarly, for $\mathcal{G}$, $G_\mathcal{G} = \langle V_\mathcal{G}, E_\mathcal{G} \rangle$.

We can now define a function to span a subgraph in the neighborhood of non-unified variables $v \in \mathcal{V}^{\bar{u}}_\mathcal{G}$ in the graph of $\mathcal{G}$. We call a connected set of edges in which no semantic roles appear, i.e., $\{\langle v, l, v' \rangle \mid l \notin \text{ARGS}\}$, a *phrase set*. Let $E(x)$ be the phrase set in E such that each vertex is connected to x with an incoming or outgoing edge, that is, $E(x) = \{(v_i, l, v_k) \in E \mid (x = v_i \vee x = v_k) \wedge l \notin \text{ARGS}\}$.

[3]Emmert-Streib et al. (2016) gives a good overview.

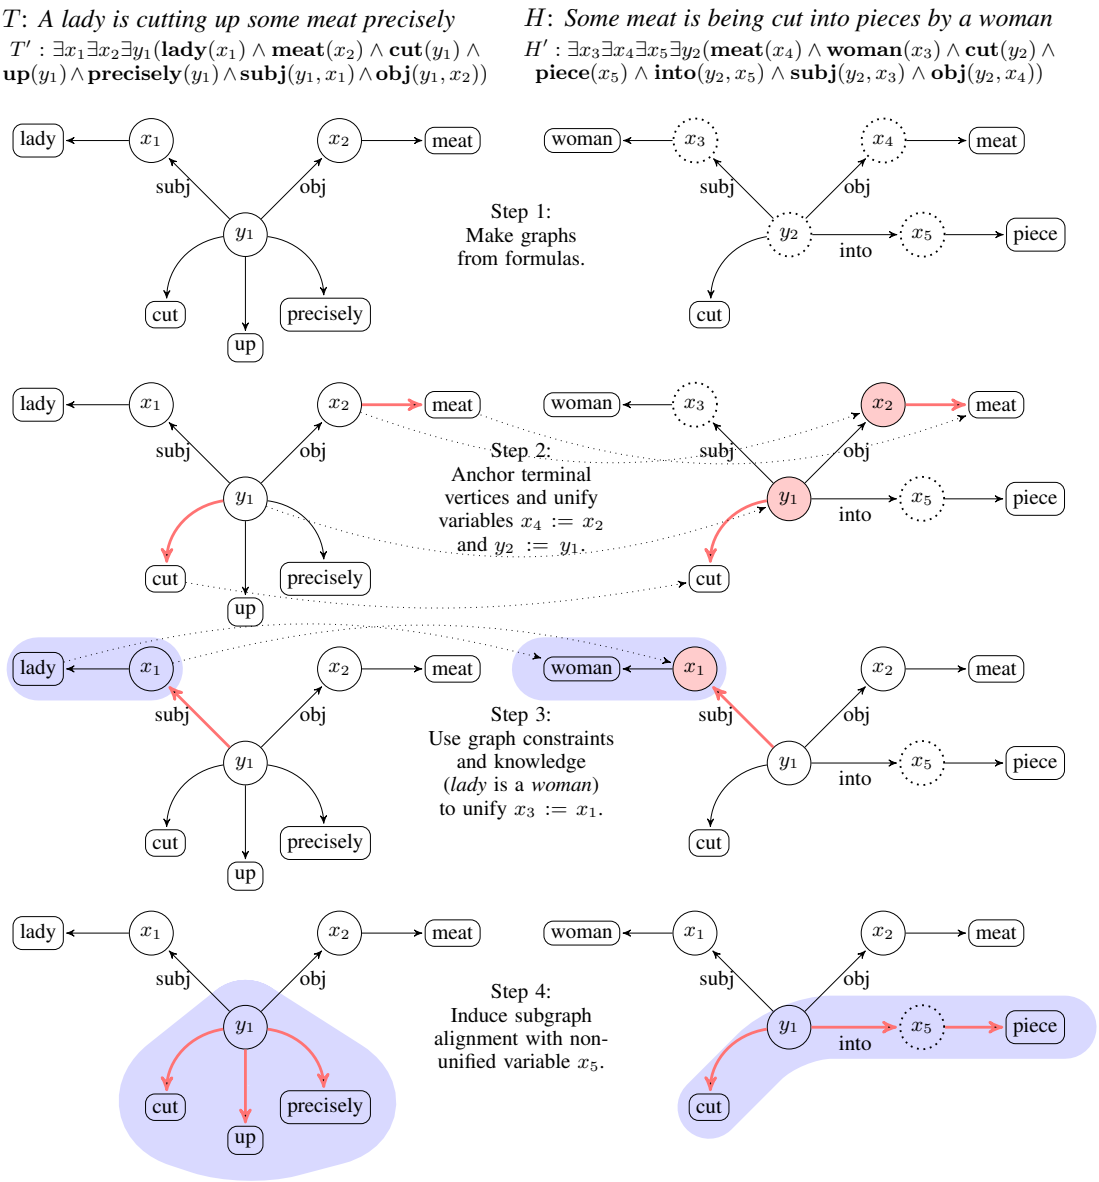

Figure 2: A graph representation of a theorem proving routine on basic formulas and variable unification. Dotted circles represent non-unified variables at each step, whereas edges without labels are attributes. The graph of the left side is the set of premises $\mathcal{P}$ and the graph of the right side is the set of sub-goals $\mathcal{G}$. Colored subgraphs represent a word or a phrase to which our axiom injection mechanism applies.

Note that $E(x)$ induces a subgraph in a given graph G and the condition $l \notin$ ARGS sets the boundaries of the subgraph by excluding the semantic roles of verb phrases. Given two phrase sets E and E', we say E' is reachable from E, written $E \sim E'$, if E and E' share at least one variable vertex. Let $\sim^*$ be the transitive closure of $\sim$. Given a set of edges $E_\mathcal{G}$ and a variable v, we define the *extended phrase set*, written Reach(v), as follows:

$$\text{Reach}(v) = \{e \in E \mid E_\mathcal{G}(v) \sim^* E\}$$

that is, the set of edges e that can be reached from v without crossing an edge with a semantic role label. This function defines a partition or equivalence class for non-unified variables $v \in \mathcal{V}_\mathcal{G}^u$, and each of these partitions induce a (possibly discontinuous) phrase in $\mathcal{G}$ that remains unproved.

The corresponding subgraph in $\mathcal{P}$ to each of these partitions is given by the vertices and edges connected with a path of length one to the unified variables that appear in Reach(v). That is,

$$\text{Corr}(v) = \{e \in E_\mathcal{P}(v'), v' \in V_\mathcal{G}^{[v]} \cap V_\mathcal{P}\}$$

where $V_\mathcal{G}^{[v]}$ denotes the vertices in the subgraph of $\mathcal{G}$ induced by the partition Reach(v).

A subgraph alignment between $\mathcal{P}$ and $\mathcal{G}$ is given by the pair of $\langle \text{Corr}(v), \text{Reach}(v) \rangle$ for all $v \in \mathcal{V}_{\mathcal{G}}^{\bar{u}}$, where the phrases can be read from the predicates in the vertices and edges labeled with prepositions.

We define a mapping $(\cdot)^\bullet$ from a labeled edge $\langle v, l, v' \rangle$ to an atomic formula as follows.

$$\langle v, l, v' \rangle^\bullet = \begin{cases} v'(v) & \text{if } l \text{ is } \mathbf{isa} \\ l(v, v') & \text{if } l \in \text{PREP} \\ l(v) = v' & \text{if } l \in \text{ARGS} \end{cases}$$

Let E be a set of labeled edges, and let $E^\bullet$ be $\{\langle v, l, v' \rangle^\bullet \mid \langle v, l, v' \rangle \in E\}$. The phrase axiom generated for each non-unified variable $v \in \mathcal{V}_{\mathcal{G}}^{\bar{u}}$ is defined as

$$\forall \theta_{\text{C}}. (\bigwedge \text{Corr}(v)^\bullet \rightarrow \exists \theta_{\text{R}}. (\bigwedge \text{Reach}(v)^\bullet)),$$

where θ_{C} is a set of free variables appearing in $\text{Corr}(v)^\bullet$ (which includes v) and θ_{R} is a set of free variables appearing in $\text{Reach}(v)^\bullet$ but not in $\text{Corr}(v)^\bullet$.

In Figure 2, the only non-unified variable in the sub-goal in step 4 is x_5, that is, $\mathcal{V}_{\mathcal{G}}^{\bar{u}} = \{x_5\}$. Then, starting from the variable x_5, $\text{Reach}(x_5)$ is

$$\{\langle y_1, \mathbf{into}, x_5 \rangle, \langle x_5, \mathbf{isa}, \mathbf{piece} \rangle\}.$$

Now $V_{\mathcal{G}}^{[x_5]} = \{y_1, x_5\}$, and thus $\text{Corr}(x_5)$ is

$$\{\langle y_1, \mathbf{isa}, \mathbf{cut} \rangle, \langle y_1, \mathbf{isa}, \mathbf{up} \rangle, \langle y_1, \mathbf{isa}, \mathbf{precisely} \rangle\}.$$

Finally, the following is the axiom generated from $\langle \text{Corr}(x_5), \text{Reach}(x_5) \rangle$[4].

$$\forall y_1 (\mathbf{cut}(y_1) \wedge \mathbf{up}(y_1) \wedge \mathbf{precisely}(y_1) \rightarrow \exists x_5 (\mathbf{into}(y_1, x_5) \wedge \mathbf{piece}(x_5))).$$

4.3 Non-basic formulas

If formulas P and G are not basic formulas (i.e., they contain logical operators other than $\wedge$ and $\exists$), they are decomposed according to inference rules of natural deduction. There are two types of inference rules: introduction rules decompose a goal formula into smaller sub-goals, and elimination rules decompose a formula in the pool of premises into smaller ones. Figure 3 shows introduction rules and elimination rules for decomposing non-basic formulas including negation, disjunction, implication, and a universal quantifier. By applying inference rules, a proof of non-basic formulas appearing in sub-goals can be decomposed to a set of subproofs that only have basic formulas in sub-goals. If a universal quantifier appears in premises, it is treated in the same way as other premises.

[4]Note that this axiom is logically equivalent to

$$\forall y_1 (\mathbf{cut}(y_1) \wedge \mathbf{up}(y_1) \wedge \mathbf{precisely}(y_1) \rightarrow \exists x_5 (\mathbf{cut}(y_1) \wedge \mathbf{into}(y_1, x_5) \wedge \mathbf{piece}(x_5)))$$

indicated in the colored subgraphs in step 4 of Figure 2.

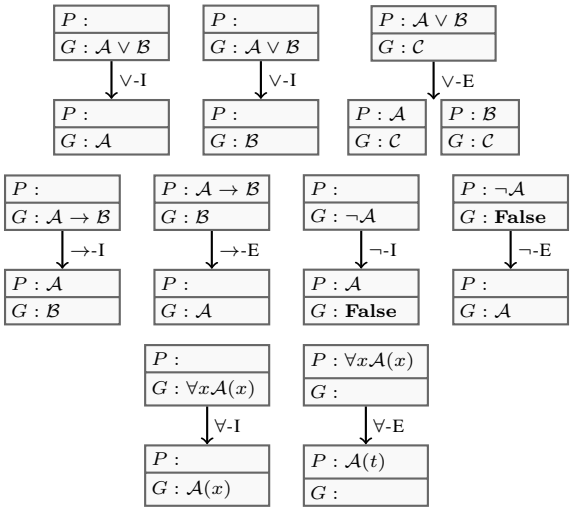

Figure 3: Inference rules used for decomposing non-basic formulas. P is a premise and G is a sub-goal. The initial formulas are at the top, with the formulas obtained by applying the inference rules shown below.

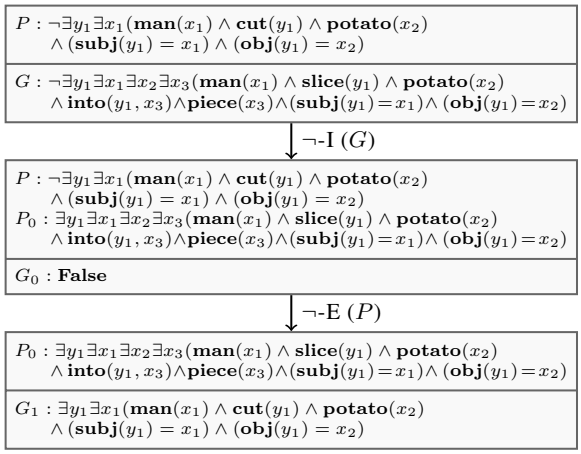

Figure 4: Proof process for the contradiction.

For example, consider the following sentence pair with the gold label "no" (contradiction):

T: *A man is not cutting a potato*

H: *A man is slicing a potato into pieces*

Figure 4 shows the proof process of $T' \Rightarrow \neg H'$. To prove the contradiction, the formulas T' and $\neg H'$ are set to P and G, respectively. Then, the negation in G is removed by applying the introduction rule $(\neg\text{-}I)$ to G. Here, **False** is the propositional constant denoting the contradiction. In the second stage of the proof, the goal is to prove **False** in G_0 from the two premises P and P_0. By applying $(\neg\text{-}E)$ to P, we can eliminate the negation from P, resulting in the new goal G_1.

As both the premise P_0 and the sub-goal G_1 are

basic formulas, the procedure described in the previous sections applies to the pair (P_0, G_1); these basic formulas are decomposed into atomic ones, and then the word-to-word abduction generates the desired axiom $\forall y_1(\mathbf{cut}(y_1) \rightarrow \mathbf{slice}(y_1))$. Finally, the graph alignment applies in the same way as described in Figure 2, which generates the phrase axiom:

$$\forall y_1(\mathbf{cut}(y_1) \rightarrow \exists x_5(\mathbf{into}(y_1, x_5) \wedge \mathbf{piece}(x_5)))$$

Using this axiom, one can complete the proof of the contradiction between T' and H'.

5 Experiments

5.1 Dataset selection

We use the SemEval-2014 version of the SICK dataset (Marelli et al., 2014) for evaluation. The SICK dataset is a dataset for semantic textual similarity (STS) as well as for RTE. It was originally designed for evaluating compositional distributional semantics, so it contains logically challenging problems involving quantifiers, negation, conjunction, and disjunction, as well as inferences with lexical and phrasal knowledge.

The SNLI dataset (Bowman et al., 2015) contains inference problems requiring phrasal knowledge. However, it is not concerned with logically challenging expressions; the semantic relationships between a premise and a hypothesis are often limited to synonym/hyponym lexical substitution, replacements of short phrases, or exact word matching. This is because hypotheses are often parallel to the premise in structures and vocabularies. The FraCaS dataset (Cooper et al., 1994) also contains logically complex problems. However, it is confined to purely logical inferences and thus does not contain problems requiring inferences with lexical and phrasal knowledge. For these reasons, we choose the SICK dataset to evaluate our method of using logical inference to extract phrasal knowledge.

The SICK dataset contains 9927 sentence pairs with a 5000/4927 training/test split. These sentence pairs are manually annotated with three types of labels *yes* (entailment), *no* (contradiction), or *unknown* (neutral) (see Table 1 for examples). In RTE tasks, we need to consider a directional relation between words such as hypernym and hyponym to prove entailment and contradiction. Hence, to extract phrasal knowledge for RTE tasks, we use the training data whose gold label is *entailment* or *contradiction*, excluding those with the *neutral* label.

5.2 Experimental setup

For the natural deduction proofs, we used ccg2lambda (Martínez-Gómez et al., 2016)[5], a higher-order automatic inference system, which converts CCG derivation trees into semantic representations and conducts natural deduction proofs automatically. We parsed the tokenized sentences of the premises and hypotheses using three wide-coverage CCG parsers: C&C (Clark and Curran, 2007), EasyCCG (Lewis and Steedman, 2014), and depccg (Yoshikawa et al., 2017). CCG derivation trees (parses) were converted into logical semantic representations based on Neo-Davidsonian event semantics (Section 3.1). The validation of semantic templates used for semantic representations was conducted exclusively on the trial split of the SICK dataset. We used Coq (Bertot and Castran, 2010), an interactive natural deduction theorem prover that we run fully automatically with a number of built-in theorem-proving routines called tactics, which include first-order logic.

We compare phrase abduction with different experimental conditions. **No axioms** is our system without axiom injection. **W2W** is the previous strategy of word abduction (Martínez-Gómez et al., 2017). **P2P** is our strategy of phrase abduction; **W2W+P2P** combines phrase abduction with word abduction. In addition, we compare our system with three purely logic-based (unsupervised) approaches: **The Meaning Factory** (Bjerva et al., 2014), **LangPro** (Abzianidze, 2015), and **UTexas** (Beltagy et al., 2014). We also compare our system with machine learning-based approaches: the current state-of-the-art deep learning model **GRU** (Yin and Schütze, 2017), a log-linear regression model **SemEval-2014 best** (Lai and Hockenmaier, 2014), and a hybrid approach combining a logistic regression model and probabilistic logic **PL+eclassif** (Beltagy et al., 2016).

5.3 Extracted paraphrases

We extracted 9445 axioms from the SICK training dataset. The proving time average to extract phrasal axioms was only 3.0 seconds for a one-sentence pair[6]. Table 2 shows some examples of

[5] Available at https://github.com/mynlp/ccg2lambda.

[6] Ours is a polynomial-time instance of the graph matching problem, where the vertex cover set (maximum number of variables in a phrase) is bounded to a small constant.

ID	Text	Hypothesis	Entailment
3941	*A boy is looking at a calendar*	*There is nobody checking a calendar*	No
5938	*Vegetables are being put into a pot by a man*	*Someone is pouring ingredients into a pot*	Yes
5930	*The man is not doing exercises*	*Two men are fighting*	Unknown

Table 1: Examples in the SICK dataset with different entailment labels and similarity scores.

Kind	Text	Hypothesis
noun phrase	***A blond woman*** *is sitting on the roof of a yellow vehicle, and two people are inside*	***A woman with blond hair*** *is sitting on the roof of a yellow vehicle, and two people are inside*
verb phrase	*The person is* ***setting fire to*** *the cameras*	*Some cameras are being* ***burned*** *by a person* ***with a blow torch***
verb phrase	*A man and a woman are* ***walking*** *together* ***through the woods***	*A man and a woman are hiking* ***through a wooded area***
prepositional phrase	*A child, who is small, is outdoors climbing steps outdoors* ***in an area full of grass***	*A small child is outdoors climbing steps* ***in a grassy area***
antonym	*A woman is* ***putting make-up on***	*The woman is* ***removing make-up***

Table 2: Examples of phrase alignments constructed by phrasal axiom injection.

	Prec.	Rec.	Acc.
GRU	–	–	87.1
PL+eclassif	–	–	85.1
SemEval2014 Best Score	81.6	81.9	84.6
The Meaning Factory	93.6	60.6	81.6
LangPro	98.0	58.1	81.4
UTexas	–	–	80.4
W2W+P2P	84.2	77.3	84.3
W2W	97.1	63.6	83.1
P2P	85.6	72.1	83.0
No axioms	98.9	46.5	76.7

Table 3: RTE results on the SICK dataset.

paraphrases we extracted from the natural deduction proof in the training set. In particular, the examples of verb phrases show our method has the potential to capture long paraphrases. Each paraphrase in Table 2 is not contained in WordNet and PPDB. There are many instances of non-contiguous phrases in the SICK dataset, in particular, verb-particle phrases. Shown in Table 2, our semantic alignment can detect non-contiguous phrases through the variable unification process, which is one of the main advantages over other shallow/syntactic methods. In addition, Table 2 shows our method is not limited to hypernym or hyponym relations, but it is also capable for detecting antonym phrases.

5.4 RTE evaluation results

Table 3 shows the experimental results. The results show that the combination of word abduction and phrase abduction improved the accuracy. When the **W2W+P2P** result is substituted for the **W2W** result, there is a 1.1% increase in accuracy (from 83.1% to 84.3%). The accuracy of **P2P** is almost equal to that of **W2W**. This is because the recall improves from 63.6% to 72.1% while the precision decreases from 97.1% to 85.6%. The increase in false positive cases caused this result; some details of false positive cases are described in the next subsection. **W2W+P2P** outperformed other purely logic-based systems. The machine learning-based approaches outperform **W2W+P2P**, but unlike these approaches, parameter estimation is not used in our method. This suggests that our method has the potential to increase the accuracy by using a classifier.

5.5 Positive examples and error analysis

Table 4 shows some positive and negative examples on RTE with the SICK dataset. For ID 9491, the sentence pair requires the paraphrase from *a field of brown grass* to *a grassy area*, not included in previous lexical knowledges. Our phrasal axiom injection can correctly generate this paraphrase from a natural deduction proof, and the system proves the entailment relation.

ID 2367 is also a positive example of phrasal axiom injection. The phrasal axiom between *set fire to cameras* and *burn cameras with a blow torch* was generated. This example shows that our semantic alignment succeeds in acquiring a general paraphrase by separating logical expressions such as *some* from content words and also by accounting for syntactic structures such as the passive-active alternation.

For ID 3628, the axiom shown in the table was extracted from the following sentence pair with

ID	Sentence Pair	Gold	Pred	Axiom
9491	*A group of four brown dogs are playing in a field of brown grass* *Four dogs are playing in a grassy area*	Yes	Yes	$\forall x_1(\mathbf{field}(x_1) \wedge \mathbf{brown}(x_1) \wedge \mathbf{grass}(x_1)$ $\rightarrow \mathbf{grassy}(x_1) \wedge \mathbf{area}(x_1))$
2367	*A person is burning some cameras with a blow torch* *The person is setting fire to the cameras*	Yes	Yes	$\forall x_1 \forall y_1(\mathbf{burn}(y_1) \wedge \mathbf{with}(y_1, x_1) \wedge \mathbf{blow\_torch}(x_1) \wedge \mathbf{camera}(\mathbf{obj}(y_1))$ $\rightarrow \mathbf{set}(y_1) \wedge \mathbf{fire}(\mathbf{obj}(y_1)) \wedge \mathbf{to}(y_1, \mathbf{obj}(y_1)) \wedge \mathbf{camera}(\mathbf{obj}(y_1)))$
3628	*A pan is being dropped over the meat* *The meat is being dropped into a pan*	Unk	Yes	$\forall y_1(\mathbf{pan}(\mathbf{obj}(y_1)) \rightarrow \mathbf{into}(y_1, \mathbf{obj}(y_1)))$
96	*A man is jumping into an empty pool* *There is no biker jumping in the air*	Unk	No	$\forall y_1(\mathbf{jump}(y_1) \rightarrow \exists x_1(\mathbf{in}(y_1, x_1) \wedge \mathbf{air}(x_1)))$ $\forall y_1(\mathbf{man}(y_1) \rightarrow \mathbf{biker}(y_1))$
408	*A group of explorers is walking through the grass* *Some people are walking*	Yes	Unk	

Table 4: Positive and negative examples on RTE from the SICK dataset.

their *entailment* label:

T_1: *A woman is putting meat in a pan*

H_1: *Someone is dropping the meat into a pan*

But the phrase *drop over* does not entail the phrase *drop into*, and a proof for the inference is over-generated in ID 3628. We extracted all possible phrasal axioms from the training dataset, so noisy axioms can be extracted as a consequence of multiple factors such as parsing errors or potential disambiguation in the training dataset. One possible solution for decreasing such noisy axioms would be to use additive composition models (Tian et al., 2016) and asymmetric learnable scoring functions to calculate the confidence on these asymmetric entailing relations between phrases.

ID 96 is also an example of over-generation of axioms. The first axiom, $\forall y_1(\mathbf{jump}(y_1) \rightarrow \exists x_1(\mathbf{in}(y_1, x_1) \wedge \mathbf{air}(x_1)))$ was extracted from the proof of $T_1 \Rightarrow H_1$:

T_1: *A child in a red outfit is jumping on a trampoline*

H_1: *A little boy in red clothes is jumping in the air*

The second axiom $\forall y_1(\mathbf{man}(y_1) \rightarrow \mathbf{biker}(y_1))$ was extracted from the proof of $T_2 \Rightarrow H_2$:

T_2: *A man on a yellow sport bike is doing a wheelie and a friend on a black bike is catching up*

H_2: *A biker on a yellow sport bike is doing a wheelie and a friend on a black bike is catching up*

Although these axioms play a role in the proofs of $T_1 \Rightarrow H_1$ and $T_2 \Rightarrow H_2$, the wrong axiom $\forall y_1(\mathbf{man}(y_1) \rightarrow \mathbf{biker}(y_1))$ causes the over-generation of a proof for the inference in ID 96. The correct one would rather be $\forall x_1 \forall y_1(\mathbf{man}(y_1) \wedge \mathbf{on}(y_1, x_1) \wedge \mathbf{bike}(x_1) \rightarrow \mathbf{biker}(y_1))$. In this case, it is necessary to bundle predicates in a noun-phrase by specifying the types of a variable (entity or event) when making phrase alignments.

For ID 408, the word *explorer* is not contained in the training entailment dataset and hence the relevant axiom $\forall x_1(\mathbf{explorer}(x_1) \rightarrow \mathbf{people}(x_1))$ was not generated. While our logic-based method enables detecting semantic phrase correspondences in a sentence pair in an unsupervised way, our next step is to predict unseen paraphrases of this type.

6 Conclusion

In this paper, we proposed a method of detecting phrase correspondences through natural deduction proofs of semantic relations between sentence pairs. The key idea is to attempt a proof with automatic phrasal axiom injection by the careful management of variable sharing during the proof construction process. Our method identifies semantic phrase alignments by monitoring the proof of a theorem and detecting unproved sub-goals and logical premises. The method of detecting semantic phrase alignments would be applicable to other semantic parsing formalisms and meaning representation languages such as abstract meaning representations (AMR) (Banarescu et al., 2013). Experiment results showed that our method detected various phrase alignments including non-contiguous phrases and antonym phrases. This result may contribute to previous phrase alignment approaches. The extracted phrasal axioms improved the accuracy of RTE tasks.

In future work, we shall enhance this methodology of phrasal axiom injection to predict unseen paraphrases. The pairs of premises and sub-goals that can be detected through the proof process conduct semantic alignments in a sentence pair. With the use of an additive composition model of distributional vectors, we can evaluate the validity of such semantic alignments. A combination of our phrasal axiom injection and additive composition model of distributional vectors has the potential to detect unseen paraphrases in a sentence pair.

Abstract

We present an effective end-to-end memory network model that jointly (*i*) predicts whether a given document can be considered as relevant evidence for a given claim, and (*ii*) extracts snippets of evidence that can be used to reason about the factuality of the target claim. Our model combines the advantages of convolutional and recurrent neural networks as part of a memory network. We further introduce a similarity matrix at the inference level of the memory network in order to extract snippets of evidence for input claims more accurately. Our experiments on a public benchmark dataset, FakeNewsChallenge, demonstrate the effectiveness of our approach.

1 Introduction

Recently, an unprecedented amount of false information has been flooding the Internet with aims ranging from affecting individual people's beliefs and decisions (Mihaylov et al., 2015; Mihaylov and Nakov, 2016) to influencing major events such as political elections (Vosoughi et al., 2018). Consequently, manual fact checking has emerged with the promise to support accurate and unbiased analysis of rumors spreading in social medias, as well as of claims made by public figures or news media.

As manual fact checking is a very tedious task, automatic fact checking has been proposed as a possible alternative. This is often broken into intermediate steps in order to alleviate the task complexity. One such step is *stance detection*, which is also useful for human experts as a stand-alone task. The task aims to identify the relative perspective of a piece of text with respect to a claim, typically modeled using labels such as *agree*, *disagree*, *discuss*, and *unrelated*; Figure 1 gives some examples.

Claim: Robert Plant Ripped up $800M Led Zeppelin Reunion Contract.	
Stance	**Snippet**
agree	Led Zeppelin's Robert Plant turned down £500m to reform supergroup...
disagree	Robert Plant's publicist has described as "rubbish" a Daily Mirror report that he rejected a £500m Led Zeppelin reunion...
discuss	Robert Plant reportedly tore up an $800 million Led Zeppelin reunion deal...
unrelated	Richard Branson's Virgin Galactic is set to launch SpaceShipTwo today...

Figure 1: Examples of snippets of text and their stance with respect to the target claim.

Here, we address the problem of stance detection using a novel model based on end-to-end memory networks (Sukhbaatar et al., 2015), which incorporates convolutional and recurrent neural networks, as well as a similarity matrix. Our model jointly addresses the problems of predicting the stance of a text with respect to a given claim, and of extracting relevant text snippets as support for the prediction of the model. We further introduce a similarity matrix, which we use at inference time in order to improve the extraction of relevant snippets.

The experimental results on the Fake News Challenge benchmark dataset show that our model, which is very feature-light, performs close to the state of the art. Our contributions can be summarized as follows: (*i*) We apply a novel memory network model enhanced with CNN and LSTM networks for stance detection. (*ii*) We further propose a novel extension of the general architecture based on a similarity matrix, which we use at inference time, and we show that this extension offers sizable performance gains. (*iii*) Finally, we show that our model is capable of extracting meaningful snippets from a given text document, which is useful not only for stance detection, but more importantly can support human experts who need to decide on the factuality of a given claim.

2 Stance Detection Memory Networks

Long-term memory is necessary to determine the stance of a long document with respect to a claim, as relevant parts of a document—paragraphs or text snippets—can indicate the perspective of a document with respect to a claim. Memory networks have been designed to remember past information (Sukhbaatar et al., 2015) and they can be particularly well-suited for stance detection since they can use a variety of inference strategies alongside their memory component.

In this section, we present a novel memory network for stance detection. It contains a new inference component that incorporates a similarity matrix to extract, with better accuracy, textual snippets that are relevant to the input claims.

2.1 Overview of the network

A memory network is a 5-tuple $\{M, I, G, O, R\}$, where the *memory* M is a sequence of objects or representations, the *input* I is a component that maps the input to its representation, the *generalization* component G (Sukhbaatar et al., 2015) updates the memory with respect to new input, the *output* O generates an output for each new input and the current memory state, and finally, the *response* R converts the output into a desired response format, e.g., a textual response or an action. These components can potentially use many different machine learning models.

Our new memory network for stance detection is a 6-tuple $\{M, I, F, G, O, R\}$, where F represents the new *inference* component. It takes an input document d as evidence and a textual statement s as a claim and converts them into their corresponding representations in the input I. Then, it passes them to the memory M. Next, the relevant parts of the input are identified in F, and afterwards they are used by G to update the memory. Finally, O generates an output from the updated memory, and converts it to a desired response format with R. The network architecture is depicted in Figure 2. We describe the components below.

2.2 Input Representation Component

The input to the stance detection algorithm is a document d as evidence and a textual statement s as a claim, (see lines 2 and 3 in Table 1). Each d is segmented into paragraphs x_j of varied lengths, where each x_j is considered as a piece of evidence for stance detection.

1	**Inputs:**
2	(1) A document (d) as a set of pieces of evidence $\{x_j\}$
3	(2) A textual statement containing a claim (s)
4	**Outputs:**
5	(1) predicting the relative perspective (or stance) of (d, s) to a claim as *agree*, *disagree*, *discuss*, *unrelated*.
6	*Inference outputs:*
7	(2) Top K evidence pieces x_j with their similarity scores
8	(3) Top K snippets of x_j with their similarity scores
9	**Memory Network Model:**
10	*1. Input memory representation (I):*
11	$d \rightarrow (X, W, E)$
12	$(X, W, E) \xrightarrow{TimeDistributed(LSTM)} \{m_1, ..., m_n\}$
13	$(X, W, E) \xrightarrow{TimeDistributed(CNN)} \{c_1, .., c_n\}$
14	$s \xrightarrow{LSTM,CNN} s_{lstm}, s_{cnn}$
15	*2. Memory (M), updating memory (G) and inference (F):*
16	$m_j = m_j \odot P^j_{tfidf}, \forall j$
17	$P^j_{lstm} = {s_{lstm}}^\intercal \times \mathbf{M} \times m_j, \forall j$
18	$c_j = c_j \odot P^j_{lstm}, \forall j$
19	$P^j_{cnn} = {s_{cnn}}^\intercal \times \mathbf{M}' \times c_j, \forall j$
20	*3. Output memory representation (O):* $o = \Big[\text{mean}(\{c_j\});$
21	$\big[\max(\{P^j_{cnn}\}); \text{mean}(\{P^j_{cnn}\})\big]; \big[\max(\{P^j_{lstm}\});$ $\text{mean}(\{P^j_{lstm}\})\big]; \big[\max(\{P^j_{tfidf}\}); \text{mean}(\{P^j_{tfidf}\})\big]\Big]$
22	*4. Generating the final prediction (R):*
23	$[o; s_{lstm}; s_{cnn}] \xrightarrow{MLP} \delta$
24	*5. Inference (F) outputs:*
25	$P^j_{cnn} \longrightarrow \{$*a set of evidence*$\} + \{$*similarity scores*$\}$
26	$M' \longrightarrow \{$*snippets*$\} + \{$*similarity scores*$\}$

Table 1: Summary of our memory network algorithm for stance detection.

Indeed, a paragraph usually presents a coherent argument, unified under one or more inter-related topics. The input component in our model converts each d into a set of pieces of evidence in a three dimensional (3D) tensor space as shown below (see line 11 in Table 1):

$$d = (X, W, E) \tag{1}$$

where $X = \{x_1, ..., x_n\}$ is a set of paragraphs considered as pieces of evidence; each x_j is represented by a set of words $W = \{w_1, ..., w_v\}$—drawn from a global vocabulary of size v—and a set of neural representations $E = \{e_1, ..., e_v\}$ for words in W. This 3D space is illustrated as a cube in Figure 2.

Each x_j is encoded from the 3D space into a semantic representation at the input component using a Long Short-Term Memory (LSTM) network. The lower left component in Figure 2 shows our LSTM network, which operates on our input as follows (see also line 12 in Table 1):

$$(X, W, E) \xrightarrow{TimeDistributed(LSTM)} \{m_1, ..., m_n\} \tag{2}$$

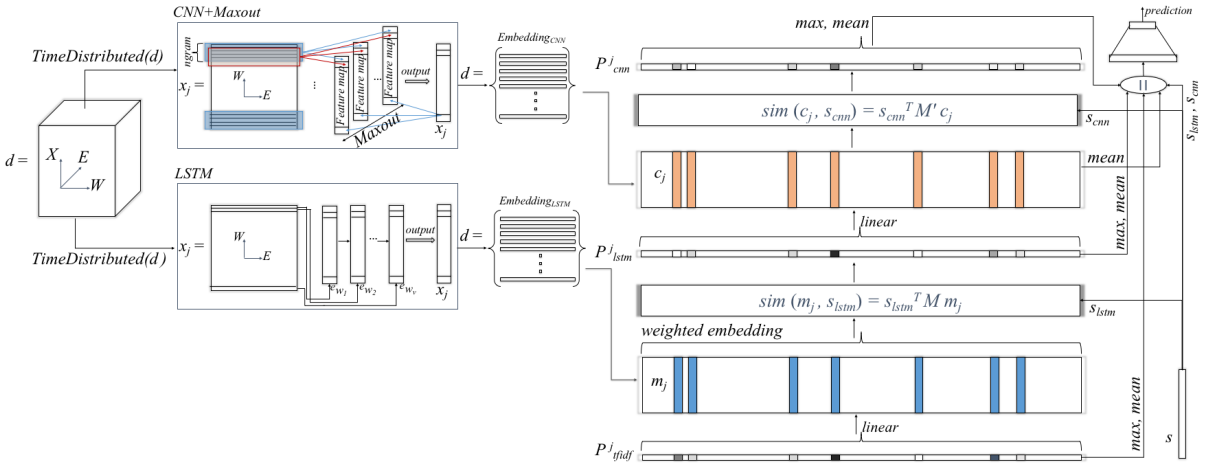

Figure 2: The architecture of our memory network model for stance detection.

where m_j is the LSTM representation of x_j, and *TimeDistributed()* indicates a wrapper that enables training the LSTM over all pieces of evidence by applying the same LSTM model to each time-step of a 3D input tensor, i.e., (X, W, E).

While LSTM networks were designed to effectively capture and memorize their inputs (Tan et al., 2016), Convolutional Neural Networks (CNNs) emphasize the local interaction between the individual words in the input word sequence, which is important for obtaining an effective representation. Here, we use a CNN in order to encode each x_j into its representation c_j as shown below (see line 13 in Table 1).

$$(X, W, E) \xrightarrow{TimeDistributed(CNN)} \{c_1, .., c_n\} \quad (3)$$

As shown in the left-top corner of Figure 2, this representation is passed as a new input to the component M of our memory network model. Moreover, we keep track of the computed n-grams from the CNN so that we can use them later in the inference and in the response components (see sections 2.3 and 2.6). For this purpose, we use a Maxout layer (Goodfellow et al., 2013) to take the maximum across k affine feature maps computed by the CNN, i.e., pooling across channels.

Previous work investigated the combination of convolutional and recurrent representations, which were fed to the other network as input (Tan et al., 2016; Donahue et al., 2015; Zuo et al., 2015; Sainath et al., 2015). In contrast, we feed individual outputs into our memory network separately, and we let it decide which representation better helps the target task. We demonstrate the effectiveness of this choice in our experiments.

Furthermore, we convert each input claim s into its representation using the corresponding LSTM and CNN networks as follows:

$$s \xrightarrow{LSTM,CNN} s_{lstm}, s_{cnn} \quad (4)$$

where s_{lstm} and s_{cnn} are the representations of s computed using $LSTM$ and CNN networks, respectively. Note that these are separate networks with different parameters from those used to encode the pieces of evidence.

Lines 10–14 of Table 1 describe the above steps in representing I in our memory network. This component encodes each input document d into a set of pieces of evidence $\{x_j\}\forall j$: it computes LSTM and CNN representations, m_j and c_j, respectively, for each x_j, and LSTM and CNN representations, s_{lstm} and s_{cnn}, for each claim s.

2.3 Inference Component

The resulting representations can serve to compute semantic similarity between claims and pieces of evidence. We define the similarity P^j_{lstm} between s and x_j as follows (see line 17 in Table 1):

$$P^j_{lstm} = s_{lstm}{}^{\intercal} \times \mathbf{M} \times m_j, \forall j \quad (5)$$

where $s_{lstm} \in \mathbb{R}^q$ and $m_j \in \mathbb{R}^d$ are the LSTM representations of s and x_j, respectively, and $M \in \mathbb{R}^{q \times d}$ is a similarity matrix capturing their similarity. For this purpose, M maps s and x_j into the same space as shown in Figure 3. M is a set of $q \times d$ parameters of the network, which are optimized during the training.

In a similar fashion, we compute the similarity P^j_{cnn} between x_j and s using the CNN representations as follows (see line 19 in Table 1):

$$P^j_{cnn} = s_{cnn}{}^{\intercal} \times \mathbf{M'} \times c_j, \forall j \quad (6)$$

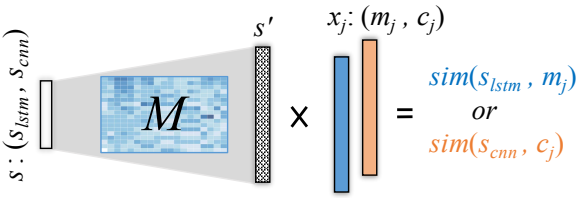

Figure 3: Matching a claim s and a piece of evidence x_j using a similarity matrix M. Here, s_{lstm} and s_{cnn} are the LSTM and CNN representations of s, whereas m_j and c_j are the LSTM and CNN representations of x_j.

where $s_{cnn} \in \mathbb{R}^{q'}$ and $c_j \in \mathbb{R}^{d'}$ are the representations of s and x_j obtained with CNN, respectively. The similarity matrix $M' \in \mathbb{R}^{q' \times d'}$ is a set of $q' \times d'$ parameters of the network and is optimized during the training. P^j_{lstm} and P^j_{cnn} indicate the claim-evidence similarity vectors computed based on the LSTM and on the CNN representations of s and x_j, respectively.

The rationale behind using the similarity matrix is that in our memory network model, as Figure 3 shows, we seek a transformation of the input claim such that $s' = M \times s$ in order to obtain the closest facts to the claim.

In fact, the relevant parts of the input document with respect to the input claim can be captured at a different level, e.g., using M' for the n-gram level or using the claim-evidence P^j_{lstm} or $P^j_{cnn}, \forall j$ at the paragraph level. We note that (*i*) P^j_{lstm} uses LSTM to take the word order and long-length dependencies into account, and (*ii*) P^j_{cnn} uses CNN to take n-grams and local dependencies into account, as explained in sections 2.2 and 2.3. Additionally, we compute another semantic similarity vector, P^j_{tfidf}, by applying a cosine similarity between the TF.IDF (Spärck Jones, 2004) representation of x_j and s. This is particularly useful for stance detection as it can help detect unrelated pieces of evidence.

2.4 Memory and Generalization Components

The information flow and updates in the memory is as follows: first, the representation vector $\{m_j\}\forall j$ is passed to the memory and updated using the claim-evidence similarity vector $\{P^j_{tfidf}\}$:

$$m_j = m_j \odot P^j_{tfidf}, \forall j \tag{7}$$

The reason for this weighting is to filter out most unrelated evidence with respect to the claim. The updated m_j in conjunction with s_{lstm} are used by the inference component–component F to compute $\{P^j_{lstm}\}$ as explained in Section 2.3.

Then, $\{P^j_{lstm}\}$ is used to update the new input set $\{c_j\}\forall j$ to the memory:

$$c_j = c_j \odot P^j_{lstm}, \forall j \tag{8}$$

Finally, the updated c_j in conjunction with s_{cnn} are used to compute P^j_{cnn} as explained in Sec. 2.3.

2.5 Output Representation Component

In memory networks, the memory output depends on the final goal, which, in our case, is to detect the relative perspective of a document to a claim. For this purpose, we apply the following equation:

$$o = \Big[\text{mean}(\{c_j\}); \big[\max(\{P^j_{cnn}\}); \text{mean}(\{P^j_{cnn}\})\big]; \big[\max(\{P^j_{lstm}\}); \text{mean}(\{P^j_{lstm}\})\big]; \big[\max(\{P^j_{tfidf}\}); \text{mean}(\{P^j_{tfidf}\})\big]\Big] \tag{9}$$

where $\text{mean}(\{c_j\})$ is the average vector of c_j representations. Furthermore, we compute the maximum and the average similarity between each piece of evidence and the claim using P^j_{tfidf}, P^j_{lstm} and P^j_{cnn}, which are computed for each evidence and claim in the inference component F. The maximum similarity identifies the part of document x_j that is most similar to the claim, while the average similarity measures the overall similarity between the document and the claim.

2.6 Response and Output Generation

This component computes the final stance of a document with respect to a claim. For this purpose, the concatenation of vectors o, s_{lstm} and s_{cnn} is fed into a Multi-Layer Perceptron (MLP), where a softmax predicts the stance of the document with respect to the claim, as shown below (see also lines 22–23 in Table 1):

$$[o; s_{lstm}; s_{cnn}] \xrightarrow{MLP} \delta \tag{10}$$

where δ is a softmax function. In addition to the resulting stance, we extract snippets from the input document that best indicate the perspective of the document with respect to the claim. For this purpose, we use P^j_{cnn} and M' as explained in Section 2.3 (see also lines 24–26 in Table 1).

The overall model is shown in Figure 2 and a summary of the model is presented in Table 1. All the model parameters, including those of (*i*) CNN and LSTM in I, (*ii*) the similarity matrices M and M' in F, and (*iii*) the MLP in R, are jointly learned during the training process.

3 Experiments and Evaluation

3.1 Data

We use the dataset provided by the Fake News Challenge,[1] where each example consists of a claim–document pair with the following possible relations between them: *agree* (the document agrees with the claim), *disagree* (the document disagrees with the claim), *discuss* (the document discusses the same topic as the claim, but does not take a stance with respect to the claim), *unrelated* (the document discusses a different topic than the topic of the claim). The data includes a total of 75.4K claim–document pairs, which link 2.5K unique articles with 2.5K unique claims, i.e., each claim is associated with 29.8 articles on average.

3.2 Settings

We use 100-dimensional word embeddings from GloVe (Pennington et al., 2014), which were trained on two billion tweets. We further use Adam as an optimizer and categorical cross-entropy as a loss. We use 100-dimensional units for the LSTM embeddings, and 100 feature maps with filter width of 5 for the CNN. We consider the first $p = 9$ paragraphs for each document, where p is the median of the number of paragraphs.

We optimize the hyper-parameters of the models using a validation dataset (20% of the training data). Finally, as the data is largely imbalanced towards the *unrelated* class, during training, we randomly select an equal number of instances from each class at each epoch.

3.3 Evaluation Measures

We use the following evaluation measures:

Accuracy: The number of correctly classified examples divided by the total number of examples. It is equivalent to micro-averaged F_1.

Macro-F1: We calculate F_1 for each class, and then we average across all classes.

Weighted Accuracy: This is a weighted, two-level scoring scheme, which is applied to each test example. First, if the example is from the *unrelated* class and the model correctly predicts it, the score is incremented by 0.25; otherwise, if the example is *related* and the model predicts *agree*, *disagree*, or *discuss*, the score is incremented by 0.25. Second, there is a further increment by 0.75 for each *related* example if the model predicts the correct label: *agree*, *disagree*, or *discuss*.

[1] Available at www.fakenewschallenge.org

Finally, the score is normalized by dividing it by the total number of test examples. The rationale behind this metric is that the binary *related/unrelated* classification task is expected to be much easier, while also being arguably less relevant to fake news detection than the stance detection task, which aims to further classify relevant instances as *agree*, *disagree*, or *discuss*. Therefore, the former task is given less weight and the latter task is given more weight through the weighted accuracy metric.

3.4 Baselines

Given the imbalanced nature of our data, we use two baselines in which we label all testing examples with the same label: (*i*) *unrelated* and (*ii*) *discuss*. The former is the majority class baseline, which is a reasonable baseline for *Accuracy* and *macro-F_1*, while the latter is a potentially better baseline for *Weighted Accuracy*.

We further use CNN and LSTM, and combinations thereof as baselines, since they form components of our model, and also because they yield state-of-the-art results for text, image, and video classification (Tan et al., 2016; Donahue et al., 2015; Zuo et al., 2015; Sainath et al., 2015).

Finally, we include the official baseline from the challenge, which is a Gradient Boosting classifier with word and n-gram overlap features, as well as indicators for refutation and polarity.

3.5 Our Models

sMemNN: This is our model presented in Figure 2. Note that unlike the CNN+LSTM and the LSTM+CNN baselines above, which feed the output of one network into the other one, the sMemNN model feeds the individual outputs of both the CNN and the LSTM networks into the memory network, and lets it decide how much to rely on each of them. This consideration also facilitates reasoning and explaining model predictions, as we will discuss in more detail below.

sMemNN (dotProduct): This is a version of sMemNN, where the similarity matrices are replaced by the dot product between the representation of the claims and of the evidence. For this purpose, we first project the claim representation to a dense layer that has the same size as the representation of each piece of evidence, and then we compute the dot product between the resulting representation and the representation of the evidence.

Methods	Total Parameters	Trainable Parameters	Weighted Accuracy	Macro-F1	Accuracy
1. All-*unrelated*	–	–	39.37	20.96	72.20
2. All-*discuss*	–	–	43.89	7.47	17.57
3. CNN	2.7M	188.7K	40.66	24.44	41.53
4. LSTM	2.8M	261.3K	57.23	37.23	60.21
5. CNN+LSTM	4.2M	361.5K	42.02	27.36	48.54
6. LSTM+CNN	2.8M	281.5K	60.21	40.33	65.36
7. Gradient Boosting	–	–	75.20	46.13	86.32
8. sMemNN (dotProduct)	5.4M	275.2K	75.13	50.21	83.85
9. sMemNN	5.5M	377.5K	78.97	56.75	87.27
10. sMemNN (with TF)	110M	105M	**81.23**	**56.88**	**88.57**

Table 2: Evaluation results on the test data.

sMemNN (with TF): Since our LSTM and CNN networks use a limited number of starting paragraphs[2] for an input document, we enrich our model with the BOW representation of documents and claims as well as their TF.IDF-based cosine similarity. We concatenate these vectors with the memory outputs (section 2.5) and pass them to the R component (section 2.6) of sMemNN. We expect these BOW vectors provide useful information that are not initially incorporated into the sMemNN model.

3.6 Results

Table 2 reports the performance of all models on the test dataset. The All-*unrelated* and the All-*discuss* baselines perform poorly across the evaluation measures, except for All-*unrelated*, which achieves high accuracy, which is due to *unrelated* being by far the dominant class in the dataset.

Next, we can see that the LSTM model consistently outperforms the CNN across all evaluation measures. Although the larger number of parameters of the LSTM can play a role, we believe that its superiority comes from it being able to remember previously observed relevant pieces of text.

Next, we see systematic improvements for the combinations of the CNN and the LSTM models: CNN+LSTM is better than CNN alone, and LSTM+CNN is better than LSTM alone. Better performance is achieved by the LSTM+CNN model, where claims and evidence are first processed by a LSTM and then fed into a CNN.

The Gradient Boosting model achieves sizable improvement over the above baseline neural models. However, we should note that these neural models do not have the rich hand-crafted features that were used in the Gradient Boosting model.

[2]Due to the long length of documents, it is impractical to consider all paragraphs when training LSTM and CNN.

Row 9 shows the results for our memory network model (sMemNN), which consistently outperforms all other baseline models across all evaluation metrics, achieving 10.62 and 3.77 points of absolute improvement in terms of Macro-F1 and Weighted Accuracy, respectively, over the best baseline (Gradient Boosting). We believe this is due to the memory network being able to capture good text snippets. As we will see below, these snippets are also useful for explaining the model's predictions. Comparing row 9 to row 8, we can see the importance of our proposed similarity matrix: replacing that matrix by a simple dot product hurts the performance of the model considerably across all evaluation measures, thus lowering it to the level of the Gradient Boosting model.

Finally, row 10 shows the results for our memory network model enriched by BOW representation. As we expected, it improves the performance of sMemNN - perhaps by capturing useful information from paragraphs beyond the starting few.

To put the results of sMemNN in perspective, we should mention that the best system at the Fake News Challenge (Baird et al., 2017) achieved a macro-F1 of 57.79, which is not significantly different from our results at the 0.05 significance level (p-value=0.53). Yet, they have an ensemble combining the feature-rich Gradient Boosting system with neural networks. In contrast, we only use raw text as input and no ensembles, and our main goal is to study a new memory network model and its explainability component.

Further analysis of the outputs (namely, the confusion matrices) of the different models we experimented with reveals the following general trends: (*i*) The *unrelated* examples are easy to detect, and most models show high performance for this class. (*ii*) The *agree* and the *disagree* examples are often misclassified as *discuss* by the baseline models.

Claim 1: man saved from bear attack - thanks to his justin bieber ringtone		
Evidence Id	$\mathbf{P^j_{cnn}}$	**Evidence Snippet**
2069-3	0.89	... fishing in the yakutia republic , russia , igor vorozhbitsyn is lucky to be alive after his justin bieber ringtone , baby , scared off a bear that was attacking him [0.41] ...
2069-7	1.0	... but as the bear clawed vorozhbitsyn ' s face and back his mobile phone rang , the ringtone selected was justin bieber ' s hit song baby . rightly startled [1.00] , the bear retreated back into [0.39] the forest ...
true label: *agree*; **predicted label:** *agree*		

Claim 2: 50ft crustacean , dubbed crabzilla , photographed lurking beneath the waters in whitstable		
Evidence Id	$\mathbf{P^j_{cnn}}$	**Evidence Snippet**
24835-1	0.0046	... a marine biologist has killed off claims [-0.0008] that a giant crab is [0.0033] living on the kent coast - insisting the image is probably a well - doctored hoax [0.0012] ...
24835-7	-0.0008	... i don ' t know what the currents are like around that harbour or what sort of they might produce in the sand , but i think it ' s more conceivable that someone is playing [0.0007] about with the photo ...
true label: *disagree*; **predicted label:** *disagree*		

Table 3: Examples of highly ranked snippets of evidence for an input claim, which are automatically extracted by our inference component. The P^j_{cnn} column and the values in the top-right corner of the highlighted snippets show the similarity between the claim and evidence, and between the claim and snippets of the evidence, respectively.

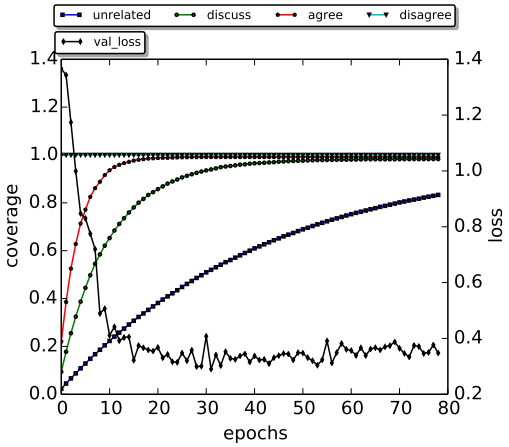

Figure 4: Effect of data coverage. The left y-axis shows the fraction of data observed during training (coverage), the right y-axis shows the loss during training.

This is mainly because the document that discusses a claim often shares the same topic with the claim, but then it does not take a stance with respect to that claim. (*iii*) The *disagree* examples are the most difficult ones for all models, probably because they represent by far the smallest class.

4 Discussion

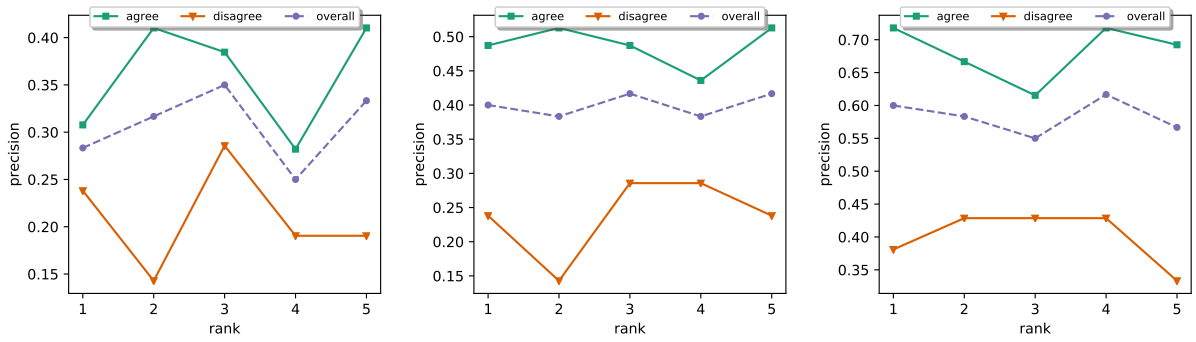
4.1 Training Data Coverage

As discussed previously, we balance the data at each training iteration by randomly selecting z instances from each of the four target classes, where z is the size of the class with the minimum number of training instances. Here, we investigate the amount of training data that gets actually used.

For this purpose, at each training iteration, we report the proportion of the training instances from each class that have been used for training so far, either at the current or at any of the previous iterations. As Figure 4 shows, our random data sampling procedure eventually covers almost all training instances. Since the *disagree* class is the smallest, its instances remain fully covered throughout the process. Moreover, almost all other related instances, i.e., *agree* and *discuss*, are observed during training, as well as a large fraction of the dominating *unrelated* examples. Note that the model achieves its best (lowest) loss on the validation dataset at iteration 31, when almost all *related* training instances are observed. This happens while the corresponding fraction for the *unrelated* pairs is around 50%, i.e., a considerable number of the *unrelated* instances are not required to be used for training.

4.2 Explainability

One of the main advantages of our memory network model, compared to the baselines and to related work in general, is that it has the capacity to explain its predictions by extracting snippets from each piece of evidence that supports its prediction. As we explained in Section 2.3, our inference component predicts the similarity between each piece of evidence x_j and the claim s at the n-grams level using the similarity matrix M' and the claim-evidence similarity vector P^j_{cnn}. Below, we explore our model's explainability in more detail.



(a) n-grams (b) consecutive n-grams (c) sentences

Figure 5: Prediction explainability. Sub-figures (a)-(c) show the precision of our model at explaining its predictions when the pieces of evidence are (a) fixed-length n-grams ($n = 5$), (b) combinations of several consecutive n-grams with similar scores, or (c) the entire sentence, if it includes at least one extracted n-gram snippet.

Table 3 shows examples of two claims and the snippets extracted as evidence. Column P^j_{cnn} shows the overall similarity between the evidence and the corresponding claim as computed by the inference component of our model. The highlighted texts are the snippets with the highest similarity to the claim as extracted by the same component. The values on the snippets' top-right show the claim-snippet similarity values obtained by the inference component.

Note that all snippets are fixed-length, namely 5-grams; however, in case there are several consecutive n-grams with similar scores, for better illustration, we combine them into a single snippet and we report their average values (see the snippet for evidence 2069-3). As these examples show, our model can accurately predict the stance of these pieces of evidence against their corresponding claims. Also, claim 2 and its corresponding evidence are shown at the second row of Table 3. As this example shows, the similarity values associated with snippets are either too small or negative, e.g., see the similarity value for the snippet "*biologist has killed off claims*." We can see that these help the model to make accurate predictions.

We conduct the following experiment to quantify the performance of our memory network at explaining its predictions: we randomly sample 100 *agree/disagree* claim–document examples from our gold data, and we manually evaluate the top five pieces of evidence that our model provides to support/oppose the corresponding claims. [3]

Figure 5(a) shows the precision of our memory network model at explaining its predictions when each supporting/opposing piece of evidence is an n-gram snippet of fixed length ($n = 5$) for the *agree* and the *disagree* classes, and their combinations at the top-k ranks, $k = \{1, \ldots, 5\}$. We can see in the figure that the model achieves precision of 0.28, 0.32, 0.35, 0.25, and 0.33 at ranks 1–5. Moreover, we find that it can accurately identify useful key phrases such as *officials declared the video*, *according to previous reports*, *believed will come*, *president in his tweets* as supporting pieces of evidence, and *proved a hoax*, *shot down a cnn report*, *would be skeptical* as opposing pieces of evidence.

Note that this relatively low precision of our memory network model at explaining its *agree/disagree* predictions is mainly due to the unsupervised nature of this task as no gold snippets justifying the document's gold stance with respect to the target claim are available in the Fake News Challenge dataset. [4]

Furthermore, our evaluation setup is at the n-gram level in Figure 5(a). However, if we conduct a more coarse-grained evaluation where we combine consecutive n-grams with similar scores into a single snippet, the precision for these new snippets will improve to 0.40, 0.38, 0.42, 0.38, and 0.42 at ranks 1–5, as Figure 5(b) shows. If we further extend the evaluation to the sentence level, the precision will jump to 0.60, 0.58, 0.55, 0.62, and 0.57 at ranks 1–5, as we can see in Figure 5(c).

[3] In 76 cases, our model correctly classified the *agree/disagree* examples when the evaluation was conducted, and it further provided arguably adequate snippets.

[4] Some other recent datasets, to be presented at this same HLT-NAACL'2018 conference, do have such gold evidence annotations (Baly et al., 2018; Thorne et al., 2018).

5 Related Work

While stance detection is an interesting task in its own right, e.g., for media monitoring, it is also an important component for fact checking and veracity inference.[5] Automatic fact checking was envisioned by Vlachos and Riedel (2014) as a multi-step process that (*i*) identifies check-worthy statements (Hassan et al., 2015; Gencheva et al., 2017; Jaradat et al., 2018), (*ii*) generates questions to be asked about these statements (Karadzhov et al., 2017), (*iii*) retrieves relevant information to create a knowledge base (Shiralkar et al., 2017), and (*iv*) infers the veracity of these statements, e.g., using text analysis (Castillo et al., 2011; Rashkin et al., 2017) or information from external sources (Mihaylova et al., 2018; Karadzhov et al., 2017; Popat et al., 2017).

There have been some nuances in the way researchers have defined the stance detection task. SemEval-2016 Task 6 (Mohammad et al., 2016) targets stances with respect to some target proposition, e.g., entities, concepts or events, as *in-favor*, *against*, or *neither*. The winning model in the task was based on transfer learning: a Recurrent Neural Network trained on a large Twitter corpus was used to predict task-relevant hashtags and to initialize a second recurrent neural network trained on the provided dataset for stance prediction (Zarrella and Marsh, 2016). Subsequently, Zubiaga et al. (2016) detected the stance of tweets toward rumors and hot topics using linear-chain conditional random fields (CRFs) and tree CRFs that analyze tweets based on their position in tree-like conversational threads.

Most commonly, stance detection is defined with respect to a *claim*, e.g., as in the 2017 Fake News Challenge. The best system in the challenge was an ensemble of gradient-boosted decision trees with rich features (e.g., *sentiment*, *word2vec*, *singular value decomposition* (*SVD*) and *TF.IDF* features, etc.) and a deep convolutional neural network to address the stance detection problem (Baird et al., 2017).

Unlike the above work, we use a feature-light memory network that jointly infers the stance and highlights relevant snippets of evidence with respect to a given claim.

[5] Yet, stance detection and fact checking are typically supported by separate datasets. Two notable upcoming exceptions, both appearing in this HLT-NAACL'2018, are (Thorne et al., 2018) for English and (Baly et al., 2018) for Arabic.

6 Conclusion

We studied the problem of stance detection, which aims to predict whether a given document supports, challenges, or just discusses a given claim. The nature of the task requires a machine learning model to focus on the relevant paragraphs of the evidence. Moreover, in order to understand whether a paragraph supports a claim, there is a need to refer to information in other paragraphs. CNNs or LSTMs are not well-suited for this task as they cannot model complex dependencies such as semantic relationships with respect to entire previous paragraphs. In contrast, memory networks are exactly designed to remember previous information. However, given the large size of documents and paragraphs, basic memory networks do not handle well irrelevant and noisy information, which we confirmed in our experiments.

Thus, we proposed a novel extension of general memory networks based on a similarity matrix and a stance filtering component, which we apply at the inference level, and we have shown that this extension offers sizable performance gains making memory networks competitive. Moreover, our model can extract meaningful snippets from documents that can explain the stance of a given claim.

In future work, we plan to extend the inference component to select an optimal set of explanations for each prediction, and to explain the model as a whole, not only at the instance level.

Abstract

We present a gradient-tree-boosting-based structured learning model for jointly disambiguating named entities in a document. Gradient tree boosting is a widely used machine learning algorithm that underlies many top-performing natural language processing systems. Surprisingly, most works limit the use of gradient tree boosting as a tool for regular classification or regression problems, despite the structured nature of language. To the best of our knowledge, our work is the first one that employs the structured gradient tree boosting (SGTB) algorithm for collective entity disambiguation. By defining global features over previous disambiguation decisions and jointly modeling them with local features, our system is able to produce globally optimized entity assignments for mentions in a document. Exact inference is prohibitively expensive for our globally normalized model. To solve this problem, we propose Bidirectional Beam Search with Gold path (BiBSG), an approximate inference algorithm that is a variant of the standard beam search algorithm. BiBSG makes use of global information from both past and future to perform better local search. Experiments on standard benchmark datasets show that SGTB significantly improves upon published results. Specifically, SGTB outperforms the previous state-of-the-art neural system by near 1% absolute accuracy on the popular AIDA-CoNLL dataset.[1]

1 Introduction

Entity disambiguation (ED) refers to the process of linking an entity mention in a document to its corresponding entity record in a reference knowledge base (e.g., Wikipedia or Freebase). As a core information extraction task, ED plays an important role in the language understanding pipeline, underlying a variety of downstream applications such as relation extraction (Mintz et al., 2009; Riedel et al., 2010), knowledge base population (Ji and Grishman, 2011; Dredze et al., 2010), and question answering (Berant et al., 2013; Yih et al., 2015). This task is challenging because of the inherent ambiguity between mentions and the referred entities. Consider, for example, the mention 'Washington', which can be linked to a city, a state, a person, an university, or a lake (Fig. 1).

Fortunately, simple and effective features have been proposed to capture the ambiguity that are designed to model the similarity between a mention (and its local context) and a candidate entity, as well as the relatedness between entities that co-occur in a single document. These are typically statistical features estimated from entity-linked corpora, and similarity features that are pre-computed using distance metrics such as cosine. For example, a key feature for ED is the *prior probability* of an entity given a specific mention, which is estimated from mention-entity co-occurrence statistics. This simple feature alone can yield 70% to 80% accuracy on both news and Twitter texts (Lazic et al., 2015; Guo et al., 2013).

To capture the non-linear relationships between the low-dimensional dense features like statistical features, sophisticated machine learning models such as neural networks and gradient tree boosting are preferred over linear models. In particular, gradient tree boosting has been shown to be highly competitive for ED in recent work (Yang and Chang, 2015; Yamada et al., 2016). However, although achieving appealing results, existing gradient-tree-boosting-based ED systems typically operate on each individual mention, without attempting to jointly resolve entity mentions in a document together. Joint entity disambiguation has been shown to significantly boost performance when used in conjunction with other machine learning techniques (Ratinov et al., 2011; Hoffart et al., 2011). However, how to train a

Proceedings of NAACL-HLT 2018, pages 777–786
New Orleans, Louisiana, June 1 - 6, 2018.

global gradient tree boosting model that produces coherent entity assignments for all the mentions in a document is still an open question.

In this work, we present, to the best of our knowledge, the first structured gradient tree boosting (SGTB) model for collective entity disambiguation. Building on the general SGTB framework introduced by Yang and Chang (2015), we develop a globally normalized model for ED that employs a conditional random field (CRF) objective (Lafferty et al., 2001). The model permits the utilization of global features defined between the current entity candidate and the entire decision history for previous entity assignments, which enables the global optimization for all the entity mentions in a document. As discussed in prior work (Smith and Johnson, 2007; Andor et al., 2016), globally normalized models are more expressive than locally normalized models.

As in many other global models, our SGTB model suffers from the difficulty of computing the partition function (normalization term) for training and inference. We adopt beam search to address this problem, in which we keep track of multiple hypotheses and sum over the paths in the beam. In particular, we propose Bidirectional Beam Search with Gold path (BiBSG) technique that is specifically designed for SGTB model training. Compared to standard beam search strategies, BiBSG reduces model variance and also enjoys the advantage in its ability to consider both past and future information when predicting an output.

Our contributions are:

- We propose a SGTB model for collectively disambiguating entities in a document. By jointly modeling local decisions and global structure, SGTB is able to produce globally optimal entity assignments for all the mentions.
- We present BiBSG, an efficient algorithm for approximate bidirectional inference. The algorithm is tailored to SGTB models, which can reduce model variance by generating more point-wise functional gradients for estimating the auxiliary regression models.
- SGTB achieves state-of-the-art (SOTA) results on various popular ED datasets, and it outperforms the previous SOTA systems by 1-2% absolute accuracy on the AIDA-CoNLL (Hoffart et al., 2011) dataset.

2 Model

In this section, we present a SGTB model for collective entity disambiguation. We first formally define the task of ED, and then describe a structured learning formalization for producing globally coherent entity assignments for mentions in a document. Finally, we show how to optimize the model using functional gradient descent.

For an input document, assume that we are given all the mentions of named entities within it. Also assume that we are given a lexicon that maps each mention to a set of entity candidates in a given reference entity database (e.g., Wikipedia or Freebase). The ED system maps each mention in the document to an entry in the entity database. Since a mention is often ambiguous on its own (i.e., the lexicon maps the mention to multiple entity candidates), the ED system needs to leverage two types of contextual information for disambiguation: local information based on the entity mention and its surrounding words, and global information that exploits the document-level coherence of the predicted entities. Note that modeling entity-entity coherence is very challenging, as the long-range dependencies between entities correspond to exponentially large search space.

We formalize this task as a structured learning problem. Let $\mathbf{x}$ be a document with T target mentions, and $\mathbf{y} = \{y_t\}_{t=1}^{T}$ be the entity assignments of the mentions in the document. We use $S(\mathbf{x}, \mathbf{y})$ to denote the joint scoring function between the input document and the output structure. In traditional NLP tasks, such as part-of-speech tagging and named entity recognition, we often rely on low-order Markov assumptions to decompose the global scoring function into a summation of local functions. ED systems, however, are often required to model nonlocal phenomena, as any pair of entities is potentially interdependent. Therefore, we choose the following decomposition:

$$S(\mathbf{x}, \mathbf{y}) = \sum_{t=1}^{T} F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}), \qquad (1)$$

where $F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1})$ is a factor scoring function. Specifically, a local prediction y_t depends on all the *previous decisions*, $\mathbf{y}_{1:t-1}$ in our model, which resembles recurrent neural network (RNN) models (Elman, 1990; Hochreiter and Schmidhuber, 1997).

We adopt a CRF loss objective, and define a

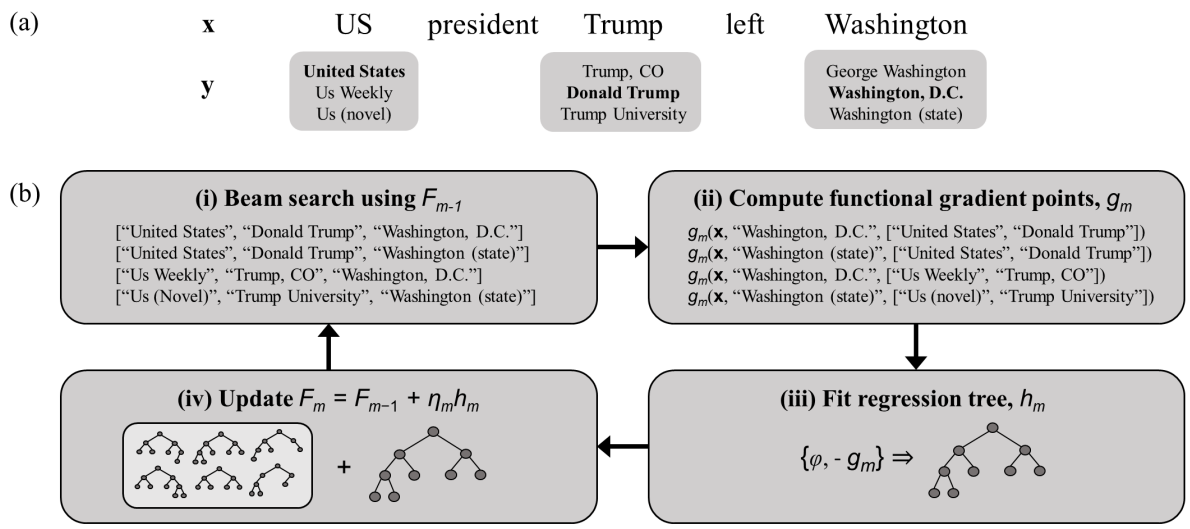

Figure 1: (a) Example document $\mathbf{x}$ with entity candidates for each mention (gold entities are in **bold**); (b) the m-th SGTB update iteration: (i) conduct beam search to sample candidate entity sequences (§ 3), (ii) compute point-wise functional gradients for each candidate sequence, (iii) fit a regression tree to the negative functional gradient points with input features, ϕ, (iv) update the factor scoring function, F, by adding the trained regression tree.

distribution over possible output structures as follows:

$$p(\mathbf{y}|\mathbf{x}) = \frac{\exp\{\sum_{t=1}^{T} F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1})\}}{Z(\mathbf{x})}, \quad (2)$$

where

$$Z(\mathbf{x}) = \sum_{\mathbf{y}' \in Gen(\mathbf{x})} \exp\{\sum_{t=1}^{T} F(\mathbf{x}, y'_t, \mathbf{y}'_{1:t-1})\}$$

and $Gen(\mathbf{x})$ is the set of all possible sequences of entity assignments depending on the lexicon. $Z(\mathbf{x})$ is then a global normalization term. As shown in previous work, globally normalized models are very expressive, and also avoid the label bias problem (Lafferty et al., 2001; Andor et al., 2016). The inference problem is to find

$$\arg\max_{\mathbf{y} \in Gen(\mathbf{x})} p(\mathbf{y}|\mathbf{x}) = \arg\max_{\mathbf{y} \in Gen(\mathbf{x})} \sum_{t=1}^{T} F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}). \quad (3)$$

2.1 Structured gradient tree boosting

An overview of our SGTB model is shown in Fig. 1. The model minimizes the negative log-likelihood of the data,

$$\begin{aligned} L(\mathbf{y}^*, S(\mathbf{x}, \mathbf{y})) &= -\log p(\mathbf{y}^*|\mathbf{x}) \\ &= \log Z(\mathbf{x}) - S(\mathbf{x}, \mathbf{y}^*), \end{aligned} \quad (4)$$

where $\mathbf{y}^*$ is the gold output structure.

In a standard CRF, the factor scoring function is typically assumed to have this form: $F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}) = \theta^\top \phi(\mathbf{x}, y_t, \mathbf{y}_{1:t-1})$, where $\phi(\mathbf{x}, y_t, \mathbf{y}_{1:t-1})$ is the feature function and θ are the model parameters. The key idea of SGTB is that, instead of defining a parametric model and optimizing its parameters, we can directly optimize the factor scoring function $F(\cdot)$ iteratively by performing gradient descent in function space. In particular, suppose $F(\cdot) = F_{m-1}(\cdot)$ in the m-th iteration, we will update $F(\cdot)$ as follows:

$$\begin{aligned} F_m(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}) = F_{m-1}(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}) \\ - \eta_m g_m(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}), \end{aligned} \quad (5)$$

where

$$\begin{aligned} g_m(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}) &= \frac{\partial L(\mathbf{y}^*, S(\mathbf{x}, \mathbf{y}))}{\partial F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}))} \\ &= p(\mathbf{y}_{1:t}|\mathbf{x}) - \mathbf{1}[\mathbf{y}_{1:t} = \mathbf{y}^*_{1:t}] \end{aligned} \quad (6)$$

is the functional gradient, η_m is the learning rate, and $\mathbf{1}[\cdot]$ represents an indicator function, which returns 1 if the predicted sequence matches the gold one, and 0 otherwise. We initialize $F(\cdot)$ to 0 ($F_0(\cdot) = 0$).

We can approximate the negative functional gradient $-g_m(\cdot)$ with a regression tree model $h_m(\cdot)$ by fitting the training data $\{\phi(\mathbf{x}^{(i)}, y_t^{(i)}, \mathbf{y}_{1:t-1}^{(i)})\}$ to the point-wise negative functional gradients (also known as residuals) $\{-g_m(\mathbf{x}^{(i)}, y_t^{(i)}, \mathbf{y}_{1:t-1}^{(i)})\}$. Then the factor scoring

function can be obtained by

$$F(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}) = \sum_{m=1}^{M} \eta_m h_m(\mathbf{x}, y_t, \mathbf{y}_{1:t-1}), \tag{7}$$

where $h_m(\mathbf{x}, y_t, \mathbf{y}_{1:t-1})$ is called a basis function. We set $\eta_m = 1$ in this work.

3 Training

Training the SGTB model requires computing the point-wise functional gradients with respect to training documents and candidate entity sequences. This is challenging, due to the exponential output structure search space. First, we are not able to enumerate all possible candidate entity sequences. Second, computing the conditional probabilities shown in Eq. 6 is intractable, as it is prohibitively expensive to compute the partition function $Z(\mathbf{x})$ in Eq. 2. Beam search can be used to address these problems. We can compute point-wise functional gradients for candidate entity sequences in the beam, and approximately compute the partition function by summing over the elements in the beam.

In this section, we present a bidirectional beam search training algorithm that always keeps the gold sequence in the beam. The algorithm is tailored to SGTB, and improves standard training methods in two aspects: (1) it reduces model variance by collecting more point-wise function gradients to train a regression tree; (2) it leverages information from both past and future to conduct better local search.

3.1 Beam search with gold path

The early update (Collins and Roark, 2004) and LaSO (Daumé III and Marcu, 2005; Xu and Fern, 2007) strategies are widely adopted with beam search for updating model parameters in previous work. Both methods keep track of the location of the gold path in the beam while decoding a training sequence. A gradient update step will be taken if the gold path falls out of the beam at a specific time step t or after the last step T. Adapting the strategies to SGTB training is straightforward. We will compute point-wise functional gradients for all candidate entity sequences after time step T or when the gold sequence falls out the beam. Both early update and LaSO are typically applied to online learning scenarios, in which model parameters are updated after passing one or a few training sequences.

SGTB training, however, fits the batch learning paradigm. In each training epoch, a SGTB model will be updated only once using the regression tree model fit on the point-wise negative functional gradients. The gradients are calculated with respect to the output sequences obtained from beam search. We propose a simple training strategy that computes and collects point-wise functional gradients at every step of a training sequence. In addition, instead of passively monitoring the gold path, we always keep the gold path in the beam to ensure that we have valid functional gradients at each time step. The new beam search training method, Beam Search with Gold path (BSG), generates much more point-wise functional gradients than early update or LaSO, which can reduce the variance of the auxiliary regression tree model. As a result, SGTB trained with BSG consistently outperforms early update or LaSO in our exploratory experiments, and it also requires fewer training epochs to converge.[2]

3.2 Bidirectional beam search

During beam search, if we consider a decision made at time step t, the joint probability $p(\mathbf{y}|\mathbf{x})$ can be factorized around t as follows:

$$\begin{aligned} p(\mathbf{y}|\mathbf{x}) = p(\mathbf{y}_{1:t-1}|\mathbf{x}) \cdot p(y_t|\mathbf{y}_{1:t-1}, \mathbf{x}) \\ \cdot p(\mathbf{y}_{t+1:T}|y_t, \mathbf{y}_{1:t-1}, \mathbf{x}). \end{aligned} \tag{8}$$

Traditional beam search performs inference in a unidirectional (left-to-right) fashion. Since the beam search at time step t considers only the beam sequences that were committed to so far, $\{\mathbf{y}_{1:t-1}\}$, it effectively approximates the above probability by assuming that all futures are equally likely, i.e. $p(\mathbf{y}_{t+1:T}|y_t, \mathbf{y}_{1:t-1}, \mathbf{x})$ is uniform. Therefore, at any given time, there is no information from the future when incorporating the global structure.

In this work, we adopt a Bidirectional Beam Search (BiBS) methodology that incorporates multiple beams to take future information into account (Sun et al., 2017). It makes two simplifying assumptions that better approximate the joint probability above while remaining tractable: (1) future predictions are independent of past predictions given y_t; (2) $p(y_t)$ is uniform. These yield the following approximation:

$$\begin{aligned} p(\mathbf{y}_{t+1:T}|y_t, \mathbf{y}_{1:t-1}, \mathbf{x}) = p(\mathbf{y}_{t+1:T}|y_t, \mathbf{x}) \\ \propto p(y_t|\mathbf{y}_{t+1:T}, \mathbf{x}) \cdot p(\mathbf{y}_{t+1:T}|\mathbf{x}). \end{aligned} \tag{9}$$

[2] Early update and LaSO perform similarly, thus we only report results for early update in § 5.

Substituting this back into Eq. 8 therefore yields:

$$p(\mathbf{y}|\mathbf{x}) \propto p(\mathbf{y}_{1:t-1}|\mathbf{x}) \cdot p(y_t|\mathbf{y}_{1:t-1}, \mathbf{x}) \cdot p(y_t|\mathbf{y}_{t+1:t}, \mathbf{x}) \cdot p(\mathbf{y}_{t+1:T}|\mathbf{x}), \quad (10)$$

which decomposes into multiplication of a forward probability and a backward probability. In (Sun et al., 2017), these are retrieved from forward and backward recurrent networks, whereas in our work we use the joint scores (log probabilities shown in Eq. 1) computed for partial sequences from forward and backward beams.

Algorithm 1: Bidirectional Beam Search with Gold path (BiBSG)

Input : input document $\mathbf{x}$, candidate sequences $\{\mathbf{y}\}$, joint scoring function $S(\mathbf{x}, \mathbf{y}_{t_1:t_2})$
Output: beam sequence set C
$C \leftarrow \emptyset$
while *not converged* **do**
  // forward beam search
  for $t = 1, \cdots, T$ **do**
    $C^{(F)} \leftarrow \text{top-B}_{\mathbf{y}_{1:t}}[S(\mathbf{x}, \mathbf{y}_{1:t}) + S(\mathbf{x}, \mathbf{y}_{T:t})]$
    // add gold subsequence
    $C^{(F)} \leftarrow C^{(F)} \cup \{\mathbf{y}^*_{1:t}\}$
    $C \leftarrow C \cup C^{(F)}$
  end
  // backward beam search
  for $t = T, \cdots, 1$ **do**
    $C^{(B)} \leftarrow \text{top-B}_{\mathbf{y}_{T:t}}[S(\mathbf{x}, \mathbf{y}_{T:t}) + S(\mathbf{x}, \mathbf{y}_{1:t})]$
    // add gold subsequence
    $C^{(B)} \leftarrow C^{(B)} \cup \{\mathbf{y}^*_{T:t}\}$
    $C \leftarrow C \cup C^{(B)}$
  end
end

The full inference algorithm, Bidirectional Beam Search with Gold path (BiBSG), is presented in Alg. 1. When performing the forward pass to update the forward beam, forward joint scores, $S(\mathbf{x}, \mathbf{y}_{1:t})$, are computed with respect to current forward beam, and backward joint scores, $S(\mathbf{x}, \mathbf{y}_{T:t})$, are computed with respect to previous backward beam. A similar procedure is used for the backward pass. The search converges very fast, and we use two rounds of bidirectional search as a good approximation. Finally, SGTB-BiBSG compares the conditional probabilities $p(\mathbf{y}^{(\cdot)}|\mathbf{x})$ of the best scoring output sequences $\mathbf{y}^{(\text{F})}$ and $\mathbf{y}^{(\text{B})}$ obtained from the forward and backward beams. The final prediction is the sequence with the higher conditional probability score.

4 Implementation

We provide implementation details of our SGTB systems, including entity candidate generation, adopted local and global features, and some efforts to make training and inference faster.

4.1 Candidate selection

We use a mention prior $\hat{p}(y|x)$ to select entity candidates for a mention x. Following Ganea and Hofmann (2017), the prior is computed by averaging mention prior probabilities built from mention-entity hyperlink statistics from Wikipedia[3] and a large Web corpus (Spitkovsky and Chang, 2012). Given a mention, we select the top 30 entity candidates according to $\hat{p}(y|x)$.

We also use a simple heuristic proposed by Ganea and Hofmann (2017) to improve candidate selection for persons: for a mention x, if there are mentions of persons that contain x as a continuous subsequence of words, then we consider the candidate set obtained from the longest mention for the mention x.

4.2 Features

The feature function $\phi(\mathbf{x}, y_t, \mathbf{y_{1:t-1}})$ can be decomposed into the summation of a local feature function $\phi_L(\mathbf{x}, y_t)$ and a global feature function $\phi_G(y_t, \mathbf{y}_{1:t-1})$.

Local features We consider standard local features that have been used in prior work, including mention priors $p(y|x)$ obtained from different resources; entity popularity features based on Wikipedia page view count statistics;[4] named entity recognition (NER) type features given by an in-house NER system trained on the CoNLL 2003 NER data (Tjong Kim Sang and De Meulder, 2003); entity type features based on Freebase type information; and three textual similarity features proposed by Yamada et al. (2016).[5]

Global features Three features are utilized to characterize entity-entity relationships: entity-entity co-occurrence counts obtained from Wikipedia, and two cosine similarity scores between entity vectors based on entity embeddings from (Ganea and Hofmann, 2017) and Freebase entity embeddings released by Google[6]

[3] We use a Wikipedia snapshot as of Feb. 2017.

[4] We obtain the statistics of Feb. 2017 and Dec. 2011 from https://dumps.wikimedia.org/other/pagecounts-ez/merged/ .

[5] We obtain embeddings jointly trained for words and entities from (Ganea and Hofmann, 2017).

[6] https://code.google.com/archive/p/word2vec/

respectively. We denote the entity-entity features between entities y_t and $y_{t'}$ as $\phi_E(y_t, y_{t'})$.

At step t of a training sequence, we quantify the coherence of y_t with respect to previous decisions $\mathbf{y}_{1:y-1}$ by first extracting entity-entity features between y_t and $y_{t'}$ where $1 \leq t' \leq t-1$, and then aggregating the information to have a global feature vector $\phi_G(y_t, \mathbf{y}_{1:t-1})$ of a fixed length:

$$\phi_G(y_t, \mathbf{y}_{1:t-1}) = \sum_{t'=1}^{t-1} \frac{\phi_E(y_t, y_{t'})}{t-1} \oplus \max_{t'=1}^{t-1} \phi_E(y_t, y_{t'}),$$

where $\oplus$ denotes concatenation of vectors.

4.3 Efficiency

Global models are powerful and effective, but often at a cost of efficiency. We discuss ways to speed up training and inference for SGTB models.

Many of the adopted features such as mention priors and entity-entity co-occurrences can be extracted once and retrieved later with just a hash map lookup. The most expensive features are the cosine similarity features based on word and entity embeddings. By normalizing the embeddings to have a unit norm, we can obtain the similarity features using dot products. We find this simple preprocessing makes feature extraction faster by two orders of magnitude.

SGTB training can be easily parallelized, as the computation of functional gradients are independent for different documents. During each training iteration, we randomly split training documents into different partitions, and then calculate the point-wise functional gradients for documents of different partitions in parallel.

5 Experiments

In this section, we evaluate SGTB on some of the most popular datasets for ED. After describing the experimental setup, we compare SGTB with previous state-of-the-art (SOTA) ED systems and present our main findings in § 5.3.

5.1 Data

We use six publicly available datasets to validate the effectiveness of SGTB. AIDA-CoNLL (Hoffart et al., 2011) is a widely adopted dataset for ED based on the CoNLL 2003 NER dataset (Tjong Kim Sang and De Meulder, 2003). It is further split into training (AIDA-train), development (AIDA-dev), and test (AIDA-test) sets.[7] AQUAINT (Milne and Witten, 2008), MSNBC (Cucerzan, 2007), and ACE (Ratinov et al., 2011) are three datasets for Wikification, which also contain Wikipedia concepts beyond named entities. These datasets were recently cleaned and updated by Guo and Barbosa (2016). WIKI and CWEB are automatically annotated datasets built from the ClueWeb and Wikipedia corpora by Guo and Barbosa (2016). The statistics of these datasets are available in Table 1.

Dataset	# mention	# doc	# mention per doc
AIDA-train	18,448	946	19.5
AIDA-dev	4,791	216	22.1
AIDA-test	4,485	231	19.4
AQUAINT	727	50	14.5
MSNBC	656	20	32.8
ACE	257	36	7.1
CWEB	11,154	320	34.8
WIKI	6,821	320	21.3

Table 1: Statistics of the ED datasets used in this work.

5.2 Experimental settings

Following previous work (Guo and Barbosa, 2016; Ganea and Hofmann, 2017), we evaluate our models on both *in-domain* and *cross-domain* testing settings. In particular, we train our models on AIDA-train set, tune hyperparameters on AIDA-dev set, and test on AIDA-test set (in-domain testing) and all other datasets (cross-domain testing). We follow prior work and report in-KB accuracies for AIDA-test and Bag-of-Title (BoT) F1 scores for the other test sets.

Two AIDA-CoNLL specific resources have been widely used in previous work. In order to have fair comparisons with these works, we also adopt them only for the AIDA datasets. First, we use a mention prior obtained from aliases to candidate entities released by Hoffart et al. (2011) along with the two priors described in § 4.1. Second, we also experiment with PPRforNED, an entity candidate selection system released by Pershina et al. (2015). It is unclear how candidates were pruned, but the entity candidates generated by this system have high recall and low ambiguity, and they contribute to some of the best results reported for AIDA-test (Yamada et al., 2016; Sil et al., 2018).

[7] AIDA-dev and AIDA-test are also referred as AIDA-a and AIDA-b datasets in previous work.

Competitive systems We implement four competitive ED systems, and three of them are based on variants of our proposed SGTB algorithm.[8] *Gradient tree boosting* is a local model that employs only local features to make independent decisions for every entity mention. Note that our local model is different from that presented by Yamada et al. (2016), where they treat ED as binary classification for each mention-entity pair. *SGTB-BS* is a Structured Gradient Tree Boosting model trained with Beam Search with early update strategy. *SGTB-BSG* uses Beam Search with Gold path training strategy presented in § 3.1. Finally, *SGTB-BiBSG* exploits Bidirectional Beam Search with Gold path to leverage information from both past and future for better local search.

In addition, we compare against best published results on all the datasets. To ensure fair comparisons, we group results according to candidate selection system that different ED systems adopted.

Parameter tuning We tune all the hyperparameters on the AIDA-dev set. We use recommended hyperparameter values from scikit-learn to train regression trees, except for the maximum depth of the tree, which we choose from $\{3, 5, 8\}$. After a set of preliminary experiments, we select the beam size from $\{3, 4, 5, 6\}$. The best values for the two hyperparameters are 3 and 4 respectively. As mentioned in § 2, the learning rate is set to 1. We train SGTB for at most 500 epochs (i.e., fit at most 500 regression trees). During training, we check the performance on the development set every 25 epochs to perform early stopping. Training takes 3 hours for SGTB-BS and SGTB-BSG, and takes 9 hours for SGTB-BiBSG on 16 threads.

5.3 Results

In-domain results In-domain evaluation results are presented in Table 2. As shown, SGTB achieves much better performance than all previously published results. Specifically, SGTB-BiBSG outperforms the previous SOTA system (Ganea and Hofmann, 2017) by 0.8% accuracy, and improves upon the best published results when employing the PPRforNED candidate selection system by 1.9% accuracy. Global information is clearly useful, as it helps to boost the performance by 2-4 points of accuracy, depending on the candidate generation system. In terms of beam search training strategies, BiBSG consistently outperforms BSG and beam search with early update. By employing more point-wise functional gradients to train the regression trees and leveraging global information from both past and future to carry on local search, BiBSG is able to find better global solutions than alternative training strategies.

[8] Our implementations are based on the scikit-learn package (Pedregosa et al., 2011).

Table 2: In-domain evaluation: in-KB accuracy results on the AIDA-test set. Checked PPRforNED indicates that the system uses PPRforNED (Pershina et al., 2015) to select candidate entities.The best results are in **bold**.

Cross-domain results As presented in Table 3, cross-domain experimental results are a little more mixed. SGTB-BS and SGTB-BSG perform quite competitively compared with SGTB-BiBSG. In a cross-domain evaluation setting, the test data is drawn from a different distribution as the training data. Therefore, less expressive models may be preferred as they may learn more abstract representations that will generalize better to out-of-domain data. Nevertheless, our SGTB models achieve better performance than best published results on three of the five popular ED datasets. Specifically, SGTB-BS outperforms the prior SOTA system by absolute 4% F1 on the CWEB dataset, and SGTB-BiBSG performs consistently well across different datasets.

6 Related work

Entity disambiguation Most ED systems consist of a local component that models relatedness between a mention and a candidate entity, as well as a global component that produces coherent entity assignments for all mentions within a document. Recent research has largely focused on joint resolution of entities, which is usually performed by maximizing the global topical coherence between entities. As discussed above, directly optimizing the coherence objective is computationally intractable, and several heuristics and approximations have been proposed to address the problem. Hoffart et al. (2011) use an iterative heuristic to remove unpromising mention-entity edges. Yamada et al. (2016) employ a two-stage approach, in which global information is incorporated in the second stage based on local decisions from the first stage. Approximate inference techniques have been widely adopted for ED. Cheng and Roth (2013) use an integer linear program (ILP) solver. Belief propagation (BP) and its variant loopy belief propagation (LBP) have been used by Ganea et al. (2016) and Ganea and Hofmann (2017) respectively. We employ another standard approximate inference algorithm, beam search, in this work. To make beam search a better fit for SGTB training, we propose BiBSG that improves beam search training on stability and effectiveness.

Structured gradient tree boosting Gradient tree boosting has been used in some of the most accurate systems for a variety of classification and regression problems (Babenko et al., 2011; Wu et al., 2010; Yamada et al., 2016). However, gradient tree boosting is seldom studied in the context of structured learning, with only a few exceptions. Dietterich et al. (2004) propose TreeCRF that replaces the linear scoring function of a CRF with a scoring function given by a gradient tree boosting model. TreeCRF achieves comparable or better results than CRF on some linear chain structured prediction problems. Bagnell et al. (2007) extend the Maximum Margin Planning (MMP; Ratliff et al., 2006) algorithm to structured prediction problems by learning new features using gradient boosting machines. Yang and Chang (2015) present a general SGTB framework that is flexible in the choice of loss functions and specific structures. They also apply SGTB to the task of tweet entity linking with a special non-overlapping structure. By decomposing the structures into local substructures, exact inference is tractable in all the aforementioned works. Our work shows that we can train SGTB models efficiently and effectively even with approximate inference. This extends the utility of SGTB models to a wider range of interesting structured prediction problems.

7 Conclusion and future work

In this paper, we present a structured gradient tree boosting model for entity disambiguation. Entity coherence modeling is challenging, as exact inference is prohibitively expensive due to the pairwise entity relatedness terms in the objective function. We propose an approximate inference algorithm, BiBSG, that is designed specifically for SGTB to solve this problem. Experiments on benchmark ED datasets suggest that the expressive SGTB models are extremely good at dealing with the task of ED. SGTB significantly outperforms all previous systems on the AIDA-CoNLL dataset,

and it also achieves SOTA results on many other ED datasets even in the cross-domain evaluation setting. SGTB is a family of structured learning algorithms that can be potentially applied to other core NLP tasks. In the future, we would like to investigate the effectiveness of SGTB on other information extraction tasks, such as relation extraction and coreference resolution.

Abstract

Ontologies compartmentalize types and relations in a target domain and provide the semantic backbone needed for a plethora of practical applications. Very often different ontologies are developed independently for the same domain. Such "parallel" ontologies raise the need for a process that will establish alignments between their entities in order to unify and extend the existing knowledge. In this work, we present a novel entity alignment method which we dub *DeepAlignment*. DeepAlignment refines pre-trained word vectors aiming at deriving ontological entity descriptions which are tailored to the ontology matching task. The absence of explicit information relevant to the ontology matching task during the refinement process makes DeepAlignment completely unsupervised. We empirically evaluate our method using standard ontology matching benchmarks. We present significant performance improvements over the current state-of-the-art, demonstrating the advantages that representation learning techniques bring to ontology matching.

1 Introduction

Translation across heterogeneous conceptual systems is an important challenge for cognitive science (Goldstone and Rogosky, 2002; Stolk et al., 2016). Ontology Matching constitutes the task of establishing correspondences between semantically related entities (i.e. classes and properties) from different ontologies, as illustrated in Figure 1. Similarly, ontology matching is crucial for accomplishing a mutual understanding across heterogeneous artificial cognitive agents (Taylor, 2015). However, despite the many proposed solutions, it is widely accepted that there is no solution robust enough to deal with the high ontological linguistic variability (Shvaiko and Euzenat, 2008, 2013); hampering, thus, the discovery of shared meanings.

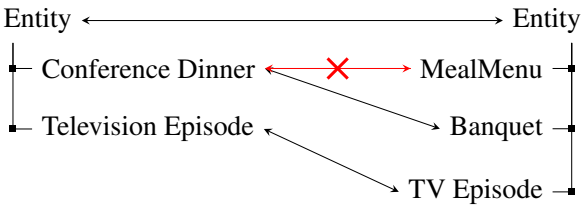

Figure 1: Example of alignments (black lines) and misalignments (red crossed lines) between ontologies.

Research in automatic ontology matching has focused on engineering features from terminological, structural, extensional (ontology instances) and semantic model information extracted from the ontological model. These features are then used to compute ontological entity similarities that will guide the ontology matching. Deriving such features for a given problem is an extremely time consuming task. To make matters worse, these features do not transfer in other domains. As Cheatham and Hitzler (2013) have recently shown, the performance of ontology matching based on different textual features varies greatly with the type of ontologies under consideration.

At the same time, machine learning research is characterised by a shift from feature engineering based approaches to feature and representation learning as a result of the performance improvements brought by deep learning methods. A by now classical example is the unsupervised learning of semantic word representations based on the *distributional hypothesis* (Harris, 1954), i.e. the assumption that semantically similar or related words appear in similar contexts (Deerwester et al., 1990; Bengio et al., 2003; Mikolov et al., 2013a,c; Pennington et al., 2014). Word vectors have the potential to bring significant value to on-

Proceedings of NAACL-HLT 2018, pages 787–798
New Orleans, Louisiana, June 1 - 6, 2018.

tology matching given the fact that a great deal of ontological information comes in textual form.

One drawback of these semantic word embeddings is that they tend to coalesce the notions of *semantic similarity* and *conceptual association* (Hill et al., 2016b). For instance, the word "harness" is highly related to the word "horse", as they share strong associations, i.e. a harness is often used on horses (Lofi, 2016). From an ontological point of view, however, these types should not be similar. Moreover, as unsupervised learning requires even larger text corpora, the learned vectors tend to bring closer words with similar frequency instead of similar meaning (Faruqui et al., 2016). Clearly, word representations that reflect frequency instead of meaning is an undesired feature if we seek to exploit word vectors for ontology matching; alignment based on such representations will reflect similar frequency instead of similar meaning.

A number of lightweight vector space representation refining techniques were introduced recently in an effort to correct these biases (Faruqui et al., 2015; Mrkšić et al., 2016). They use synonymy and antonymy constraints extracted from semantic lexicons to refine the learned word representations and make them better suited for semantic similarity tasks. Such methods are a way to inject domain-specific knowledge to tailor the learned word representations to a given task. As a result, we can exploit the synonymy/antonymy constraints to learn semantic word representations that are better candidates for ontology matching.

In this paper we learn representations of ontological entities instead of feature engineering them. We use the learned representations to compute the entities' semantic distances and to subsequently perform the ontology matching task. In order to represent the ontological entities, we exploit the textual information that accompanies them. We represent words by learning their representations using synonymy and antonymy constraints extracted from general lexical resources and information captured implicitly in ontologies. We cast the problem of ontology matching as an instance of the Stable Marriage problem (Gale and Shapley, 1962) using the entities semantic distances.

Our approach has a number of advantages. The word embeddings we establish are tailored to the domains and ontologies we want to match. The method relies on a generic unsupervised representation learning solution which is important given the small size of training sets in ontology matching problems. We evaluate our approach on the Conference dataset provided by the Ontology Alignment Evaluation Initiative (OAEI) campaign and on a real world alignment scenario between the Schema.org and the DBpedia Ontologies. We compare our method to state-of-the-art ontology matching systems and show significant performance gains on both benchmarks. Our approach demonstrates the advantages that representation learning can bring to the task of ontology matching and shows a novel way to study the problem in the setting of recent advances in NLP.

2 Related Work

2.1 Selecting Features for Ontology Matching

The vast majority of ontology matching research follows the feature engineering approach (Wang and Xu, 2008; Cruz et al., 2009; Khadir et al., 2011; Jiménez-Ruiz and Grau, 2011; Fahad et al., 2012; Ngo and Bellahsene, 2012; Gulić et al., 2016). Features are generated using a broad range of techniques (Anam et al., 2015; Harispe et al., 2015), ranging from the exploitation of terminological information, including structural similarities and logical constraints, such as datatype properties, cardinality constraints, etc.

Ontology matching is done by acting on the aforementioned features in different ways. Heuristic methods that rely on aggregation functions, such as *max, min, average, weighted sum*, etc., to fuse the information found in these features are quite popular (Anam et al., 2015). Other approaches use first order logic and cast ontology matching as a satisfiability problem (Giunchiglia et al., 2004; Jiménez-Ruiz and Grau, 2011).

Several works exploit supervised machine learning for Ontology Matching. Mao et al. (2011) cast ontology mapping as a binary classification problem. They generate various domain independent features to describe the characteristics of the entities and train an SVM classifier on a set which provides positive and negative examples of entity alignments. In general, the number of real alignments is orders of magnitude smaller than the number of possible alignments which introduces a serious class imbalance problem (Mao et al., 2008) hindering learning. Since we only use supervision to refine the word vector representations we avoid altogether the class imbalance problem.

2.2 Deep Learning for Ontology Matching

Deep learning has so far limited impact on ontology matching. To the best of our knowledge, only two approaches, (Zhang et al., 2014; Xiang et al., 2015), have explored the use of unsupervised deep learning techniques. Zhang et al. (2014) are considered to be the first ones that use word vectors in ontology matching. They train *word2vec* (Mikolov et al., 2013a) vectors on Wikipedia. They use the semantic transformations to complement the lexical information, i.e. names, labels and comments, describing entities. Their entity matching strategy is based on maximum similarity; for every entity e in the source ontology O, the algorithm finds the most similar entity e' in the target ontology O'. Their experiments on the OAEI benchmarks show that their techniques, even when combined with classical NLP techniques, could not outperform the state-of-the-art. In contrast, we refine pre-trained word embeddings with the intention of leveraging a new word vector set that is tailored to the ontology matching task.

Xiang et al. (2015) propose an entity representation learning algorithm based on Stacked Auto-Encoders (Bengio et al., 2007). To describe an entity they use a combination of its class ID, labels, comments, properties descriptions and its instances' descriptions. The entities' similarity is computed with a fixed point algorithm. They perform the entity matching using the Stable Marriage algorithm. Training such powerful models with so small training sets is problematic. We overcome this by using a transfer learning approach, known to reduce learning sample complexity (Pentina and Ben-David, 2015), to adapt pre-trained word vectors to a given ontological domain.

3 DeepAlignment

We present an ontology matching approach that uses information from ontologies and additional knowledge sources to extract synonymy/antonymy relations which we use to refine pre-trained word vectors so that they are better suited for the ontology matching task. We represent each ontological entity as the bag of words of its textual description, which we complement with the refined word embeddings. We match the entities of two different ontologies using the Stable Marriage algorithm over the entities' pairwise distances. We compute the aforementioned distances using a variant of a document similarity metric.

3.1 Preliminaries

Before we proceed with the presentation of the method, we will provide a formal definition of what an entity correspondence is. Given two ontologies O and O', we define the correspondence between two entities $e \in O$ and $e' \in O'$ as the five-element tuple:

$$cor_{e,e'} =< id, e, e', r, n > \quad (1)$$

where r is a matching relation between e and e' (e.g., equivalence, subsumption) and $n \in [0, 1]$ is the degree of confidence of the matching relation between e and e' (Euzenat and Shvaiko, 2013). The id holds the unique identifier of the mapping. Unlike the majority of ontology alignment systems which discover one-to-one equivalence mappings (Anam et al., 2015), we focus on discovering many-to-many mappings. We will also introduce some additional notation used in the paper. Let $u_1, u_2 \in \mathbb{R}^d$ be two d-dimensional vectors, we compute their cosine distance as follows: $d(u_1, u_2) = 1 - cos(u_1, u_2)$. For $x \in \mathbb{R}$, we define the *rectifier* activation function as: $\tau(x) = \max(x, 0)$.

3.2 Learning Domain Specific Word Vectors

The *counter-fitting* method (Mrkšić et al., 2016) uses synonymy and antonymy relations extracted from semantic lexicons to refine and adapt pre-trained word embeddings for given semantic similarity tasks. We broaden the concept of antonymy relations and allow for a larger class of ontology relations to define antonymies. This allows us to inject domain knowledge encoded in ontologies and produce more appropriate word vectors for the ontology matching task. In the rest of the section we revise the main elements of the counter-fitting method and describe how we can exploit it for learning domain specific word embeddings.

Let $V = \{v_1, v_2, \dots v_N\}$ be an indexed set of word vectors of size N. The counter-fitting method transforms a pretrained vector set V into a new one $V' = \{v'_1, v'_2, \dots v'_N\}$, based on a set of synonymy and antonymy constraints S and A, respectively. This is done by solving the following non-convex optimization problem:

$$\min_{V'} \kappa_1 AR(V') + \kappa_2 SA(V') + \kappa_3 VSP(V, V')$$

The $AR(V')$ function defined as:

$$AR(V') = \sum_{(u,w)\in A} \tau(1 - d(v'_u, v'_w))$$

is called *antonym repel* and pushes the refined word vectors of "antonymous" words to be away from each other. As we already mentioned, we extend the notion of antonymy relations with respect to its more narrow traditional linguistic definition. We consider that two entities in a given ontology are "antonymous" if they have not been explicitly stated as equivalent, in the sense of a logical assertion or a synonymy relation found in a semantic lexicon.

The $SA(V')$ function defined as:

$$SA(V') = \sum_{(u,w)\in S} d(v'_u, v'_w)$$

is called *synonym attract* and brings closer the transformed word vectors of synonyms. In order to extract synonymy information we search for paraphrases in semantic lexicons. Concretely, let $\omega_1 = \{word_1^1, word_2^1, \ldots, word_m^1\}$, $\omega_2 = \{word_1^2, word_2^2, \ldots, word_n^2\}$ be the textual information of two entities from different ontologies. If the combination $\{word_i^1, word_j^2\}$ or $\{word_j^2, word_i^1\}$ for some $i \in \{1, \ldots, m\}$ and $j \in \{1, \ldots, n\}$ appears as a paraphrase in any semantic lexicon then we add the synonymy information (u, w) in the set S of synonymy constraints.

The $VSP(V, V')$ function defined as:

$$VSP(V, V') = \sum_{i=1}^{N} \sum_{j\in N(i)} \tau(d(v'_i, v'_j) - d(v_i, v_j))$$

forces the refined vector space to reflect the original word-vector distances. $N(i)$ is the set of words that lie within ρ distance from the i-th word vector in the original vector-space. The experiments show that the value of ρ does not affect significantly the performance of the whole algorithm, so for computational efficiency we fix it to $\rho = 0.05$. We minimize the objective function with stochastic gradient descent (SGD). We use as a convergence criterion the norm of the gradient. We continue updating the model until this is smaller than 10^{-5}. In our experiments we typically observe convergence with less than 25 iterations.

3.3 Semantic Distance Between Entities

As before, let V' be the refined word vectors and $\omega_1 = \{word_1^1, word_2^1, \ldots, word_m^1\}$, $\omega_2 = \{word_1^2, word_2^2, \ldots, word_n^2\}$ be the textual information that describes two entities from different ontologies. The textual information of an entity can be extracted from different sources, such as the entity's name, label, comments, etc. We replace the appearance of a word with its refined word vector. Hence, we end up with two sets of word vectors Q and S, respectively. In order to do the matching of the entities of two ontologies we use a semantic distance over the entities' representations, here the set of word vectors associated with each entity.

There have been many ways to compute the semantic similarity of two word sets, such as the *Word Moving Distance* (Kusner et al., 2015) and the *Dual Embedding Space Model* (DESM) (Nalisnick et al., 2016). We will base our semantic distance δ on a slight variation of the DESM similarity metric. Our metric δ computes the distance of two sets of word vectors Q and S as follows:

$$\delta(Q, S) = \frac{1}{|Q|} \sum_{q_i \in Q} d(q_i, \bar{S}) \qquad (2)$$

where $\bar{S} = \frac{1}{|S|} \sum_{s_j \in S} \frac{s_j}{\|s_j\|}$ is the normalised average of the word embeddings that constitute the set of words S.

Hence, one of the word vectors' sets is represented by the centroid of its normalized vectors. The overall set-to-set distance δ is the normalized average of the cosine distance d between the computed centroid and the other's set word vectors. A first observation is that the introduced distance is not symmetric. Ideally, we would expect the semantic distance of two word sets to be irrelevant of the order of the inputs. To make it symmetric, we redefine the distance between two sets of word vectors as:

$$dis(\omega_1, \omega_2) = \max(\delta(Q, S), \delta(S, Q)) \qquad (3)$$

It is important to note that $dis(\omega_1, \omega_2)$ is not a proper distance metric as it does not satisfy the triangle inequality property. Despite this fact, it has proved to work extremely well on all the ontology matching scenarios.

3.4 Ontology Matching

Similar to the work in (Xiang et al., 2015) we use the extension of the Stable Marriage Assignment

problem to unequal sets (Gale and Shapley, 1962; McVitie and Wilson, 1970). The stable marriage algorithm computes one-to-one mappings based on a preference $m \times n$ matrix, where m and n is the number of entities in ontologies O and O', respectively. Note that the violation of the triangle inequality by our semantic distance (equation 3) is not an impediment to the Stable Marriage algorithm (Gale and Shapley, 1962).

The majority of the ontology matching systems produce equivalence mappings with cardinality one-to-one. Hence, one entity e in ontology O can be mapped to at most one entity in e' in O' and vice versa. According to a recent review (Anam et al., 2015) only two out of almost twenty ontology matching systems provide solutions to detect many-to-many mappings. However, ontology designers focus on different degrees of granularity, so it is expected that one entity from some ontology can correspond to more than one entities in another ontology and vice-verca.

To address this problem, we present an algorithm that extends the one-to-one mappings of the previous step to many-to-many. The basic idea is that some alignments that were omitted by the Stable Marriage solution were very close to the optimal alignment and they should also be included in the final alignment set. However, despite the use of refined word vectors, we cannot completely avoid the problems that come from the semantic similarity and conceptual association coalescence. The solution of this problem comes from the observation that we can add the constraint that the mapping should be extended only in the case that the new entity that will be added will share a subsumption relation with the existing one. Below we give a more formal definition of what we will call an ϵ-optimal mapping between two entities e and e' that belong to two different ontologies O and O' respectively.

Definition 1 *Let $e \rightarrow e'$ be the optimal mapping - produced by the Stable Marriage Solution - from the entity $e \in O$ to the entity $e' \in O'$, where O and O' are two different ontologies. Let $e \rightarrow e''$ be another mapping, where $e'' \in O'$. Given an $\epsilon > 0$, we call the mapping $e \rightarrow e''$ ϵ-optimal with respect to the mapping $e \rightarrow e'$ if and only if the following two hold:*

- $|dis(\omega_1, \omega_2) - dis(\omega_1, \omega_3)| < \epsilon$, *where ω_1, ω_2, ω_3 is the textual information of entities e, e' and e'', respectively.*

Algorithm 1 extendMap(e, h, $\mathcal{O}'$, P_e, $i_{e'}$, n, ϵ, r)

Require: source entity: e
hash function from integers to entities: h
subsumption's transitive closure: $\mathcal{O}'$
sorted (increasingly) preference matrix: P_e
index of optimal solution: $i_{e'}$
number of target's ontology entities: n
$\epsilon-$optimality value: ϵ
number of relatives: r

Ensure: sequence of the $\epsilon-$optimal mappings

```
Initialization: list = ∅
opt = P_e[i_{e'}]
e' = h(i_{e'})
for i = min(i_{e'} + 1, n) to min(i_{e'} + r, n) do
    tmp = P_e[i]
    if abs(opt − tmp) < ε then
        e_i = h(i)
        if (e_i, e') ∈ O' or (e', e_i) ∈ O' then
            list.append(e → e_i)
        end if
    end if
end for
```

- *e' and e'' should be logically related with a subsumption relation. Equivalently, there must be either a logical assertion that e' is subclass of e'' or e'' is subclass of e'.*

The *subsumption restriction* requires that the extended alignments share a taxonomic relation, in order to avoid matchings between entities that are conceptually associated. We iteratively search for ϵ-optimal mappings according to the algorithm 1 to extend the established one-to-one mappings to many-to-many. For efficiency reasons, we do not check all the entities, but only the r closest entities according to the $dis(\omega_1, \omega_2)$ distance. As a final step, we iteratively pass through all the produced alignments and we discard those with $dis(\omega_1, \omega_2)$ greater than a hyperparameter value $thres$.

4 Experiments

In this section, we present the experiments we performed on the OAEI conference dataset and in one real word alignment scenario between the Schema.org and DBpedia ontologies. One of the main problems that we have encountered with the comparative evaluation of our algorithm is that even though numerous ontology matching algorithms exist, for only a very small portion of them either the respective software or the system's out-

put is publicly available. To the best of our knowledge, among all the systems tested in the conference dataset only AML (Cruz et al., 2009) and LogMap (Jiménez-Ruiz and Grau, 2011) are publicly available. As it happens these are two of the state-of-the-art systems. Moreover, AML offers solutions to detect many-to-many alignments (Faria et al., 2015) and, thus, constitutes a competitive baseline against which we will compare the performance of extendMap which also provides many-to-many alignments.

When training to refine the vector representations an unbalanced proportion of synonymy and antonymy constraints sets can cause problems; the set with the lower cardinality will have limited impact on the final word representations. To overcome this problem, we run an additional step of the counter-fitting procedure, using only a small random subset of the supernumerary constraints and all constraints of the minority set. We randomly undersample the larger set and reduce its cardinality to that of the smaller set. We call this additional step the *recounter-fitting* process. To demonstrate the importance of the recounter-fitting process and test the behavior of the pre-trained word vectors in the absence of synonymy and/or antonymy relations, we have conducted additional experiments which we also present.

In all of our experiments we have applied the counter-fitting process upon the Paragram-SL999 word vectors provided by Wieting et al. (2015). With respect to the textual information extracted for each entity, we have only used the entity's ID (rdf:ID). To estimate the precision, recall and $F1$ measure of all the systems, that we consider for testing, and check for the statistical significance of the results we use an approximate randomization test with 1048576 shuffles, as described in Yeh (2000).

4.1 Semantic Lexicons

Let $\omega_1 = \{word_1^1, word_2^1, \ldots, word_m^1\}$, $\omega_2 = \{word_1^2, word_2^2, \ldots, word_n^2\}$ be the textual information that accompanies two entities from different ontologies. We extracted the synonymy and antonymy constraints that we used in the experiments from the following semantic lexicons:

WordNet: a well known lexical database for the English language (Miller, 1995). In our experiments we did not use WordNet synonyms. Instead, we have included WordNet antonymy pairs together with the "antonymy" relations extracted by the ontologies. The strategy that we have followed in order to create the WordNet's antonymy pairs is that every two words with antonymous word senses, we have considered them as antonyms.

PPDB 2.0: the latest release of the Paraphrase Database (Pavlick et al., 2015). We have used this database in two different ways. We have used the largest available single-token terms (XXXL version) in the database and we have extracted the *Equivalence* relations as synonyms, and the *Exclusion* relations as antonyms. Additionally, we have searched the whole XXXL version of PPDB for paraphrases based on the words appeared in two entities from different ontologies. Namely, our strategy was the following: If the pair $(word_i^1, word_j^2)$ or the pair $(word_j^2, word_i^1)$ appeared on the PPDB and their type of relation was not *Exclusion*, we considered it as synonym.

WikiSynonyms: a semantic lexicon which is built by exploiting the Wikipedia redirects to discover terms that are mostly synonymous (Dakka and Ipeirotis, 2008). In our experiments we have used it only on the Schema.org[1] - DBpedia[2] scenario. Our strategy was the following: we search if there exist synonyms in the WikiSynonyms for the ω_1 and ω_2. If this is the case, we extract them and we stop there. In the opposite case we extract the synonyms for each $word_i^1$ and $word_j^2$.

4.2 Hyperparameter Tuning

We tuned the hyperparameters on a set of 100 alignments which we generated by randomly sampling the synonyms and antonyms extracted from WordNet and PPDB. We chose the vocabulary of the 100 alignments so that it is disjoint to the vocabulary that we used in the alignment experiments, described in the evaluation benchmarks, in order to avoid any information leakage from training to testing. We tuned to maximize the $F1$ measure. In particular, we did a coarse grid search over a parameter space for $\kappa_1, \kappa_2, \kappa_3$, r, ϵ and $thres$. We considered $\kappa_1, \kappa_2 \in [0.35, 0.45]$ and $\kappa_3 \in [0.1, 0.2]$ with common step 0.01, $r \in [1, 10]$ with step 1, $\epsilon \in [0.01, 0.1]$ with step 0.01 and $thres \in [0.3, 0.7]$ with step 0.05. We trained for 25 epochs for each hyperparameter using SGD.

[1] https://github.com/schemaorg/schemaorg/blob/sdo-callisto/data/releases/3.2/schema.ttl

[2] http://downloads.dbpedia.org/2014/dbpedia_2014.owl.bz2

The best values were the following: $\kappa_1 = 0.4$, $\kappa_2 = 0.4$, $\kappa_3 = 0.1$, $r = 8$, $\epsilon = 0.07$ and $thres = 0.5$. We used the selected configuration on all the alignment scenarios described below.

4.3 Evaluation Benchmarks

One of our evaluation benchmarks comes from the Ontology Alignment Evaluation Initiative (OAEI), which organizes annual campaigns for evaluating ontology matching systems. The external to OAEI evaluation benchmark comes from the provided alignments between the Schema.org and the DBpedia ontologies. We provide some further details for each dataset below:

OAEI Conference Dataset: It contains 7 ontologies addressing the same domain, namely the conference organization. These ontologies are suitable for ontology matching task because of their heterogeneous character of origin. The overall performance (micro-precision, micro-recall, micro-F1) of the systems is tested upon 21 different test cases. Specifically, we summed up the individual true positives, false positives and false negatives based on the system results for the different ontology matching tasks and, in the next step, we computed the performance metrics. The original reference alignment is not closed under the alignment relation, so the transitive closure should be computed before proceeding on the evaluation of the systems.

Schema.org - DBpedia Alignment: It corresponds to the incomplete mapping of the Schema.org and DBpedia ontologies. Schema.org is a collaborative, community activity with a mission to create, maintain, and promote schemas for structured data on the Internet, on web pages, in email messages, and beyond. On the other hand, DBpedia is a crowd-sourced community effort to extract structured information from Wikipedia and make this information available on the Web. This alignment corresponds to a real case scenario between two of the most widely used ontologies in the web today.

4.4 Experimental Results

All the systems presented in the Conference dataset experiments (Table 1) fall into the category of feature engineering. CroMatch (Gulić et al., 2016), AML (Cruz et al., 2009), XMap (Djeddi and Khadir, 2010) perform ontology matching based on heuristic methods that rely on aggregation functions. LogMap and LogMapBio (Jiménez-Ruiz and Grau, 2011) use logic-based reasoning over the extracted features and cast the ontology matching to a satisfiability problem.

4.4.1 OAEI Conference Dataset

Table 1 shows the performance of our algorithm compared to the five top performing systems on the Conference 2016 benchmark, according to the results published in OAEI[3]. DeepAligment achieves the highest micro-$F1$ measure and the highest recall. We were able to perform statistical significance test only for the two systems that were publicly available. DeepAlignment is significantly better than both of them with a $p\text{-}value \leq 0.05$. In order to explore the performance effect of the many-to-many mappings that DeepAlignment produces we also did experiments where our extendMap algorithm was not used, thus generating only one-to-one alignments. We give these results under the DeepAlignment$_*$ listing. It can be seen that DeepAlignment$_*$ achieves the same level of recall as the state-of-the-art systems and this with no feature engineering. When we compare the performance of DeepAlignment$_*$ and DeepAlignment we see that the use of extendMap generates correct many-to-many alignments and thus it does not produce large numbers of false positives. In any case, however, we retain a small precision which indicates a semantic similarity and conceptual association coalescence.

System	Precision	Recall	Micro-F1
DeepAlignment	0.71	**0.80**	**0.75**
CroMatch	0.76	0.69	0.72
AML	0.79	0.65	0.71
DeepAlignment$_*$	0.68	0.68	0.68
XMap	0.81	0.58	0.67
LogMap	0.79	0.58	0.66
LogMapBio	0.75	0.58	0.65
StringEquiv	0.83	0.50	0.62

Table 1: Results on Conference OAEI dataset. StringEquiv corresponds to ontology matching by simple string equivalence check.

We perform additional experiments to investigate the importance of the counter-fitting step, which are summarized in Table 2. In all of these experiments, we have applied the extendMap algorithm. The last row of Table 2, corresponds to the best result reported in Table 1. The first row

[3] http://oaei.ontologymatching.org/2016/

gives the results of executing the algorithm without the counter-fitting process, just by providing the Paragram-SL999 word vectors.

Parameters		Precision	Recall	Micro-F1
Synonyms	**Antonyms**			
No	No	0.63	0.55	0.59
No	Yes	0.67	0.51	0.58
Yes	No	0.69	0.72	0.71
Yes	Restricted	0.65	0.78	0.71
Yes	Yes	**0.71**	**0.80**	**0.75**

Table 2: Experiments on Conference OAEI dataset.

The results support the importance of the counter-fitting process, which succeeds in tailoring the word embeddings to the ontology matching task. By injecting only antonymy information (second row), we observe an increase in precision, but a decrease in recall. This behavior is due to the fact that the antonym repel factor imposes an orthogonality constraint to the word vectors, leading to higher values of the dis distance. In absence of synonymy information, the majority of words tend to become "antonymous". The third row of Table 2 gives the performance when we also include synonyms extracted from PPDB but no antonymy information. We can see that this leads to a large increase of all the recorded performance metrics. Finally, we also include antonymy information only from the Cmt and the Conference ontologies found in the Conference dataset. This has two effects: an increase in recall, but a decrease in precision. This can be explained by the fact that even though all ontologies describe the same domain the description granularity provided by each of them is not capable of giving all the antonymy relations needed to provide more refined alignments.

4.4.2 Schema.org - DBpedia Alignment

Table 3 summarizes the obtained results from the matching of the Schema.org and DBpedia ontologies. The fact that the alignment is incomplete restricts us on testing the performance only on the recall. To make the comparison as fair as possible, we did not apply the extendMap algorithm. We should highlight that we have applied the recounter-fitting process because the synonyms that we have extracted from the PPDB and WikiSynonyms were very few compared to the constructed "antonyms". The results of the LogMap system show a quite similar behavior with the experiments conducted in the conference dataset. However the recall of AML is zero. It

System	Recall
DeepAlignment$_*$	0.82
LogMap	0.5
AML	0

Table 3: Results on aligning Schema.org and DBpedia ontologies.

discovers none of the available alignments even though it manages to recall other quite reasonable matchings, which, however, are not included in the ground truth. According to our understanding, this might be an indication of the absence of domain transferability of the extracted features as well as of the implemented metrics. We summarize in Table 4 the results of the experiments we did on the two domains to study the effect of counter-fitting and recounter-fitting. As we can see, even without the counter-fitting, the semantic embeddings show quite good results. This provides evidence on the importance of using representation learning techniques instead of the classical feature engineering choice. By injecting only antonymy information (second row), we observe a different behavior in the recall metric compared to the one presented in Table 2. This can be explained by the fact that while the antonym repel factor imposes an orthogonality constraint, its effect is by no means universal to the whole word vector space. Therefore, a misalignment can be pushed far away leaving the space open for a true alignment to be detected. With the addition of the extracted synonyms, we observe an increase of 0.13 in the recall. However, the insertion of the extracted "antonyms" leads to lower performance. This shows practically the importance of applying the recounter-fitting process that allows both the synonym attract and the antonym repel factors to affect the word vectors.

Parameters			Recall
Recounter-fitting	**Synonyms**	**Antonyms**	
No	No	No	0.71
No	No	Yes	0.76
No	Yes	No	0.84
No	Yes	Yes	0.76
Yes	Yes	Restricted	**0.82**

Table 4: Experiments on aligning Schema.org and DBpedia ontologies. Restricted indicates that we choose only a small random subset of the antonymy constraints.

4.5 Further Analysis

DeepAlignment vs. initial word vectors. To investigate the impact of the initial pre-trained word vectors on DeepAlignment's performance, we carried out two additional experiments, this time using a set of word2vec vectors (Mikolov et al., 2013b), trained on the Google news dataset[4]. We report and compare the obtained results to the ones produced by the use of Paragram-SL999 vectors in Table 5. In the absence of counter-fitting,

Counter fitting	Word Vectors	Conference			Schema.org DBpedia
		P	R	Micro-F1	R
No	word2vec	0.64	0.52	0.58	0.74
No	Paragram	0.63	0.55	0.59	0.71
Yes	word2vec	0.67	0.75	0.71	0.75
Yes	Paragram	0.71	0.80	0.75	0.76

Table 5: Dependency of DeepAlignment's performance on the choice of the initial word vectors[6].

the word2vec vectors achieve better results on the Schema.org - DBpedia scenario, however, they exhibit lower performance on the conference dataset. This observation is in accordance with recent studies (Hill et al., 2016a) which show that different word vectors optimization objectives yield representations tailored to different applications and domains. After the application of the counter-fitting process, the use of Paragram-SL999 vectors leads to a better performance. This fact provides additional evidence that word vectors which reflect semantic similarity are better candidates for being further tailored to the ontology matching task.

DeepAlignment vs. resources' coverage. The choice and coverage of the different lexical resources may have a determining factor on the performance of DeepAlignment. For that reason, we present in Table 6 a set of experiments where we exclude a part of the synonymy/antonymy relations from the various semantic lexicons. For both the matching scenarios, we experimented with excluding all the antonyms from PPDB and WikiSynonyms. For the conference dataset, we additionaly experimented with including only a subset of PPDB synonyms (50% coverage). Finally, we carried out one experiment where we excluded all the synonymy information extracted from WikiSynonyms for the Schema.org - DBpedia scenario. The resulted performance is presented in the rows 1, 4, 2, 5 of Table 6, respectively. The reported results provide evidence that the greater the coverage of synonyms and antonyms, the greater the performance of DeepAlignment will be.

Dataset	Experiment Setting	P	R	Micro-F1
Conference	With no antonyms from PPDB & WikiSynonyms	0.67	0.76	0.71
	With only a subset of the PPDB synonyms	0.67	0.76	0.71
	With all the available synonyms/antonyms	0.71	0.80	0.75
Schema.org DBpedia	With no antonyms from PPDB & WikiSynonyms	-	0.76	-
	With no synonyms from WikiSynonyms	-	0.73	-
	With all the available synonyms & antonyms	-	0.76	-

Table 6: Dependency of DeepAlignment's performance on the external resources' coverage[6].

5 Conclusion

In this paper, we propose the refinement of pre-trained word vectors with the purpose of deriving ontological entity descriptions which are tailored to the ontology matching task. The refined word representations are learned so that they incorporate domain knowledge encoded in ontologies as well as knowledge extracted from semantic lexicons. The refinement procedure does not use any explicit information relevant to the ontology matching task making the entity representation task completely unsupervised. We perform ontology matching by applying the Stable Marriage algorithm over the entities' pairwise distances. Our experimental results demonstrate significant performance gains over the state-of-the-art and show a novel way to study the problem of ontology matching under the setting of NLP.

Abstract

Recurrent neural networks have achieved state-of-the-art results in many artificial intelligence tasks, such as language modeling, neural machine translation, speech recognition and so on. One of the key factors to these successes is big models. However, training such big models usually takes days or even weeks of time even if using tens of GPU cards. In this paper, we propose an efficient architecture to improve the efficiency of such RNN model training, which adopts the group strategy for recurrent layers, while exploiting the representation rearrangement strategy between layers as well as time steps. To demonstrate the advantages of our models, we conduct experiments on several datasets and tasks. The results show that our architecture achieves comparable or better accuracy comparing with baselines, with a much smaller number of parameters and at a much lower computational cost.

1 Introduction

Recurrent Neural Networks (RNNs) have been widely used for sequence learning, and achieved state-of-the-art results in many artificial intelligence tasks in recent years, including language modeling (Zaremba et al., 2014; Merity et al., 2017), neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2014), and speech recognition (Graves et al., 2013).

To get better accuracy, recent state-of-the-art RNN models are designed toward big scale, include going deep (stacking multiple recurrent layers) (Pascanu et al., 2013a) and/or going wide (increasing dimensions of hidden states). For example, an RNN based commercial Neural Machine Translation (NMT) system would employ tens of layers in total, resulting in a large model with hundreds of millions of parameters (Wu et al., 2016). However, when the model size increases, the computational cost, as well as the memory needed for the training, increases dramatically. The training cost of aforementioned NMT model reaches as high as 10^{19} FLOPs, and the training procedure spends several days with even 96 GPU cards (Wu et al., 2016) – such complexity is prohibitively expensive.

While above models benefit from big neural networks, it is observed that such networks often have redundancy of parameters (Kim and Rush, 2016), motivating us to improve parameter efficiency and design more compact architectures that are more efficient in training while keeping good performance. Recently, many efficient architectures for convolution neural networks (CNNs) have been proposed to reduce training cost in computer vision domain. Among them, the group convolution is one of the most widely used and successful attempts (Szegedy et al., 2015; Chollet, 2016; Zhang et al., 2017b), which splits the channels into groups and conducts convolution separately for each group. It's essentially a diagonal sparse operation to the convolutional layer, which reduces the number of parameters as well as the computation complexity linearly w.r.t. the group size. Empirical results for such group convolution optimization show great speed up with small degradation on accuracy. In contrast, there are very limited attempts for designing better architectures for RNNs.

Inspired by those works on CNNs, in this paper, we generalize the group idea to RNNs to conduct recurrent learning in the group level. Different from CNNs, there are two kinds of parameter redundancy in RNNs: (1) the weight matrices transforming a low-level feature representation to a high-level one may contain redundancy, and (2) the recurrent weight matrices transferring the hidden state of the current step to the hidden state of the next step may also contain redundancy. Therefore, when designing efficient RNNs, we need to consider both the kinds of redundancy.

Proceedings of NAACL-HLT 2018, pages 799–808
New Orleans, Louisiana, June 1 - 6, 2018.

We present a simple architecture for efficient sequence learning which consists of *group recurrent* layers and *representation rearrangement* layers. First, in a recurrent layer, we split both the input of the sequence and the hidden states into disjoint groups, and do recurrent learning separately for each group. This operation clearly reduces the model complexity, and can learn *intra-group* features efficiently. However, it fails to capture dependency cross different groups. To recover the *inter-groups* correlation, we further introduce a representation rearrangement layer between any two consecutive recurrent layers, as well as any two time steps. With these two operations, we explicitly factorize a recurrent temporal learning into *intra-group* temporal learning and *inter-group* temporal learning with a much smaller number of parameters.

The group recurrent layer we proposed is equivalent to the standard recurrent layer with a block-diagonal sparse weight matrix. That is, our model employs a uniform sparse structure which can be computed very efficiently. To show the advantages of our model, we analyze the computation cost and memory usage comparing with standard recurrent networks. The efficiency improvement is linear to the number of groups. We conduct experiments on language modeling, neural machine translation and abstractive summarization by using a state-of-the-art RNN architecture as baseline. The results show that our model can achieve comparable or better accuracy, with a much smaller number of parameters and in a shorter training time.

The remainder of this paper is organized as follows. We first present our newly proposed architecture and conduct in depth analysis on its efficiency improvement. Then we show a series of empirical study to verify the effectiveness of our methods. Finally, to better position our work, we introduce some related work and then conclude our work.

2 Architecture

In this section, we introduce our proposed architecture for RNNs. Before getting into the details of the group recurrent layer and representation rearrangement layer in our architecture, we first revisit the vanilla RNNs.

An RNN is a neural network with recurrent layers that capture temporal dynamics of a sequence with arbitrary length. It recursively applies a transition function to its internal hidden state for each symbol of input sequence. The hidden state at time step t is computed as a function f of the current input symbol x_t and the previous hidden state h_{t-1} in a recurrent form:

$$h_t = f\left(x_t, h_{t-1}\right). \tag{1}$$

For vanilla RNN, the commonly used state-to-state transition function is,

$$h_t = tanh\left(Wx_t + Uh_{t-1}\right), \tag{2}$$

where W is the input-to-hidden weight matrix, U is the state-to-state recurrent weight matrix, and $tanh$ is the hyperbolic tangent function. Our work is independent to the choices of the recurrent function (f in Equation 1). For simplicity, in the following, we take the vanilla RNN as an example to introduce and analyze our new architecture.

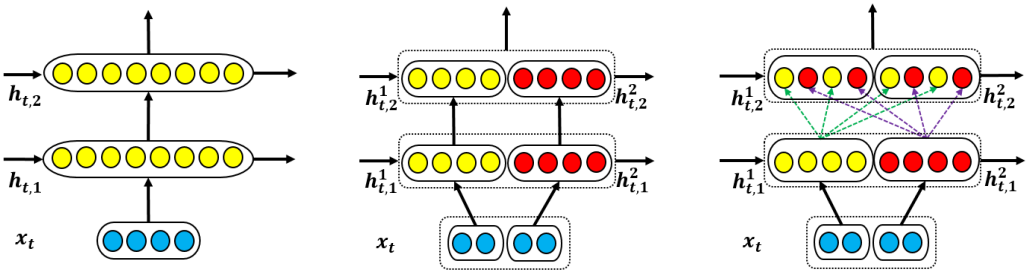
We aim to design an efficient RNN architecture by reducing the parameter redundancy while keeping accuracy at the same time. Inspired by the success of group convolution in CNN, our architecture employs the group strategy to achieve a sparsely connected structure between neurons of recurrent layers, and employs the representation rearrangement to recover the correlation that may destroyed by the sparsity. At a high level, we explicitly factorize the recurrent learning as inter-group recurrent learning and intra-group recurrent learning. In the following, we will describe our RNN architecture in detail, which consists of a group recurrent layer for intra-group correlation and a representation rearrangement layer for inter-group correlation.

2.1 Group recurrent layer for intra-group correlation

For standard recurrent layer, the model complexity increases quadratically with the dimension of hidden state. Suppose the input x is with dimension M, while the hidden state is with dimension N. Then, for standard vanilla RNN cell, according to Equation 2, the number of parameters, as well as the computation cost is

$$N^2 + N * M. \tag{3}$$

It's obvious that the hidden state dimension largely determines the model complexity. Optimization on reducing computation w.r.t the hidden state is the key to improve the overall efficiency. Accordingly, we present a group recurrent



(a) (b) (c)

Figure 1: Illustration of group recurrent network architecture. $h^k_{t,i}$ represents the hidden state of k-th group in i-th layer for time step t (a) The standard recurrent neural networks. (b) The group recurrent neural networks without representation rearrangement. This is efficient but the output only depends on the input in corresponding feature group. (c) Our proposed group recurrent neural network architecture, constituted with group recurrent layer and representation rearrangement layer.

layer which adopts a group strategy to approximate the standard recurrent layer. Specifically, we consider to split both the input x_t and hidden state h_t into K disjoint groups as $\{x^1_t, x^2_t, ..., x^K_t\}$ and $\{h^1_t, h^2_t, ..., h^K_t\}$ respectively, where x^i_t, h^i_t represent the input and hidden state for i-th group at time step t. Based on this split, we then perform recurrent computation in every group independently. This will captures the *intra-group* temporal correlation within the sequence. Formally, in the group recurrent layer, we first compute the hidden state of each group h^i_t as

$$h^i_t = f_i(x^i_t, h^i_{t-1}), i = 1, 2, ..., K. \quad (4)$$

Then, concatenating all the hidden states from each group together,

$$h_t = concat(h^1_t, h^2_t, ..., h^K_t) \quad (5)$$

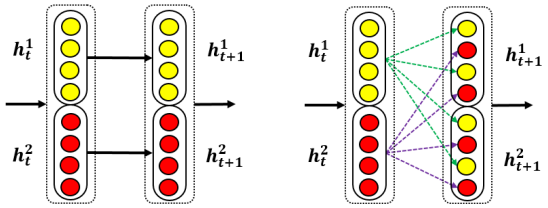
we get the output of the group recurrent layer. The group recurrent layer is illustrated as Figure 2(a) and Figure 1(b).

Obviously, by splitting the features and hidden states into K groups, the number of parameters and the computation cost of recurrent layer reduce to

$$K * ((\frac{N}{K})^2 + \frac{N}{K} * \frac{M}{K}) = \frac{N^2 + N * M}{K} \quad (6)$$

Comparing Equation 3 with Equation 6, the group recurrent is K times more efficient than the standard recurrent layer, in terms of both computational cost and number of parameters.

Although the theoretical computational cost is attractive, the speedup ratio also depends on the implementation details. A naive implementation of Equation 4 would introduce a *for* loop, which is not efficient since the additional overhead and poor parallelism. In order to really achieve linear speed up, we employ a *batch matrix multiplication* to assemble the computation of different groups in a single round of matrix multiplication. This operation is critical especially when each group isn't big enough to fully utilize the entire GPU computation power.



(a) (b)

Figure 2: Illustration of group recurrent network along the temporal direction. (a) The group recurrent neural network without representation rearrangement. (b) Our proposed group recurrent neural network with representation rearrangement.

2.2 Representation rearrangement for inter-group correlation

Group recurrent layer is K times more efficient comparing with the standard recurrent layer. But, it only captures the temporal correlation inside a single feature group and fails to learn dependency across features from different groups. more specifically, the internal state of RNN only contains history from corresponding group (Figure

1(b)). Similar problem also exists in the vertical direction of group recurrent layers (Figure 2(a)). Consider a network with multiple stacked group recurrent layers, the output of the specific group are only get from the corresponding input group. Obviously, there will be a significant drop of representation power since many feature correlations are cut off by this architecture.

To recover the *inter-group* correlations, one simple way is adding a projection layer to transform the hidden state outputted by the group recurrent layer, like the 1×1 convolution used in depthwise separable convolutional (Chollet, 2016). However, such method would bring additional N^2 computation complexity and model parameters.

Inspired by the idea of permuting channels between convolutional layers in recent CNN architectures (Zhang et al., 2017a,b), we propose to add representation rearrangement layer between consecutive group recurrent layers (Figure 1(c)), as well as the time steps within a group recurrent layer (Figure 2(b)). The representation rearrangement aims to rearrange the hidden representation, to make sure the subsequent layers, or time steps, can see features from all input groups.

The representation rearrangement layer is parameter-free and simple. We leverage the same implementation in (Zhang et al., 2017b) to conduct the rearrangement. It's finished with basic tensor operations *reshape*, and *transpose*, which brings (almost) no runtime overhead in our experiments. Consider the immediate representation $h_t \in R^N$ outputted by group recurrent layer with group number K. First, we reshape the representation to add an additional group dimension, resulting in a tensor with new shape $(K, N/K)$. Second, we transpose the two dimensions of the temporary tensor, changing the tensor shape to $(N/K, K)$. Finally, we reshape the tensor along the first axis to restore the representation to its original shape (a vector of size N). Figure 3 illustrates the operations with a simple example whose representation is with size 8 and group number is 2.

Combining the group recurrent layer and representation rearrangement layer, we rebuild the recurrent layer into an efficient and effective layer. We note that, different from convolutional neural networks that are only deep in space, the stack RNNs are deep in both space and time. Figure 1 illustrates our architecture along the spatial direction, and Figure 2 illustrates our architecture along the temporal direction. By applying group operation and representation rearrangement in both space and time, we build a new recurrent neural network with high efficiency.

3 Discussion

In this section, we analyze the relation between group recurrent layer and standard recurrent layer, and discuss the advantages of group recurrent networks.

3.1 Relation to standard recurrent layer

The group recurrent layer in Equation 4 and 5 can be re-formulated as

$$h_t = \tanh\Big(\begin{bmatrix} W^1 & 0 & \cdots & 0 \\ 0 & W^2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & W^K \end{bmatrix} \begin{bmatrix} x_t^1 \\ x_t^2 \\ \vdots \\ x_t^K \end{bmatrix} + \begin{bmatrix} U^1 & 0 & \cdots & 0 \\ 0 & U^2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & U^K \end{bmatrix} \begin{bmatrix} h_t^1 \\ h_t^2 \\ \vdots \\ h_t^K \end{bmatrix} \Big) \tag{7}$$

From the reformulation, we can see group recurrent layer is equivalent to standard recurrent layer with block-diagonal sparse weight matrix. Our method employs a group level sparsity in recurrent computation, leading to a uniform sparse structure. This uniform sparse structure can enjoy the efficient computing of dense matrix, as we discussed in Section 2.1. This reformulation also shows that there is no connection across neurons in different groups. Increasing the group number will lead to higher sparse rate. This sparse structure may limit the representation ability of our model. In order to recover the correlation across different groups, we add representation rearrangement to make up for representation ability.

3.2 Model capacity

We have shown that with same width of recurrent layer, our architecture with group number K achieves a compact model, which has K times less number of parameters than the standard recurrent network. Therefore with same number of parameters, group recurrent networks can provide more possibility to try more complex model without any

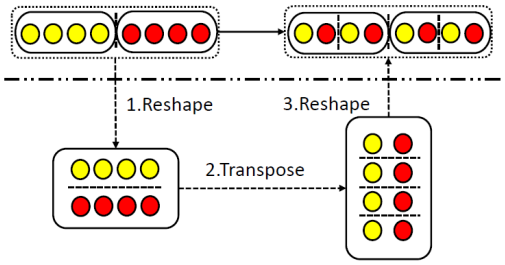


Figure 3: Illustration of the implementation of representation rearrangement with basic tensor operation.

additional computation and parameter overhead. Given a standard recurrent neural network, we can construct a corresponding group recurrent neural network with same number of parameters, but with K times wider, or with K times deeper. A factor smaller than K would make our networks still effective than standard recurrent network, but with wider and/or deeper recurrent layers. This could somehow compensate the potential performance drop due to the aggressive sparsity when group number is too large. Therefore, our architecture provides large model space to find a better trade-off between parameter and performance given a fixed resource budget. And our model is a more effective RNN architecture when the network goes deeper and wider.

At last, we note that our architecture focuses on improving the efficiency of recurrent layers. Thus the whole parameter and computational cost reduction depend on the ratio of recurrent layer in the entire network. Consider a text classification task, a often used RNN model would introduce an embedding layer for the input tokens and a softmax layer for the output, making the parameter reduction and speedup for the whole network is not strictly linear with the group number. However, we argue that for deeper and/or wider RNN whose recurrent layers dominate the parameter and computational cost, our method would enjoy more efficiency improvement.

4 Experiments

In this section, we present results on three sequence learning tasks to show the effectiveness of our method: 1). language modeling; 2). neural machine translation; 3). abstractive summarization.

4.1 Language modeling

For evaluating the effectiveness of our approach, we perform language modeling over Penn Treebak (PTB) dataset (Marcus et al., 1993). We use the data preprocessed by (Mikolov et al., 2010) [1], which consists of $929K$ training words, $73K$ validation words, and $82K$ test words. It has $10K$ words in its vocabulary. We compare our method (named Group LSTM) with the standard LSTM baseline (Zaremba et al., 2014) and its two variants with Bayesian dropout (named LSTM + BD) (Gal and Ghahramani, 2016) and with word tying (named LSTM + WT) (Press and Wolf, 2017). Following the big model settings in (Zaremba et al., 2014; Gal and Ghahramani, 2016; Inan et al., 2016) , all experiments use a two-layer LSTM with $1,500$ hidden units and an embedding of size $1,500$. We set group number 2 in this experiment since PTB is a relative simple dataset. We use Stochastic Gradient Descent (SGD) to train all models.

Results We compare the word level perplexity obtained by the standard LSTM baseline models and our group variants, in which we replace the standard LSTM layer with our group LSTM layer. As shown in Table 1, Group LSTM achieves comparable performance with the standard LSTM baseline, but with a 27% parameter reduction. A variant using Bayesian dropout (BD) is proposed by (Gal and Ghahramani, 2016) to prevent overfitting and improve performance. We test our model with LSTM + BD, achieving similar results with above comparison. Finally, we compare our model with the recently proposed word tying (WT) technology, which ties input embedding and output embedding with same weights. Our model achieves even better perplexity than the results reported by (Press and Wolf, 2017). Since word tying reduces the number of parameters of embedding and softmax layers, thus improving the ratio of LSTM layer parameter. Our method achieves a 35% parameter reduction.

4.2 Neural machine translation

We then study our model in neural machine translation. We conduct experiments on two translation tasks, German-English task (De-En for short) and English-German task (En-De for short). For De-En translation, we use data from the De-En ma-

Table 1: Single model complexity on validation and test sets for the Penn Treebank language modeling task. BD is Bayesian dropout. WT is word tying.

chine translation track of the IWSLT 2014 evaluation campaign (Cettolo et al., 2014). We follow the pre-processing described in previous works (Wu et al., 2017). The training data comprises about $153K$ sentence pairs. The size of validation data set is $6,969$, and the test set is $6,750$. For En-De translation, we use a widely adopted dataset (Jean et al., 2015; Wu et al., 2016). Specifically, part of data in WMT'14 is used as the training data, which consists of 4.5M sentences pairs. *newstest2012* and *newstest2013* are concatenated as the validation set and *newstest2014* acts as test set. These two datasets are preprocessed by byte pair encoding (BPE) with vocabulary of $25K$ and $30K$ for De-En and En-De respectively, and the max length of sub-word sentence is 64.

Our model is based on RNNSearch model (Bahdanau et al., 2014), but replacing the standard LSTM layer with our group LSTM layer. Therefore, we name our model as Group RNNSearch model. The model is constructed by LSTM encoder and decoder with attention, where the first layer of encoder is bidirectional LSTM. For De-En, we use two layers for both encoder and decoder. The embedding size is 256, which is same as the hidden size for all LSTM layers. As for En-De, we use four layers for encoder and decoder [2]. The embedding size is 512 and the hidden size is 1024 [3]. All the models are trained by Adadelta (Zeiler, 2012) with initial learning rate 1.0. The gradient is clipped with threshold 2.5. The mini-batch size is 32 for De-En and 128 for En-De. We use dropout (Srivastava et al., 2014) with rate 0.1 for all layers except the layer before softmax with 0.5. We halve the learning rate according to the validation performance.

[2]For easy to implement, we still keep the first layer with attention computation in the decoder as original LSTM layer.

[3]In our implementation, suppose the hidden size is d, after the first bi-directional LSTM layer in the encoder, the hidden size of the above LSTM layers in the encoder should be $2 \times d$.

Model	Params	BLEU
NPMT (Huang et al., 2017)	Unclear	30.08
RNNSearch	6.0M	31.03
2 Group RNNSearch	**4.3M**	**31.08**
4 Group RNNSearch	3.4M	30.96
8 Group RNNSearch	3.0M	30.73
16 Group RNNSearch	2.7M	30.35

Table 2: BLEU scores on IWSLT 2014 De-En test set. We report BLEU score results together with number of parameters of recurrent layers.

Model	Params	BLEU
DeepLAU (Wang et al., 2017)	Unclear	23.80
GNMT (Wu et al., 2016)	160M‡	24.61
2 Group RNNSearch	111M	23.93
4 Group RNNSearch	78M	23.61

Table 3: BLEU scores on WMT'14 En-De test set. We report BLEU score results together with number of parameters of recurrent layers. Numbers with ‡ are approximately calculated by ourselves according to the settings described in the paper.

Results We compute tokenized case-sensitive BLEU (Papineni et al., 2002) [4] score as evaluation metric. For decoding, we use beam search (Sutskever et al., 2014) with beam size 5.

From Table 2, we can observe that on De-En task, Group RNNSearch models achieve comparable or better BLEU score compared with the RNNSearch but with much less number of parameters. Specifically, with group number 2 and 4, we achieve about 28% and 43% parameter reduction of recurrent layers respectively. Note that our results also outperform the state-of-the-art result reported in NPMT (Huang et al., 2017).

The En-De translation results are shown in Table 3. We compare our Group RNNSearch models with Google's GNMT system (Wu et al., 2016) and DeepLAU (Wang et al., 2017). Our 4

[4]https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

Group RNNSearch model achieves 23.61, which is comparable to DeepLAU (23.80). Our 2 Group RNNSearch model achieves a BLEU score of 23.93, slightly less than GNMT (24.61), but outperforms the DeepLAU. More importantly, our Group RNNSearch models decrease more than 30% and 50% RNN parameters with 2 groups and 4 groups respectively compared with GNMT.

4.3 Abstractive summarization

At last, we valid our approach on abstractive summarization task. We train on the Gigaword corpus (Graff and Cieri, 2003) and pre-process it identically to (Rush et al., 2015; Shen et al., 2016), resulting in $3.8M$ training article-headline pairs, $190K$ for validation and $2,000$ for test. Similar to (Shen et al., 2016), we use a source and target vocabulary consisting of $30K$ words.

The model is almost same as the one used in De-En machine translation, which is a two layers RNNSearch model, except that the embedding size is 512, and the LSTM hidden size in both encoder and decoder is 512. The initial values of all weight parameters are uniformly sampled between $(-0.05, 0.05)$. We train our Group RNNSearch model by Adadelta (Zeiler, 2012) with learning rate 1.0 and gradient clipping threshold 1.5 (Pascanu et al., 2013b). The mini-batch size is 64.

Results We evaluate the summarization task by commonly used ROUGE (Lin, 2004) F1 score. During decoding, we use beam search with beam size 10. The results are shown in Table 4.

From Table 4, we can observe that the performance is consistent with machine translation task. Our Group RNNSearch model achieves comparable results with RNNSearch, and our 2 Group RNNSearch model even outperforms RNNSearch baseline. Besides, we compare with several other widely adopted methods, our models also show strong performance. Therefore, we can keep the good performance even though we reduce the parameters of the recurrent layers by nearly 50%, which greatly proves the effectiveness of our method.

4.4 Ablation analysis

In addition to showing that group RNN can achieve competing or better performance with much less number of parameters, we further study the effect of group number to training speed and convergence, and the effect of representation rearrangement to performance. Due to space limitation, we only report results for language modeling on PTB dataset; for other tasks we have similar results.

Model	Params	R-1	R-2	R-L
(Rush et al., 2015)	-	29.8	11.9	26.9
(Luong et al., 2015)	-	33.1	14.4	30.7
(Chopra et al., 2016)	-	33.8	15.9	31.1
RNNSearch	24.1M	34.4	15.8	31.8
2 Group RNNSearch	**17.0M**	**34.8**	**15.9**	**32.1**
4 Group RNNSearch	13.5M	34.3	15.7	31.6
8 Group RNNSearch	11.8M	34.3	15.6	31.6
16 Group RNNSearch	10.9M	33.8	15.3	31.2

Table 4: ROUGE F1 scores on abstractive summarization test set. RG-N stands for N-gram based ROUGE F1 score, RG-L stands for longest common subsequence based ROUGE F1 score. Params stands for the parameters of the recurrent layers.

Group	without	with (improvement)
2	82.5	**78.6 (+4.7%)**
4	86.6	**82.6 (+4.6%)**

Table 5: The effect of representation rearrangement to model performance.

In Figure 4, the left one shows that how number of parameters and training speed vary when group number ranging from 1 to 16. We can see that the number of parameters (of recurrent layers) is reduced linearly when increasing number of groups. In the meantime, we also achieves substantial speed up about throughput when increasing group number. We note that the speedup is sub-linear instead of linear since our method focuses on the speedup on recurrent layers, as discussed in Section 3.2. Besides, we also compare the convergence curve in the right of Figure 4, which shows that our method (almost) doesn't slow down the convergence in terms of epoch number. Considering the throughput speedup of our method, we can accelerate training by a large margin.

At last, we study the role that representation rearrangement layer plays in our architecture. We compare Group LSTM with and without representation rearrangement between layers and time steps, with the group number 2 and 4 respectively. From Table 5, we can see that the models with representation rearrangement consistently outperforms the ones without representation rearrangement. This shows the representation rearrangement is critical for group RNN.

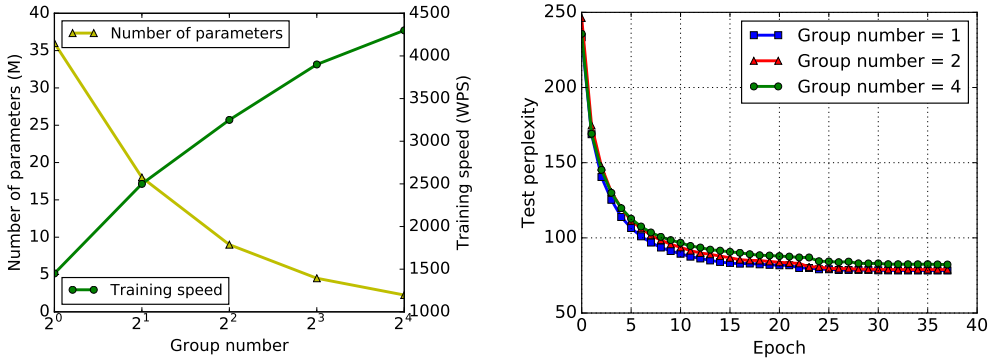

Figure 4: Illustration of group recurrent network analysis. Left: The number of parameters and the training speed (word per second, WPS) on different group numbers. Right: The test perplexity (convergence curve) along the training epochs.

5 Related Work

Improving RNN efficiency for sequence learning is a hot topic in recent deep learning research. For parameter and computation reduction, LightRNN (Li et al., 2016) is proposed to solve big vocabulary problem with a 2-component shared embedding, while our work addresses the parameter redundancy caused by recurrent layers. To speed up RNN, Persistent RNN (Diamos et al., 2016) is proposed to improve the RNN computation throughput by mapping deep RNN efficiently onto GPUs, which exploits GPU's inverted memory hierarchy to reuse network weights over multiple time steps. (Neil et al., 2017) proposes delta networks for optimizing the matrix-vector multiplications in RNN computation by considering the temporal properties of the data. Quasi-RNN (Bradbury et al., 2016) and SRU (Lei and Zhang, 2017) are proposed for speeding up RNN computation by designing novel recurrent units which relax dependency between time steps. Different from these works, we optimize RNN from the perspective of network architecture innovation by adopting a group strategy.

There is a long history about the group idea in deep learning, especially in convolutional neural networks, aiming to improve the computation efficiency and parameter efficiency. Such works can date back at least to AlexNet (Krizhevsky et al., 2012), which splits the convolutional layers into 2 independent groups for the ease of model-parallelism. The Inception (Szegedy et al., 2015) architecture proposes a module that employs uniform sparsity to improve the parameter efficiency. Going to the extreme of Inception, the Xception (Chollet, 2016) adopts a depthwise separable convolution, where each spatial convolution only works on a single channel. MobileNet (Howard et al., 2017) uses the same idea for efficient mobile model. IGCNet (Zhang et al., 2017a) and ShuffleNet (Zhang et al., 2017b) also adopt the group convolution idea, and further permute the features across consecutive layers. Similar to these works, we also exploit the group strategy. But we focus on efficient sequence learning with RNN, which, different from CNN, contains an internal memory and an additional temporal direction. In the RNN literature, there is only one paper (Kuchaiev and Ginsburg, 2017), to our best knowledge, exploiting the group strategy. However, this work assumes the features are group independent, thus failing to capturing the inter-group correlation. Our work employs a representational rearrangement mechanism, which avoids the assumption and improves the performance, as shown in our empirical experiments.

6 Conclusion

We have presented an efficient RNN architecture for sequence learning. Our architecture employs a group recurrent layer to learn intra-group correlation efficiently, and representation rearrangement layer to recover inter-group correlation for keeping representation ability. We demonstrate our model is more efficient in terms of parameters and computational cost. We conduct extensive experiments on language modeling, neural machine translations and abstractive summarization, showing that our method achieves competing performance with much less computing resource.

Abstract

In this paper we introduce a new publicly available dataset for verification against textual sources, FEVER: Fact Extraction and VERification. It consists of 185,445 claims generated by altering sentences extracted from Wikipedia and subsequently verified without knowledge of the sentence they were derived from. The claims are classified as SUPPORTED, REFUTED or NOTENOUGHINFO by annotators achieving 0.6841 in Fleiss κ. For the first two classes, the annotators also recorded the sentence(s) forming the necessary evidence for their judgment. To characterize the challenge of the dataset presented, we develop a pipeline approach and compare it to suitably designed oracles. The best accuracy we achieve on labeling a claim accompanied by the correct evidence is 31.87%, while if we ignore the evidence we achieve 50.91%. Thus we believe that FEVER is a challenging testbed that will help stimulate progress on claim verification against textual sources.

1 Introduction

The ever-increasing amounts of textual information available combined with the ease in sharing it through the web has increased the demand for verification, also referred to as fact checking. While it has received a lot of attention in the context of journalism, verification is important for other domains, e.g. information in scientific publications, product reviews, etc.

In this paper we focus on verification of textual claims against textual sources. When compared to textual entailment (TE)/natural language inference (Dagan et al., 2009; Bowman et al., 2015), the key difference is that in these tasks the passage to verify each claim is given, and in recent years it typically consists a single sentence, while in verification systems it is retrieved from a large set of documents in order to form the evidence. Another related task is question answering (QA), for which approaches have recently been extended to handle large-scale resources such as Wikipedia (Chen et al., 2017). However, questions typically provide the information needed to identify the answer, while information missing from a claim can often be crucial in retrieving refuting evidence. For example, a claim stating "Fiji's largest island is Kauai." can be refuted by retrieving "Kauai is the oldest Hawaiian Island." as evidence.

Progress on the aforementioned tasks has benefited from the availability of large-scale datasets (Bowman et al., 2015; Rajpurkar et al., 2016). However, despite the rising interest in verification and fact checking among researchers, the datasets currently used for this task are limited to a few hundred claims. Indicatively, the recently conducted Fake News Challenge (Pomerleau and Rao, 2017) with 50 participating teams used a dataset consisting of 300 claims verified against 2,595 associated news articles which is orders of magnitude smaller than those used for TE and QA.

In this paper we present a new dataset for claim verification, FEVER: Fact Extraction and VERification. It consists of 185,445 claims manually verified against the introductory sections of Wikipedia pages and classified as SUPPORTED, REFUTED or NOTENOUGHINFO. For the first two classes, systems and annotators need to also return the combination of sentences forming the necessary evidence supporting or refuting the claim (see Figure 1). The claims were generated by human annotators extracting claims from Wikipedia and mutating them in a variety of ways, some of which were meaning-altering. The verification of each

Proceedings of NAACL-HLT 2018, pages 809–819
New Orleans, Louisiana, June 1 - 6, 2018.

claim was conducted in a separate annotation process by annotators who were aware of the page but not the sentence from which original claim was extracted and thus in 31.75% of the claims more than one sentence was considered appropriate evidence. Claims require composition of evidence from multiple sentences in 16.82% of cases. Furthermore, in 12.15% of the claims, this evidence was taken from multiple pages.

To ensure annotation consistency, we developed suitable guidelines and user interfaces, resulting in inter-annotator agreement of 0.6841 in Fleiss κ (Fleiss, 1971) in claim verification classification, and 95.42% precision and 72.36% recall in evidence retrieval.

To characterize the challenges posed by FEVER we develop a pipeline approach which, given a claim, first identifies relevant documents, then selects sentences forming the evidence from the documents and finally classifies the claim w.r.t. evidence. The best performing version achieves 31.87% accuracy in verification when requiring correct evidence to be retrieved for claims SUPPORTED or REFUTED, and 50.91% if the correctness of the evidence is ignored, both indicating the difficulty but also the feasibility of the task. We also conducted oracle experiments in which components of the pipeline were replaced by the gold standard annotations, and observed that the most challenging part of the task is selecting the sentences containing the evidence. In addition to publishing the data via our website[1], we also publish the annotation interfaces[2] and the baseline system[3] to stimulate further research on verification.

2 Related Works

Vlachos and Riedel (2014) constructed a dataset for claim verification consisting of 106 claims, selecting data from fact-checking websites such as PolitiFact, taking advantage of the labelled claims available there. However, in order to develop claim verification components we typically require the justification for each verdict, including the sources used. While this information is usually available in justifications provided by the journalists, they are not in a machine-readable form. Thus, also considering the small number of claims, the task defined by the dataset proposed remains too challenging for the ML/NLP methods currently available. Wang (2017) extended this approach by including all 12.8K claims available by Politifact via its API, however the justification and the evidence contained in it was ignored in the experiments as it was not machine-readable. Instead, the claims were classified considering only the text and the metadata related to the person making the claim. While this rendered the task amenable to current NLP/ML methods, it does not allow for verification against any sources and no evidence needs to be returned to justify the verdicts.

Claim: The Rodney King riots took place in the most populous county in the USA.

[wiki/Los_Angeles_Riots]
The 1992 Los Angeles riots, also known as the Rodney King riots were a series of riots, lootings, arsons, and civil disturbances that occurred in Los Angeles County, California in April and May 1992.

[wiki/Los_Angeles_County]
Los Angeles County, officially the County of Los Angeles, is the most populous county in the USA.

Verdict: Supported

Figure 1: Manually verified claim requiring evidence from multiple Wikipedia pages.

The Fake News challenge (Pomerleau and Rao, 2017) modelled verification as stance classification: given a claim and an article, predict whether the article supports, refutes, observes (neutrally states the claim) or is irrelevant to the claim. It consists of 50K labelled claim-article pairs, combining 300 claims with 2,582 articles. The claims and the articles were curated and labeled by journalists in the context of the Emergent Project (Silverman, 2015), and the dataset was first proposed by Ferreira and Vlachos (2016), who only classified the claim w.r.t. the article headline instead of the whole article. Similar to recognizing textual entailment (RTE) (Dagan et al., 2009), the systems were provided with the sources to verify against, instead of having to retrieve them.

A differently motivated but closely related dataset is the one developed by Angeli and Manning (2014) to evaluate natural logic inference for common sense reasoning, as it evaluated sim-

[1] http://fever.ai
[2] https://github.com/awslabs/fever
[3] https://github.com/sheffieldnlp/fever-baselines

ple claims such as "not all birds can fly" against textual sources — including Wikipedia — which were processed with an Open Information Extraction system (Mausam et al., 2012). However, the claims were small in number (1,378) and limited in variety as they were derived from eight binary ConceptNet relations (Tandon et al., 2011).

Claim verification is also related to the multilingual Answer Validation Exercise (Rodrigo et al., 2009) conducted in the context of the TREC shared tasks. Apart from the difference in dataset size (1,000 instances per language), the key difference is that the claims being validated were answers returned to questions by QA systems. The questions and the QA systems themselves provide additional context to the claim, while in our task definition the claims are outside any particular context. In the same vein, Kobayashi et al. (2017) collected a dataset of 412 statements in context from high-school student exams that were validated against Wikipedia and history textbooks.

3 Fact extraction and verification dataset

The dataset was constructed in two stages[4] :

Claim Generation Extracting information from Wikipedia and generating claims from it.

Claim Labeling Classifying whether a claim is supported or refuted by Wikipedia and selecting the evidence for it, or deciding there's not enough information to make a decision.

3.1 Task 1 - Claim Generation

The objective of this task was to generate claims from information extracted from Wikipedia. We used the June 2017 Wikipedia dump, processed it with Stanford CoreNLP (Manning et al., 2014), and sampled sentences from the introductory sections of approximately 50,000 popular pages.[5]

The annotators were given a sentence from the sample chosen at random, and were asked to generate a set of **claims** containing a single piece of information, focusing on the entity that its original Wikipedia page was about. We asked the annotators to generate claims about a single fact which could be arbitrarily complex and allowed for a variety of expressions for the entities.

If only the source sentences were used to generate claims then this would result in trivially verifiable claims, as the new claims would in essence be simplifications and paraphrases. At the other extreme, if we allowed world knowledge to be freely incorporated it would result in claims that would be hard to verify on Wikipedia alone. We address this issue by introducing a **dictionary**: a list of terms that were (hyper-)linked in the original sentence, along with the first sentence from their corresponding Wikipedia pages. Using this dictionary, we provide additional knowledge that can be used to increase the complexity of the generated claims in a controlled manner.

The annotators were also asked to generate **mutations** of the claims: altered versions of the original claims, which may or may not change whether they are supported by Wikipedia, or even if they can be verified against it. Inspired by the operators used in Natural Logic Inference (Angeli and Manning, 2014), we specified six types of mutation: paraphrasing, negation, substitution of an entity/relation with a similar/dissimilar one, and making the claim more general/specific.

During trials of the annotation task, we discovered that the majority of annotators had difficulty generating non-trivial negation mutations (e.g. mutations beyond adding "not" to the original). Besides providing numerous examples for each mutation, we also redesigned the annotation interface so that all mutation types were visible at once and highlighted mutations that contained "not" in order to discourage trivial negations. Finally, we provided the annotators with an ontology diagram to illustrate the different levels of entity similarity and class membership.

This process resulted in claims (both extracted and mutated) with a mean length of 9.4 tokens which is comparable to the average hypothesis length of 8.3 tokens in Bowman et al. (2015).

3.2 Task 2 - Claim Labeling

The annotators were asked to label each individual claim generated during Task 1 as SUPPORTED, REFUTED or NOTENOUGHINFO. For the first two cases, the annotators were asked to find the evidence from any page that supports or refutes the claim (see Figure 2 for a screenshot of the interface). In order to encourage inter-annotator consistency, we gave the following general guideline:

[4]The annotation guidelines for both stages are provided in the supplementary materials

[5]These consisted of 5,000 from a Wikipedia 'most accessed pages' list and the pages hyperlinked from them.

> If I was given only the selected sentences, do I have strong reason to believe the claim is true (supported) or stronger reason to believe the claim is false (refuted). If I'm not certain, what additional information (dictionary) do I have to add to reach this conclusion.

In the annotation interface, all sentences from the introductory section of the page for the main entity of the claim and of every linked entity in those sentences were provided as a default source of evidence (left-hand side in Fig. 2). Using this interface the annotators recorded the sentences necessary to justify their classification decisions. In order to allow exploration beyond the main and linked pages, we also allowed annotators to add an arbitrary Wikipedia page by providing its URL and the system would add its introductory section as additional sentences that could be then selected as evidence (right-hand side in Fig. 2). The title of the page could also be used as evidence to resolve co-reference, but this decision was not explicitly recorded. We did not set a hard time limit for the task, but the annotators were advised not to spend more than 2-3 minutes per claim. The label NOTENOUGHINFO was used if the claim could not be supported or refuted by any amount of information in Wikipedia (either because it is too general, or too specific).

3.3 Annotators

The annotation team consisted of a total of 50 members, 25 of which were involved only in the first task. All annotators were native US English speakers and were trained either directly by the authors, or by experienced annotators. The interface for both tasks was developed by the authors in collaboration with an initial team of two annotators. Their notes and suggestions were incorporated into the annotation guidelines.

The majority of the feedback received from the annotators was very positive: they found the task engaging and challenging, and after the initial stages of annotation they had developed an understanding of the needs of the task which let them discuss solutions about edge cases as a group.

3.4 Data Validation

Given the complexity of the second task (claim labeling), we conducted three forms of data validation: 5-way inter-annotator agreement, agreement against *super-annotators* (defined in Section 3.4.2), and manual validation by the authors. The validation for claim generation was done implicitly during claim labeling. As a result 1.01% of claims were skipped, 2.11% contained typos and 6.63% of the generated claims were flagged as too vague/ambiguous and were excluded e.g. or "Sons of Anarchy premiered.".

3.4.1 5-way Agreement

We randomly selected 4% ($n = 7506$) of claims which were not skipped to be annotated by 5 annotators. We calculated the Fleiss κ score (Fleiss, 1971) to be 0.6841 which we consider encouraging given the complexity of the task. In comparison Bowman et al. (2015) reported a κ of 0.7 for a simpler task, since the annotators were given the premise/evidence to verify a hypothesis against without the additional task of finding it.

3.4.2 Agreement against *Super-Annotators*

We randomly selected 1% of the data to be annotated by *super-annotators*: expert annotators with no suggested time restrictions. The purpose of this exercise was to provide as much coverage of evidence as possible. We instructed the *super-annotators* to search over the whole Wikipedia for every possible sentence that could be used as evidence. We compared the regular annotations against this set of evidence and the precision/recall was 95.42% and 72.36% respectively.

3.4.3 Validation by the Authors

As a final quality control step, we chose 227 examples and annotated them for accuracy of the labels and the evidence provided. We found that 91.2% of the examples were annotated correctly. 3% of the claims were mistakes in claim generation that had not been flagged during labeling. We found a similar number of these claims which did not meet the guidelines during a manual error analysis of the baseline system (Section 5.8).

3.4.4 Findings

When compared against the *super-annotators*, all except two annotators achieved $> 90\%$ precision and all but 9 achieved recall $> 70\%$ in evidence retrieval. The majority of the low-recall cases are for claims such as "Akshay Kumar is an actor." where the *super-annotator* added 34 sentences as evidence, most of them being filmography listings (e.g. "In 2000, he starred in the Priyadarshan-directed comedy Hera Pheri").

Figure 2: Screenshot of Task 2 - Claim Labeling

During the validation by the authors, we found that most of the examples that were annotated incorrectly were cases where the label was correct, but the evidence selected was not sufficient (only 4 out of 227 examples were labeled incorrectly according to the guidelines).

We tried to resolve this issue by asking our annotators to err on the side of caution. For example, while the claim "Shakira is Canadian" could be labeled as REFUTED by the sentence "Shakira is a Colombian singer, songwriter, dancer, and record producer", we advocated that unless more explicit evidence is provided (e.g. "She was denied Canadian citizenship"), the claim should be labeled as NOTENOUGHINFO, since dual citizenships are permitted, and the annotators' world knowledge should not be factored in.

A related issue is entity resolution. For a claim like "David Beckham was with United.", it might be trivial for an annotator to accept "David Beckham made his European League debut playing for Manchester United." as supporting evidence. This implicitly assumes that "United" refers to "Manchester United", however there are many Uniteds in Wikipedia and not just football clubs, e.g. United Airlines. The annotators knew the page of the main entity and thus it was relatively easy to resolve ambiguous entities. While we provide this information as part of the dataset, we argue that it should only be used for system training/development.

4 Baseline System Description

We construct a simple pipelined system comprising three components: document retrieval, sentence-level evidence selection and textual entailment. Each component is evaluated in isolation through oracle evaluations on the development set and we report the final accuracies on the test set.

Document Retrieval We use the document retrieval component from the DrQA system (Chen et al., 2017) which returns the k nearest documents for a query using cosine similarity between binned unigram and bigram Term Frequency-Inverse Document Frequency (TF-IDF) vectors.

Sentence Selection Our simple sentence selection method ranks sentences by TF-IDF similarity to the claim. We sort the most-similar sentences first and tune a cut-off using validation accuracy on the development set. We evaluate both DrQA and a simple unigram TF-IDF implementation to rank the sentences for selection. We further evaluate impact of sentence selection on the RTE module by predicting entailment given the original documents without sentence selection.

Recognizing Textual Entailment We compare two models for recognizing textual entailment. For a simple well-performing baseline, we selected Riedel et al. (2017)'s submission from the 2017 Fake News Challenge. It is a multi-layer perceptron (**MLP**) with a single hidden layer which uses term frequencies and TF-IDF cosine similarity between the claim and evidence as features.

Evaluating the state-of-the-art in RTE, we used a decomposable attention (**DA**) model between the claim and the evidence passage (Parikh et al., 2016). We selected it because at the time of development this model was the highest scoring system for the Stanford Natural Language Inference task (Bowman et al., 2015) with publicly available code that did not require the input text to be parsed syntactically, nor was an ensemble.

The RTE component must correctly classify a claim as NOTENOUGHINFO when the evidence retrieved is not relevant or informative. However, the instances labeled as NOTENOUGHINFO have no evidence annotated, thus cannot be used to train RTE for this class. To overcome this issue, we simulate training instances for the NOTENOUGHINFO through two methods: sampling a sentence from the nearest page (NEARESTP) to the claim as evidence using our document retrieval component and sampling a sentence from Wikipedia uniformly at random (RANDOMS).

5 Experiments

5.1 Dataset Statistics

We partitioned the annotated claims into training, development and test sets. We ensured that each Wikipedia page used to generate claims occurs in exactly one set. We reserved a further 19,998 examples for use as a test set for a shared task.

Split	SUPPORTED	REFUTED	NEI
Training	80,035	29,775	35,639
Dev	3,333	3,333	3,333
Test	3,333	3,333	3,333
Reserved	6,666	6,666	6,666

Table 1: Dataset split sizes for SUPPORTED, REFUTED and NOTENOUGHINFO (NEI) classes

5.2 Evaluation

Predicting whether a claim is SUPPORTED, REFUTED or NOTENOUGHINFO is a 3-way classification task that we evaluate using accuracy. In the case of the first two classes, appropriate evidence must be provided, at a sentence-level, to justify the classification. We consider an answer returned correct for the first two classes only if correct evidence is returned. Given that the development and test datasets have balanced class distributions, a random baseline will have $\sim 33\%$ accuracy if one ignores the requirement for evidence for SUPPORTED and REFUTED.

We evaluate the correctness of the evidence retrieved by computing the F_1-score of all the predicted sentences in comparison to the human-annotated sentences for those claims requiring evidence on our complete pipeline system (Section 5.7). As in Fig. 1, some claims require multi-hop inference involving sentences from more than one document to be correctly supported as SUPPORTED/REFUTED. In this case all sentences must be selected for the evidence to be marked as correct. We report this as the proportion of *fully supported claims*. Some claims may be equally supported by different pieces of evidence; in this case one complete set of sentences should be predicted.

Systems that select information that the annotators did not will be penalized in terms of precision. We recognize that it is not feasible to ensure that the evidence selection annotations are complete, nevertheless we argue that they are useful for automatic evaluation during system development. For a more reliable evaluation we advocate crowd-sourcing annotations of false-positive predictions at a later date in a similar manner to the TAC KBP Slot Filler Validation (Ellis et al., 2016).

5.3 Document Retrieval

The document retrieval component of the baseline system returns the k nearest documents to the claim using the DrQA (Chen et al., 2017) TF-IDF implementation to return the k-nearest documents. In the scenario where evidence from multiple documents is required, k must be greater than this figure. We simulate the upper bound in accuracy using an oracle 3-way RTE classifier that predicts SUPPORTED/REFUTED ones correctly only if the documents containing the supporting/refuting evidence are returned by document retrieval and always predicts NOTENOUGHINFO instances correctly independently of the evidence. Results are shown in Table 2.

5.4 Sentence Selection

Mirroring document retrieval, we extract the top l-most similar sentences from the k-most relevant documents using TF-IDF vector similarity. We modified document retrieval component of DrQA (Chen et al., 2017) to select sentences using bigram TF-IDF with binning and compared this to a simple unigram TF-IDF implementation using NLTK (Loper and Bird, 2002). Using the param-

k	Fully Supported (%)	Oracle Accuracy (%)
1	25.31	50.21
5	55.30	70.20
10	65.86	77.24
25	75.92	83.95
50	82.49	90.13
100	86.59	91.06

Table 2: Dev. set document retrieval evaluation.

eters $k = 5$ documents and $l = 5$ sentences, 55.30% of claims (excluding NOTENOUGHINFO) can be fully supported or refuted by the retrieved documents before sentence selection (see Table 2). After applying the sentence selection component, 44.22% of claims can be fully supported using the extracted sentences with DrQA and only 34.03% with NLTK. This would yield oracle accuracies of 62.81% and 56.02% respectively.

5.5 Recognizing Textual Entailment

The RTE component is trained on labeled claims paired with sentence-level. Where multiple sentences are required as evidence, the strings are concatenated. As discussed in Section 4, such data is not annotated for claims labeled NOTENOUGHINFO, thus we compare random sampling-based and similarity-based strategies for generating it. We evaluate classification accuracy on the development set in an oracle evaluation, assuming correct evidence sentences are selected (Table 3). Additionally, for the DA model, we predict entailment given evidence, using the AllenNLP (Gardner et al., 2017) pre-trained Stanford Natural Language Inference (SNLI) model for comparison.

Model	Accuracy (%)		
	NEARESTP	RANDOMS	SNLI
MLP	65.13	73.81	-
DA	80.82	88.00	38.54

Table 3: Oracle classification on claims in the development set using gold sentences as evidence

The random sampling (RANDOMS) approach (where a sentence is sampled at random from Wikipedia in place of evidence for claims labeled as NOTENOUGHINFO) yielded sentences that were not only semantically different to the claim, but also unrelated. While the the accuracy of models trained with sampling approach is higher in oracle evaluation setting, this may not yield a better system in the pipeline setting. In contrast, the nearest page (NEARESTP) method samples a sentence from the highest-ranked page returned by our document retrieval module. This simulates finding related information that may not be sufficient to support or refute a claim. We will evaluate both RANDOMS and NEARESTP in the full pipeline setting, but we will not pursue the SNLI-trained model further as it performed substantially worse.

5.6 Full Pipeline

The complete pipeline consists of the DrQA document retrieval module (Section 5.3), DrQA-based sentence retrieval module (Section 5.4), and the decomposable attention RTE model (Section 5.5). The two parameters: k, describing the number documents and l, describing the number sentences to return were found using grid-search optimizing the RTE accuracy with the DA model. For the pipeline, we set $k = 5$ and $l = 5$ and report the development set accuracy, both with and without the requirement to provide correct evidence for the SUPPORTED/REFUTED predictions (marked as **ScoreEv** and **NoScoreEv** respectively).

Model	Accuracy (%)	
	NoScoreEv	ScoreEv
MLP / NP	41.86	19.04
MLP / RS	40.63	19.42
DA / NP	52.09	**32.57**
DA / RS	50.37	23.53

Table 4: Full pipeline results on development set

The decomposable attention model trained with NEARESTP is the most accurate when evidence is considered. Inspection of the confusion matrices shows that the RANDOMS strategy harms recall for the NOTENOUGHINFO class. This is due to the difference between the sampled pages in the training set and the ones retrieved in the development set causing related but uninformative evidence to be misclassified as SUPPORTED and REFUTED.

Ablation of the sentence selection module We evaluate the impact of the sentence selection module on both the RTE accuracy by removing it.

While the sentence selection module may improve accuracy in the RTE component, it is discarding sentences that are required as evidence to support claims, harming performance (see Section 5.4). We assess the accuracies in both oracle setting (similar to Section 5.5) (see Table 5) as well as in the full pipeline (see Table 6).

In the oracle setting, the decomposable attention models are worst affected by removal of the sentence selection module: exhibiting an substantial decrease in accuracy. The NEARESTP training regime exhibits a 17% decrease and the RANDOMS accuracy decreases by 19%, despite near-perfect recall of the NOTENOUGHINFO class.

Model	Oracle Accuracy (%)	
	NEARESTP	RANDOMS
MLP	57.16	73.36
DA	63.68	69.05

Table 5: Oracle accuracy on claims in the dev. set using gold documents as evidence (c.f. Table 3).

In the pipeline setting, we run the RTE component without sentence selection using $k = 5$ most similar predicted documents. The removal of the sentence selection component decreased the accuracy (NOSCOREEV) approximately 10% for both decomposable attention models.

Model	Accuracy (%)	
	NEARESTP	RANDOMS
MLP	38.85	40.45
DA	41.57	40.62

Table 6: Pipeline accuracy on the dev. set without the sentence selection module (c.f. Table 4).

5.7 Evaluating Full Pipeline on Test Set

We evaluate our pipeline approach on the test set based on the results observed in Section 5.6. First, we use DrQA to select select 5 documents nearest to the claim. Then, we select 5 sentences using our DrQA-based sentence retrieval component and concatenate them. Finally, we predict entailment using the Decomposable Attention model trained with the NEARESTP strategy. The classification accuracy is 31.87%. Ignoring the requirement for correct evidence (**NoScoreEv**) the accuracy is 50.91%, which highlights that while the systems were predicting the correct label, the evidence selected was different to that which the human annotators chose. The recall of the document and sentence retrieval modules for claims which required evidence on the test set was 45.89% (considering complete groups of evidence) and the precision 10.79%. The resulting F_1 score is 17.47%.

5.8 Manual Error Analysis

Using the predictions on the test set, we sampled 961 of the predictions with an incorrect label or incorrect evidence and performed a manual analysis. Of these, 28.51% ($n = 274$) had the correct predicted label but did not satisfy the requirements for evidence. The information retrieval component of the pipeline failed to identify any correct evidence in 58.27% ($n = 560$) of cases which accounted for the large disparity between accuracy of the system when evidence was and was not considered. Where suitable evidence was found, the RTE component incorrectly classified 13.84% ($n = 133$) of claims.

The pipeline retrieved new evidence that had not been identified by annotators in 21.85% ($n = 210$) of claims. This was in-line with our expectation given the measured recall rate of annotators (see Section 3.4.2), who achieved recall of 72.36% of evidence identified by the super-annotators.

We found that 4.05% ($n = 41$) of claims did not meet our guidelines. Of these, there were 11 claims which could be checked without evidence as these either tautologous or self-contradictory. Some correct claims appeared ungrammatical due to the mis-parsing of named entities (e.g. *Exotic Birds* is the name of a band but could be parsed as a type of animal). Annotator errors (where the wrong label was applied) were present in 1.35% ($n = 13$) of incorrectly classified claims.

Interestingly, our system found new evidence that contradicted the gold evidence in 0.52% ($n = 5$) of cases. This was caused either by entity resolution errors or by inconsistent information present in Wikipedia pages (e.g. Pakistan was described as having both the 41st and 42nd largest GDP in two different pages).

5.9 Ablation of Training Data

To evaluate whether the size of the dataset is suitable for training the RTE component of the pipeline, we plot the learning curves for the DA and MLP models (Fig. 3). For each model, we

trained 5 models with different random initializations using the NEARESTP method (see Section 5.5). We selected the highest performing model when evaluated on development set and report the oracle RTE accuracy on the test set. We observe that with fewer than 6000 training instances, the accuracy of DA is unstable. However, with more data, its accuracy increases with respect to the log of the number of training instances and exceeds that of MLP. While both learning curves exhibit the typical diminishing return trends, they indicate that the dataset is large enough to demonstrate the differences of models with different learning capabilities.

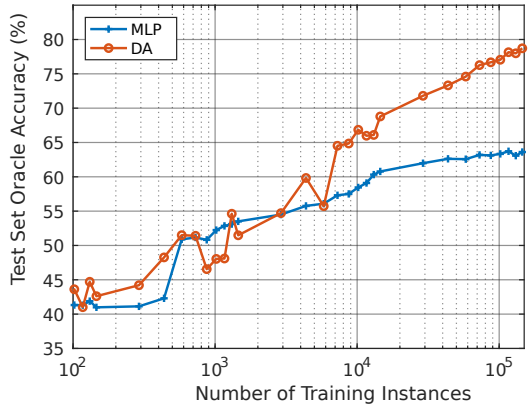

Figure 3: Learning curves for the RTE models.

6 Discussion

The pipeline presented and evaluated in the previous section is one possible approach to the task proposed in our dataset, but we envisage different ones to be equally valid and possibly better performing. For instance, it would be interesting to test how approaches similar to natural logic inference (Angeli and Manning, 2014) can be applied, where a knowledge base/graph is constructed by reading the textual sources and then a reasoning process over the claim is applied, possibly using recent advances in neural theorem proving (Rocktäschel and Riedel, 2017). A different approach could be to consider a combination of question generation (Heilman and Smith, 2010) followed by a question answering model such as BiDAF (Seo et al., 2016), possibly requiring modification as they are designed to select a single span of text from a document rather than return one or more sentences as per our scoring criteria. The sentence-level evidence annotation in our dataset will help develop models selecting and attending to the relevant information from multiple documents and non-contiguous passages. Not only will this enhance the interpretability of predictions, but also facilitate the development of new methods for reading comprehension.

Another use case for the FEVER dataset is claim extraction: generating short concise textual facts from longer encyclopedic texts. For sources like Wikipedia or news articles, the sentences can contain multiple individual claims, making them not only difficult to parse, but also hard to evaluate against evidence. During the construction on the FEVER dataset, we allowed for an extension of the task where simple claims can be extracted from multiple complex sentences.

Finally, we would like to note that while we chose Wikipedia as our textual source, we do not consider it to be the only source of information worth considering in verification, hence not using TRUE or FALSE in our classification scheme. We expect systems developed on the dataset presented to be portable to different textual sources.

7 Conclusions

In this paper we have introduced FEVER, a publicly available dataset for fact extraction and verification against textual sources. We discussed the data collection and annotation methods and shared some of the insights obtained during the annotation process that we hope will be useful to other large-scale annotation efforts.

In order to evaluate the challenge this dataset presents, we developed a pipeline approach that comprises information retrieval and textual entailment components. We showed that the task is challenging yet feasible, with the best performing system achieving an accuracy of 31.87%.

We also discussed other uses for the FEVER dataset and presented some further extensions that we would like to work on in the future. We believe that FEVER will provide a stimulating challenge for claim extraction and verification systems.

Acknowledgments

The work reported was partly conducted while James Thorne was at Amazon Research Cambridge. Andreas Vlachos is supported by the EU H2020 SUMMA project (grant agreement number 688139). The authors would like to thank the team of annotators involved in preparing this dataset.

Abstract

We study the problem of textual relation embedding with distant supervision. To combat the wrong labeling problem of distant supervision, we propose to embed textual relations with *global statistics* of relations, i.e., the co-occurrence statistics of textual and knowledge base relations collected from the entire corpus. This approach turns out to be more robust to the training noise introduced by distant supervision. On a popular relation extraction dataset, we show that the learned textual relation embedding can be used to augment existing relation extraction models and significantly improve their performance. Most remarkably, for the top 1,000 relational facts discovered by the best existing model, the precision can be improved from 83.9% to 89.3%.

1 Introduction

Relation extraction requires deep understanding of the relation between entities. Early studies mainly use hand-crafted features (Kambhatla, 2004; Zhou et al., 2005), and later kernel methods are introduced to automatically generate features (Zelenko et al., 2003; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Zhang et al., 2006). Recently neural network models have been introduced to embed words, relations, and sentences into continuous feature space, and have shown a remarkable success in relation extraction (Socher et al., 2012; Zeng et al., 2014; Xu et al., 2015b; Zeng et al., 2015; Lin et al., 2016). In this work, we study the problem of embedding *textual relations*, defined as the shortest dependency path[1] between two entities in the dependency graph of a sentence, to improve relation extraction.

Textual relations are one of the most discriminative textual signals that lay the foundation of many relation extraction models (Bunescu and Mooney, 2005). A number of recent studies have explored textual relation embedding under the supervised setting (Xu et al., 2015a,b, 2016; Liu et al., 2016), but the reliance on supervised training data limits their scalability. In contrast, we embed textual relations with *distant supervision* (Mintz et al., 2009), which provides much larger-scale training data without the need of manual annotation. However, the assertion of distant supervision, "*any* sentence containing a pair of entities that participate in a knowledge base (KB) relation is likely to express the relation," can be violated more often than not, resulting in many wrongly labeled training examples. A representative example is shown in Figure 1. Embedding quality is thus compromised by the noise in training data.

Our main contribution is a novel way to combat the wrong labeling problem of distant supervision. Traditional embedding methods (Xu et al., 2015a,b, 2016; Liu et al., 2016) are based on *local statistics*, i.e., individual textual-KB relation pairs like in Figure 1 (Left). Our key hypothesis is that *global statistics is more robust to noise than local statistics*. For individual examples, the relation label from distant supervision may be wrong from time to time. But when we zoom out to consider the entire corpus, and collect the global co-occurrence statistics of textual and KB relations, we will have a more comprehensive view of relation semantics: The semantics of a textual relation can then be represented by its co-occurrence distribution of KB relations. For example, the distribution in Figure 1 (Right) indicates that the textual relation SUBJECT $\xleftarrow{\text{nsubjpass}}$ *born* $\xrightarrow{\text{nmod:in}}$ OBJECT mostly means `place_of_birth`, and is also a good indicator of `nationality`, but not `place_of_death`. Although it is still wrongly labeled with `place_of_death` a number of times, the negative impact becomes negligible. Similarly,

* Equally contributed.

...	...	...

Figure 1: The wrong labeling problem of distant supervision, and how to combat it with global statistics. *Left*: conventional distant supervision. Each of the textual relations will be labeled with both KB relations, while only one is correct (blue and solid), and the other is wrong (red and dashed). *Right*: distant supervision with global statistics. The two textual relations can be clearly distinguished by their co-occurrence distribution of KB relations. Statistics are based on the annotated ClueWeb data released in (Toutanova et al., 2015).

we can confidently believe that SUBJECT $\xleftarrow{\text{nsubj}}$ *died* $\xrightarrow{\text{nmod:in}}$ OBJECT means `place_of_death` in spite of the noise. Textual relation embedding learned on such global statistics is thus more robust to the noise introduced by the wrong labeling problem.

We augment existing relation extractions using the learned textual relation embedding. On a popular dataset introduced by Riedel et al. (2010), we show that a number of recent relation extraction models, which are based on local statistics, can be greatly improved using our textual relation embedding. Most remarkably, a new best performance is achieved when augmenting the previous best model with our relation embedding: The precision of the top 1,000 relational facts discovered by the model is improved from 83.9% to 89.3%, a 33.5% decrease in error rate. The results suggest that relation embedding with global statistics can capture complementary information to existing local statistics based models.

The rest of the paper is organized as follows. In Section 2 we discuss related work. For the modeling part, we first describe how to collect global co-occurrence statistics of relations in Section 3, then introduce a neural network based embedding model in Section 4, and finally discuss how to combine the learned textual relation embedding with existing relation extraction models in Section 5. We empirically evaluate the proposed method in Section 6, and conclude in Section 7.

2 Related Work

Relation extraction is an important task in information extraction. Early relation extraction methods are mainly feature-based (Kambhatla, 2004; Zhou et al., 2005), where features in various levels, including POS tags, syntactic and dependency parses, are integrated in a max entropy model. With the popularity of kernel methods, a large number of kernel-based relation extraction methods have been proposed (Zelenko et al., 2003; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Zhang et al., 2006). The most related work to ours is by Bunescu and Mooney (Bunescu and Mooney, 2005), where the importance of shortest dependency path for relation extraction is first validated.

More recently, relation extraction research has been revolving around neural network models, which can alleviate the problem of exact feature matching of previous methods and have shown a remarkable success (e.g., (Socher et al., 2012; Zeng et al., 2014)). Among those, the most related are the ones embedding shortest dependency paths with neural networks (Xu et al., 2015a,b, 2016; Liu et al., 2016). For example, Xu et al. (2015b) use a RNN with LSTM units to embed shortest dependency paths without typed dependency relations, while a convolutional neural network is used in (Xu et al., 2015a). However, they are all based on the supervised setting with a limited scale. In contrast, we embed textual relations with distant supervision (Mintz et al., 2009), which provides much larger-scale training data at a low cost.

Various efforts have been made to combat the long-criticized wrong labeling problem of distant supervision. Riedel et al. (2010), Hoffmann et al. (2011), and Surdeanu et al. (2012) have attempted a multi-instance learning (Dietterich et al., 1997) framework to soften the assumption of distant supervision, but their models are still feature-based. Zeng et al. (2015) combine multi-instance learning with neural networks, with the assumption that at least one of the contextual sentences of an entity pair is expressing the target relation, but this will lose useful information in the neglected sentences. Instead, Lin et al. (2016) use all the contextual sentences, and introduce an attention mechanism to weight the contextual sentences. Li et al. (2017) also use an attention

mechanism to weight contextual sentences, and incorporate additional entity description information from knowledge bases. Luo et al. (2017) manage to alleviate the negative impact of noise by modeling and learning noise transition patterns from data. Liu et al. (2017) propose to infer the true label of a context sentence using a truth discovery approach (Li et al., 2016). Wu et al. (2017) incorporate adversarial training, i.e., injecting random perturbations in training, to improve the robustness of relation extraction. Using PCNN+ATT (Lin et al., 2016) as base model, they show that adversarial training can improve its performance by a good margin. However, the base model implementation used by them performed inferior to the one in the original paper and in ours, and therefore the results are not directly comparable. No prior study has exploited global statistics to combat the wrong labeling problem of distant supervision. Another unique aspect of this work is that we focus on compact textual relations, while previous studies along this line have focused on whole sentences.

In universal schema (Riedel et al., 2013) for KB completion and relation extraction as well as its extensions (Toutanova et al., 2015; Verga et al., 2016), a binary matrix is constructed from the entire corpus, with entity pairs as rows and textual/KB relations as columns. A matrix entry is 1 if the relational fact is observed in training, and 0 otherwise. Embeddings of entity pairs and relations, either directly or via neural networks, are then learned on the matrix entries, which are still individual relational facts, and the wrong labeling problem remains. Global co-occurrence frequencies (see Figure 1 (Right)) are not taken into account, which is the focus of this study. Another distinction is that our method directly models the association between textual and KB relations, while universal schema learns embedding for shared entity pairs and use that as a bridge between the two types of relations. It is an interesting venue for future research to comprehensively compare these two modeling approaches.

3 Global Statistics of Relations

When using a corpus to train statistical models, there are two levels of statistics to exploit: *local* and *global*. Take word embedding as an example. The skip-gram model (Mikolov et al., 2013) is based on local statistics: During training, we sweep through the corpus and slightly tune the embedding model in each local window (e.g., 10 consecutive words). In contrast, in global statistics based methods, exemplified by latent semantic analysis (Deerwester et al., 1990) and GloVe (Pennington et al., 2014), we process the entire corpus to collect global statistics like word-word co-occurrence counts, normalize the raw statistics, and train an embedding model directly on the normalized global statistics.

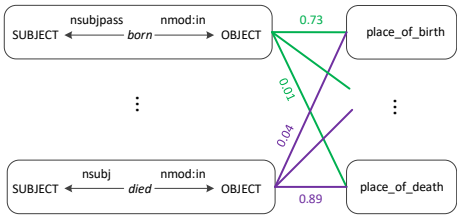

Figure 2: Relation graph. The left node set is textual relations, and the right node set is KB relations. The raw co-occurrence counts are normalized such that the KB relations corresponding to the same textual relation form a valid probability distribution. Edges are colored by textual relation and weighted by normalized co-occurrence statistics.

Most existing studies on relation extraction are based on local statistics of relations, i.e., models are trained on individual relation examples. In this section, we describe how we collect global co-occurrence statistics of textual and KB relations, and how to normalize the raw statistics. By the end of this section a bipartite *relation graph* like Figure 2 will be constructed, with one node set being textual relations $\mathcal{T}$, and the other being KB relations $\mathcal{R}$. The edges are weighted by the normalized co-occurrence statistics of relations.

3.1 Relation Graph Construction

Given a corpus and a KB, we first do entity linking on each sentence, and do dependency parsing if at least two entities are identified[2]. For each entity pair (e, e') in the sentence, we extract the fully lexicalized shortest dependency path as a textual relation t, forming a *relational fact* (e, t, e'). There are two outcomes from this step: a set of textual relations $\mathcal{T} = \{t_i\}$, and the *support* $S(t_i)$ for each t_i. The support of a textual relation is a *multiset* containing the entity pairs of the textual relation. The *multiplicity* of an entity pair, $m_{S(t_i)}(e, e')$, is the number of occurrences of the corresponding relational fact (e, t_i, e') in

[2]In the experiments entity linking is assumed given, and dependency parsing is done using Stanford Parser (Chen and Manning, 2014) with universal dependencies.

the corpus. For example, if the support of t_i is $S(t_i) = \{(e_1, e_1'), (e_1, e_1'), (e_2, e_2'), \dots\}$, entity pair (e_1, e_1') has a multiplicity of 2 because the relational fact (e_1, t_i, e_1') occur in two sentences. We also get a set of KB relations $\mathcal{R} = \{r_j\}$, and the support $S(r_j)$ of a KB relation r_j is the set of entity pairs having this relation in the KB, i.e., there is a relational fact (e, r_j, e') in the KB. The number of *co-occurrences* of a textural relation t_i and a KB relation r_j is

$$n_{ij} = \sum_{(e,e') \in S(r_j)} m_{S(t_i)}(e, e'), \qquad (1)$$

i.e., every occurrence of relational fact (e, t_i, e') is counted as a co-occurrence of t_i and r_j if $(e, e') \in S(r_j)$. A bipartite relation graph can then be constructed, with $\mathcal{T}$ and $\mathcal{R}$ as the node sets, and the edge between t_i and r_j has weight n_{ij} (no edge if $n_{ij} = 0$), which will be normalized later.

3.2 Normalization

The raw co-occurrence counts have a heavily skewed distribution that spans several orders of magnitude: A small portion of relation pairs co-occur highly frequently, while most relation pairs co-occur only a few times. For example, a textual relation, SUBJECT $\xleftarrow{\text{nsubjpass}}$ *born* $\xrightarrow{\text{nmod:in}}$ OBJECT, may co-occur with the KB relation `place_of_birth` thousands of times (e.g., "*Michelle Obama was born in Chicago*"), while a synonymous but slightly more compositional textual relation, SUBJECT $\xleftarrow{\text{nsubjpass}}$ *born* $\xrightarrow{\text{nmod:in}}$ *city* $\xrightarrow{\text{nmod:of}}$ OBJECT, may only co-occur with the same KB relation a few times in the entire corpus (e.g., "*Michelle Obama was born in the city of Chicago*"). Learning directly on the raw co-occurrence counts, an embedding model may put a disproportionate amount of weight on the most frequent relations, and may not learn well on the majority of rarer relations. Proper normalization is therefore necessary, which will encourage the embedding model to learn good embedding not only for the most frequent relations, but also for the rarer relations.

A number of normalization strategies have been proposed in the context of word embedding, including correlation- and entropy-based normalization (Rohde et al., 2005), positive pointwise mutual information (PPMI) (Bullinaria and Levy, 2007), and some square root type transformation (Lebret and Collobert, 2014). A shared goal is to reduce the impact of the most frequent words, e.g., "the" and "is," which tend to be less informative for the purpose of embedding.

We have experimented with a number of normalization strategies and found that the following strategy works best for textual relation embedding: For each textual relation, we normalize its co-occurrence counts to form a probability distribution over KB relations. The new edge weights of the relation graph thus become $w_{ij} = \tilde{p}(r_j|t_i) = n_{ij} / \sum_{j'} n_{ij'}$. Every textual relation is now associated with a set of edges whose weights sum up to 1. We also experimented with PPMI and smoothed PPMI with $\alpha = 0.75$ (Levy et al., 2015) that are commonly used in word embedding. However, the learned textual relation embedding turned out to be not very helpful for relation extraction. One possible reason is that PPMI (even the smoothed version) gives inappropriately large weights to rare relations (Levy et al., 2015). There are many textual relations that correspond to none of the target KB relations but are falsely labeled with some KB relations a few times by distant supervision. PPMI gives large weights to such falsely labeled cases because it thinks these events have a chance significantly higher than random.

4 Textual Relation Embedding

Next we discuss how to learn embedding of textual relations based on the constructed relation graph. We call our approach **Glo**bal **R**elation **E**mbedding (GloRE) in light of global statistics of relations.

4.1 Embedding via RNN

Given the relation graph, a straightforward way of relation embedding is matrix factorization, similar to latent semantic analysis (Deerwester et al., 1990) for word embedding. However, textual relations are different from words in that they are sequences composed of words and typed dependency relations. Therefore, we use recurrent neural networks (RNNs) for embedding, which respect the compositionality of textual relations and can learn the shared sub-structures of different textual relations (Toutanova et al., 2015). For the examples in Figure 1, an RNN can learn, from both textual relations, that the shared dependency relation "nmod:in" is indicative of location modifiers. It is worth noting that other models like convolutional neural networks can also be used, but it is not the focus of this paper to compare all the alternative embedding models; rather, we aim to show

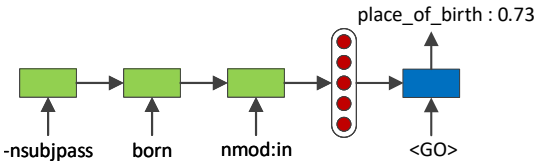

Figure 3: Embedding model. *Left*: A RNN with GRU for embedding. *Middle*: embedding of textual relation. *Right*: a separate GRU cell to map a textual relation embedding to a probability distribution over KB relations.

the effectiveness of global statistics with a reasonable embedding model.

For a textual relation, we first decompose it into a sequence of tokens $\{x_1, ..., x_m\}$, which includes lexical words and directional dependency relations. For example, the textual relation SUBJECT $\xleftarrow{\text{nsubjpass}}$ *born* $\xrightarrow{\text{nmod:in}}$ OBJECT is decomposed to a sequence of three tokens $\{-\text{nsubjpass}, \text{born}, \text{nmod:in}\}$, where "$-$" represents a left arrow. Note that we include directional dependency relations, because both the relation type and the direction are critical in determining the meaning of a textual relation. For example, the dependency relation "nmod:in" often indicates a location modifier and is thus strongly associated with location-related KB relations like `place_of_birth`. The direction also plays an important role. Without knowing the direction of the dependency relations, it is impossible to distinguish `child_of` and `parent_of`.

An RNN with gated recurrent units (GRUs) (Cho et al., 2014) is then applied to consecutively process the sequence as shown in Figure 3. We have also explored more advanced constructs like attention, but the results are similar, so we opt for a vanilla RNN in consideration of model simplicity.

Let ϕ denote the function that maps a token x_l to a fixed-dimensional vector, the hidden state vectors of the RNN are calculated recursively:

$$\boldsymbol{h}_l = \text{GRU}\big(\phi(x_l), \boldsymbol{h}_{l-1}\big). \tag{2}$$

GRU follows the definition in Cho et al. (2014).

4.2 Training Objective

We use global statistics in the relation graph to train the embedding model. Specifically, we model the semantics of a textual relation as its co-occurrence distribution of KB relations, and learn textual relation embedding to reconstruct the corresponding co-occurrence distributions.

We use a separate GRU cell followed by softmax to map a textual relation embedding to a distribution over KB relations; the full model thus resembles the sequence-to-sequence architecture (Sutskever et al., 2014). Given a textual relation t_i and its embedding $\boldsymbol{h}_m$, the predicted conditional probability of a KB relation r_j is thus:

$$p(r_j|t_i) = \text{softmax}(\text{GRU}(\phi(<\text{GO}>), \boldsymbol{h}_m))_j, \tag{3}$$

where $()_j$ denotes the j-th element of a vector, and <GO>is a special token indicating the start of decoding. The training objective is to minimize

$$\Theta = \frac{1}{|\mathcal{E}|} \sum_{i,j:\tilde{p}(r_j|t_i)>0} \left(\log p(r_j|t_i) - \log \tilde{p}(r_j|t_i)\right)^2, \tag{4}$$

where $\mathcal{E}$ is the edge set of the relation graph. It is modeled as a regression problem, similar to GloVe (Pennington et al., 2014).

Baseline. We also define a baseline approach where the unnormalized co-occurrence counts are directly used. The objective is to maximize:

$$\Theta' = \frac{1}{\sum_{i,j} n_{ij}} \sum_{i,j:n_{ij}>0} n_{ij} \log p(r_j|t_i). \tag{5}$$

It also corresponds to local statistics based embedding, i.e., when the embedding model is trained on individual occurrences of relational facts with distant supervision. Therefore, we call it **Lo**cal **R**elation **E**mbedding (LoRE).

5 Augmenting Relation Extraction

Learned from global co-occurrence statistics of relations, our approach provides semantic matching information of textual and KB relations, which is often complementary to the information captured by existing relation extraction models. In this section we discuss how to combine them together to achieve better relation extraction performance.

We follow the setting of distantly supervised relation extraction. Given a text corpus and a KB with relation set $\mathcal{R}$, the goal is to find new relational facts from the text corpus that are not already contained in the KB. More formally, for each entity pair (e, e') and a set of *contextual sentences* C containing this entity pair, a relation extraction model assigns a score $E(z|C)$ to each candidate relational fact $z = (e, r, e'), r \in \mathcal{R}$. On the

other hand, our textual relation embedding model works on the sentence level. It assign a score $G(z|s)$ to each contextual sentence s in C as for how well the textual relation t between the entity pair in the sentence matches the KB relation r, i.e., $G(z|s) = p(r|t)$. It poses a challenge to aggregate the sentence-level scores to get a set-level score $G(z|C)$, which can be used to combine with the original score $E(z|C)$ to get a better evaluation of the candidate relational fact.

One straightforward aggregation is max pooling, i.e., only using the largest score $\max_{s \in C} G(z|s)$, similar to the at-least-one strategy used by Zeng et al. (2015). But it will lose the useful signals from those neglected sentences (Lin et al., 2016). Because of the wrong labeling problem, mean pooling is problematic as well. The wrongly labeled contextual sentences tend to make the aggregate scores more evenly distributed and therefore become less informative. The number of contextual sentences positively supporting a relational fact is also an important signal, but is lost in mean pooling.

Instead, we use summation with a trainable cap:

$$G(z|C) = \min\left(cap, \sum_{s \in C} G(z|s)\right), \qquad (6)$$

In other words, we additively aggregate the signals from all the contextual sentences, but only to a bounded degree.

We simply use a weighted sum to combine $E(z|C)$ and $G(z|C)$, where the trainable weights will also handle the possibly different scale of scores generated by different models:

$$\tilde{E}(z|C) = w_1 E(z|C) + w_2 G(z|C). \qquad (7)$$

The original score $E(z|C)$ is then replaced by the new score $\tilde{E}(z|C)$. To find the optimal values for w_1, w_2 and cap, we define a hinge loss:

$$\Theta_{Merge} = \frac{1}{K} \sum_{k=1}^{K} \max\left\{0, 1 + \tilde{E}(z_k^-) - \tilde{E}(z_k^+)\right\}, \qquad (8)$$

where $\{z_k^+\}_{k=1}^K$ are the true relational facts from the KB, and $\{z_k^-\}_{k=1}^K$ are false relational facts generated by replacing the KB relation in true relational facts with incorrect KB relations.

Data	# of sentences	# of entity pairs	# of relational facts from KB

Table 1: Statistics of the NYT dataset.

6 Experiments

In this experimental study, we show that GloRE can greatly improve the performance of several recent relation extraction models, including the previous best model on a standard dataset.

6.1 Experimental Setup

Dataset. Following the literature (Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016), we use the relation extraction dataset introduced in (Riedel et al., 2010), which was generated by aligning New York Times (NYT) articles with Freebase (Bollacker et al., 2008). Articles from year 2005-2006 are used as training, and articles from 2007 are used as testing. Some statistics are listed in Table 1. There are 53 target KB relations, including a special relation NA indicating that there is no target relation between entities.

We follow the approach described in Section 3 to construct the relation graph from the NYT training data. The constructed relation graph contains 321,447 edges with non-zero weight. We further obtain a training set and a validation set from the edges of the relation graph. We have observed that using a validation set totally disjoint from the training set leads to unstable validation loss, so we randomly sample 300K edges as the training set, and another 60K as the validation set. The two sets can have some overlap. For the merging model (Eq. 8), 10% of the edges are reserved as the validation set.

Relation extraction models. We evaluate with four recent relation extraction models whose source code is publicly available[3]. We use the optimized parameters provided by the authors.

- **CNN+ONE** and **PCNN+ONE** (Zeng et al., 2015): A convolutional neural network (CNN) is used to embed contextual sentences for relation classification. Multi-instance learning with at-least-one (ONE) assumption is used to combat the wrong labeling problem. In PCNN, piecewise max pooling is

[3] https://github.com/thunlp/NRE

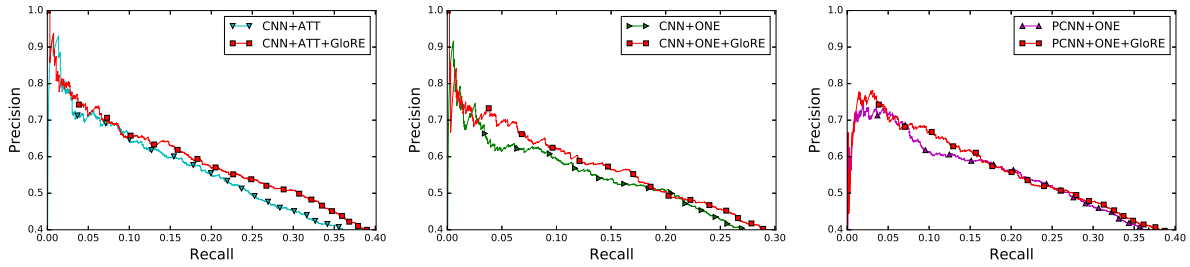

Figure 4: Held-out evaluation: other base relation extraction models and the improved versions when augmented with GloRE.

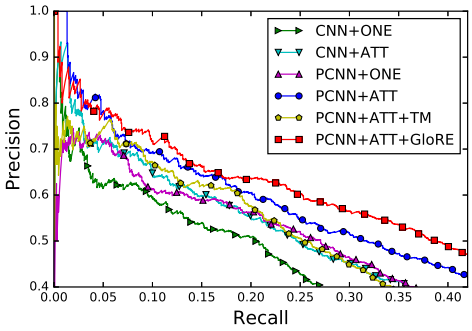

Figure 5: Held-out evaluation: the previous best-performing model can be further improved when augmented with GloRE. PCNN+ATT+TM is a recent model (Luo et al., 2017) whose performance is slightly inferior to PCNN+ATT. Because the source code is not available, we did not experiment to augment this model with GloRE. Another recent method (Wu et al., 2017) incorporates adversarial training to improve PCNN+ATT, but the results are not directly comparable (see Section 2 for discussion). Finally, Ji et al. (2017) propose a model similar to PCNN+ATT, but the performance is inferior to PCNN+ATT and is not shown here for clarity.

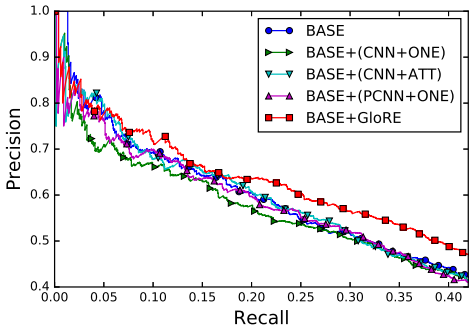

Figure 6: Held-out evaluation: GloRE brings the largest improvement to BASE (PCNN+ATT), which further shows that GloRE captures useful information for relation extraction that is complementary to existing models.

used to handle the three pieces of a contextual sentence (split by the two entities) separately.

- **CNN+ATT** and **PCNN+ATT** (Lin et al., 2016): Different from the at-least-one assumption which loses information in the neglected sentences, these models learn soft attention weights (ATT) over contextual sentences and thus can use the information of all the contextual sentences. *PCNN+ATT is the best-performing model on the NYT dataset.*

Evaluation settings and metrics. Similar to previous work (Riedel et al., 2010; Zeng et al., 2015), we use two settings for evaluation: (1) Held-out evaluation, where a subset of relational facts in KB is held out from training (Table 1), and is later used to compare against newly discovered relational facts. This setting avoids human labor but can introduce some false negatives because of the incompleteness of the KB. (2) Manual evaluation, where the discovered relational facts are manually judged by human experts. For held-out evaluation, we report the precision-recall curve. For manual evaluation, we report $Precision@N$, i.e., the precision of the top N discovered relational facts.

Implementation. Hyper-parameters of our model are selected based on the validation set. For the embedding model, the mini-batch size is set to 128, and the state size of the GRU cells is 300. For the merging model, the mini-batch size is set to 1024. We use Adam with parameters recommended by the authors for optimization. Word embeddings are initialized with the 300-dimensional word2vec vectors pre-trained on the Google News corpus[4]. Early stopping based on the validation set is employed. Our model is implemented using Tensorflow (Abadi et al., 2016), and the source code is available at https://github.com/pputiu/GloRE.

[4] https://code.google.com/archive/p/word2vec/

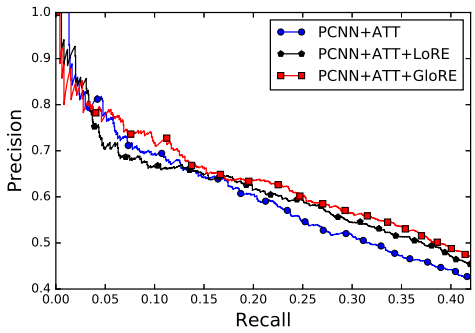

Figure 7: Held-out evaluation: LoRE vs. GloRE.

6.2 Held-out Evaluation

Existing Models + GloRE. We first show that our approach, GloRE, can improve the performance of the previous best-performing model, PCNN+ATT, leading to a new state of the art on the NYT dataset. As shown in Figure 5, when PCNN+ATT is augmented with GloRE, a consistent improvement along the precision-recall curve is observed. It is worth noting that although PCNN+ATT+GloRE seems to be inferior to PCNN+ATT when recall < 0.05, as we will show via manual evaluation, it is actually due to false negatives.

We also show in Figure 4 that the improvement brought by GloRE is general and not specific to PCNN+ATT; the other models also get a consistent improvement when augmented with GloRE.

To investigate whether the improvement brought by GloRE is simply from ensemble, we also augment PCNN+ATT with the other three base models in the same way as described in Section 5. The results in Figure 6 show that pairwise ensemble of existing relation extraction models does not yield much improvement, and GloRE brings much larger improvement than the other models.

In summary, the held-out evaluation results suggest that GloRE captures useful information for relation extraction that is not captured by these local statistics based models.

LoRE v.s. GloRE. We compare GloRE with the baseline approach LoRE (Section 4) to show the advantage of normalization on global statistics. We use PCNN+ATT as the base relation extraction model. As shown in Figure 7, GloRE consistently outperforms LoRE. It is worth noting that LoRE can still improve the base relation extraction model when recall > 0.15, further confirming the usefulness of directly embedding textual relations in addition to sentences.

Precision@N	100	300	500	700	900	1000
PCNN+ATT	**97.0**	93.7	92.8	89.1	85.2	83.9
PCNN+ATT+LoRE	**97.0**	95.0	94.2	91.6	89.6	87.0
PCNN+ATT+GloRE	**97.0**	**97.3**	**94.6**	**93.3**	**90.1**	**89.3**

Table 2: Manual evaluation: false negatives from held-out evaluation are manually corrected by human experts.

6.3 Manual Evaluation

Due to the incompleteness of the knowledge base, held-out evaluation introduces some false negatives. The precision from held-out evaluation is therefore a lower bound of the true precision. To get a more accurate evaluation of model performance, we have human experts to manually check the false relational facts judged by held-out evaluation in the top 1,000 predictions of three models, PCNN+ATT, PCNN+ATT+LoRE and PCNN+ATT+GloRE, and report the corrected results in Table 2. Each prediction is examined by two human experts who reach agreement with discussion. To ensure fair comparison, the experts are not aware of the provenance of the predictions. Under manual evaluation, PCNN+ATT+GloRE achieves the best performance in the full range of N. In particular, for the top 1,000 predictions, GloRE improves the precision of the previous best model PCNN+ATT from 83.9% to 89.3%. The manual evaluation results reinforce the previous observations from held-out evaluation.

6.4 Case Study

Table 3 shows two examples. For better illustration, we choose entity pairs that have only one contextual sentence.

For the first example, PCNN+ATT predicts that most likely there is no KB relation between the entity pair, while both LoRE and GloRE identify the correct relation with high confidence. The textual relation clearly indicates that the head entity is (appos) a criminologist at (nmod:at) the tail entity.

For the second example, there is no KB relation between the entity pair, and PCNN+ATT is indeed able to rank NA at the top. However, it is still quite confused by `nationality`, probably because it has learned that sentences about a person and a country with many words about profession ("poet," "playwright," and "novelist")

Contextual Sentence	Textual Relation	PCNN+ATT Predictions	LoRE Predictions	GloRE Predictions
[**Alfred Blumstein**]$_{head}$, a criminologist at [**Carnegie Mellon University**]$_{tail}$, called ...	$\xleftarrow{\text{appos}}$ criminologist $\xrightarrow{\text{nmod:at}}$	NA (0.63) **employee_of** (0.36) founder_of (0.00)	**employee_of** (1.00) NA (0.00) founder_of (0.00)	**employee_of** (0.96) NA (0.02) founder_of (0.02)
[**Langston Hughes**]$_{head}$, the American poet, playwright and novelist, came to [**Spain**]$_{tail}$ to ...	$\xleftarrow{\text{-nsubj}}$ came $\xrightarrow{\text{to}}$	**NA** (0.58) nationality (0.38) place_lived (0.01)	place_of_death (0.35) **NA** (0.33) nationality (0.21)	**NA** (0.73) contain_location (0.07) employee_of (0.06)

Table 3: Case studies. We select entity pairs that have only one contextual sentence, and the head and tail entities are marked. The top 3 predictions from each model with the associated probabilities are listed, with the correct relation bold-faced.

likely express the person's nationality. As a result, its prediction on NA is not very confident. On the other hand, GloRE learns that if a person "came to" a place, likely it is not his/her birthplace. In the training data, due to the wrong labeling problem of distant supervision, the textual relation is wrongly labeled with `place_of_death` and `nationality` a couple of times, and both PCNN+ATT and LoRE suffer from the training noise. Taking advantage of global statistics, GloRE is more robust to such noise introduced by the wrong labeling problem.

7 Conclusion

Our results show that textual relation embedding trained on global co-occurrence statistics captures useful relational information that is often complementary to existing methods. As a result, it can greatly improve existing relation extraction models. Large-scale training data of embedding can be easily solicited from distant supervision, and the global statistics of relations provide a natural way to combat the wrong labeling problem of distant supervision.

The idea of relation embedding based on global statistics can be further expanded along several directions. In this work we have focused on embedding textual relations, but it is in principle beneficial to jointly embed knowledge base relations and optionally entities. Recently a joint embedding approach has been attempted in the context of knowledge base completion (Toutanova et al., 2015), but it is still based on local statistics, i.e., individual relational facts. Joint embedding with global statistics remains an open problem. Compared with the size of the training corpora for word embedding (up to hundred of billions of tokens), the NYT dataset is quite small in scale. Another interesting venue for future research is to construct much larger-scale distant supervision datasets to train general-purpose textual relation embedding that can help a wide range of downstream relational tasks such as question answering and textual entailment.

Implicit Argument Prediction with Event Knowledge

Abstract

Implicit arguments are not syntactically connected to their predicates, and are therefore hard to extract. Previous work has used models with large numbers of features, evaluated on very small datasets. We propose to train models for implicit argument prediction on a simple cloze task, for which data can be generated automatically at scale. This allows us to use a neural model, which draws on narrative coherence and entity salience for predictions. We show that our model has superior performance on both synthetic and natural data. [1]

1 Introduction

When parts of an event description in a text are missing, this event cannot be easily extracted, and it cannot easily be found as the answer to a question. This is the case with *implicit arguments*, as in this example from the reading comprehension dataset of Hermann et al. (2015):

> **Text:** More than 2,600 people have been infected by Ebola in Liberia, Guinea, Sierra Leone and Nigeria since the *outbreak* began in December, according to the World Health Organization. Nearly 1,500 have *died*.
>
> **Question:** The X outbreak has killed nearly 1,500.

In this example, it is Ebola that broke out, and Ebola was also the cause of nearly 1,500 people dying, but the text does not state this explicitly. *Ebola* is an implicit argument of both *outbreak* and *die*, which is crucial to answering the question.

We are particularly interested in implicit arguments that, like *Ebola* in this case, do appear in the text, but not as syntactic arguments of their predicates. Event knowledge is key to determining implicit arguments. In our example, diseases are maybe the single most typical things to *break out*, and diseases also typically kill people.

The task of identifying implicit arguments was first addressed by Gerber and Chai (2010) and Ruppenhofer et al. (2010). However, the datasets for the task were very small, and to our knowledge there has been very little further development on the task since then.

In this paper, we address the data issue by training models for implicit argument prediction on a simple cloze task, similar to the narrative cloze task (Chambers and Jurafsky, 2008), for which data can be generated automatically at scale. This allows us to train a neural network to perform the task, building on two insights. First, event knowledge is crucial for implicit argument detection. Therefore we build on models for narrative event prediction (Granroth-Wilding and Clark, 2016; Pichotta and Mooney, 2016a), using them to judge how coherent the narrative would be when we fill in a particular entity as the missing (implicit) argument. Second, the omitted arguments tend to be salient, as *Ebola* is in the text from which the above example is taken. So in addition to narrative coherence, our model takes into account entity salience (Dunietz and Gillick, 2014).

In an evaluation on a large automatically generated dataset, our model clearly outperforms even strong baselines, and we find salience features to be important to the success of the model. We also evaluate against a variant of the Gerber and Chai (2012) model that does not rely on gold features, finding that our simple neural model outperforms their much more complex model.

Our paper thus makes two major contributions. 1) We propose an argument cloze task to generate synthetic training data at scale for implicit argument prediction. 2) We show that neural event

Proceedings of NAACL-HLT 2018, pages 831–840
New Orleans, Louisiana, June 1 - 6, 2018.

models for narrative schema prediction can be used on implicit argument prediction, and that a straightforward combination of event knowledge and entity salience can do well on the task.

2 Related Work

While dependency parsing and semantic role labeling only deal with arguments that are available in the syntactic context of the predicate, implicit argument labeling seeks to find argument that are not syntactically connected to their predicates, like *Ebola* in our introductory example.

The most relevant work on implicit argument prediction came from Gerber and Chai (2010), who built an implicit arguments dataset by selecting 10 nominal predicates from NomBank (Meyers et al., 2004) and manually annotating implicit arguments for all occurrences of these predicates. In an analysis of their data they found implicit arguments to be very frequent, as their annotation added 65% more arguments to NomBank. Gerber and Chai (2012) also trained a linear classifier for the task relying on many hand-crafted features, including gold features from FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005) and NomBank. This classifier has, to the best of our knowledge, not been outperformed by follow-up work (Laparra and Rigau, 2013; Schenk and Chiarcos, 2016; Do et al., 2017). We evaluate on the Gerber and Chai dataset below. Ruppenhofer et al. (2010) also introduced an implicit argument dataset, but we do not evaluate on it as it is even smaller and much more complex than Gerber and Chai (2010). More recently, Modi et al. (2017) introduced the referent cloze task, in which they predicted a manually removed discourse referent from a human annotated narrative text. This task is closely related to our argument cloze task.

Since we intend to exploit event knowledge in predicting implicit arguments, we here refer to recent work on statistical script learning, started by Chambers and Jurafsky (2008, 2009). They introduced the idea of using statistical information on coreference chains to induce prototypical sequences of narrative events and participants, which is related to the classical notion of a script (Schank and Abelson, 1977). They also proposed the narrative cloze evaluation, in which one event is removed at random from a sequence of narrative events, then the missing event is predicted given all context events. We use a similar trick to define a cloze task for implicit argument prediction, discussed in Section 3.

Many follow-up papers on script learning have used neural networks. Rudinger et al. (2015) showed that sequences of events can be efficiently modeled by a log-bilinear language model. Pichotta and Mooney (2016a,b) used an LSTM to model a sequence of events. Granroth-Wilding and Clark (2016) built a network that produces an event representation by composing its components. To do the cloze task, they select the most probable event based on pairwise event coherence scores. For our task we want to do something similar: We want to predict how coherent a narrative would be with a particular entity candidate filling the implicit argument position. So we take the model of Granroth-Wilding and Clark (2016) as our starting point.

The Hermann et al. (2015) reading comprehension task, like our cloze task, requires systems to guess a removed entity. However in their case the entity is removed in a summary, not in the main text. In their case, the task typically amounts to finding a main text passage that paraphrases the sentence with the removed entity; this is not the case in our cloze task.

3 The Argument Cloze Task

We present the **argument cloze** task, which allows us to automatically generate large scale data for training (Section 6.1) and evaluation (Section 5.1).

In this task, we randomly remove an entity from an argument position of one event in the text. The entity in question needs to appear in at least one other place in the text. The task is then for the model to pick, from all entities appearing in the text, the one that has been removed. We first define what we mean by an event, then what we mean by an entity. Like Pichotta and Mooney (2016a); Granroth-Wilding and Clark (2016), we define an *event* e as consisting of a verbal predicate v, a subject s, a direct object o, and a prepositional object p (along with the preposition). Here we only allow one prepositional argument in the structure, to avoid variable length input in the event composition model.[2] By an *entity*, we mean a coreference chain with a length of at least two – that is, the entity needs to appear at least twice in the text.

For example, from a piece of raw text (Figure

[2]In case of multiple prepositional objects, we select the one that is closest to the predicate.

Manville Corp. said it will build a $ 24 million power plant to provide electricity to its Igaras pulp and paper mill in Brazil .

The company said the plant will ensure that it has adequate energy for the mill and will reduce the mill's energy costs .

(a) A piece of raw text from OntoNotes corpus.

e_1: (*provide-pred*, —, *electricity-dobj*, ***??-prep_to***)

x_0 = The company x_1 = mill x_2 = power plant

(c) Example of an argument cloze task for *prep_to* of e_1.

Figure 1: Example of automatically extracted events and entities and an argument cloze task.

1a), we automatically extract a sequence of events from a dependency parse, and a list of entities from coreference chains. In Figure 1b, e_0~e_4 are events, x_0~x_2 are entities. The arguments *electricity-dobj* and *energy-dobj* are not in coreference chains and are thus not candidates for removal. An example of the argument cloze task is shown in Figure 1c. Here the *prep_to* argument of e_1 has been removed.

Coreference resolution is very noisy. Therefore we use gold coreference annotation for creating evaluation data, but automatically generated coreference chains for creating training data.

4 Methods

4.1 Modeling Narrative Coherence

We model implicit argument prediction as selecting the entity that, when filled in as the implicit argument, makes the overall most coherent narrative. Suppose we are trying to predict the direct object argument of some target event e_t. Then we complete e_t by putting an entity candidate into the direct object argument position, and check the coherence of the resulting event with the rest of the narrative. Say we have a sequence of events $e_1, e_2, \ldots, e_n$ in a narrative, and a list of entity candidates $x_1, x_2, \ldots, x_m$. Then for any candidate x_j, we first complete the target event to be

$$e_t(j) = (v_t, s_t, x_j, p_t), \quad j = 1, \ldots, m \qquad (1)$$

where v_t, s_t, and p_t are the predicate, subject, and prepositional object of e_t respectively, and x_j is filled as the direct object. (Event completion for omitted subjects and prepositional objects is analogous.)

Then we compute the narrative coherence score S_j of the candidate x_j by[3]

$$S_j = \max_{c=1,\, c\neq t}^{n} coh\left(\vec{e_t(j)}, \vec{e_c}\right), \quad j = 1, \ldots, m \qquad (2)$$

where $\vec{e_t(j)}$ and $\vec{e_c}$ are representations for the completed target event $e_t(j)$ and one context event e_c, and coh is a function computing a coherence score between two events, both depending on the model being used. The candidate x_j with the highest score S_j is then selected as our prediction.

4.2 The Event Composition Model

To model coherence (coh) between a context event and a target event, we build an event composition model consisting of three parts, as shown in Figure 2: event components are representated through **event-based word embeddings**, which encode event knowledge in word representations; the **argument composition network** combines the components to produce event representations; and the **pair composition network** compute a coherence score for two event representations.

This basic architecture is as in the model of Granroth-Wilding and Clark (2016). However our model is designed for a different task, argument cloze rather than narrative cloze, and for our task entity-specific information is more important. We therefore create the training data in a different way, as described in Section 4.2.1. We now discuss the three parts of the model in more detail.

Event-Based Word Embeddings The model takes word embeddings of both predicates and

[3] We have also tried using the sum instead of the maximum, but it did not perform as well across different models and datasets.

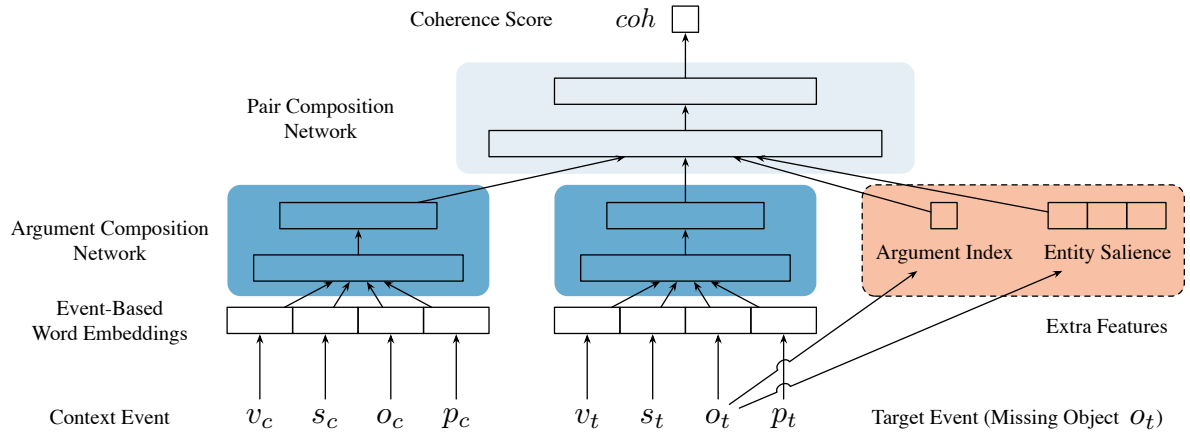

Figure 2: Diagram for event composition model. ***Input***: a context event and a target event. ***Event-Based Word Embeddings***: embeddings for components of both events that encodes event knowledge. ***Argument Composition Network***: produces an event representation from its components. ***Pair Composition Network***: computes a coherence score *coh* from two event representations. ***Extra Features***: argument index and entity salience features as additional input to the pair composition network.

arguments as input to compute event representations. To better encode event knowledge in word level, we train an SGNS (skip-gram with negative sampling) word2vec model (Mikolov et al., 2013) with event-specific information. For each extracted event sequence, we create a sentence with the predicates and arguments of all events in the sequence. An example of such a training sentence is given in Figure 3.

build-pred company-subj plant-dobj provide-pred electricity-dobj mill-prep_to ensure-pred plant-*subj has-pred company-subj energy-dobj mill-prep_for reduce-pred plant-subj cost-dobj*

Figure 3: Event-based word2vec training sentence, constructed from events and entities in Figure 1b.

Argument Composition Network The argument composition network (dark blue area in Figure 2) is a two-layer feedforward neural network that composes an event representation from the embeddings of its components. Non-existent argument positions are filled with zeros.

Pair Composition Network The pair composition network (light blue area in Figure 2) computes a coherence score *coh* between 0 and 1, given the vector representations of a context event and a target event. The coherence score should be high when the target event contains the correct argument, and low otherwise. So we construct the training objective function to distinguish the correct argument from wrong ones, as described in Equation 3.

4.2.1 Training for Argument Prediction

To train the model to pick the correct candidate, we automatically construct training samples as event triples consisting of a context event e_c, a positive event e_p, and a negative event e_n. The context event and positive event are randomly sampled from an observed sequence of events, while the negative event is generated by replacing one argument of positive event by a random entity in the narrative, as shown in Figure 4.

x_0 = The company x_1 = mill x_2 = power plant

Context: (*build-pred*, x_0-*subj*, x_2-*dobj*, –)
Positive: (*reduce-pred*, **x_2-*subj***, *cost-dobj*, –)
Negative: (*reduce-pred*, **x_1-*subj***, *cost-dobj*, –)

Figure 4: Example of an event triple constructed from events and entities in Figure 1b.

We want the coherence score between e_c and e_p to be close to 1, while the score for e_c and e_n should be close to 0. Therefore, we train the model to minimize cross-entropy as follows:

$$\frac{1}{m}\sum_{i=1}^{m} -\log(coh(e_{ci}, e_{pi})) - \log(1 - coh(e_{ci}, e_{ni})) \quad (3)$$

where e_{ci}, e_{pi}, and e_{ni} are the context, positive, and negative events of the ith training sample respectively.

4.3 Entity Salience

Implicit arguments tend to be salient entities in the document. So we extend our model by entity salience features, building on recent work by Dunietz and Gillick (2014), who introduced a simple model with several surface level features for entity salience detection. Among the features they used, we discard those that require external resources, and only use the remaining three features, as illustrated in Table 1. Dunietz and Gillick found *mentions* to be the most powerful indicator for entity salience among all features. We expect similar results in our experiments, however we include all three features in our event composition model for now, and conduct an ablation test afterwards.

Feature	Description
1st_loc	Index of the sentence where the first mention of the entity appears
head_count	Number of times the head word of the entity appears
mentions	A vector containing the numbers of named, nominal, pronominal, and total mentions of the entity

Table 1: Entity salience features from Dunietz and Gillick (2014).

The entity salience features are directly passed into the pair composition network as additional input. We also add an extra feature for argument position index (encoding whether the missing argument is a subject, direct object, or prepositional object), as shown in the red area in Figure 2.

5 Evaluation Datasets

5.1 Argument Cloze Evaluation

Previous implicit argument datasets were very small. To overcome that limitation, we automatically create a large and comprehensive evaluation dataset, following the **argument cloze** task setting in Section 3.

Since the events and entities are extracted from dependency labels and coreference chains, we do not want to introduce systematic error into the evaluation from imperfect parsing and coreference algorithms. Therefore, we create the evaluation set from OntoNotes (Hovy et al., 2006), which contains human-labeled dependency and coreference annotation for a large corpus. So the extracted events and entities in the evaluation set are gold. Note that this is only for evaluation; in training we do not rely on any gold annotations (Section 6.1).

There are four English sub-corpora in OntoNotes Release 5.0[4] that are annotated with dependency labels and coreference chains. Three of them, which are mainly from broadcast news, share similar statistics in document length, so we combine them into a single dataset and name it **ON-SHORT** as it consists mostly of short documents. The fourth subcorpus is from the *Wall Street Journal* and has significantly longer documents. We call this subcorpus **ON-LONG** and evaluate on it separately. Some statistics are shown in Table 2.

	ON-SHORT	ON-LONG
# doc	1027	597
# test cases	13018	18208
Avg # entities	12.06	36.95

Table 2: Statistics on argument cloze datasets.

5.2 The Gerber and Chai (G&C) Dataset

The implicit argument dataset from Gerber and Chai (2010) (referred as **G&C** henceforth) consists of 966 human-annotated implicit argument instances on 10 nominal predicates.

To evaluate our model on G&C, we convert the annotations to the input format of our model as follows: We map nominal predicates to their verbal form, and semantic role labels to syntactic argument types based on the NomBank frame definitions. One of the examples (after mapping semantic role labels) is as follows:

> [Participants]$_{subj}$ will be able to transfer [money]$_{dobj}$ to [other investment funds]$_{prep\_to}$. The [investment]$_{pred}$ choices are limited to [a stock fund and a money-market fund]$_{prep\_to}$.

For the nominal predicate *investment*, there are three arguments missing (*subj*, *dobj*, *prep_to*). The model first needs to determine that each of those argument positions in fact has an implicit filler. Then, from a list of candidates (not shown here), it

[4]LDC Catalog No. LDC2013T19

needs to select *Participants* as the implicit *subj* argument, *money* as the implicit *dobj* argument, and either *other investment funds* or *a stock fund and a money-market fund* as the implicit *prep_to*.

6 Experiments

6.1 Implementation Details

We train our neural model using synthetic data as described in Section 3. For creating the training data, we do not use gold parses or gold coreference chains. We use the 20160901 dump of English Wikipedia[5], with 5,228,621 documents in total. For each document, we extract plain text and break it into paragraphs, while discarding all structured data like lists and tables[6]. We construct a sequence of events and entities from each paragraph, by running Stanford CoreNLP (Manning et al., 2014) to obtain dependency parses and coreference chains. We lemmatize all verbs and arguments. We incorporate negation and particles in verbs, and normalize passive constructions. We represent each argument by the corresponding entity's representative mention if it is linked to an entity, otherwise by its head lemma. We keep verbs and arguments with counts over 500, together with the 50 most frequent prepositions, leading to a vocabulary of 53,345 tokens; all other words are replaced with an out-of-vocabulary token. The most frequent verbs (with counts over 100,000) are down-sampled.

For training the event-based word embeddings, we create pseudo-sentences (Section 4.2) from all events of all sequences (approximately 87 million events) as training samples. We train an SGNS word2vec model with embedding size = 300, window size = 10, subsampling threshold = 10^{-4}, and negative samples = 10, using the Gensim package (Řehůřek and Sojka, 2010).

For training the event composition model, we follow the procedure described in Section 4.2.1, and extract approximately 40 million event triples as training samples[7]. We use a two-layer feed-forward neural network with layer sizes 600 and 300 for the argument composition network, and another two-layer network with layer sizes 400 and 200 for the pair composition network. We use cross-entropy loss with ℓ_2 regularization of 0.01. We train the model using stochastic gradient descent (SGD) with a learning rate of 0.01 and a batch size of 100 for 20 epochs.

To study how the size of the training set affects performance, we downsample the 40 million training samples to another set of 8 million training samples. We refer to the resulting models as **EVENTCOMP-8M** and **EVENTCOMP-40M**.

6.2 Evaluation on Argument Cloze

For the synthetic argument cloze task, we compare our model with 3 baselines.

RANDOM Randomly select one entity from the candidate list.

MOSTFREQ Always select the entity with highest number of mentions.

EVENTWORD2VEC Use the event-based word embeddings described in Section 4.2 for predicates and arguments. The representation of an event e is the sum of the embeddings of its components, i.e.,

$$\vec{e} = \vec{v} + \vec{s} + \vec{o} + \vec{p} \tag{4}$$

where $\vec{v}, \vec{s}, \vec{o}, \vec{p}$ are the embeddings of verb, subject, object, and prepositional object, respectively. The coherence score of two events in this baseline model is their cosine similarity. Like in our main model, the coherence score of the candidate is then the maximum pairwise coherence score, as described in Section 4.1.

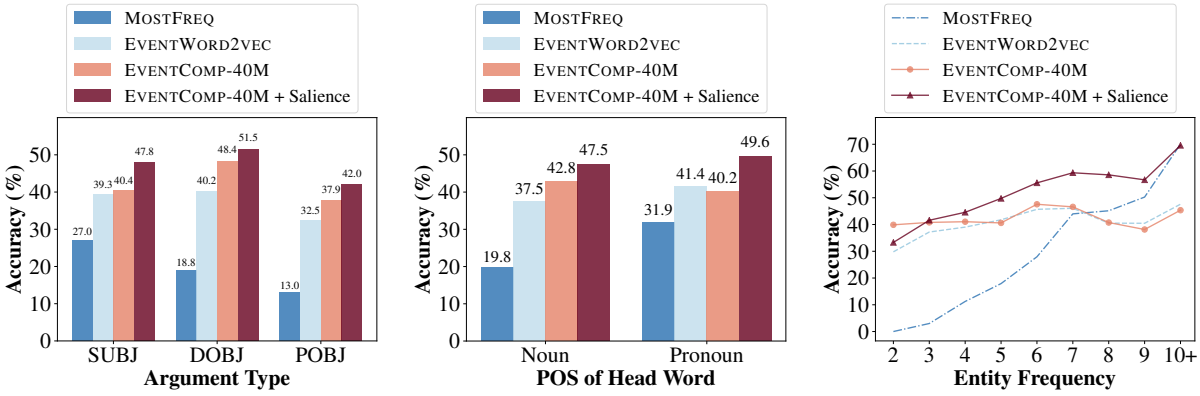
The evaluation results on the ON-SHORT dataset are shown in Table 3. The EVENTWORD2VEC baseline is much stronger than the other two, achieving an accuracy of 38.40%. In fact, EVENTCOMP-8M by itself does not do better than EVENTWORD2VEC, but adding entity salience greatly boosts performance. Using more training data (EVENTCOMP-40M) helps by a substantial margin both with and without entity salience features.

To see which of the entity salience features are important, we conduct an ablation test with the EVENTCOMP-8M model on ON-SHORT. From the results in Table 4, we can see that in our task, as in Dunietz and Gillick (2014), the entity mentions features, i.e., the numbers of named, nominal, pronominal, and total mentions of the entity, are most helpful. In fact, the other two features even decrease performance slightly.

[5] https://dumps.wikimedia.org/enwiki/

[6] We use the WikiExtractor tool at https://github.com/attardi/wikiextractor.

[7] We only sample one negative event for each pair of context and positive events for fast training, though more training samples are easily accessible.



(a) Accuracy by Argument Type (b) Accuracy by POS of Head Word (c) Accuracy by Entity Frequency

Figure 5: Performance of EventComp (with and without entity salience) and two baseline models by (a) argument type, (b) part-of-speech tag of the head word of the entity, and (c) entity frequency.

	Accuracy (%)
Random	8.29
MostFreq	22.76
EventWord2vec	38.40
EventComp-8M	38.26
+ entity salience	45.05
EventComp-40M	41.89
+ entity salience	**47.75**

Table 3: Evaluation on ON-Short.

Features	Accuracy (%)
no entity salience feature	38.26
– *mentions*	39.02
– *head_count*	**45.71**
– *1st_loc*	**45.65**
all entity salience features	45.05

Table 4: Ablation test on entity salience features. (Using EventComp-8M on ON-Short.)

We take a closer look at several of the models in Figure 5. Figure 5a breaks down the results by the argument type of the removed argument. On subjects, the EventWord2vec baseline matches the performance of EventComp, but not on direct objects and prepositional objects. Subjects are semantically much less diverse than the other argument types, as they are very often animate. A similar pattern is apparent in Figure 5b, which has results by the part-of-speech tag of the head word of the removed entity. Note that an entity is a coreference chain, not a single mention; so when the head word is a pronoun, this is an entity which has only pronoun mentions. A pronoun entity provides little semantic content beyond, again, animacy. And again, EventWord2vec performs well on pronoun entities, but less so on entities described by a noun. It seems that EventWord2vec can pick up on a coarse-grained pattern such as animate/inanimate, but not on more fine-grained distinctions needed to select the right noun, or to select a fitting direct object or prepositional object. This matches the fact that EventWord2vec gets a less clear signal on the task, in two respects: It gets much less information than EventComp on the distinction between argument positions,[8] and it only looks at overall event similarity while EventComp is trained to detect narrative coherence. Entity salience contributes greatly across all argument types and parts of speech, but more strongly on subjects and pronouns. This is again because subjects, and pronouns, are semantically less distinct, so they can only be distinguished by relative salience.

Figure 5c analyzes results by the frequency of the removed entity, that is, by its number of mentions. The MostFreq baseline, unsurprisingly, only does well when the removed entity is a highly frequent one. The EventComp model is much better than MostFreq at picking out the right entity when it is a rare one, as it can look at the semantic content of the entity as well as its frequency. Entity salience boosts the performance of EventComp in particular for frequent entities.

The ON-Long dataset, as discussed in Section 5.1, consists of OntoNotes data with much

[8] As shown in Figure 3, the "words" for which embeddings are computed are role-lemma pairs.

longer documents than found in ON-SHORT. Evaluation results on ON-LONG are shown in Table 5. Although the overall numbers are lower than those for ON-SHORT, we are selecting from 36.95 candidates on average, more than 3 times more than for ON-SHORT. Considering that the accuracy of randomly selecting an entity is as low as 2.71%, the performance of our best performing model, with an accuracy of 27.87%, is quite good.

	Accuracy (%)
RANDOM	2.71
MOSTFREQ	17.23
EVENTWORD2VEC	21.49
EVENTCOMP-8M	18.79
+ entity salience	26.23
EVENTCOMP-40M	21.79
+ entity salience	**27.87**

Table 5: Evaluation on ON-LONG.

6.3 Evaluation on G&C

The G&C data differs from the Argument Cloze data in two respects. First, not every argument position that seems to be open needs to be filled: The model must additionally make a **fill / no-fill decision**. Whether a particular argument position is typically filled is highly predicate-specific. As the small G&C dataset does not provide enough data to train our neural model on this task, we instead train a simple logistic classifier, the **fill / no-fill classifier**, with a small subset of shallow lexical features used in Gerber and Chai (2012), to make the decision. These features describe the syntactic context of the predicate. We use only 14 features; the original Gerber and Chai model had more than 80 features, and our re-implementation, described below, has around 60.

The second difference is that in G&C, an event may have multiple open argument positions. In that case, the task is not just to select a candidate entity, but also to determine which of the open argument positions it should fill. So the model must do **multi implicit argument prediction**. We can flexibly adapt our method for training data generation to this case. In particular, we create extra negative training events, in which an argument of the positive event has been moved to another argument position in the same event, as shown in Figure 6. We can then simply train our EVENTCOMP model on this extended training data. We refer to the extra training process as **multi-arg training**.

x_0 = The company x_1 = mill x_2 = power plant

Context: (*build-pred*, x_0-*subj*, x_2-*dobj*, —)
Positive: (*reduce-pred*, **x_2-*subj***, *cost-dobj*, —)
Negative: (*reduce-pred*, —, *cost-dobj*, **x_2-*prep***)

Figure 6: Event triples for training multi implicit argument prediction.

We compare our models to that of Gerber and Chai (2012). However, their original logistic regression model used many features based on gold annotation from FrameNet, PropBank and NomBank. To create a more realistic evaluation setup, we re-implement a variant of their original model by removing gold features, and name it GCAUTO. Results from GCAUTO are directly comparable to our models, as both are trained on automatically generated features. [9]

	P	R	F_1
Gerber and Chai (2012)	57.9	44.5	50.3
GCAUTO	49.9	40.1	44.5
EVENTCOMP-8M	8.9	27.9	13.5
+ fill / no-fill classifier	22.0	22.3	22.1
+ multi-arg training	43.5	44.1	43.8
+ entity salience	45.7	46.4	**46.1**
EVENTCOMP-40M	9.4	30.3	14.3
+ fill / no-fill classifier	23.7	24.0	23.9
+ multi-arg training	46.7	47.3	47.0
+ entity salience	49.3	49.9	**49.6**

Table 6: Evaluation on G&C dataset.

We present the evaluation results in Table 6. The original EVENTCOMP models do not perform well, which is as expected since the model is not designed to do the *fill / no-fill decision* and *multi implicit argument prediction* tasks as described above. With the fill / no-fill classifier, precision rises by around 13 points because this classifier prevents many false positives. With additional multi-arg training, F_1 score improves by another 22-23 points. At this point, our model

[9] To be fair, we also tested adding the fill / no-fill classifier to GCAUTO. However the classifier only increases precision at the cost of reducing recall, and GCAUTO already has higher precision than recall. The resulting F_1 score is actually worse, and thus is not reported here.

achieves a performance comparable to the much more complex G&C reimplementation GCAUTO. Adding entity salience features further boosts both precision and recall, showing that implicit arguments do tend to be filled by salient entities, as we had hypothesized. Again, more training data substantially benefits the task. Our best performing model, at 49.6 F_1, clearly outperforms GCAUTO, and is comparable with the original Gerber and Chai (2012) model trained with gold features. [10]

7 Conclusion

In this paper we have addressed the task of implicit argument prediction. To support training at scale, we have introduced a simple cloze task for which data can be generated automatically. We have introduced a neural model, which frames implicit argument prediction as the task of selecting the textual entity that completes the event in a maximally narratively coherent way. The model prefers salient entities, where salience is mainly defined through the number of mentions. Evaluating on synthetic data from OntoNotes, we find that our model clearly outperforms even strong baselines, that salience is important throughout for performance, and that event knowledge is particularly useful for the (more verb-specific) object and prepositional object arguments. Evaluating on the naturally occurring data from Gerber and Chai, we find that in a comparison without gold features, our model clearly outperforms the previous state-of-the-art model, where again salience information is important.

The current paper takes a first step towards predicting implicit arguments based on narrative coherence. We currently use a relatively simple model for local narrative coherence; in the future we will turn to models that can test global coherence for an implicit argument candidate. We also plan to investigate how the extracted implicit arguments can be integrated into a downstream task that makes use of event information, in particular we would like to experiment with reading comprehension.

Acknowledgments

This research was supported by NSF grant IIS 1523637. We also acknowledge the Texas Advanced Computing Center for providing grid resources that contributed to these results, and we would like to thank the anonymous reviewers for their valuable feedback.

[10] We also tried fine tune our model on the G&C dataset with cross validation, but the model severely overfit, possibly due to the very small size of the dataset.

Improving Temporal Relation Extraction with a Globally Acquired Statistical Resource

Abstract

Extracting temporal relations (*before, after, overlapping*, etc.) is a key aspect of understanding events described in natural language. We argue that this task would gain from the availability of a resource that provides prior knowledge in the form of the temporal order that events *usually* follow. This paper develops such a resource – a probabilistic knowledge base acquired in the news domain – by extracting temporal relations between events from the New York Times (NYT) articles over a 20-year span (1987–2007). We show that existing temporal extraction systems can be improved via this resource. As a byproduct, we also show that interesting statistics can be retrieved from this resource, which can potentially benefit other time-aware tasks. The proposed system and resource are both publicly available[1].

1 Introduction

Time is an important dimension of knowledge representation. In natural language, temporal information is often expressed as relations between events. Reasoning over these relations can help figuring out when things happened, estimating how long things take, and summarizing the timeline of a series of events. Several recent SemEval workshops are a good showcase of the importance of this topic (Verhagen et al., 2007, 2010; Uz-Zaman et al., 2013; Llorens et al., 2015; Minard et al., 2015; Bethard et al., 2015, 2016, 2017).

One of the challenges in temporal relation extraction is that it requires high-level prior knowledge of the temporal order that events *usually* follow. In Example 1, we have deleted events from several snippets from CNN, so that we cannot use our prior knowledge of those events. We are also told that ***e1*** and ***e2*** have the same tense, and ***e3*** and ***e4*** have the same tense, so we cannot resort to their tenses to tell which one happens earlier. As a result, it is very difficult even for humans to figure out the temporal relations (referred to as "TempRels" hereafter) between those events. This is because rich temporal information is encoded in the events' names, and this often plays an indispensable role in making our decisions. In the first paragraph of Example 1, it is difficult to understand what really happened without the actual event verbs; let alone the TempRels between them. In the second paragraph, things are even more interesting: if we had ***e3:dislike*** and ***e4:stop***, then we would know easily that "I dislike" occurs *after* "they stop the column". However, if we had ***e3:ask*** and ***e4:help***, then the relation between ***e3*** and ***e4*** is now reversed and ***e3*** is *before* ***e4***. We are in need of the event names to determine the TempRels; however, we do not have them in Example 1. In Example 2, where we show the complete sentences, the task has become much easier for humans due to our prior knowledge, namely, that explosion *usually* leads to casualties and that people *usually* ask before they get help. Motivated by these examples (which are in fact very common), we believe in the importance of such a prior knowledge in determining TempRels between events.

Example 1: Difficulty in understanding TempRels when event content is missing. Note that ***e1*** and ***e2*** have the same tense, and ***e3*** and ***e4*** have the same tense.
More than 10 people have (***e1:***), police said. A car (***e2:***) on Friday in the middle of a group of men playing volleyball.
The first thing I (***e3:***) is that they (***e4:***) writing this column.

However, most existing systems only make use of rather local features of these events, which cannot represent the prior knowledge humans have

die	explode	14	83
...			

Table 1: **TEMPROB is a unique source of information of the temporal order that events *usually* follow.** The probabilities below do not add up to 100% because less frequent relations are omitted. The word sense numbers are not shown here for convenience.

about these events and their "typical" order. As a result, existing systems almost always attempt to solve the situations shown in Example 1, even when they are actually presented with input as in Example 2. The **first contribution** of this work is thus the construction of such a resource in the form of a probabilistic knowledge base, constructed from a large New York Times (NYT) corpus. We hereafter name our resource *TEMporal relation PRObabilistic knowledge Base* (TEMPROB), which can potentially benefit many time-aware tasks. A few example entries of TEMPROB are shown in Table 1. **Second**, we show that existing TempRel extraction systems can be improved using TEMPROB, either in a local method or in a global method (explained later), by a significant margin in performance on the benchmark TimeBank-Dense dataset (Cassidy et al., 2014).

Example 2: The original sentences in Example 1.
More than 10 people have (***e1:died***), police said. A car (***e2:exploded***) on Friday in the middle of a group of men playing volleyball.
The first thing I (***e3:ask***) is that they (***e4:help***) writing this column.

The rest of the paper is organized as follows. Section 2 provides a literature review of TempRels extraction in NLP. Section 3 describes in detail the construction of TEMPROB. In Sec. 4, we show that TEMPROB can be used in existing TempRels extraction systems and lead to significant improvement. Finally, we conclude in Sec. 5.

2 Related Work

The TempRels between events can be represented by an edge-labeled graph, where the nodes are events, and the edges are labeled with TempRels (Chambers and Jurafsky, 2008; Do et al., 2012; Ning et al., 2017). Given all the nodes, we work on the TempRel extraction task, which is to assign labels to the edges in a temporal graph (a "vague" or "none" label is often included to account for the non-existence of an edge).

Early work includes Mani et al. (2006); Chambers et al. (2007); Bethard et al. (2007); Verhagen and Pustejovsky (2008), where the problem was formulated as learning a classification model for determining the label of every edge *locally* without referring to other edges (i.e., local methods). The predicted temporal graphs by these methods may violate the transitive properties that a temporal graph should possess. For example, given three nodes, ***e1***, ***e2***, and ***e3***, a local method can possibly classify (***e1***,***e2***)=*before*, (***e2***,***e3***)=*before*, and (***e1***,***e3***)=*after*, which is obviously wrong since *before* is a transitive relation and (***e1***,***e2***)=*before* and (***e2***,***e3***)=*before* dictate that (***e1***,***e3***)=*before*. Recent state-of-the-art methods, (Chambers et al., 2014; Mirza and Tonelli, 2016), circumvented this issue by growing the predicted temporal graph in a multi-step manner, where transitive graph closure is performed on the graph every time a new edge is labeled. This is conceptually solving the structured prediction problem greedily. Another family of methods resorted to Integer Linear Programming (ILP) (Roth and Yih, 2004) to get exact inference to this problem (i.e., global methods), where the entire graph is solved simultaneously and the transitive properties are enforced naturally via ILP constraints (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Denis and Muller, 2011; Do et al., 2012). A most recent work brought this idea even further, by incorporating structural constraints into the learning phase as well (Ning et al., 2017).

The TempRel extraction task has a strong dependency on prior knowledge, as shown in our earlier examples. However, very limited attention has been paid to generating such a resource and to make use of it; to our knowledge, the TEMPROB proposed in this work is completely new. We find that the *time-sensitive relations* proposed in Jiang et al. (2016) is a close one in literature (although it is still very different). Jiang et al. (2016) worked on the knowledge graph completion task. Based on YAGO2 (Hoffart et al., 2013) and Freebase (Bollacker et al., 2008), it manually selects a small number of relations that are time-sensitive (10 relations from YAGO2 and 87 relations from Freebase, respectively). Exemplar relations are wasBornIn→diedIn→ and graduateFrom→workAt, where → means temporally be-

fore.

Our work significantly differs from the time-sensitive relations in Jiang et al. (2016) in the following aspects. First, scale difference: Jiang et al. (2016) can only extract a small number of relations (<100), but we work on general semantic frames (tens of thousands) and the relations between any two of them, which we think has broader applications. Second, granularity difference: the smallest granularity in Jiang et al. (2016) is one year[2], i.e., only when two events happened in different years can they know the temporal order of them, but we can handle implicit temporal orders without having to refer to the physical time points of events (i.e., the granularity can be arbitrarily small). Third, domain difference: while Jiang et al. (2016) extracts time-sensitive relations from structured knowledge bases (where events are explicitly anchored to a time point), we extract relations from unstructured natural language text (where the physical time points may not even exist in text). Our task is more general and it allows us to extract much more relations, as reflected by the 1st difference above.

Another related work is the VerbOcean (Chklovski and Pantel, 2004), which extracts temporal relations between pairs of verbs using manually designed lexico-syntactic patterns (there are in total 12 such patterns), in contrast to the automatic extraction method proposed in this work. In addition, the only termporal relation considered in VerbOceans is *before*, while we also consider relations such as *after*, *includes*, *included*, *equal*, and *vague*. As expected, the total numbers of verbs and *before* relations in VerbOcean is about 3K and 4K, respectively, both of which are much smaller than TEMPROB, which contains 51K verb frames (i.e., disambiguated verbs), 9.2M $(verb1, verb2, relation)$ entries, and up to 80M temporal relations altogether.

All these differences necessitate the construction of a new resource for TempRel extraction, which we explain below.

3 TEMPROB: A Probabilistic Resource for TempRels

In the TempRel extraction task, people have usually assumed that events are already given. However, to construct the desired resource, we need to extract events (Sec. 3.1) and extract TempRels (Sec. 3.2), from a large, unannotated[3] corpus (Sec. 3.3). We also show some interesting statistics discovered in TEMPROB that may benefit other tasks (Sec. 3.4). In the next, we describe each of these elements.

3.1 Event Extraction

Extracting events and the relations between them (e.g., coreference, causality, entailment, and temporal) have long been an active area in the NLP community. Generally speaking, an event is considered to be an action associated with corresponding participants involved in this action. In this work, following (Peng and Roth, 2016; Peng et al., 2016; Spiliopoulou et al., 2017) we consider semantic-frame based events, which can be directly detected via off-the-shelf semantic role labeling (SRL) tools. This aligns well with previous works on event detection (Hovy et al., 2013; Peng et al., 2016).

Depending on the events of interest, the SRL results are often a superset of events and need to be filtered afterwards (Spiliopoulou et al., 2017). For example, in ERE (Song et al., 2015) and Event Nugget Detection (Mitamura et al., 2015), events are limited to a set of predefined types (such as "Business", "Conflict", and "Justice"); in the context of TempRels, existing datasets have focused more on predicate verbs rather than nominals[4] (Pustejovsky et al., 2003; Graff, 2002; UzZaman et al., 2013). Therefore, we only look at verb semantic frames in this work due to the difficulty of getting TempRel annotation for nominal events, and we will use "verb (semantic frames)" interchangeably with "events" hereafter in this paper.

3.2 TempRel Extraction

Given the events extracted in a given article (i.e., given the nodes in a graph), we next explain how the TempRels are extracted (that is, the edge labels in the graph).

3.2.1 Features

We adopt the commonly used feature set in TempRel extraction (Do et al., 2012; Ning et al., 2017) and here we simply list them for reproducibility. For each pair of nodes, the follow-

[2]We notice that the smallest granularity in Freebase itself is one day, but Jiang et al. (2016) only used years.

[3]Unannotated with TempRels.

[4]Some nominal events were indeed annotated in TimeBank (Pustejovsky et al., 2003), but their annotation did not align well with modern nominal-SRL methods.

ing features are extracted. (i) The part-of-speech (POS) tags from each individual verb and from its neighboring three words. (ii) The distance between them in terms of the number of tokens. (iii) The modal verbs between the event mention (i.e., will, would, can, could, may and might). (iv) The temporal connectives between the event mentions (e.g., before, after and since). (v) Whether the two verbs have a common synonym from their synsets in WordNet (Fellbaum, 1998). (vi) Whether the input event mentions have a common derivational form derived from WordNet. (vii) The head word of the preposition phrase that covers each verb, respectively.

3.2.2 Learning

With the features defined above, we need to train a system that can annotate the TempRels in each document. The TimeBank-Dense dataset (TB-Dense) (Cassidy et al., 2014) is known to have the best quality in terms of its high density of TempRels and is a benchmark dataset for the TempRel extraction task. It contains 36 documents from TimeBank (Pustejovsky et al., 2003) which were re-annotated using the dense event ordering framework proposed in (Cassidy et al., 2014). We follow its label set (denoted by R) of *before*, *after*, *includes*, *included*, *equal*, and *vague* in this study.

Due to the slight event annotation difference in TBDense, we collect our training data as follows. We first extract all the verb semantic frames from the raw text of TBDense. Then we only keep those semantic frames that are matched to an event in TBDense (about 85% semantic frames are kept in this stage). By doing so, we can simply use the TempRel annotations provided in TBDense. Hereafter the TBDense dataset used in this paper refers to this version unless otherwise specified.

We group the TempRels by the sentence distance of the two events of each relation[5]. Then we use the averaged perceptron algorithm (Freund and Schapire, 1998) implemented in the Illinois LBJava package (Rizzolo and Roth, 2010) to learn from the training data described above. Since only relations that have sentence distance 0 or 1 are annotated in TBDense, we will have two classifiers, one for same sentence relations, and one for neighboring sentence relations, respectively.

[5]That is, the difference of the appearance order of the sentence(s) containing the two target events.

Note that TBDense was originally split into Train (22 docs), Dev (5 docs), and Test (9 docs). In all subsequent analysis, we combined Train and Dev and we performed 3-fold cross validation on the 27 documents (in total about 10K relations) to tune the parameters in any classifier.

3.2.3 Inference

When generating TEMPROB, we need to process a large number of articles, so we adopt the greedy inference strategy described earlier due to its computational efficiency (Chambers et al., 2014; Mirza and Tonelli, 2016). Specifically, we apply the same-sentence relation classifier before the neighboring-sentence relation classifier; whenever a new relation is added in this article, a transitive graph closure is performed immediately. By doing this, if an edge is already labeled during the closure phase, it will not be labeled again, so conflicts are avoided.

3.3 Corpus

As mentioned earlier, the source corpus on which we are going to construct TEMPROB is comprised of NYT articles from 20 years (1987-2007)[6]. It contains more than 1 million documents and we extract events and corresponding features from each document using the Illinois Curator package (Clarke et al., 2012) on Amazon Web Services (AWS) Cloud. In total, we discovered 51K unique verb semantic frames and 80M relations among them in the NYT corpus (15K of the verb frames had more than 20 relations extracted and 9K had more than 100 relations).

3.4 Interesting Statistics

We first describe the notations that we are going to use. We denote the set of all verb semantic frames by V. Let $D_i, i = 1, \ldots, N$ be the i-th document in our corpus, where N is the total number of documents. Let $G_i = (V_i, E_i)$ be the temporal graph inferred from D_i using the approach described above, where $V_i \subseteq V$ is the set of verbs/events extracted in D_i and $E_i = \{(v_m, v_n, r_{mn})\}_{m<n} \subseteq V_i \times V_i \times R$ is the edge set of D_i, which is composed of TempRel triplets; specifically, a TempRel triplet $(v_m, v_n, r_{mn}) \in E_i$ represents that in document D_i, the TempRel between v_m and v_n is r_{mn}. Due to the symmetry in TempRels, we only keep the triplets with $m < n$ in E_i. Assuming that the

[6]https://catalog.ldc.upenn.edu/LDC2008T19

verbs in V_i are ordered by their appearance order in text, then $m < n$ means that in the i-th document, v_m appears earlier in text than v_n does.

Given the usual confusion between that one event is *temporally before* another and that one event is *physically appearing* before another in text, we will refer to temporally before as **T-Before** and physically before as **P-Before**. Using this language, for example, E_i only keeps the triplets that v_m is P-Before v_n in D_i.

3.4.1 Extreme cases

We first show extreme cases that some events are *almost always* labeled as T-Before or T-After in the corpus. Specifically, for each pair of verbs $v_i, v_j \in V$, we define the following ratios:

$$\eta_b = \frac{C(v_i, v_j, before)}{C(v_i, v_j, before) + C(v_i, v_j, after)}, \eta_a = 1 - \eta_b, \tag{1}$$

where $C(v_i, v_j, r)$ is the count of v_i P-Before v_j with TempRel $r \in R$:

$$C(v_i, v_j, r) = \sum_{i=1}^{N} \sum_{(v_m, v_n, r_{mn}) \in E_i} \mathcal{I}_{\{v_m = v_i \& v_n = v_j \& r_{mn} = r\}}, \tag{2}$$

where $\mathcal{I}_{\{\cdot\}}$ is the indicator function. Add-one smoothing technique from language modeling is used to avoid divided-by-zero errors. In Table 2, we show some event pairs with either $\eta_b > 0.9$ (upper part) or $\eta_a > 0.9$ (lower part).

We think the examples from Table 2 are intuitively appealing: ***chop*** happens before ***taste***, ***clean*** happens after ***contaminate***, etc. More interestingly, in the lower part of the table, we show pairs in which the physical order is different from the temporal order: for example, when ***achieve*** is P-Before ***desire***, it is still labeled as T-After in most cases (104 out of 111 times), which is correct intuitively. In practice, e.g., in the TBDense dataset (Cassidy et al., 2014), roughly 30%-40% of the P-Before pairs are T-After. Therefore, it is important to be able to capture their temporal order rather than simply taking their physical order if one wants to understand the temporal implication of verbs.

3.4.2 Distribution of Following Events

For each verb v, we define the marginal count of v being P-Before to arbitrary verbs with TempRel $r \in R$ as $C(v, r) = \sum_{v_i \in V} C(v, v_i, r)$. Then for every other verb v', we define

$$P(v \text{ T-Before } v' | v \text{ T-Before}) \triangleq \frac{C(v, v', before)}{C(v, before)}, \tag{3}$$

Example Pairs		#T-Before	#T-After
chop.01	taste.01	133	8
concern.01	protect.01	110	10
conspire.01	kill.01	113	6
debate.01	vote.01	48	5
dedicate.01	promote.02	67	7
fight.01	overthrow.01	98	8
achieve.01	desire.01	7	104
admire.01	respect.01	7	121
clean.02	contaminate.01	3	82
defend.01	accuse.01	13	160
die.01	crash.01	8	223
overthrow.01	elect.01	3	100

Table 2: **Several extreme cases from TEMPROB**, where some event is almost always labeled to be T-Before or T-After throughout the NYT corpus. By "extreme", we mean that either the probability of T-Before or T-After is larger than 90%. The upper part of the table shows the pairs that are both P-Before and T-Before, while the lower part shows the pairs that are P-Before but T-After. In TEMPROB, there are about 7K event pairs being extreme cases.

which is the probability of v T-Before v', conditioned on v T-Before anything. Similarly, we define

$$P(v \text{ T-After } v' | v \text{ T-After}) \triangleq \frac{C(v, v', after)}{C(v, after)}. \tag{4}$$

For a specific verb, e.g., v=***investigate***, each verb $v' \in V$ is sorted by the two conditional probabilities above. Then the most probable verbs that temporally precede or follow v are shown in Fig. 1, where the y-axes are the corresponding conditional probabilities. We can see reasonable event sequences like {***involve***, ***kill***, ***suspect***, ***steal***}→***investigate***→{***report***, ***prosecute***, ***pay***, ***punish***}, which indicates the possibility of using TEMPROB for event sequence predictions or story cloze tasks. There are also suspicious pairs like ***know*** in the T-Before list of ***investigate*** (Fig. 1a), ***report*** in the T-Before list of ***bomb*** (Fig. 1b), and ***play*** in the T-After list of ***mourn*** (Fig. 1c). Since the arguments of these verb frames are not considered here, whether these few seemingly counter-intuitive pairs come from system error or from a special context needs further investigation.

4 Experiments

In the above, we have explained the construction of TEMPROB and shown some interesting examples from it, which were meant to visualize its correctness. In this section, we first quantify the correctness of the prior obtained in TEMPROB, and

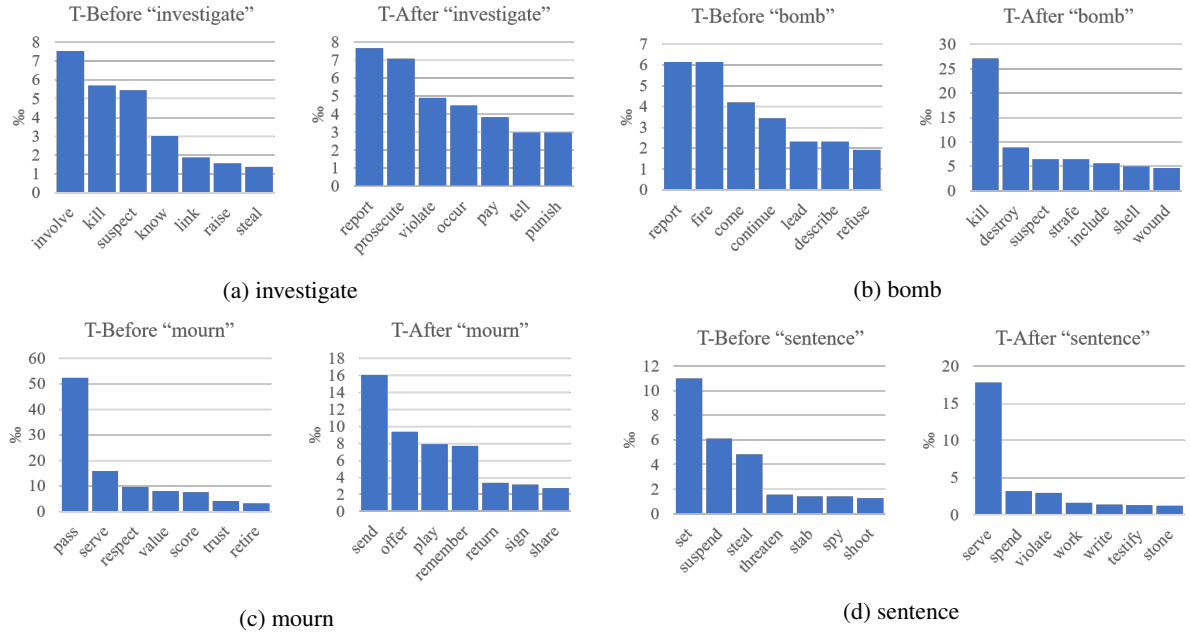

Figure 1: **Top events that most frequently precede or follow "investigate", "bomb", "mourn", or "sentence" in time**, sorted by their conditional probabilities in ‰. Word senses have been disambiguated and the "bomb" and "sentence" here are their verb meanings. There are some possible errors (e.g., ***report*** is T-Before ***bomb***) and some unclear pairs (e.g., ***know*** is T-Before ***investigate*** and ***play*** is T-After ***mourn***), but overall the event sequences discovered here are reasonable. More examples can be found in the appendix.

then show TEMPROB can be used to improve existing TempRel extraction systems.

4.1 Quality Analysis of TEMPROB

In Table 2, we showed examples with either η_b or $\eta_a > 0.9$. We argued that they *seem* correct. Here we quantify the "correctness" of η_b and η_a based on TBDense. Specifically, we collected all the gold T-Before and T-After pairs. Let $\tau \in [0.5, 1)$ be a constant threshold. Imagine a naive predictor such that for each pair of events v_i and v_j, if $\eta_b > \tau$, it predicts that v_i is T-Before v_j; if $\eta_a > \tau$, it predicts that v_i is T-After v_j; otherwise, it predicts that v_i is T-Vague to v_j. We expect that a higher η_b (or η_a) represents a higher confidence for an instance to be labeled T-Before (or T-After).

Table 3 shows the performance of this predictor, which meets our expectation and thus justifies the validity of TEMPROB. As we gradually increase the value of τ in Table 3, the precision increases in roughly the same pace with τ, which indicates that the values of η_b and η_a[7] from TEMPROB indeed represent the confidence level. The decrease in recall is also expected because more examples are labeled as T-Vague when τ is larger.

To further justify the quality, we also used another dataset that is not in the TempRel domain. Instead, we downloaded the EventCausality dataset[8] (Do et al., 2011). For each causally related pair ***e1*** and ***e2***, if EventCausality annotates that ***e1*** causes ***e2***, we changed it to be T-Before; if EventCausality annotates that ***e1*** is caused by ***e2***, we changed it to be T-after. Therefore, based on the assumption that the cause event is T-Before the result event, we converted the EventCausality dataset to be a TempRel dataset and it thus could also be used to evaluate the quality of TEMPROB. We adopted the same predictor used in Table 3

Threshold τ	Dist=0		Dist=1	
	P	R	P	R
0.5	65.6	61.3	58.5	53.3
0.6	69.8	44.5	60.5	36.9
0.7	74.6	29.2	63.6	18.7
0.8	81.0	13.9	64.8	6.9
0.9	82.9	5.0	76.9	1.2

Table 3: **Validating η_b and η_a from TEMPROB** based on the T-Before and T-After examples in TBDense. Performances are decomposed into same sentence examples (Dist=0) and contiguous sentence examples (Dist=1). A larger threshold leads to a higher precision, so η_b and η_a indeed represent a notion of confidence.

[7] Recall the definitions of η_b and η_a in Eq. (1).

[8] http://cogcomp.org/page/resource_view/27

with $\tau = 0.5$ and in Table 4, we compared it with two baselines: (i) always predicting T-Before and (ii) always predicting T-After. First, the accuracy (66.2%) in Table 4 is rather consistent with its counterpart in Table 3, confirming the stability of statistics from TEMPROB. Second, by directly using the prior statistics η_b and η_a from TEMPROB, we can improve the precision of both labels with a significant margin relative to the two baselines (17.0% for "T-Before" and 15.9% for "T-After"). Overall, the accuracy was improved by 11.5%.

System	T-Before		T-After		Acc.
	P	R	P	R	
T-Before Only	54.7	100.0	0	0	54.7
T-After Only	0	0	45.3	100	45.3
$\tau = 0.5$	71.7	63.3	61.2	69.8	66.2

Table 4: **Further justification of η_b and η_a from TEMPROB on the EventCausality dataset**. The thresholding predictor from Table 3 with $\tau = 0.5$ is used here. Compared to always predicting the majority label (i.e., T-Before in this case), $\tau = 0.5$ significantly improved the performance for both labels, with the overall accuracy improved by 11.5%.

4.2 Improving TempRel Extraction

The original purpose of TEMPROB was to improve TempRel extraction. We show it from two perspectives: How effective the prior distributions obtained from TEMPROB are (i) as features in local methods and (ii) as regularization terms in global methods. The results below were evaluated on the test split of TB-Dense (Cassidy et al., 2014).

4.2.1 Improving Local Methods

We first test how well the prior distributions from TEMPROB can be used as features in improving local methods for TempRel extraction. In Table 5, we used the original feature set proposed in Sec. 3.2.1 as the baseline, and added the prior distribution obtained from TEMPROB on top of it. Specifically, we added η_b (see Eq. (1)) and $\{f_r\}_{r\in R}$, respectively, where $\{f_r\}_{r\in R}$ is the prior distributions of all labels, i.e.,

$$f_r(v_i, v_j) = \frac{C(v_i, v_j, r)}{\sum_{r'\in R} C(v_i, v_j, r')},\ r \in R. \quad (5)$$

Recall function C is defined in Eq. (2). All comparisons were decomposed to same sentence relations (Dist=0) and neighboring sentence relations (Dist=1) for a better understanding of the behavior. All classifiers were trained using the averaged perceptron algorithm (Freund and Schapire, 1998) and tuned by 3-fold cross validation.

From Table 5, we can see that simply adding η_b into the feature set could improve the original system F_1 by 1.8% (Dist=0) and 3.0% (Dist=1). If we further add as features the full set of prior distributions $\{f_r\}_{r\in R}$, the improvement comes to 2.7% and 6.5%, respectively. Noticing that the feature is more helpful for Dist=1, we think that it is because distant pairs usually have less lexical dependency and thus need more prior information provided by our new feature. With Dist=0 and Dist=1 combined (numbers not shown in the Table), the 3rd line improved the "original" by 4.7% in F_1 and by 5.1% in the temporal awareness F-score (another metric used in the TempEval3 workshop).

Feature Set	Dist=0			Dist=1		
	P	R	F_1	P	R	F_1
Original	44.5	57.1	50.0	49.0	36.9	42.1
$+\eta_b$	46.2	58.9	51.8	55.3	38.1	45.1
$+\{f_r\}_{r\in R}$	46.9	60.1	52.7	51.3	46.2	48.6

Note The performances here are consistently lower than those in Table 3 because in Table 3, only T-Before and T-After examples are considered, but here all labels are taken into account and the problem is more practical and harder.

Table 5: **Using prior distributions derived from TEMPROB as features in an example local method.** Incorporating η_b to the original feature set already yields better performance. By using the full set of prior distributions, $\{f_r\}_{r\in R}$, the final system improves the original in almost all metrics, and the improvement is statistically significant with $p<0.005$ per the McNemar's test.

4.2.2 Improving Global Methods

As mentioned earlier in Sec. 2, many systems adopt a global inference method via integer linear programming (ILP) (Roth and Yih, 2004) to enforce transitivity constraints over an entire temporal graph (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Denis and Muller, 2011; Do et al., 2012; Ning et al., 2017). In addition to the usage shown in Sec. 4.2.1, the prior distributions from TEMPROB can also be used to regularize the conventional ILP formulation. Specifically, in each document, let $\mathcal{I}_r(ij) \in \{0, 1\}$ be the indicator function of relation r for event i and event j; let $x_r(ij) \in [0, 1]$ be the corresponding softmax score obtained from the local classifiers (depending on the sentence distance between i and j). Then the ILP objective for global inference is

formulated as follows.

$$\hat{\mathcal{I}} = \underset{\mathcal{I}}{\text{argmax}} \sum_{ij \in \mathcal{E}} \sum_{r \in R} (x_r(ij) + \underline{\lambda f_r(ij)}) \mathcal{I}_r(ij) \quad (6)$$

$$\text{s.t.} \quad \underset{\text{(uniqueness)}}{\Sigma_r \mathcal{I}_r(ij) = 1}, \ \underset{\text{(symmetry)}}{\mathcal{I}_r(ij) = \mathcal{I}_{\bar{r}}(ji)},$$

$$\underset{\text{(transitivity)}}{\mathcal{I}_{r_1}(ij) + \mathcal{I}_{r_2}(jk) - \Sigma_{m=1}^{M} \mathcal{I}_{r_3^m}(ik) \leq 1},$$

for all distinct events i, j, and k, where $\mathcal{E} = \{ij \mid \text{sentence dist}(i,j) \leq 1\}$, λ adjusts the regularization term and was heuristically set to 0.5 in this work, $\bar{r}$ is the reverse relation of r, and M is the number of possible relations for r_3 when r_1 and r_2 are true. Note our difference from the ILP in (Ning et al., 2017) is the underlined regularization term $f_r(ij)$ (which itself is defined in Eq. (5)) obtained from TEMPROB.

No.	System	P	R	F_1	F_{aware}
1	Baseline	48.1	44.4	46.2	42.5
2	+Feature: $\{f_r\}_{r \in R}$	50.6	52.0	51.3	49.1
3	+Regularization	51.3	53.0	52.1	49.6

Table 6: **Regularizing global methods by the prior distribution derived from TEMPROB.** The "+" means adding a component on top of its preceding line. F_{aware} is the temporal awareness F-score, another evaluation metric used in TempEval3. The baseline system is to use (unregularized) ILP on top of the original system in Table 5. System 3 is the proposed. Per the McNemar's test, System 3 is significantly better than System 1 with $p<0.0005$.

We present our results on the test split of TBDense in Table 6, which is an ablation study showing step-by-step improvements in two metrics. In addition to the straightforward precision, recall, and F_1 metric, we also compared the F_1 of the temporal awareness metric used in TempEval3 (UzZaman et al., 2013). The awareness metric performs graph reduction and closure before evaluation so as to better capture how useful a temporal graph is. Details of this metric can be found in UzZaman and Allen (2011); UzZaman et al. (2013); Ning et al. (2017).

In Table 6, the baseline used the original feature set proposed in Sec. 3.2.1 and applied global ILP inference with transitivity constraints. Technically, it is to solve Eq. (6) with $\lambda = 0$ (i.e., unregularized) on top of the original system in Table 5. Apart from some implementation details, this baseline is also the same as many existing global methods as Chambers and Jurafsky (2008); Do et al. (2012). System 2, "+Feature: $\{f_r\}_{r \in R}$", is to add prior distributions as features when training the local classifiers. Technically, the scores $x_r(ij)$'s in Eq. (6) used by baseline were changed. We know from Table 5 that adding $\{f_r\}_{r \in R}$ made the local decisions better. Here the performance of System 2 shows that this was also the case for the global decisions made via ILP: both precision and recall got improved, and F_1 and awareness were both improved by a large margin, with 5.1% in F_1 and 6.6% in awareness F_1. On top of this, System 3 sets $\lambda = 0.5$ in Eq. (6) to add regularizations to the conventional ILP formulation. The sum of these regularization terms represents a confidence score of how coherent the predicted temporal graph is to our TEMPROB, which we also want to maximize. Even though a considerable amount of information from TEMPROB had already been encoded as features (as shown by the large improvements by System 2), these regularizations were still able to further improve the precision, recall and awareness scores. To sum up, the total improvement over the baseline system brought by TEMPROB is 5.9% in F_1 and 7.1% in awareness F_1, both with a notable margin. Table 7 furthermore decomposes this improvement into each TempRel label.

Label	P	R	F_1
before	+0.3	+15	+6
after	+4	+4	+4
equal	+11	0	+2
includes	+17	0	+0.2
included	+8	0	+2
vague	+3	-4	-1

Table 7: **Label-wise performance improvement of System 3 over System 1 in Table 6.** We can see that incorporating TEMPROB improves the recall of *before* and *after*, and improves the precision of all labels, with a slight drop in the recall of *vague*.

To compare with state-of-the-art systems, which all used gold event properties (i.e., Tense, Aspect, Modality, and Polarity), we retrained System 3 in Table 6 with these gold properties and show the results in Table 8. We reproduced the results of CAEVO[9] (Chambers et al., 2014) and Ning et al. (2017)[10] and evaluated them on the partial TBDense test split[11]. Under both metrics, the

[9] https://github.com/nchambers/caevo

[10] http://cogcomp.org/page/publication_view/822

[11] There are 731 relations in the partial TBDense test split (201 *before*, 138 *after*, 39 *includes*, 31 *included*, 14 *equal*, and 308 *vague*).

proposed system achieved the best performance. An interesting fact is that even without these gold properties, our System 3 in Table 6 was already better than CAEVO (on Line 1) and Ning et al. (2017) (on Line 2) in both metrics. This is appealing because in practice, those gold properties may not exist, but our proposed system can still generate state-of-the-art performance without them.

*Note that TEMPROB is only available for events extracted by SRL (See Sec. 3.2.2 for details).
**Augment the output of Line 3 with predictions from Ning et al. (2017).

Table 8: **Comparison of the proposed TempRel extraction method with two best-so-far systems using two metrics.** Since TEMPROB is only on SRL verb events, *Partial* TBDense is the focus of our work, where we can see significant improvement brought by simply using the prior knowledge from TEMPROB. Per the McNemar's test, Line 3 is better than Line 2 with $p<0.0005$. For interested readers, we also naively augmented the proposed method to the *complete* TBDense and show state-of-the-art performance on it.

For readers who are interested in the complete TBDense dataset, we also performed a naive augmentation as follows. Recall that System 3 only makes predictions to a subset of the complete TBDense dataset. We kept this subset of predictions, and filled the missing predictions by Ning et al. (2017). Performances of this naively augmented proposed system is compared with CAEVO and Ning et al. (2017) on the *complete* TBDense dataset. We can see that by replacing with predictions from our proposed system, Ning et al. (2017) got a better precision, recall, F_1, and awareness F_1, which is the new state-of-the-art on all reported performances on this dataset. Note that the awareness F_1 scores on Lines 4-5 are consistent with reported values in Ning et al. (2017). To our knowledge, the results in Table 8 is the first in literature that reports performances in both metrics, and it is promising to see that the proposed method outperformed state-of-the-art methods in both metrics.

5 Conclusion

Temporal relation (TempRel) extraction is an important and challenging task in NLP, partly due to its strong dependence on prior knowledge. Motivated by practical examples, this paper argues that a resource of the temporal order that events *usually* follow is helpful. To construct such a resource, we automatically processed a large corpus from NYT with more than 1 million documents using an existing TempRel extraction system and obtained the *TEMporal relation PRObabilistic knowledge Base* (TEMPROB). The TEMPROB is a good showcase of the capability of such prior knowledge, and it has shown its power in improving existing TempRel extraction systems on a benchmark dataset, TBDense. The resource and the system reported in this paper are both publicly available[12] and we hope that it can foster more investigations into time-related tasks.

Multimodal Named Entity Recognition for Short Social Media Posts

Seungwhan Moon[1,2], **Leonardo Neves**[2], **Vitor Carvalho**[3]

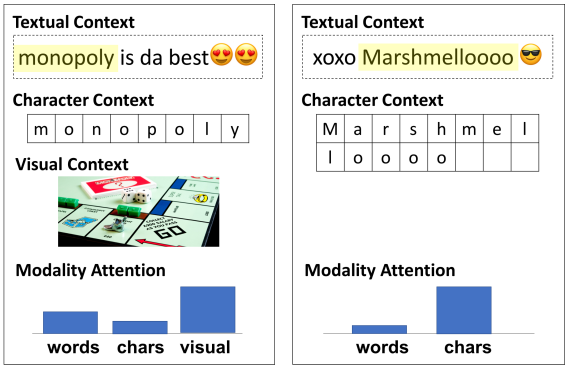
Abstract

We introduce a new task called Multimodal Named Entity Recognition (MNER) for noisy user-generated data such as tweets or Snapchat captions, which comprise short text with accompanying images. These social media posts often come in inconsistent or incomplete syntax and lexical notations with very limited surrounding textual contexts, bringing significant challenges for NER. To this end, we create a new dataset for MNER called SnapCaptions (Snapchat image-caption pairs submitted to public and crowd-sourced stories with fully annotated named entities). We then build upon the state-of-the-art Bi-LSTM word/character based NER models with 1) a deep image network which incorporates relevant visual context to augment textual information, and 2) a generic *modality-attention* module which learns to attenuate irrelevant modalities while amplifying the most informative ones to extract contexts from, adaptive to each sample and token. The proposed MNER model with modality attention significantly outperforms the state-of-the-art text-only NER models by successfully leveraging provided visual contexts, opening up potential applications of MNER on myriads of social media platforms.

1 Introduction

Social media with abundant user-generated posts provide a rich platform for understanding events, opinions and preferences of groups and individuals. These insights are primarily hidden in unstructured forms of social media posts, such as in free-form text or images without tags. Named entity recognition (NER), the task of recognizing named entities from free-form text, is thus a critical step for building structural information, allowing for its use in personalized assistance, recommendations, advertisement, etc.

While many previous approaches (Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2015; Huang et al., 2015; Lafferty et al., 2001) on NER have shown success for well-formed text in recognizing named entities via word context resolution (*e.g.* LSTM with word embeddings) combined with character-level features (*e.g.* CharLSTM/CNN), several additional challenges remain for recognizing named entities from extremely short and coarse text found in social media posts. For instance, short social media posts often do not provide enough textual contexts to resolve polysemous entities (*e.g.* "monopoly is da best 😍", where 'monopoly' may refer to a board game (named entity) or a term in economics). In addition, noisy text includes a huge number of unknown tokens due to inconsistent lexical notations and frequent mentions of various newly trending entities (*e.g.* "xoxo Marshmellooo 😎", where 'Marshmellooo' is a mis-spelling of a known entity 'Marshmello', a



(a) (b)

Figure 1: **Multimodal NER + modality attention**. (a) Visual contexts help recognizing polysemous entity names ('Monopoly' as in a board game versus an economics term). (b) Modality attention successfully suppresses word embeddings of a unknown token ('Marshmellooo' with erroneously trailing 'o's), and focuses on character-based context (*e.g.* capitalized first letter, and lexical similarity to a known named entity ('Marshmello', a music producer)) for correct prediction.

Proceedings of NAACL-HLT 2018, pages 852–860
New Orleans, Louisiana, June 1 - 6, 2018.

music producer), making word embeddings based neural networks NER models vulnerable.

To address the challenges above for social media posts, we build upon the state-of-the-art neural architecture for NER with the following two novel approaches (Figure 1). First, we propose to leverage auxiliary modalities for additional context resolution of entities. For example, many popular social media platforms now provide ways to compose a post in multiple modalities - specifically image and text (*e.g. Snapchat* captions, *Twitter* posts with image URLs), from which we can obtain additional context for understanding posts. While "monopoly" in the previous example is ambiguous in its textual form, an accompanying snap image of a board game can help disambiguate among polysemous entities, thereby correctly recognizing it as a named entity.

Second, we also propose a general modality attention module which chooses per decoding step the most informative modality among available ones (in our case, word embeddings, character embeddings, or visual features) to extract context from. For example, the modality attention module lets the decoder attenuate the word-level signals for unknown word tokens (*e.g.* "Marshmellooooo" with trailing 'o's) and amplifies character-level features intsead (*e.g.* capitalized first letter, lexical similarity to other known named entity token 'Marshmello', etc.), thereby suppressing noise information ("UNK" token embedding) in decoding steps. Note that most of the previous literature in NER or other NLP tasks combine word and character-level information with naive concatenation, which is vulnerable to noisy social media posts. When an auxiliary image is available, the modality attention module determines to amplify this visual context *e.g.* in disambiguating polysemous entities, or to attenuate visual contexts when they are irrelevant to target named entities, *e.g.* selfies, etc. Note that the proposed modality attention module is distinct from how attention is used in other sequence-to-sequence literature (*e.g.* attending to a specific token within an input sequence). Section 2 provides the detailed literature review.

Our contributions are three-fold: we propose (1) an LSTM-CNN hybrid multimodal NER network that takes as input both image and text for recognition of a named entity in text input. To the best of our knowledge, our approach is the first work to incorporate visual contexts for named entity recognition tasks. (2) We propose a general *modality attention* module that selectively chooses modalities to extract primary context from, maximizing information gain and suppressing irrelevant contexts from each modality (we treat words, characters, and images as separate modalities). (3) We show that the proposed approaches outperform the state-of-the-art NER models (**both** with and without using additional visual contexts) on our new MNER dataset *SnapCaptions*, a large collection of informal and extremely short social media posts paired with unique images.

2 Related Work

Neural models for NER have been recently proposed, producing state-of-the-art performance on standard NER tasks. For example, some of the end-to-end NER systems (Passos et al., 2014; Chiu and Nichols, 2015; Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016) use a recurrent neural network usually with a CRF (Lafferty et al., 2001; McCallum and Li, 2003) for sequence labeling, accompanied with feature extractors for words and characters (CNN, LSTMs, etc.), and achieve the state-of-the-art performance mostly without any use of gazetteers information. Note that most of these work aggregate textual contexts via concatenation of word embeddings and character embeddings. Recently, several work have addressed the NER task specifically on noisy short text segments such as Tweets, etc. (Baldwin et al., 2015; Aguilar et al., 2017). They report performance gains from leveraging external sources of information such as lexical information (*e.g.* POS tags, etc.) and/or from several preprocessing steps (*e.g.* token substitution, etc.). Our model builds upon these state-of-the-art neural models for NER tasks, and improves the model in two critical ways: (1) incorporation of visual contexts to provide auxiliary information for short media posts, and (2) addition of the modality attention module, which better incorporates word embeddings and character embeddings, especially when there are many missing tokens in the given word embedding matrix. Note that we do not explore the use of gazetteers information or other auxiliary information (POS tags, etc.) (Ratinov and Roth, 2009) as it is not the focus of our study.

Attention modules are widely applied in several deep learning tasks (Xu et al., 2015; Chan

et al., 2015; Sukhbaatar et al., 2015; Yao et al., 2015). For example, they use an attention module to attend to a subset within a single input (a part/region of an image, a specific token in an input sequence of tokens, etc.) at each decoding step in an encoder-decoder framework for image captioning tasks, etc. (Rei et al., 2016) explore various attention mechanisms in NLP tasks, but do not incorporate visual components or investigate the impact of such models on noisy social media data. (Moon and Carbonell, 2017) propose to use attention for a subset of discrete source samples in transfer learning settings. Our modality attention differs from the previous approaches in that we attenuate or amplifies each modality input as a whole among multiple available modalities, and that we use the attention mechanism essentially to map heterogeneous modalities in a single joint embedding space. Our approach also allows for reuse of the same model for predicting labels even when some of the modalities are missing in input, as other modalities would still preserve the same semantics in the embeddings space.

Multimodal learning is studied in various domains and applications, aimed at building a joint model that extracts contextual information from multiple modalities (views) of parallel datasets.

The most relevant task to our multimodal NER system is the task of multimodal machine translation (Elliott et al., 2015; Specia et al., 2016), which aims at building a better machine translation system by taking as input a sentence in a source language as well as a corresponding image. Several standard sequence-to-sequence architectures are explored (*e.g.* a target-language LSTM decoder that takes as input an image first).

Other previous literature include study of Canonical Correlation Analysis (CCA) (Dhillon et al., 2011) to learn feature correlations among multiple modalities, which is widely used in many applications. Other applications include image captioning (Xu et al., 2015), audio-visual recognition (Moon et al., 2015), visual question answering systems (Antol et al., 2015), etc.

To the best of our knowledge, our approach is the first work to incorporate visual contexts for named entity recognition tasks.

3 Proposed Methods

Figure 2 illustrates the proposed multimodal NER (MNER) model. First, we obtain word embeddings, character embeddings, and visual features (Section 3.1). A Bi-LSTM-CRF model then takes as input a sequence of tokens, each of which comprises a word token, a character sequence, and an image, in their respective representation (Section 3.2). At each decoding step, representations from each modality are combined via the modality attention module to produce an entity label for each token (3.3). We formulate each component of the model in the following subsections.

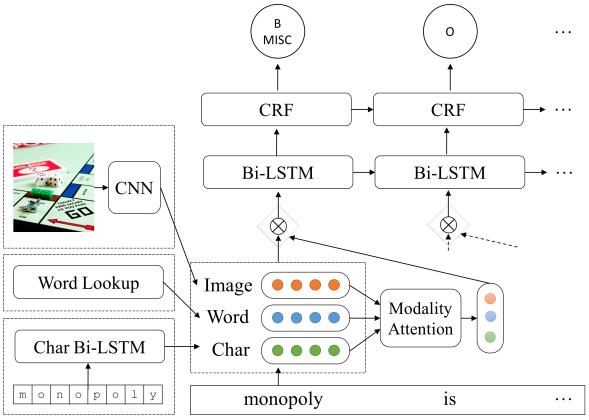


Figure 2: The main architecture for our multimodal NER (MNER) network with modality attention. At each decoding step, word embeddings, character embeddings, and visual features are merged with modality attention. Bi-LSTM/CRF takes as input each token and produces an entity label.

Notations: Let $\mathbf{x} = \{\mathbf{x}_t\}_{t=1}^{T}$ a sequence of input tokens with length T, with a corresponding label sequence $\mathbf{y} = \{\mathbf{y}_t\}_{t=1}^{T}$ indicating named entities (*e.g.* in standard BIO formats). Each input token is composed of three modalities: $\mathbf{x}_t = \{\mathbf{x}_t^{(w)}, \mathbf{x}_t^{(c)}, \mathbf{x}_t^{(v)}\}$ for word embeddings, character embeddings, and visual embeddings representations, respectively.

3.1 Features

Similar to the state-of-the-art NER approaches (Lample et al., 2016; Ma and Hovy, 2016; Aguilar et al., 2017; Passos et al., 2014; Chiu and Nichols, 2015; Huang et al., 2015), we use both word embeddings and character embeddings.

Word embeddings are obtained from an unsupervised learning model that learns co-occurrence statistics of words from a large external corpus, yielding word embeddings as distributional semantics (Mikolov et al., 2013). Specifically, we use pre-trained embeddings from GloVE (Pennington et al., 2014).

Character embeddings are obtained from a Bi-LSTM which takes as input a sequence of characters of each token, similarly to (Lample et al., 2016). An alternative approach for obtaining character embeddings is using a convolutional neural network as in (Ma and Hovy, 2016), but we find that Bi-LSTM representation of characters yields empirically better results in our experiments.

Visual embeddings: To extract features from an image, we take the final hidden layer representation of a modified version of the convolutional network model called Inception (GoogLeNet) (Szegedy et al., 2014, 2015) trained on the ImageNet dataset (Russakovsky et al., 2015) to classify multiple objects in the scene. Our implementation of the Inception model has deep 22 layers, training of which is made possible via "network in network" principles and several dimension reduction techniques to improve computing resource utilization. The final layer representation encodes discriminative information describing what objects are shown in an image, which provide auxiliary contexts for understanding textual tokens and entities in accompanying captions.

Incorporating this visual information onto the traditional NER system is an open challenge, and multiple approaches can be considered. For instance, one may provide visual contexts only as an initial input to decoder as in some encoder-decoder image captioning systems (Vinyals et al., 2015). However, we empirically observe that an NER decoder which takes as input the visual embeddings at every decoding step (Section 3.2), combined with the modality attention module (Section 3.3), yields better results.

Lastly, we add a transform layer for each feature *e.g.* $\mathbf{x}_t^{(w)}, \mathbf{x}_t^{(c)}, \mathbf{x}_t^{(v)} := \sigma_w(\mathbf{x}_t^{(w)}), \sigma_c(\mathbf{x}_t^{(c)}), \sigma_v(\mathbf{x}_t^{(v)})$ before it is fed to the NER entity LSTM.

3.2 Bi-LSTM + CRF for Multimodal NER

Our MNER model is built on a Bi-LSTM and CRF hybrid model. We use the following implementation for the entity Bi-LSTM.

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{xi}\mathbf{h}_{t-1} + \mathbf{W}_{ci}\mathbf{c}_{t-1}) \\
\mathbf{c}_t &= (1 - \mathbf{i}_t) \odot \mathbf{c}_{t-1} \\
&\quad + \mathbf{i}_t \odot \tanh(\mathbf{W}_{xc}\overline{\mathbf{x}_t} + \mathbf{W}_{hc}\mathbf{h}_{t-1}) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{xo}\overline{\mathbf{x}_t} + \mathbf{W}_{ho}\mathbf{h}_{t-1} + \mathbf{W}_{co}\mathbf{c}_t) \\
\mathbf{h}_t &= \text{LSTM}(\overline{\mathbf{x}_t}) \qquad (1) \\
&= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

where $\overline{\mathbf{x}_t}$ is a weighted average of three modalities $\mathbf{x}_t = \{\mathbf{x}_t^{(w)}; \mathbf{x}_t^{(c)}; \mathbf{x}_t^{(v)}\}$ via the modality attention module, which will be defined in Section 3.3. Bias terms for gates are omitted here for simplicity of notation.

We then obtain bi-directional entity token representations $\overleftrightarrow{\mathbf{h}_t} = [\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]$ by concatenating its left and right context representations. To enforce structural correlations between labels in sequence decoding, $\overleftrightarrow{\mathbf{h}_t}$ is then passed to a conditional random field (CRF) to produce a label for each token maximizing the following objective.

$$\mathbf{y}^* = \underset{\mathbf{y}}{\text{argmax}}\, p(\mathbf{y}|\overleftrightarrow{\mathbf{h}}; \mathbf{W}_{\text{CRF}}) \qquad (2)$$

$$p(\mathbf{y}|\overleftrightarrow{\mathbf{h}}; \mathbf{W}_{\text{CRF}}) = \frac{\prod_t \psi_t(\mathbf{y}_{t-1}, \mathbf{y}_t; \overleftrightarrow{\mathbf{h}})}{\sum_{\mathbf{y}'} \prod_t \psi_t(\mathbf{y'}_{t-1}, \mathbf{y'}_t; \overleftrightarrow{\mathbf{h}})}$$

where $\psi_t(\mathbf{y}', \mathbf{y}'; \overleftrightarrow{\mathbf{h}})$ is a potential function, $\mathbf{W}_{\text{CRF}}$ is a set of parameters that defines the potential functions and weight vectors for label pairs $(\mathbf{y}', \mathbf{y}')$. Bias terms are omitted for brevity of formulation.

The model can be trained via log-likelihood maximization for the training set $\{(\mathbf{x}_i, \mathbf{y}_i)\}$:

$$\mathcal{L}(\mathbf{W}_{\text{CRF}}) = \sum_i \log p(\mathbf{y}|\overleftrightarrow{\mathbf{h}}; \mathbf{W}) \qquad (3)$$

3.3 Modality Attention

The modality attention module learns a unified representation space for multiple available modalities (*e.g.* words, characters, images, etc.), and produces a single vector representation with aggregated knowledge among multiple modalities, based on their weighted importance. We motivate this module from the following observations.

A majority of the previous literature combine the word and character-level contexts by simply concatenating the word and character embeddings at each decoding step, *e.g.* $\mathbf{h}_t = \text{LSTM}([\mathbf{x}_t^{(w)}; \mathbf{x}_t^{(c)}])$ in Eq.1. However, this naive concatenation of two modalities (word and characters) results in inaccurate decoding, specifically for unknown word token embeddings (*e.g.* an all-zero vector $\mathbf{x}_t^{(w)} = \mathbf{0}$ or a random vector $\mathbf{x}_t^{(w)} = \boldsymbol{\epsilon} \sim U(-\sigma, +\sigma)$ is assigned for any unknown token $\mathbf{x}_t$, thus $\mathbf{h}_t = \text{LSTM}([\mathbf{0}; \mathbf{x}_t^{(c)}])$ or $\text{LSTM}([\epsilon; \mathbf{x}_t^{(c)}])$). While this concatenation approach does not cause significant errors for well-formatted text, we observe that it induces performance degradation for our social media post

datasets which contain a significant number of missing tokens.

Similarly, naive merging of textual and visual information (*e.g.* $\mathbf{h}_t = \text{LSTM}([\mathbf{x}_t^{(w)}; \mathbf{x}_t^{(c)}; \mathbf{x}_t^{(v)}])$) yields suboptimal results as each modality is treated equally informative, whereas in our datasets some of the images may contain irrelevant contexts to textual modalities. Hence, ideally there needs a mechanism in which the model can effectively turn the *switch* on and off the modalities adaptive to each sample.

To this end, we propose a general modality attention module, which adaptively attenuates or emphasizes each modality as a whole at each decoding step t, and produces a soft-attended context vector $\overline{\mathbf{x}_t}$ as an input token for the entity LSTM.

$$[\mathbf{a}_t^{(w)}, \mathbf{a}_t^{(c)}, \mathbf{a}_t^{(v)}] = \sigma\big(\mathbf{W}_m \cdot [\mathbf{x}_t^{(w)}; \mathbf{x}_t^{(c)}; \mathbf{x}_t^{(v)}] + \mathbf{b}_m\big)$$

$$\alpha_t^{(m)} = \frac{\exp(\mathbf{a}_t^{(m)})}{\sum_{m' \in \{w,c,v\}} \exp(\mathbf{a}_t^{(m')})} \quad \forall m \in \{w, c, v\}$$

$$\overline{\mathbf{x}_t} = \sum_{m \in \{w,c,v\}} \alpha_t^{(m)} \mathbf{x}_t^{(m)} \tag{4}$$

where $\alpha_t = [\alpha_t^{(w)}; \alpha_t^{(c)}; \alpha_t^{(v)}] \in \mathbb{R}^3$ is an attention vector at each decoding step t, and $\overline{\mathbf{x}_t}$ is a final context vector at t that maximizes information gain for $\mathbf{x}_t$. Note that the optimization of the objective function (Eq.1) with modality attention (Eq.4) requires each modality to have the same dimension (*e.g.* $\mathbf{x}_t^{(w)}, \mathbf{x}_t^{(c)}, \mathbf{x}_t^{(v)} \in \mathbb{R}^p$), and that the transformation via $\mathbf{W}_m$ essentially enforces each modality to be mapped into the same unified subspace, where the weighted average of which encodes discrimitive features for recognition of named entities.

When visual context is not provided with each token (as in the traditional NER task), we can define the modality attention for word and character embeddings only in a similar way:

$$[\mathbf{a}_t^{(w)}, \mathbf{a}_t^{(c)}] = \sigma\big(\mathbf{W}_m \cdot [\mathbf{x}_t^{(w)}; \mathbf{x}_t^{(c)}] + \mathbf{b}_m\big) \tag{5}$$

$$\alpha_t^{(m)} = \frac{\exp(\mathbf{a}_t^{(m)})}{\sum_{m' \in \{w,c\}} \exp(\mathbf{a}_t^{(m')})} \quad \forall m \in \{w, c\}$$

$$\overline{\mathbf{x}_t} = \sum_{m \in \{w,c\}} \alpha_t^{(m)} \mathbf{x}_t^{(m)}$$

Note that while we apply this modality attention module to the Bi-LSTM+CRF architecture (Section 3.2) for its empirical superiority, the module itself is flexible and thus can work with other NER architectures or for other multimodal applications.

4 Empirical Evaluation

4.1 SnapCaptions Dataset

The **SnapCaptions** dataset is composed of 10K user-generated image (snap) and textual caption pairs where named entities in captions are manually labeled by expert human annotators (entity types: PER, LOC, ORG, MISC). These captions are collected exclusively from snaps submitted to public and crowd-sourced stories (aka Snapchat *Live Stories* or *Our Stories*). Examples of such public crowd-sourced stories are "New York Story" or "Thanksgiving Story", which comprise snaps that are aggregated for various public events, venues, etc. All snaps were posted between year 2016 and 2017, and do not contain raw images or other associated information (only textual captions and obfuscated visual descriptor features extracted from the pre-trained Inception-Net are available). We split the dataset into train (70%), validation (15%), and test sets (15%). The captions data have average length of 30.7 characters (5.81 words) with vocabulary size 15,733, where 6,612 are considered unknown tokens from Stanford GloVE embeddings (Pennington et al., 2014). Named entities annotated in the SnapCaptions dataset include many of new and emerging entities, and they are found in various surface forms (various nicknames, typos, etc.) To the best of our knowledge, *SnapCaptions* is the only dataset that contains natural image-caption pairs with expert-annotated named entities.

4.2 Baselines

Task: given a caption and a paired image (if used), the goal is to label every token in a caption in BIO scheme (B: beginning, I: inside, O: outside) (Sang and Veenstra, 1999). We report the performance of the following state-of-the-art NER models as baselines, as well as several configurations of our proposed approach to examine contributions of each component (W: word, C: char, V: visual).

- Bi-LSTM/CRF (W only): only takes word token embeddings (Stanford GloVE) as input. The rest of the architecture is kept the same.
- Bi-LSTM/CRF + Bi-CharLSTM (C only): only takes a character sequence of each word token as input. (No word embeddings)

Modalities	Model	4 Entity Types (%)			Segmentation (%)		
		Prec.	Recall	F1	Prec.	Recall	F1
C	Bi-LSTM/CRF + Bi-CharLSTM	5.0	28.1	8.5	68.6	10.8	18.6
W	Bi-LSTM/CRF	38.2	53.3	44.6	82.5	50.1	62.4
W + C	(Aguilar et al., 2017)	45.9	48.9	47.4	74.0	61.7	67.3
W + C	(Ma and Hovy, 2016)	46.0	51.9	48.7	76.8	61.0	68.0
W + C	(Lample et al., 2016)	47.7	49.9	48.8	74.4	63.3	68.4
W + C	Bi-LSTM/CRF + Bi-CharLSTM w/ Modality Attention	49.4	51.7	50.5	75.7	63.3	68.9
W + C + V	Bi-LSTM/CRF + Bi-CharLSTM + Inception	**50.5**	52.3	51.4	71.9	**66.5**	**69.1**
W + C + V	Bi-LSTM/CRF + Bi-CharLSTM + Inception w/ Modality Attention	48.7	**58.7**	**52.4**	**77.4**	60.6	68.0

Table 1: NER performance on the *SnapCaptions* dataset with varying modalities (W: word, C: char, V: visual). We report precision, recall, and F1 score for both entity types recognition (PER, LOC, ORG, MISC) and entity segmentation (untyped recognition - named entity or not) tasks.

- Bi-LSTM/CRF + Bi-CharLSTM (W+C) (Lample et al., 2016): takes as input both word embeddings and character embeddings extracted from a Bi-CharLSTM. Entity LSTM takes concatenated vectors of word and character embeddings as input tokens.
- Bi-LSTM/CRF + CharCNN (W+C) (Ma and Hovy, 2016): uses character embeddings extracted from a CNN instead.
- Bi-LSTM/CRF + CharCNN (W+C) + Multi-task (Aguilar et al., 2017): trains the model to perform both recognition (into multiple entity types) as well as segmentation (binary) tasks.
- (**proposed**) Bi-LSTM/CRF + Bi-CharLSTM with modality attention (W+C): uses the modality attention to merge word and character embeddings.
- (**proposed**) Bi-LSTM/CRF + Bi-CharLSTM + Inception (W+C+V): takes as input visual contexts extracted from InceptionNet as well, concatenated with word and char vectors.
- (**proposed**) Bi-LSTM/CRF + Bi-CharLSTM + Inception with modality attention (W+C+V): uses the modality attention to merge word, character, and visual embeddings as input to entity LSTM.

4.3 Results: SnapCaptions Dataset

Table 1 shows the NER performance on the *Snap Captions* dataset. We report both entity types recognition (PER, LOC, ORG, MISC) and named entity segmentation (named entity or not) results.

Parameters: We tune the parameters of each model with the following search space (bold indicate the choice for our final model): character embeddings dimension: {25, 50, 100, **150**, 200, 300}, word embeddings size: {25, 50, 100, **150**, 200, 300}, LSTM hidden states: {25, 50, **100**, 150, 200, 300}, and $\overline{x}$ dimension: {25, 50, 100, **150**, 200, 300}. We optimize the parameters with Adagrad (Duchi et al., 2011) with batch size 10, learning rate 0.02, epsilon 10^{-8}, and decay 0.0.

Main Results: When visual context is available (W+C+V), we see that the model performance greatly improves over the textual models (W+C), showing that visual contexts are complimentary to textual information in named entity recognition tasks. In addition, it can be seen that the modality attention module further improves the entity type recognition performance for (W+C+V). This result indicates that the modality attention is able to focus on the most effective modality (visual, words, or characters) adaptive to each sample to maximize information gain. Note that our text-only model (W+C) with the modality attention module also significantly outperform the state-of-the-art baselines (Aguilar et al., 2017; Ma and Hovy, 2016; Lample et al., 2016) that use the same textual modalities (W+C), showing the effectiveness of the modality attention module for textual models as well.

Error Analysis: Table 2 shows example cases where incorporation of visual contexts affects prediction of named entities. For example, the token 'curry' in the caption *"The curry's* 🏆*"* is polysemous and may refer to either a type of food or a famous basketball player 'Stephen Curry', and the surrounding textual contexts do not provide

	Caption (target)	Visual Tags	GT	Prediction	
				(W+C+V)	(W+C)
+	*"The curry's 🏆"*	parade, marching, urban area, ...	B-PER	B-PER	O
	"Grandma w dat lit Apple Crisp"	funnel cake, melting, frozen, ...	O	O	B-ORG
	"Okay duke dumont 😍"	DJ, guitarist, circus, ...	B,I-PER	B,I-PER	O,O
	"CSI with my hubby"	TV, movie, television, ...	B-MISC	B-MISC	B-ORG
	"Twin day at angel stadium"	stadium, arena, stampede, ...	B,I-LOC	B,I-LOC	O,O
	"LETS GO CID"	drum, DJ, drummer, ...	B-PER	B-PER	O
	"MARSHMELLOOOOOOOOS"	DJ, night, martini, ...	B-PER	B-PER	O
-	*"Y'all come see me at bojangles. 😊"*	floor, tile, airport terminal, ...	B-ORG	O	B-ORG
	"If u're not watching this season of bachelorette ur doing LIFE WRONG"	monitor, suite, cubicle, ...	B-MISC	O	B-MISC

Table 2: Error analysis: **when do images help NER**? Ground-truth labels (GT) and predictions of our model with vision input (W+C+V) and the one without (W+C) for the underlined named entities (or false positives) are shown. For interpretability, visual tags (label output of InceptionNet) are presented instead of actual feature vectors used.

enough information to disambiguate it. On the other hand, visual contexts (visual tags: 'parade', 'urban area', ...) provide similarities to the token's distributional semantics from other training examples (*e.g.* snaps from "NBA Championship Parade Story"), and thus the model successfully predicts the token as a named entity. Similarly, while the text-only model erroneously predicts 'Apple' in the caption *"Grandma w dat lit Apple Crisp"* as an organization (*e.g.* Apple Inc.), the visual contexts (describing objects related to food) help disambiguate the token, making the model predict it correctly as a non-named entity (a fruit). Trending entities (musicians or DJs such as 'CID', 'Duke Dumont', 'Marshmello', etc.) are also recognized correctly with strengthened contexts from visual information (describing concert scenes) despite lack of surrounding textual contexts. A few cases where visual contexts harmed the performance mostly include visual tags that are unrelated to a token or its surrounding textual contexts.

Visualization of Modality Attention: Figure 3 visualizes the modality attention module at each decoding step (each column), where amplified modality is represented with darker color, and attenuated modality is represented with lighter color.

For the image-aided model (W+C+V; upper row in Figure 3), we confirm that the modality attention successfully attenuates irrelevant signals (*e.g.* selfies, etc.) and amplifies relevant modality-based contexts in prediction of a given token. In the example of "*disney word essential = coffee*" with visual tags *selfie, phone, person*, the modality attention successfully attenuates distracting visual signals and focuses on textual modalities, consequently making correct predictions. The named entities in the examples of "*Beautiful night atop The Space Needle*" and "*Splash Mountain*" are challenging to predict because they are composed of common nouns (space, needle, splash, mountain), and thus they often need additional contexts to correctly predict. In the training data, visual contexts make stronger indicators for these named entities (space needle, splash mountain), and the modality attention module successfully attends more to stronger signals.

For text-only model (W+C), we observe that performance gains mostly come from the modality attention module better handling tokens unseen during training or unknown tokens from the pre-trained word embeddings matrix. For example, while *WaRriOoOrs* and *Kooler Matic* are missing tokens in the word embeddings matrix, it successfully amplifies character-based contexts (*e.g.* capitalized first letters, similarity to known entities 'Golden State Warriors') and suppresses word-based contexts (word embeddings for unknown tokens *e.g.* 'WaRriOoOrs'), leading to correct predictions. This result is significant because it shows performance of the model, with an almost identical architecture, can still improve without having to scale the word embeddings matrix indefinitely.

Figure 3 (b) shows the cases where the modality attention led to incorrect predictions. For example, the model predicts missing tokens *HUUUGE* and *Shampooer* incorrectly as named entities by amplifying misleading character-based contexts (*e.g.* capitalized first letters) or visual contexts (*e.g.*

Figure 3: **Visualization of modality attention** (a) successful cases and (b) unsuccessful ones from *SnapCaptions* test data. For each decoding step of a token (column), the modality attention module amplifies the most relevant modality (darker) while attenuating irrelevant modalities (lighter). The model makes final predictions based on weighted signals from all modalities. For interpretability, visual tags (label output of InceptionNet) are presented instead of actual feature vectors used. GT: ground-truth, Pred: prediction by our model. Modalities- W: words, C: characters, V: visual.

Vocab Size	w/o M.A.	w/ M.A.
100%	48.8	**50.5**
75%	48.7	**50.1**
50%	47.8	**49.6**
25%	46.4	**48.7**

Table 3: NER performance (F1) on SnapCaptions with **varying word embeddings vocabulary size**. Models being compared: (W+C) Bi-LSTM/CRF + Bi-CharLSTM w/ and w/o modality attention (M.A.)

concert scenes, associated contexts of which often include named entities in the training dataset).

Sensitivity to Word Embeddings Vocabulary Size: In order to isolate the effectiveness of the modality attention module on textual models in handling missing tokens, we report the performance with varying word embeddings vocabulary sizes in Table 3. By increasing the number of missing tokens artificially by randomly removing words from the word embeddings matrix (original vocab size: 400K), we observe that while the overall performance degrades, the modality attention module is able to suppress the peformance degradation. Note also that the performance gap generally gets bigger as we decrease the vocabulary size of the word embeddings matrix. This result is significant in that the modality attention is able to improve the model more robust to missing tokens without having to train an indefinitely large word embeddings matrix for arbitrarily noisy social media text datasets.

5 Conclusions

We proposed a new multimodal NER (MNER: image + text) task on short social media posts. We demonstrated for the first time an effective MNER system, where visual information is combined with textual information to outperform traditional text-based NER baselines. Our work can be applied to myriads of social media posts or other articles across multiple platforms which often include both text and accompanying images. In addition, we proposed the *modality attention* module, a new neural mechanism which learns optimal integration of different modes of correlated information. In essence, the modality attention learns to attenuate irrelevant or uninformative modal information while amplifying the primary modality to extract better overall representations. We showed that the modality attention based model outperforms other state-of-the-art baselines when text was the only modality available, by better combining word and character level information.

Nested Named Entity Recognition Revisited

Arzoo Katiyar and **Claire Cardie**

{arzoo, cardie}@cs.cornell.edu

Abstract

We propose a novel recurrent neural network-based approach to simultaneously handle nested named entity recognition and nested entity mention detection. The model learns a hypergraph representation for nested entities using features extracted from a recurrent neural network. In evaluations on three standard data sets, we show that our approach significantly outperforms existing state-of-the-art methods, which are feature-based. The approach is also efficient: it operates linearly in the number of tokens and the number of possible output labels at any token. Finally, we present an extension of our model that jointly learns the head of each entity mention.

1 Introduction

Named entity recognition (or named entity detection) is the task of identifying text spans associated with proper names and classifying them according to their semantic class such as person, organization, etc. It is related to the task of *mention detection* (or entity mention recognition) in which text spans referring to named, nominal or prominal entities are identified and classified according to their semantic class (Florian et al., 2004). Both named entity recognition and entity mention detection are fundamental components in information extraction systems: several downstream tasks such as relation extraction (Mintz et al., 2009), coreference resolution (Chang et al., 2013) and fine-grained opinion mining (Choi et al., 2006) rely on both.

Many approaches have been successfully employed for the tasks of named entity recognition and mention detection, including linear-chain conditional random fields (Lafferty et al., 2001) and semi-Markov conditional random fields (Sarawagi and Cohen, 2005). However, most such methods suffer from an inability to handle *nested* named entities, *nested* entity mentions, or both. As a result, the downstream tasks necessarily ignore these nested entities along with any semantic relations among them. Consider, for example, the excerpts below:

(S1) Employing the [EBV - transformed [human B cell line]$_{\text{CELL\_LINE}}$]$_{\text{CELL\_LINE}}$ SKW6.4, we demonstrate . . .

(S2) . . . [the burial site of [Sheikh Abbad]$_{\text{PERSON}}$]$_{\text{LOCATION}}$ is located . . .

S1 shows a nested named entity from the GENIA dataset (Ohta et al., 2002): "human B cell line" and "EBV - transformed human B cell line" are both considered named entities of type CELL_LINE where the former is embedded inside the latter. S2, derived from the ACE corpora[1], shows a PERSON named entity ("Sheikh Abbad") nested in an entity mention of type LOCATION ("the burial site of Sheikh Abbad"). Most existing methods for named entity recognition and entity mention detection would miss the nested entity in each sentence.

Unfortunately, nested entities can be fairly common: 17% of the entities in the GENIA corpus are embedded within another entity; in the ACE corpora, 30% of sentences contain nested named entities or entity mentions, thus warranting the development of efficient models to effectively handle these linguistic phenomena.

Feature-based methods are the most common among those proposed for handling nested named entity and entity mention recognition. Alex et al.

New Orleans, Louisiana, June 1 - 6, 2018.

(2007), for example, proposed a cascaded CRF model but it does not identify nested named entities of the same type. Finkel and Manning (2009) proposed building a constituency parser with constituents for each named entity in a sentence. Their approach is expensive, i.e., time complexity is cubic in the number of words in the sentence. Lu and Roth (2015) later proposed a mention hypergraph model for nested entity detection with linear time complexity. And recently, Muis and Lu (2017) introduced a multigraph representation based on mention separators for this task. All of these models depend on manually crafted features. In addition, they cannot be directly applied to extend current state-of-the-art recurrent neural network-based models — for flat named entity recognition (Lample et al., 2016) or the joint extraction of entities and relations (Katiyar and Cardie, 2016) — to handle nested entities.

In this paper, we propose a recurrent neural network-based model for nested named entity and nested entity mention recognition. We present a modification to the standard LSTM-based sequence labeling model (Sutskever et al., 2014) that handles both problems and operates linearly in the number of tokens and the number of possible output labels at any token. The proposed neural network approach additionally jointly models entity mention *head*[2] information, a subtask found to be useful for many information extraction applications. Our model significantly outperforms the previously mentioned hypergraph model of Lu and Roth (2015) and Muis and Lu (2017) on entity mention recognition for the ACE2004 and ACE2005 corpora. It also outperforms their model on *joint* extraction of nested entity mentions and their heads. Finally, we evaluate our approach on nested named entity recognition using the GENIA dataset and show that our model outperforms the previous state-of-the-art parser-based approach of Finkel and Manning (2009).

2 Related Work

Several methods have been proposed for named entity recognition in the existing literature as summarized by Nadeau and Sekine (2007) in their survey paper. Early techniques in the supervised domain have been based on hidden markov models (e.g., Zhou and Su (2002)) or, later, conditional random fields (CRFs) (e.g., McDonald and Pereira (2005)).

Many fewer approaches, however, have addressed the problem of nested entities. Alex et al. (2007) presented several techniques based on CRFs for nested named entity recognition for the GENIA dataset. They obtained their best results from a cascaded approach, where they applied CRFs in a specific order on the entity types, such that each CRF utilizes the output derived from previous CRFs. Their approach could not identify nested entities of the same type. Finkel and Manning (2009) proposed a CRF-based constituency parser for nested named entities such that each named entity is a constituent in the parse tree. Their model achieved state-of-the-art results on the GENIA dataset. However, the time complexity of their model is $O(n^3)$, where n is the number of tokens in the sentence, making inference slow. As a result, we do not adopt their parse tree-based representation of nested entities and propose instead a linear time directed hypergraph-based model similar to that of Lu and Roth (2015). Directed hypergraphs were also introduced for parsing by Klein and Manning (2001).

While most previous efforts for nested entity recognition were limited to named entities, Lu and Roth (2015) addressed the problem of nested entity mention detection where mentions can either be named, nominal or pronominal. Their hypergraph-based approach is able to represent the potentially exponentially many combinations of nested mentions of different types. They adopted a CRF-like log-linear approach to learn these mention hypergraphs and employed several hand-crafted features defined over the input sentence and the output hypergraph structure. Our approach also learns a similar hypergraph representation with differences in the types of nodes and edges in the hypergraph. It does not depend on any manually crafted features. Also, our model learns the hypergraph greedily and significantly outperforms their approach.

Recently, Muis and Lu (2017) introduced the notion of mention separators for nested entity mention detection. In contrast to the hypergraph representation that we and Lu and Roth (2015) adopt, they learn a multigraph representation and are able to perform exact inference on their structure. It is an interesting orthogonal possible approach for nested entity mention detection. How-

[2]This involves identifying the headword of a named entity or entity mention.

ever, we will show that our model also outperforms their approach on all tasks.

Recently, recurrent neural networks (RNNs) have been widely applied to several sequence labeling tasks achieving state-of-the-art results. Lample et al. (2016) proposed neural models based on long short term memory networks (LSTMs) and CRFs for named entity recognition and another transition-based approach inspired by shift-reduce parsers. Both models achieve performance comparable to a state-of-the-art model (Luo et al., 2015), but neither handles nested named entities.

3 Encoding Scheme

Figure 1 shows the desired sequence tagging output for each of three overlapping PER entities ("his", "his fellow pilot" and "his fellow pilot David Williams") according to the standard BILOU tag scheme. Our approach relies on the fact that we can (1) represent these three tag sequences in the single hypergraph structure of Figure 2 and then (2) design an LSTM-based neural network that produces the correct nested entity hypergraph for a given input sentence. In the paragraphs just below we provide a general description of hypergraphs and our task-specific use of them. Sections 3.1 and 3.2 describe the hypergraph construction process; Section 4 presents the LSTM-based sequence tagging method for automating hypergraph construction.

We express our structured prediction problem such that it corresponds to building a hypergraph that encodes the token-level gold labels for all entities in the input sentence.[3] In particular, we represent the problem as a directed hypergraph. For those new to this formalism, directed hypergraphs are very much like standard directed graphs except that nodes are connected by hyperarcs that connect a *set* of tail nodes to a *set* of head nodes. To better explain our desired output structure, we further distinguish between two types of hyperarcs — *normal edges* (or arcs) that connect a single tail node to a single head node, and *hyperarcs* that contain more than one node either as the head or as the tail. The former are shown as straight lines in Figure 2; the latter as curved edges.

In our encoding of nested entities, a hyperarc is introduced when two or more entity mentions requiring different label types are present at the same position. In Figure 2, for example, the nodes "O" (corresponding to the input token "that") and the nodes "U_PER" and "B_PER" (corresponding to the input token "his") are connected by a hyperarc because three entity mentions start at this time step from the tail "O" node (two of which share the "B_PER" tag).[4]

3.1 Hypergraph Construction

Let us first discuss how the problem of nested entity recognition can be expressed as finding a hypergraph. Our goal is to represent the BILOU tag sequences associated with "his", "his fellow pilot" and "his fellow pilot David Williams" as the single hypergraph structure of Figure 2. This is accomplished by collapsing the shared states (labels) in the output entity label sequences into a single state as shown in Figure 2: e.g., the three "O" labels for "that" become a single "O"; the two "B_PER" labels at "his" are collapsed into one "B_PER" node that joins "U_PER", the latter of which represents the entity mention "his". Thus at any time step, the representation size is bounded by the number of possible output states instead of the potentially exponential number of output sequences. We then also adjust the directed edges such that they have the same type of head node and the same type of tail node as before in Figure 1.

If we look closely at Figure 2 then we realise that there is an extra "O" node in the hypergraph corresponding to the token "his" which did not appear in any entity output sequence in Figure 1: in our task-specific hypergraph construction we make sure that there is an "O" node at every timestep to model the possibility of beginning of a new entity. The need for this will become more clear in Section 4.

Note that the hypergraph representation of our model is similar to Lu and Roth (2015). Also, the expressiveness of our model is exactly the same as Lu and Roth (2015); Muis and Lu (2017). The major difference in the two approaches is in learning.

[3] We note that the complete hypergraph for the example in Figure 1 would include nodes for all possible label types at each timestep and all possible hyperarcs between them. In this work, however, we only greedily build a sub-hypergraph for the gold labels when training.

[4] In contrast, note that the nodes "L_PER" and "O" corresponding to the input token "pilot" and the node "O" corresponding to the token "David" are connected by normal edges. Hence, our hypergraph structure contains only one special kind of hyperarc which connects a single tail node to multiple head nodes. We do not have hyperarcs that connect multiple tail nodes to a single head node.

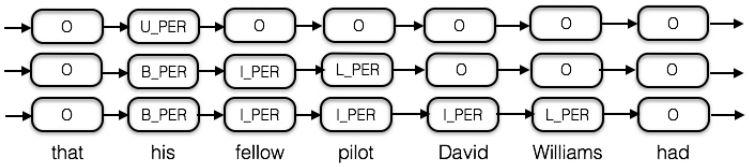

Figure 1: Nested entity mentions in an unfolded hypergraph. Each row corresponds to an entity mention sequence using the well known B_ (beginning of mention), I_ (inside a mention), L_ (last token of an entity mention), O (outside any entity mention), U_ (a single-token entity mention) tagging scheme.

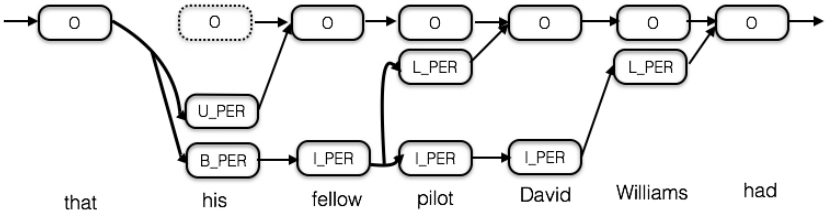

Figure 2: Directed hypergraph constructed for the example shown in Figure 1. Curved edges represent hyperarcs and straight edges are normal edges.

3.2 Edge Probability

In this section, we discuss our assignment of probabilities to all the possible edges from a tail node which helps in the greedy construction of the hypergraph. Thus at any timestep t, let g_{t-1} be the tail node and x be the current word of the sentence; then we model probability distribution over all the possible types of head nodes (different output tag types) conditioned on the tail node and the current word token. In our work we use hidden representations learned from an LSTM model as features to learn these probability distributions using a cross-entropy objective.

It is important to note that there are two types of directed edges in this hypergraph – simple edges for which there is only one head node for every tail node which can be learned as in a traditional sequence labeling task, or hyperarcs that connect more than one head node to a tail node. We learn the set of head nodes connected to a tail node by expressing it as a multi-label learning problem as described in Section 5.

3.3 Extracting Entity Mentions

As described in Section 3.2, we can assign probabilities to the different types of edges in the hypergraph and at the time of decoding we choose for each token the (normal) edge(s) with maximum probability and the hyperarcs with probability above a predefined threshold. Thus, we can extract edges at the time of decoding. Ultimately, however, we are interested in extracting nested entities from the hypergraph. For this, we construct an adjacency matrix from the edges discovered and perform depth-first search from the sentence-initial token to discover the entity mentions. This is described in detail in Section 5.1.

4 Method

We use a standard LSTM-based sequence labeling model to learn the nested entity hypergraph structure for an input sentence. Figure 3 shows part of the network structure. It is a standard bi-directional LSTM network except for a difference in the top hidden layer. When computing the representation of the top hidden layer L at any time step t, in addition to making use of the hidden unit representation from the previous time step $t-1$ and hidden unit representation from the preceding layer $L-1$, we also input the label embedding of the gold labels from the previous time step. For the token "fellow" in Figure 3, for example, we compute three different top hidden layer representations, conditioned respectively on the three labels "U_PER", "B_PER" and "O" from the previous time step $t-1$. Thus, we can model complex interactions between the input and the output. Before passing the learned hidden representation to the next time step, we average the three different top hidden layer representations. In this manner, we can model the interactions between the different overlapping labels and also it is computation-

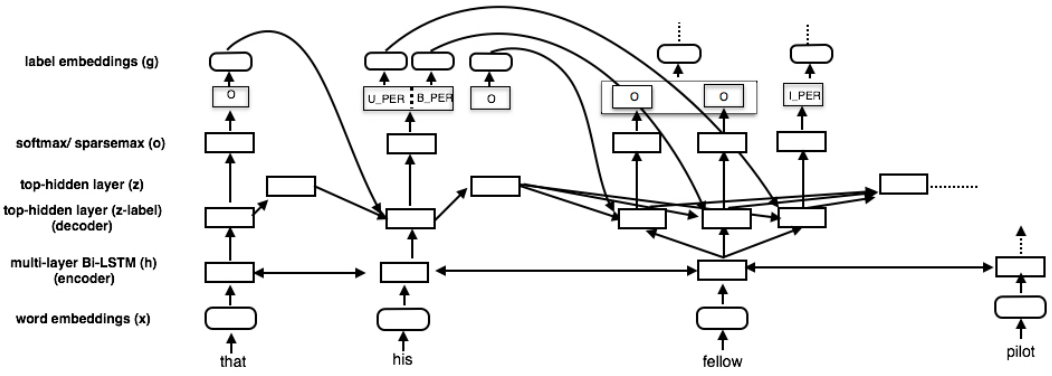

Figure 3: Dynamically computed network structure based on bi-LSTMs for nested entity mention extraction. We show part of the structure for the entity mentions in the running example in Figure 1.

ally less expensive than storing the hidden layer representations for each label sequence.

4.1 Multi-layer Bi-LSTM

We use a multi-layer bi-directional LSTM encoder, for its strength in capturing long-range dependencies between tokens, a useful property for information extraction tasks.

Using LSTMs, we can compute the hidden state $\overrightarrow{\boldsymbol{h}}_t$ in the forward direction and $\overleftarrow{\boldsymbol{h}}_t$ in the backward direction for every token, and use a linear combination of them as the token representation:

$$\overrightarrow{\boldsymbol{h}}_t^{(l)} = \text{LSTM}(\boldsymbol{x}_t, \overrightarrow{\boldsymbol{h}}_{t-1})$$
$$\overleftarrow{\boldsymbol{h}}_t^{(l)} = \text{LSTM}(\boldsymbol{x}_t, \overleftarrow{\boldsymbol{h}}_{t+1})$$
$$\boldsymbol{z}_t^{(l)} = \overrightarrow{\boldsymbol{V}}\overrightarrow{\boldsymbol{h}}_t^{(l)} + \overleftarrow{\boldsymbol{V}}\overleftarrow{\boldsymbol{h}}_t^{(l)} + \boldsymbol{b}^l$$

4.2 Top Hidden Layer

At the top hidden layer, we have a decoder-style model, with a crucial twist to accommodate the hypergraph structure, which may have multiple gold labels at the previous step. At each token t and *for each* gold label at the previous step g_{t-1}^k, our network takes the hidden representation from the previous layer $\boldsymbol{z}_t^{(L-1)}$, the hidden decoder state $\boldsymbol{h}_{t-1}^{(L)}$, as well as the gold label embedding $\boldsymbol{g}_{t-1}^k$ from the previous time step, and computes:

$$\boldsymbol{h}_t^{(L),k} = \text{LSTM}(\boldsymbol{z}_t^{(L-1)}, \boldsymbol{h}_{t-1}^{(L)}, \boldsymbol{g}_{t-1}^k)$$

Unlike the encoder LSTM, this decoder LSTM is single-directional and bifurcates when multiple gold labels are present. We use the decoder hidden states $\boldsymbol{h}_t^{(L),k}$ in the output layer for prediction, as explained in Section 4.3. However, before passing the hidden representation to the next time step we average $\boldsymbol{h}_t^{(L),k}$ over all the gold labels k:

$$\boldsymbol{h}_t^{(L)} = \frac{1}{|G_{t-1}|}\sum_k \boldsymbol{h}_t^{(L),k}$$

Thus, $\boldsymbol{h}_t^{(L)}$ summarizes the information for all the gold labels from the previous time step.

4.3 Entity Extraction

For each token t and previous gold label g_{t-1}^k, we use the decoder state $\boldsymbol{h}_t^{(L),k}$ to predict a *probability distribution* over the possible candidate labels using a linear layer followed by a normalizing transform (illustrated below with softmax). The outputs can be interpreted as conditional probabilities for the next label given the current gold label:

$$\boldsymbol{o}_t^k = \boldsymbol{U}\boldsymbol{h}_t^{(L),k} + \boldsymbol{b}$$
$$\hat{\boldsymbol{e}}_t^k = \text{softmax}(\boldsymbol{o}_t^k)$$
$$p(y_t = c | y_{t-1} = g_{t-1}^k) = (\boldsymbol{e}_t^k)_c$$

Special care is required, however, since the desired output has hyperarcs. As shown in Figure 2, there is an hyperarc between "I_PER" corresponding to the token "fellow" and the label set "L_PER" and "I_PER" corresponding to the token "pilot". Thus, in our network structure conditioned on the previous label "I_PER" in this case, we would like to predict both "L_PER" and "I_PER" as the next labels. To accommodate this, we use a multi-label training objective, as described in Section 5.

5 Training

We train our model using two different multi-label learning objectives. The idea is to represent the

	ACE2004			ACE2005

Our model (sparsemax)	**73.6**	**71.8**	**72.7**	**70.6**	**70.4**	**70.5**

Table 1: Performance on ACE2004 and ACE2005 test set on mention extraction and classification.

gold labels as a distribution over all possible labels, encoded as a vector $\boldsymbol{e}$. Hence, for simple edges, the distribution has a probability of 1 for the unique gold label ($\boldsymbol{e}_g = 1$), and 0 everywhere else. For hyperarcs, we distribute the probability mass uniformly over all the gold labels in the gold label set ($\boldsymbol{e}_g^k = \frac{1}{|G|}$ for all k). Thus, for the example described earlier in Section 4.3, both the labels "L_PER" and "I_PER" receive a probability of 0.5 in the gold label distribution $\boldsymbol{e}_t^k$, conditioned on the label "I_PER" from the previous time step.

Softmax. Our first training method uses softmax to estimate the predicted probabilities, and the KL-divergence multi-label loss between the true distribution $\boldsymbol{e}_t^k$ and the predicted distribution $\hat{\boldsymbol{e}}_t^k = \text{softmax}(\boldsymbol{o}_t^k)$:

$$\ell_{t(\text{softmax})}^k = -\sum_c \left(\boldsymbol{e}_t^k\right)_c \log\left(\hat{\boldsymbol{e}}_t^k\right)_c$$

Sparsemax. Our second training method makes use of *sparsemax*, recently introduced by Martins and Astudillo (2016) as a sparse drop-in replacement to softmax, as well as a loss function. Unlike softmax, which always outputs a nonzero probability for any output, sparsemax outputs zero probability for most of the unlikely classes, leading to good empirical results on multi-label tasks. For our problem, there are only a few nested entities at any timestep in the gold labels thus using a training objective that learns a sparse distribution is more appropriate. Sparsemax can be used to filter part of the output space as in the case for multi-label problems thus leaving non-zero probability on the desired output labels.

Formally, sparsemax returns the euclidean projection of its input $\boldsymbol{o}$ onto the probability simplex:

$$\hat{\boldsymbol{e}} = \text{sparsemax}(\boldsymbol{o}) := \underset{\hat{\boldsymbol{e}} \in \Delta}{\text{argmin}} \|\boldsymbol{o} - \hat{\boldsymbol{e}}\|^2$$

The corresponding loss, a sparse version of the KL divergence, is (up to a constant):

$$\ell_{t(\text{sparsemax})}^k = -2\boldsymbol{e}_t^{k\top}\boldsymbol{o}_t^k + \sum_{c:(\hat{\boldsymbol{e}}_t^k)_c \neq 0} \left((\boldsymbol{o}_t^k)_c^2 - \tau^2\right)$$

This function is convex and differentiable, and the quantity τ is a biproduct of the simplex projection, as described in Martins and Astudillo (2016).

For either choice of probability estimation, the total loss of a training sample is the sum of losses for each token and for each previous gold label:

$$\mathcal{L} = \sum_t \sum_{k \in G_{t-1}} \ell_t^k.$$

5.1 Decoding

At the time of inference, we greedily decode our hypergraph from left-to-right to find the most likely sub-hypergraph. During training, at each timestep the most likely label set is learned conditioned on a gold label from the previous timestep. However, gold labels are not available at test time. Thus, we use the predicted labels from the previous time step as an input to the current time step to find the most likely label set. We use a hard threshold T to determine the predicted label set $P_t^k = \{c : \left(\hat{\boldsymbol{e}}_t^k\right)_c > T\}$

We can get the most likely label set P_t^c for any predicted label at the previous time step $c \in P_{t-1}^k$ using the above decoding strategy. We now combine these inferences to find the most likely entity mention sequences. We construct an adjacency matrix $\boldsymbol{A}$ for each time step, such that $\boldsymbol{A}[\hat{\boldsymbol{e}}_{t-1}^c][\hat{\boldsymbol{e}}_t^k]$ += 1 for every c in the predicted label set P_t^k at timestep t conditioned on $\hat{\boldsymbol{e}}_t^k$ and for every k in predicted labels P_{t-1} at time step $t-1$. This can be viewed as a directed hypergraph with several connected components. We then perform a depth-first search on this directed hypergraph to find all the entity mentions in the sentence.

5.2 Modeling Entity Heads for ACE datasets

The ACE datasets also have annotations for mention heads along with the entity mentions. For example, a sentence with the entity mention "the U.S. embassy" also contains an annotation for its head word which is "embassy" in this case. Thus, we modify our model to also extract the head of the entity mentions for ACE dataset. We jointly model the entity mentions and their heads. To do this, we propose a simple extension to our model by only changing the output label sequence. We introduce new labels starting with "H" to indicate that the current token in the entity mention is part of its head. Thus, we only change the output label sequence for the entity mentions to include the head label: We train with the label sequence "B_ORG I_ORG H_ORG" instead of "B_ORG I_ORG L_ORG". Also, for all our entity sequences we predict the "O" tag at the end, hence we can still extract the entity mentions. At decoding time, we output the sequence of words with the "H" tag as the head words for a mention.

6 Experiments

We evaluate our model on two tasks – nested entity mention detection for the ACE corpora and nested named entity recognition for the GENIA dataset.

6.1 ACE Experiments

6.1.1 Data

We perform experiments on the English section of the ACE2004 and ACE2005 corpora. There are 7 main entity types — Person (PER), Organization (ORG), Geographical Entities (GPE), Location (LOC), Facility (FAC), Weapon (WEA) and Vehicle (VEH). For each entity type, there are annotations for the entity mention and mention heads.

6.1.2 Evaluation Metrics

We use a strict evaluation metric similar to Lu and Roth (2015): an entity mention is considered correct if both the mention span and the mention type are exactly correct. Similarly, for the task of joint extraction of entity mentions and mention heads, the mention span, head span and the entity type should all exactly match the gold label.

6.1.3 Baselines and Previous Models

We compare our model with the feature-based model (MH-F) on hypergraph structure (Lu and Roth, 2015) on both entity mention detection as well as the joint mention and mention heads extraction. We also compare with Muis and Lu (2017) on entity mention detection only as their model cannot detect head phrases of the entity mentions. Lu and Roth (2015) compare their approach with CRF-based approaches such as a linear-chain CRF, semi-markov CRF and a cascaded approach (Alex et al., 2007) and show that their model outperforms them. Hence, we do not include those results in our paper.

We also implement several LSTM-based baselines for comparison. Our first baseline is a standard sequence labeling LSTM model (LSTM-flat). A sequence model is not capable of handling the nested mentions, so we remove the embedded entity mention and keep the mention longer in length. Our second baseline is a hypergraph model (LSTM-output_layer) except that the dependencies are only modeled at the output layer and hence there are no connections to the top-hidden layer from the label embeddings from the previous timestep; instead, these connections are limited to the output layer.

6.1.4 Hyperparameters and Training Details

We use Adadelta (Zeiler, 2012) for training our models. We initialize our word vectors with 300-dimensional word2vec (Mikolov et al., 2013) word embeddings. These word embeddings are tuned during training. We regularize our network using dropout (Srivastava et al., 2014), with the dropout rate tuned on the development set. There are 3 hidden layers in our network and the dimensionality of hidden units is 100 in all our experiments. And we set the threshold T as 0.3.

6.1.5 Results

We show the performance of our approaches in Table 1 compared to the previous state-of-the-art system (Lu and Roth, 2015; Muis and Lu, 2017) on both the ACE2004 and ACE2005 datasets. We find that our LSTM-flat baseline that ignores embedded entity mentions during training performs worse than Lu and Roth (2015); however, our other neural network-based approaches all outperform the previous feature-based approach. Among the neural network-based models, we find that our models that construct a hypergraph perform better than the LSTM-flat models. Also, our approach that models dependencies between the input and the output by passing the prediction from the pre-

	ACE2004			ACE2005

MH-F (Lu and Roth, 2015)	74.4	50.0	59.8	63.4	53.8	58.3
Our model(softmax)	68.2	60.5	64.2	67.5	62.3	64.8
Our model(sparsemax)	**72.3**	**66.8**	**69.7**	**70.6**	**69.8**	**70.2**

Table 2: Performance on ACE2004 and ACE2005 test set on joint entity mention and its head prediction. Muis and Lu (2017) do not predict head of the nested entity mentions.

vious timestep as shown in Figure 3 performs better than the LSTM-output_layer model which only models dependencies at the output layer. Also, as expected, the sparsemax method that produces a sparse probability distribution performs better than the softmax approach for modeling hyperedges. In summary, our sparsemax model is the best performing model.

Joint Modeling of Heads We report the performance of our best performing models on the joint modeling of entity mentions and its head in Table 2. We show that our sparsemax model is still the best performing model. We also find that as the total number of possible labels at any timestep increases because of the way we implemented the entity heads, the gains that we get after incorporating sparsemax are significantly higher compared to the results shown in Table 1.

6.2 GENIA Experiments

6.2.1 Data

We also evaluate our model on the GENIA dataset (Ohta et al., 2002) for nested named entity recognition. We follow the same dataset split as Finkel and Manning (2009); Lu and Roth (2015); Muis and Lu (2017). Thus, the first 90% of the sentences were used in training and the remaining 10% were used for evaluation. We also consider five entity types – DNA, RNA, protein, cell line and cell type.

6.2.2 Baselines and Previous Models

We compare our model with Finkel and Manning (2009) based on a constituency CRF-based parser and the mention hypergraph model by Lu and Roth (2015) and a recent multigraph model by Muis and Lu (2017).

6.2.3 Results

Table 3 shows the performance of our different models compared to the previous models. Interestingly, our LSTM-flat model outperforms Lu and Roth (2015). We suspect that it is because we use pretrained word embeddings[5] trained on PubMed data (Pyysalo et al., 2013) whereas Lu and Roth (2015) did not have access to them. We again find that our neural network model outperforms the previous state-of-the-art (Finkel and Manning, 2009; Muis and Lu, 2017) system. However, we see that both softmax and sparsemax models perform comparably on this dataset.

Method	P	R	F1
Finkel and Manning (2009)	75.4	65.9	70.3
MH-F (Lu and Roth, 2015)	72.5	65.2	68.7
Muis and Lu (2017)	75.4	66.8	70.8
LSTM-flat	75.5	63.5	68.9
LSTM-output_layer	78.4	67.9	72.8
Our model (softmax)	76.7	**71.1**	**73.8**
Our model (sparsemax)	**79.8**	68.2	73.6

Table 3: Performance on the GENIA dataset on nested named entity recognition.

7 Error Analysis

Consistent with existing results on the joint modeling of related tasks in NLP, we find that joint modeling of heads and their entity mentions leads to an increase in F-score by 1pt (i.e., 71.4 for the sparsemax model on the ACE2005 dataset) on the performance of the entity mentions. The precision on extracting entity mentions is 72.1 (vs. 70.6 in Table 1) for our sparsemax model for the ACE2005 dataset.

Example S1 below compares the output from a softmax vs. a sparsemax model on the joint modeling of an entity mention and its head on the ACE2005 dataset. Gold-standard annotations are shown in *red*.

(S1) [[[They]]]$_{\text{PERSON}}$ don't abandon [[[[[their]]]$_{\text{PERSON}}$ patients]]$_{\text{PERSON}}$, except

[5] Word vectors trained on PubMed data are available at http://bio.nlplab.org/#source-data.

for the high premiums of a few specialities?

Based on the gold standard, the models are required to extract "their" — an entity mention of type PER as well as its head — and "their patients", which overlaps with the previous entity mention "their" and has the head word "patients". This means that the models are required to predict a hyperedge from "O" to "H_PER; B_PER". We find that the softmax model shown in *blue* can only predict the entity mention "their" omitting completely the entity mention "their patients" whereas the sparsemax model shown in *green* can predict both nested entities. Overall then, sparsemax seems to allow the modeling of hyperedges more efficiently compared to the softmax model and performance gains are due to extracting more nested entities with the help of sparsemax model.

7.1 Limitations and Future Directions

We also manually scanned the test set predictions on ACE dataset for our sparsemax model to understand its current limitations.

Document Context. Given the following sentence

(S2) [They]$_{\text{VEHICLE}}$ roar, [they]$_{\text{VEHICLE}}$ screech.

the sparsemax model predicts both entity mentions of "they" as PER entity type. Only if the previous sentence in the corpus is accessible — "And if you ride inside that tank, it is like riding in the bowels of a dragon" — can we understand that "they" in S2 refers to the tank and hence is a VEH. Thus, our model can be improved by providing additional context for each sentence rather than making predictions on each sentence in the corpus independently.

Pronominal Entity Mention (It). Next, consider examples S3 and S4:

(S3) [It]$_{\text{FACILITY}}$ also seemed to be [some kind of monitoring station]$_{\text{FACILITY}}$.

(S4) It does not matter to [these people]$_{\text{PERSON}}$ that crime has skyrocketed . . .

In the example sentences, "It" refers to a facility and an event, respectively. Our model does not distinguish between the two cases and always predicts the token "It" as a non-entity. We found this true for all occurrences of the token "It" in our test set. The incorporation of coreference information can potentially overcome this limitation.

Inconsistency in Gold-standard Annotations. We also identified potential inconsistencies in the gold-standard annotations.

(S5) . . . results may affect what happens to [both of these teams]$_{\text{ORG}}$, but in just . . .

For S5, the gold-standard annotation for "both of these teams" is an ORG entity mention with the token "teams" as its head word. Our sparsemax model identifies the entity mention correctly but instead predicts the token "both" as the head. It also identifies "these teams" as another nested entity mention with the head word "teams". In contrast, however, we also found entity mentions such as "all of the victims that get a little money" for which the gold-standard has "all" annotated as its head and another nested mention "the victims that get a little money" with "victims" as the head. We recognize this as an inconsistency in the gold-standard annotation.

8 Conclusion and Future Work

In this paper, we present a novel recurrent network-based model for nested named entity recognition and nested entity mention detection. We propose a hypergraph representation for this problem and learn the structure using an LSTM network in a greedy manner. We show that our model significantly outperforms a feature based mention hypergraph model (Lu and Roth, 2015) and a recent multigraph model (Muis and Lu, 2017) on the ACE dataset. Our model also outperforms the constituency parser-based approach of Finkel and Manning (2009) on the GENIA dataset.

In future work, it would be interesting to learn global dependencies between the output labels for such a hypergraph structure and training the model globally. We can also experiment with different representations such as the one in Finkel and Manning (2009) and use the recent advances in neural network approaches (Vinyals et al., 2015) to learn the constituency parse tree efficiently.

Simultaneously Self-Attending to All Mentions for Full-Abstract Biological Relation Extraction

Patrick Verga, Emma Strubell, Andrew McCallum

College of Information and Computer Sciences
University of Massachusetts Amherst
{pat, strubell, mccallum}@cs.umass.edu

Abstract

Most work in relation extraction forms a prediction by looking at a short span of text within a single sentence containing a single entity pair mention. This approach often does not consider interactions across mentions, requires redundant computation for each mention pair, and ignores relationships expressed across sentence boundaries. These problems are exacerbated by the document- (rather than sentence-) level annotation common in biological text. In response, we propose a model which simultaneously predicts relationships between all mention pairs in a document. We form pairwise predictions over entire paper abstracts using an efficient self-attention encoder. All-pairs mention scores allow us to perform multi-instance learning by aggregating over mentions to form entity pair representations. We further adapt to settings without mention-level annotation by jointly training to predict named entities and adding a corpus of weakly labeled data. In experiments on two Biocreative benchmark datasets, we achieve state of the art performance on the Biocreative V Chemical Disease Relation dataset for models without external KB resources. We also introduce a new dataset an order of magnitude larger than existing human-annotated biological information extraction datasets and more accurate than distantly supervised alternatives.

1 Introduction

With few exceptions (Swampillai and Stevenson, 2011; Quirk and Poon, 2017; Peng et al., 2017), nearly all work in relation extraction focuses on classifying a short span of text within a single sentence containing a single entity pair mention. However, relationships between entities are often expressed across sentence boundaries or otherwise require a larger context to disambiguate. For example, 30% of relations in the Biocreative V CDR dataset (§3.1) are expressed across sentence boundaries, such as in the following excerpt expressing a relationship between the chemical **azathioprine** and the disease **fibrosis**:

> *Treatment of psoriasis with **azathioprine**.* **Azathioprine** treatment benefited 19 (66%) out of 29 patients suffering from severe psoriasis. Haematological complications were not troublesome and results of biochemical liver function tests remained normal. Minimal cholestasis was seen in two cases and portal **fibrosis** of a reversible degree in eight. Liver biopsies should be undertaken at regular intervals if **azathioprine** therapy is continued so that structural liver damage may be detected at an early and reversible stage.

Though the entities' mentions never occur in the same sentence, the above example expresses that the chemical entity *azathioprine* can cause the side effect *fibrosis*. Relation extraction models which consider only within-sentence relation pairs cannot extract this fact without knowledge of the complicated coreference relationship between *eight* and *azathioprine treatment*, which, without features from a complicated pre-processing pipeline, cannot be learned by a model which considers entity pairs in isolation. Making separate predictions for each mention pair also obstructs multi-instance learning (Riedel et al., 2010; Surdeanu et al., 2012), a technique which aggregates entity representations from mentions in order to improve robustness to noise in the data. Like the majority of relation extraction data, most annotation for biological relations is distantly supervised, and so we could benefit from a model which is amenable to multi-instance learning.

In addition to this loss of cross-sentence and cross-mention reasoning capability, traditional mention pair relation extraction models typically introduce computational inefficiencies by independently extracting features for and scoring every pair of mentions, even when those mentions occur in the same sentence and thus could share representations. In the CDR training set, this requires separately encoding and classifying each of the 5,318 candidate mention pairs independently, versus encoding each of the 500 abstracts once. Though abstracts

Proceedings of NAACL-HLT 2018, pages 872–884
New Orleans, Louisiana, June 1 - 6, 2018.

are longer than e.g. the text between mentions, many sentences contain multiple mentions, leading to redundant computation.

However, encoding long sequences in a way which effectively incorporates long-distance context can be prohibitively expensive. Long Short Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) are among the most popular token encoders due to their capacity to learn high-quality representations of text, but their ability to leverage the fastest computing hardware is thwarted due to their computational dependence on the length of the sequence — each token's representation requires as input the representation of the previous token, limiting the extent to which computation can be parallelized. Convolutional neural networks (CNNs), in contrast, can be executed entirely in parallel across the sequence, but the amount of context incorporated into a single token's representation is limited by the depth of the network, and very deep networks can be difficult to learn (Hochreiter, 1998). These problems are exacerbated by longer sequences, limiting the extent to which previous work explored full-abstract relation extraction.

To facilitate efficient full-abstract relation extraction from biological text, we propose Bi-affine Relation Attention Networks (BRANs), a combination of network architecture, multi-instance and multi-task learning designed to extract relations between entities in biological text without requiring explicit mention-level annotation. We synthesize convolutions and self-attention, a modification of the Transformer encoder introduced by Vaswani et al. (2017), over sub-word tokens to efficiently incorporate into token representations rich context between distant mention pairs across the entire abstract. We score all pairs of mentions in parallel using a bi-affine operator, and aggregate over mention pairs using a soft approximation of the max function in order to perform multi-instance learning. We jointly train the model to predict relations and entities, further improving robustness to noise and lack of gold annotation at the mention level.

In extensive experiments on two benchmark biological relation extraction datasets, we achieve state of the art performance for a model using no external knowledge base resources in experiments on the Biocreative V CDR dataset, and outperform comparable baselines on the Biocreative VI ChemProt dataset. We also introduce a new dataset which is an order of magnitude larger than existing gold-annotated biological relation extraction datasets while covering a wider range of entity and relation types and with higher accuracy than distantly supervised datasets of the same size. We provide a strong baseline on this new dataset, and encourage its use as a benchmark for future biological relation extraction systems.[1]

2 Model

We designed our model to efficiently encode long contexts spanning multiple sentences while forming pairwise predictions without the need for mention pair-specific features. To do this, our model first encodes input token embeddings using self-attention. These embeddings are used to predict both entities and relations. The relation extraction module converts each token to a *head* and *tail* representation. These representations are used to form mention pair predictions using a bi-affine operation with respect to learned relation embeddings. Finally, these mention pair predictions are pooled to form entity pair predictions, expressing whether each relation type is expressed by each relation pair.

2.1 Inputs

Our model takes in a sequence of N token embeddings in $\mathbb{R}^d$. Because the Transformer has no innate notion of token position, the model relies on positional embeddings which are added to the input token embeddings.[2] We learn the position embedding matrix $P^{m \times d}$ which contains a separate d dimensional embedding for each position, limited to m possible positions. Our final input representation for token x_i is:

$$x_i = s_i + p_i$$

where s_i is the token embedding for x_i and p_i is the positional embedding for the ith position. If i exceeds m, we use a randomly initialized vector in place of p_i.

We tokenize the text using byte pair encoding (BPE) (Gage, 1994; Sennrich et al., 2015). The BPE algorithm constructs a vocabulary of sub-word pieces, beginning with single characters. Then, the algorithm iteratively merges the most frequent co-occurring tokens into a new token, which is added to the vocabulary. This procedure continues until a pre-defined vocabulary size is met.

BPE is well suited for biological data for the following reasons. First, biological entities often have unique mentions made up of meaningful subcomponents, such as *1,2-dimethylhydrazine*. Additionally, tokenization of chemical entities is challenging, lacking a universally agreed upon algorithm (Krallinger et al., 2015). As we demonstrate in §3.3.2, the sub-word representations produced by BPE allow the model to formulate better predictions, likely due to better modeling of rare and unknown words.

[1] Our code and data are publicly available at: https://github.com/patverga/bran.

[2] Though our final model incorporates some convolutions, we retain the position embeddings.

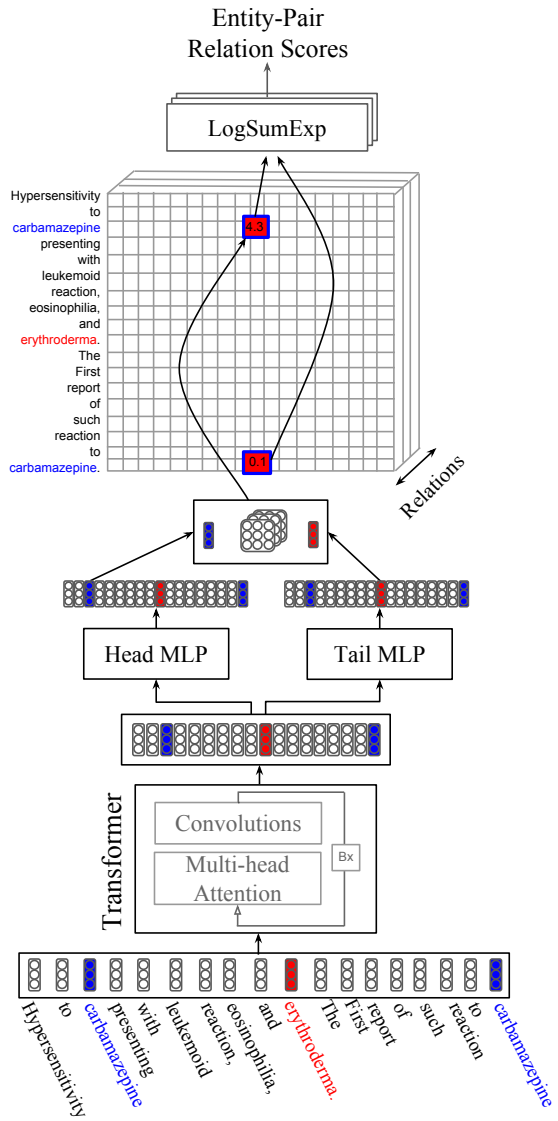

Figure 1: The relation extraction architecture. Inputs are contextually encoded using the Transformer(Vaswani et al., 2017), made up of B layers of multi-head attention and convolution subcomponents. Each transformed token is then passed through a *head* and *tail* MLP to produce two position-specific representations. A bi-affine operation is performed between each *head* and *tail* representation with respect to each relation's embedding matrix, producing a pair-wise relation affinity tensor. Finally, the scores for cells corresponding to the same entity pair are pooled with a separate LogSumExp operation for each relation to get a final score. The colored tokens illustrate calculating the score for a given pair of entities; the model is only given entity information when pooling over mentions.

2.2 Transformer

We base our token encoder on the Transformer self-attention model (Vaswani et al., 2017). The Transformer is made up of B blocks. Each Transformer block, which we denote Transformer_k, has its own set of parameters and is made up of two subcomponents: multi-head attention and a series of convolutions[3]. The output for token i of block k, $b_i^{(k)}$, is connected to its input $b_i^{(k-1)}$ with a residual connection (He et al., 2016). Starting with $b_i^{(0)} = x_i$:

$$b_i^{(k)} = b_i^{(k-1)} + \text{Transformer}_k(b_i^{(k-1)})$$

2.2.1 Multi-head Attention

Multi-head attention applies self-attention multiple times over the same inputs using separately normalized parameters (attention heads) and combines the results, as an alternative to applying one pass of attention with more parameters. The intuition behind this modeling decision is that dividing the attention into multiple heads make it easier for the model to learn to attend to different types of relevant information with each head. The self-attention updates input $b_i^{(k-1)}$ by performing a weighted sum over all tokens in the sequence, weighted by their importance for modeling token i.

Each input is projected to a key k, value v, and query q, using separate affine transformations with ReLU activations (Glorot et al., 2011). Here, k, v, and q are each in $\mathbb{R}^{\frac{d}{H}}$ where H is the number of heads. The attention weights a_{ijh} for head h between tokens i and j are computed using scaled dot-product attention:

$$a_{ijh} = \sigma\left(\frac{q_{ih}^T k_{jh}}{\sqrt{d}}\right)$$
$$o_{ih} = \sum_j v_{jh} \odot a_{ijh}$$

with $\odot$ denoting element-wise multiplication and σ indicating a softmax along the jth dimension. The scaled attention is meant to aid optimization by flattening the softmax and better distributing the gradients (Vaswani et al., 2017).

The outputs of the individual attention heads are concatenated, denoted $[\cdot;\cdot]$, into o_i. All layers in the network use residual connections between the output of the multi-headed attention and its input. Layer normalization (Ba et al., 2016), denoted $\text{LN}(\cdot)$, is then applied to the output.

$$o_i = [o_1; ...; o_h]$$
$$m_i = \text{LN}(b_i^{(k-1)} + o_i)$$

2.2.2 Convolutions

The second part of our Transformer block is a stack of convolutional layers. The sub-network used in

[3]The original Transformer uses feed-forward connections, i.e. width-1 convolutions, whereas we use convolutions with width > 1.

Vaswani et al. (2017) uses two width-1 convolutions. We add a third middle layer with kernel width 5, which we found to perform better. Many relations are expressed concisely by the immediate local context, e.g. *Michele's husband Barack*, or *labetalol-induced hypotension*. Adding this explicit n-gram modeling is meant to ease the burden on the model to learn to attend to local features. We use $C_w(\cdot)$ to denote a convolutional operator with kernel width w. Then the convolutional portion of the transformer block is given by:

$$t_i^{(0)} = \text{ReLU}(C_1(m_i))$$
$$t_i^{(1)} = \text{ReLU}(C_5(t_i^{(0)}))$$
$$t_i^{(2)} = C_1(t_i^{(1)})$$

Where the dimensions of $t_i^{(0)}$ and $t_i^{(1)}$ are in $\mathbb{R}^{4d}$ and that of $t_i^{(2)}$ is in $\mathbb{R}^d$.

2.3 Bi-affine Pairwise Scores

We project each contextually encoded token $b_i^{(B)}$ through two separate MLPs to generate two new versions of each token corresponding to whether it will serve as the first (head) or second (tail) argument of a relation:

$$e_i^{head} = W_{head}^{(1)}(\text{ReLU}(W_{head}^{(0)} b_i^{(B)}))$$
$$e_i^{tail} = W_{tail}^{(1)}(\text{ReLU}(W_{tail}^{(0)} b_i^{(B)}))$$

We use a bi-affine operator to calculate an $N \times L \times N$ tensor A of pairwise affinity scores, scoring each (head, relation, tail) triple:

$$A_{ilj} = (e_i^{head} L) e_j^{tail}$$

where L is a $d \times L \times d$ tensor, a learned embedding matrix for each of the L relations. In subsequent sections we will assume we have transposed the dimensions of A as $d \times d \times L$ for ease of indexing.

2.4 Entity Level Prediction

Our data is weakly labeled in that there are labels at the entity level but not the mention level, making the problem a form of strong-distant supervision (Mintz et al., 2009). In distant supervision, edges in a knowledge graph are heuristically applied to sentences in an auxiliary unstructured text corpus — often applying the edge label to all sentences containing the subject and object of the relation. Because this process is imprecise and introduces noise into the training data, methods like multi-instance learning were introduced (Riedel et al., 2010; Surdeanu et al., 2012). In multi-instance learning, rather than looking at each distantly labeled mention pair in isolation, the model is trained over the aggregate of these mentions and a single update is made. More recently, the weighting function of the instances has been expressed as neural network attention (Verga and McCallum, 2016; Lin et al., 2016; Yaghoobzadeh et al., 2017).

We aggregate over all representations for each mention pair in order to produce per-relation scores for each entity pair. For each entity pair (p^{head}, p^{tail}), let P^{head} denote the set of indices of mentions of the entity p^{head}, and let P^{tail} denote the indices of mentions of the entity p^{tail}. Then we use the LogSumExp function to aggregate the relation scores from A across all pairs of mentions of p^{head} and p^{tail}:

$$scores(p^{head}, p^{tail}) = \log \sum_{\substack{i \in P^{head} \\ j \in P^{tail}}} \exp(A_{ij})$$

The LogSumExp scoring function is a smooth approximation to the max function and has the benefits of aggregating information from multiple predictions and propagating dense gradients as opposed to the sparse gradient updates of the max (Das et al., 2017).

2.5 Named Entity Recognition

In addition to pairwise relation predictions, we use the Transformer output $b_i^{(B)}$ to make entity type predictions. We feed $b_i^{(B)}$ as input to a linear classifier which predicts the entity label for each token with per-class scores c_i:

$$c_i = W^{(3)} b_i^{(B)}$$

We augment the entity type labels with the BIO encoding to denote entity spans. We apply tags to the byte-pair tokenization by treating each subword within a mention span as an additional token with a corresponding B- or I- label.

2.6 Training

We train both the NER and relation extraction components of our network to perform multi-class classification using maximum likelihood, where NER classes y_i or relation classes r_i are conditionally independent given deep features produced by our model with probabilities given by the softmax function. In the case of NER, features are given by the per-token output of the transformer:

$$\frac{1}{N} \sum_{i=1}^{N} \log P(y_i \mid b_i^{(B)})$$

In the case of relation extraction, the features for each entity pair are given by the LogSumExp over pairwise scores described in § 2.4. For E entity pairs, the relation r_i is given by:

$$\frac{1}{E} \sum_{i=1}^{E} \log P(r_i \mid scores(p^{head}, p^{tail}))$$

We train the NER and relation objectives jointly, sharing all embeddings and Transformer parameters. To trade off the two objectives, we penalize the named entity updates with a hyperparameter λ.

3 Results

We evaluate our model on three datasets: The Biocreative V Chemical Disease Relation benchmark (CDR), which models relations between chemicals and diseases (§3.1); the Biocreative VI ChemProt benchmark (CPR), which models relations between chemicals and proteins (§3.2); and a new, large and accurate dataset we describe in §3.3 based on the human curation in the Chemical Toxicology Database (CTD), which models relationships between chemicals, proteins and genes.

The CDR dataset is annotated at the level of paper abstracts, requiring consideration of long-range, cross sentence relationships, thus evaluation on this dataset demonstrates that our model is capable of such reasoning. We also evaluate our model's performance in the more traditional setting which does not require cross-sentence modeling by performing experiments on the CPR dataset, for which all annotations are between two entity mentions in a single sentence. Finally, we present a new dataset constructed using strong-distant supervision (§2.4), with annotations at the document level. This dataset is significantly larger than the others, contains more relation types, and requires reasoning across sentences.

3.1 Chemical Disease Relations Dataset

The Biocreative V chemical disease relation extraction (CDR) dataset[4] (Li et al., 2016a; Wei et al., 2016) was derived from the Comparative Toxicogenomics Database (CTD), which curates interactions between genes, chemicals, and diseases (Davis et al., 2008). CTD annotations are only at the document level and do not contain mention annotations. The CDR dataset is a subset of these original annotations, supplemented with human annotated, entity linked mention annotations. The relation annotations in this dataset are also at the document level only.

3.1.1 Data Preprocessing

The CDR dataset is concerned with extracting only chemically-induced disease relationships (drug-related side effects and adverse reactions) concerning the most specific entity in the document. For example *tobacco causes cancer* could be marked as false if the document contained the more specific *lung cancer*. This can cause true relations to be labeled as false, harming evaluation performance. To address this we follow (Gu et al., 2016, 2017) and filter hypernyms according to the hierarchy in the MESH controlled vocabulary[5]. All entity pairs within the same abstract that do not have an annotated relation are assigned the NULL label.

In addition to the gold CDR data, Peng et al. (2016) add 15,448 PubMed abstracts annotated in the CTD dataset. We consider this same set of abstracts as additional training data (which we subsequently denote +Data). Since this data does not contain entity annotations, we take the annotations from Pubtator (Wei et al., 2013), a state of the art biological named entity tagger and entity linker. See §A.1 for additional data processing details. In our experiments we only evaluate our relation extraction performance and all models (including baselines) use gold entity annotations for predictions.

The byte pair vocabulary is generated over the training dataset — we use a budget of 2500 tokens when training on the gold CDR data, and a larger budget of 10,000 tokens when including extra data described above Additional implementation details are included in Appendix A.

Data split	Docs	Pos	Neg
Train	500	1,038	4,280
Development	500	1,012	4,136
Test	500	1,066	4,270
CTD	15,448	26,657	146,057

Table 1: Data statistics for the CDR Dataset and additional data from CTD. Shows the total number of abstracts, positive examples, and negative examples for each of the data set splits.

3.1.2 Baselines

We compare against the previous best reported results on this dataset not using knowledge base features.[6] Each of the baselines are ensemble methods for within- and cross-sentence relations that make use of additional linguistic features (syntactic parse and part-of-speech). Gu et al. (2017) encode mention pairs using a CNN while Zhou et al. (2016a) use an LSTM. Both make cross-sentence predictions with featurized classifiers.

3.1.3 Results

In Table 2 we show results outperforming the baselines despite using no linguistic features. We show performance averaged over 20 runs with 20 random seeds as well as an ensemble of their averaged predictions. We see a further boost in performance by adding weakly labeled data. Table 3 shows the

[4] http://www.biocreative.org/

[5] https://www.nlm.nih.gov/mesh/download/2017MeshTree.txt

[6] The highest reported score is from (Peng et al., 2016), but they use explicit lookups into the CTD knowledge base for the existence of the test entity pair.

Model	P	R	F1

– no width-5	48.2	67.2	55.7 ± 0.9
– no NER	49.9	63.8	55.5 ± 1.8

Table 3: Results on the Biocreative V CDR Dataset showing precision, recall, and F1 for various model ablations.

effects of ablating pieces of our model. 'CNN only' removes the multi-head attention component from the transformer block, 'no width-5' replaces the width-5 convolution of the feed-forward component of the transformer with a width-1 convolution and 'no NER' removes the named entity recognition multi-task objective (§2.5).

3.2 Chemical Protein Relations Dataset

To assess our model's performance in settings where cross-sentence relationships are not explicitly evaluated, we perform experiments on the Biocreative VI ChemProt dataset (CDR) (Krallinger et al., 2017). This dataset is concerned with classifying into six relation types between chemicals and proteins, with nearly all annotated relationships occurring within the same sentence.

3.2.1 Baselines

We compare our models against those competing in the official Biocreative VI competition (Liu et al., 2017). We compare to the top performing team whose model is directly comparable with ours — i.e. used a single (non-ensemble) model trained only on the training data (many teams use the development set as additional training data). The baseline models are standard state of the art relation extraction models: CNNs and Gated RNNs with attention. Each of these baselines uses mention-specific features encoding relative position of each token to the two target entities being classified, whereas our model aggregates over all mention pairs in each sentence. It is also worth noting that these models use a large vocabulary of pre-trained word embeddings, giving their models the advantage of far more model parameters, as well as additional information from unsupervised pre-training.

Model	P	R	F1
CNN†	50.7	43.0	46.5
GRU+Attention†	53.0	46.3	49.5
BRAN	48.0	54.1	**50.8** ± .01

Table 4: Precision, recall, and F1 results on the Biocreative VI Chem-Prot Dataset. † denotes results from Liu et al. (2017)

3.2.2 Results

In Table 4 we see that even though our model forms all predictions simultaneously between all pairs of entities within the sentence, we are able to outperform state of the art models classifying each mention pair independently. The scores shown are averaged across 10 runs with 10 random seeds. Interestingly, our model appears to have higher recall and lower precision, while the baseline models are both precision-biased, with lower recall. This suggests that combining these styles of model could lead to further gains on this task.

3.3 New CTD Dataset

3.3.1 Data

Existing biological relation extraction datasets including both CDR (§3.1) and CPR (§3.2) are relatively small, typically consisting of hundreds or a few thousand annotated examples. Distant supervision datasets apply document-independent, entity-level annotations to all sentences leading to a large proportion of incorrect labels. Evaluations on this data involve either very small (a few hundred) gold annotated examples or cross validation to predict the noisy, distantly applied labels (Mallory et al., 2015; Quirk and Poon, 2017; Peng et al., 2017).

We address these issues by constructing a new dataset using strong-distant supervision containing document-level annotations. The Comparative Toxicogenomics Database (CTD) curates interactions between genes, chemicals, and diseases. Each relation in the CTD is associated with a disambiguated entity pair and a PubMed article where the relation was observed.

To construct this dataset, we collect the abstracts for each of the PubMed articles with at least one curated relation in the CTD database. As in §3.1, we use PubTator to automatically tag and disambiguate the entities in each of these abstracts. If both entities in the relation are found in the abstract, we take the (abstract, relation) pair as a positive example. The evidence for the curated relation could occur anywhere in the full text article, not just the abstract. Abstracts with no recovered relations are discarded. All other entity pairs with valid types and without an annotated relation that

Types	Docs	Pos	Neg
Total	68,400	166,474	1198,493
Chemical/Disease	64,139	93,940	571,932
Chemical/Gene	34,883	63,463	360,100
Gene/Disease	32,286	9,071	266,461

Table 5: Data statistics for the new CTD dataset.

occur in the remaining abstracts are considered negative examples and assigned the NULL label. We additionally remove abstracts containing greater than 500 tokens[7]. This limit removed about 10% of the total data including numerous extremely long abstracts. The average token length of the remaining data was $\tilde{2}30$ tokens. With this procedure, we are able to collect 166,474 positive examples over 13 relation types, with more detailed statistics of the dataset listed in Table 5.

We consider relations between chemical-disease, chemical-gene, and gene-disease entity pairs downloaded from CTD[8]. We remove inferred relations (those without an associated PubMed ID) and consider only human curated relationships. Some chemical-gene entity pairs were associated with multiple relation types in the same document. We consider each of these relation types as a separate positive example.

The chemical-gene relation data contains over 100 types organized in a shallow hierarchy. Many of these types are extremely infrequent, so we map all relations to the highest parent in the hierarchy, resulting in 13 relation types. Most of these chemical-gene relations have an increase and decrease version such as increase_expression and decrease_expression. In some cases, there is also an affects relation (affects_expression) which is used when the directionality is unknown. If the affects version is more common, we map decrease and increase to affects. If affects is less common, we drop the affects examples and keep the increase and decrease examples as distinct relations, resulting in the final set of 10 chemical-gene relation types.

3.3.2 Results

In Table 7 we list precision, recall and F1 achieved by our model on the CTD dataset, both overall and by relation type. Our model predicts each of the relation types effectively, with higher performance on relations with more support.

In Table 8 we see that our sub-word BPE model out-performs the model using the Genia tokenizer (Kulick et al., 2012) even though our vocabulary size is one-fifth as large. We see a 1.7 F1 point boost in predicting Pubtator NER labels for BPE. This could be explained by the increased out-of-vocabulary (OOV) rate for named entities. Word training data has 3.01 percent OOV rate for tokens with an entity. The byte pair-encoded data has an OOV rate of 2.48 percent. Note that in both the word-tokenized and byte pair-tokenized data, we replace tokens that occur less than five times with a learned UNK token.

[7]We include scripts to generate the unfiltered set of data as well to encourage future research

Table 6: Data statistics for the new CTD dataset broken down by relation type. The first column lists relation types separated by the types of the entities. Columns 2–4 show the number of positive examples of that relation type. MP stands for metabolic processing.

Figure 2 depicts the model's performance on relation extraction as a function of distance between entities. For example, the blue bar depicts performance when removing all entity pair candidates (positive and negative) whose closest mentions are more than 11 tokens apart. We consider removing entity pair candidates with distances of 11, 25, 50, 100 and 500 (the maximum document length). The average sentence length is 22 tokens. We see that the model is not simply relying on short range relationships, but is leveraging information about distant entity pairs, with accuracy increasing as the maximum distance considered increases. Note that all results are taken from the same model trained on the full unfiltered training set.

4 Related work

Relation extraction is a heavily studied area in the NLP community. Most work focuses on news and web data (Doddington et al., 2004; Riedel et al., 2010; Hendrickx et al., 2009).[9] Recent neural net-

work approaches to relation extraction have focused on CNNs (dos Santos et al., 2015; Zeng et al., 2015) or LSTMs (Miwa and Bansal, 2016; Verga et al., 2016a; Zhou et al., 2016b) and replacing stage-wise information extraction pipelines with a single end-to-end model (Miwa and Bansal, 2016; Ammar et al., 2017; Li et al., 2017). These models all consider mention pairs separately.

There is also a considerable body of work specifically geared towards supervised biological relation extraction including protein-protein (Pyysalo et al., 2007; Poon et al., 2014; Mallory et al., 2015), drug-drug (Segura-Bedmar et al., 2013), and chemical-disease (Gurulingappa et al., 2012; Li et al., 2016a) interactions, and more complex events (Kim et al., 2008; Riedel et al., 2011). Our work focuses on modeling relations between chemicals, diseases, genes and proteins, where available annotation is often at the document- or abstract-level, rather than the

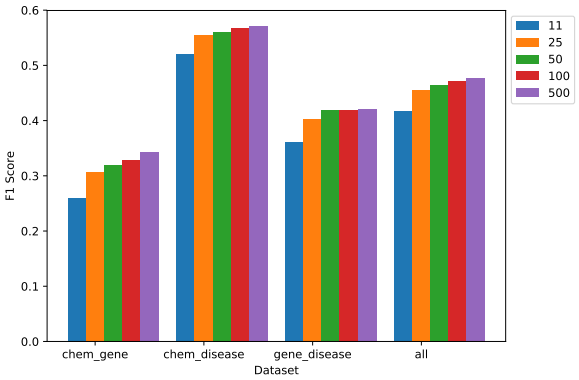

Figure 2: Performance on the CTD dataset when restricting candidate entity pairs by distance. The x-axis shows the coarse-grained relation type. The y-axis shows F1 score. Different colors denote maximum distance cutoffs.

sentence level.

Some previous work exists on cross-sentence relation extraction. Swampillai and Stevenson (2011) and Quirk and Poon (2017) consider featurized classifiers over cross-sentence syntactic parses. Most similar to our work is that of Peng et al. (2017), which uses a variant of an LSTM to encode document-level syntactic parse trees. Our work differs in three key ways. First, we operate over raw tokens negating the need for part-of-speech or syntactic parse features which can lead to cascading errors. We also use a feed-forward neural architecture which encodes long sequences far more efficiently compared to the graph LSTM network of Peng et al. (2017). Finally, our model considers all mention pairs simultaneously rather than a single mention pair at a time.

We employ a bi-affine function to form pairwise predictions between mentions. Such models have also been used for knowledge graph link prediction (Nickel et al., 2011; Li et al., 2016b), with variations such as restricting the bilinear relation matrix to be diagonal (Yang et al., 2015) or diagonal and complex (Trouillon et al., 2016). Our model is similar to recent approaches to graph-based dependency parsing, where bilinear parameters are used to score head-dependent compatibility (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017).

5 Conclusion

We present a bi-affine relation attention network that simultaneously scores all mention pairs within a document. Our model performs well on three datasets, including two standard benchmark biological relation extraction datasets and a new, large and high-quality dataset introduced in this work. Our model out-performs the previous state of the art on the Biocreative V CDR dataset despite us-

ing no additional linguistic resources or mention pair-specific features.

Our current model predicts only into a fixed schema of relations given by the data. However, this could be ameliorated by integrating our model into open relation extraction architectures such as Universal Schema (Riedel et al., 2013; Verga et al., 2016b). Our model also lends itself to other pairwise scoring tasks such as hypernym prediction, co-reference resolution, and entity resolution. We will investigate these directions in future work.

A Implementation Details

The model is implemented in Tensorflow (Abadi et al., 2015) and trained on a single TitanX gpu. The number of transformer block repeats is $B = 2$. We optimize the model using Adam (Kingma and Ba, 2015) with best parameters chosen for ϵ, β_1, β_2 chosen from the development set. The learning rate is set to 0.0005 and batch size 32. In all of our experiments we set the number of attention heads to $h = 4$.

We clip the gradients to norm 10 and apply noise to the gradients (Neelakantan et al., 2015). We tune the decision threshold for each relation type separately and perform early stopping on the development set. We apply dropout (Srivastava et al., 2014) to the input layer randomly replacing words with a special UNK token with keep probability .85. We additionally apply dropout to the input T (word embedding + position embedding), interior layers, and final state. At each step, we randomly sample a positive or negative (NULL class) minibatch with probability 0.5.

A.1 Chemical Disease Relations Dataset

Token embeddings are pre-trained using skipgram (Mikolov et al., 2013) over a random subset of 10% of all PubMed abstracts with window size 10 and 20 negative samples. We merge the train and development sets and randomly take 850 abstracts for training and 150 for early stopping. Our reported results are averaged over 10 runs and using different splits. All baselines train on both the train and development set. Models took between 4 and 8 hours to train.

ϵ was set to 1e-4, β_1 to .1, and β_2 to 0.9. Gradient noise $\eta = .1$. Dropout was applied to the word embeddings with keep probability 0.85, internal layers with 0.95 and final bilinear projection with 0.35 for the standard CRD dataset experiments. When adding the additional weakly labeled data: word embeddings with keep probability 0.95, internal layers with 0.95 and final bilinear projection with 0.5.

A.2 Chemical Protein Relations Dataset

We construct our byte-pair encoding vocabulary using a budget of 7500. The dataset contains annotations for a larger set of relation types than are used in evaluation. We train on only the relation types in the evaluation set and set the remaining types to the Null relation. The embedding dimension is set to 200 and all embeddings are randomly initialized. ϵ was set to 1e-8, β_1 to .1, and β_2 to 0.9. Gradient noise $\eta = 1.0$. Dropout was applied to the word embeddings with keep probability 0.5, internal layers with 1.0 and final bilinear projection with 0.85 for the standard CRD dataset experiments.

A.3 Full CTD Dataset

We tune separate decision boundaries for each relation type on the development set. For each prediction, the relation type with the maximum probability is assigned. If the probability is below the relation specific threshold, the prediction is set to NULL. We use embedding dimension 128 with all embeddings randomly initialized. Our byte pair encoding vocabulary is constructed with a budget of 50,000. Models took 1 to 2 days to train.

ϵ was set to 1e-4, β_1 to .1, and β_2 to 0.9. Gradient noise $\eta = .1$.Dropout was applied to the word embeddings with keep probability 0.95, internal layers with 0.95 and final bilinear projection with 0.5

Supervised Open Information Extraction

Abstract

We present data and methods that enable a supervised learning approach to Open Information Extraction (Open IE). Central to the approach is a novel formulation of Open IE as a sequence tagging problem, addressing challenges such as encoding multiple extractions for a predicate. We also develop a bi-LSTM transducer, extending recent deep Semantic Role Labeling models to extract Open IE tuples and provide confidence scores for tuning their precision-recall tradeoff. Furthermore, we show that the recently released Question-Answer Meaning Representation dataset can be automatically converted into an Open IE corpus which significantly increases the amount of available training data. Our supervised model, made publicly available,[1] outperforms the state-of-the-art in Open IE on benchmark datasets.

1 Introduction

Open Information Extraction (Open IE) systems extract tuples of natural language expressions that represent the basic propositions asserted by a sentence (see Figure 1). They have been used for a wide variety of tasks, such as textual entailment (Berant et al., 2011), question answering (Fader et al., 2014), and knowledge base population (Angeli et al., 2015). However, perhaps due to limited data, existing methods use semi-supervised approaches (Banko et al., 2007; Wu and Weld, 2010), or rule-based algorithms (Fader et al., 2011; Mausam et al., 2012; Del Corro and Gemulla, 2013). In this paper, we present new data and methods for Open IE, showing that supervised learning can greatly improve performance.

Mercury filling, particularly prevalent in the USA, was banned in the EU, partly because it causes antibiotic resistance.

(mercury filling; **particularly prevalent**; in the USA)

Figure 1: Open IE extractions from an example sentence. Each proposition is composed of a tuple with a single predicate position (in bold), and an ordered list of arguments, separated by semicolons.

We build on recent work that studies other natural-language driven representations of predicate argument structure, which can be annotated by non-experts. Recently, Stanovsky and Dagan (2016) created the first labeled corpus for evaluation of Open IE by an automatic translation from question-answer driven semantic role labeling (QA-SRL) annotations (He et al., 2015). We extend these techniques and apply them to the QAMR corpus (Michael et al., 2018), an open variant of QA-SRL that covers a wider range of predicate-argument structures (Section 5). The combined dataset is the first corpus that is large and diverse enough to train an accurate extractor.

To train on this data, we formulate Open IE as a sequence labeling problem. We introduce a novel approach that can extract multiple, overlapping tuples for each sentence (Section 3), extending recent deep BIO taggers used for semantic role labeling (Zhou and Xu, 2015; He et al., 2017). We also introduce a method to calculate extraction confidence, allowing us to effectively trade off precision and recall (Section 4).

Experiments demonstrate that our approach out-

New Orleans, Louisiana, June 1 - 6, 2018.

performs state-of-the-art Open IE systems on several benchmarks (Section 6), including three that were collected independently of our work (Xu et al., 2013; de Sá Mesquita et al., 2013; Schneider et al., 2017). This shows that for Open IE, careful data curation and model design can push the state of the art using supervised learning.

2 Background

In this section we survey existing Open IE systems, against which we compare our system, and available data for the task, that we will use for training and testing our model.

2.1 Different Open IE Systems and Flavors

Open IE's original goal (Banko et al., 2007) was to extend traditional (closed) information extraction, such that *a*ll of the propositions asserted by a given input sentence are extracted (see Figure 1 for examples). The broadness of this definition, along with the lack of a standard benchmark dataset for the task, prompted the development of various Open IE systems tackling different facets of the task.

While most Open IE systems aim to extract the common case of verbal binary propositions (i.e, subject-verb-object tuples), some systems specialize in other syntactic constructions, including noun-mediated relations (Yahya et al., 2014; Pal and Mausam, 2016), n-ary relations (Akbik and Löser, 2012), or nested propositions (Bhutani et al., 2016).

Many different modeling approaches have also been developed for Open IE. Some of the early systems made use of distant supervision (Banko et al., 2007; Wu and Weld, 2010), while the current best systems use rule-based techniques to extract predicate-argument structures as a post-processing step over an intermediate representation. ReVerb (Fader et al., 2011) extracts Open IE propositions from part of speech tags, OLLIE (Mausam et al., 2012), ClausIE (Del Corro and Gemulla, 2013) and PropS (Stanovsky et al., 2016) post-process dependency trees, and Open IE4[2] extracts tuples from Semantic Role Labeling (SRL) structures. These systems typically associate a confidence metric with each extraction, which allows end applications to trade off precision and recall.

2.2 Open IE Corpora

Recent work addressed the lack of labeled reference Open IE datasets for comparatively evaluating extractors. Stanovsky and Dagan (2016) created a large Open IE corpus (OIE2016) for verbal predicates by automatic conversion from QA-SRL (He et al., 2015), a variant of traditional SRL that labels arguments of verbs with simple, template-based natural language questions. Schneider et al. (2017) aggregated datasets annotated independently in previous Open IE efforts (WEB and NYT (de Sá Mesquita et al., 2013), PENN (Xu et al., 2013), and OIE2016) into a common benchmarking suite.

In addition to these, we create and make available a new Open IE training corpus, All Words Open IE (AW-OIE), derived from Question-Answer Meaning Representation (QAMR) (Michael et al., 2018), a recent extension of the QA-SRL paradigm to free-form questions over a wide range of predicate types (see Section 5). Table 1 presents more details on these datasets.

3 Task Formulation

In this work, we choose to model an Open IE proposition as a tuple consisting of a single predicate operating over a non-empty set of arguments, where the predicate and the arguments are contiguous spans from the sentence. As with traditional (binary) Open IE, every tuple should be asserted by the sentence and the order of the tuple elements should be such that it would be naturally interpretable when reading from left to right (for example, see the third tuple in Figure 1). As we show in following sections, this formulation intuitively lends itself to BIO tagging, while being expressive enough to capture a wide range of propositions.

Formally, given an input sentence S =

Table 2: Example sentences and respective Open IE extractions. The first line in each example presents the input pairs $(S,\ p)$, where S is the input sentence, and the predicate head, p, is denoted with an underline. Below the inputs we present the corresponding Open IE extractions. The corresponding encodings are presented below the dashed lines, where subscripts indicate the associated BIO label. Demonstrating: (a) the encoding of a multi-word predicate, (b) several arguments collapsed into the same ***A0*** argument position, (c) argument position deviating from the sentence ordering.

$(w_1, \ldots, w_n)$, a tuple consists of $(\mathbf{x_1}, \ldots, \mathbf{x_m})$, where each x_i is a contiguous subspan of S. One of the x_i is distinguished as the *predicate* (marked in bold in Figure 1), while the other spans are considered its arguments. Following this definition, we reformulate Open IE as a sequence labeling task, using a custom BIO[3] (Ramshaw and Marcus, 1995; Sang and Veenstra, 1999) scheme adapted from recent deep SRL models (He et al., 2017).

In our formulation, the set of Open IE tuples for a sentence S are grouped by predicate head-word p, as shown in Table 2. For instance, example (b) lists two tuples for the predicate head "born", which is underlined in the sentence. Grouping tuples this way allows us to run the model once for each predicate head, and accumulate the predictions across predicates to produce the final set of extractions.

Open IE tuples deviate from SRL predicate-argument structures in two major respects. First, while SRL generally deals with single-word predicates, Open IE uses multi-word predicates that often incorporate modals and embedded predicates. For example, the first tuple in the table includes the embedded predicate **claimed that he won**. Second, Open IE generates multiple extractions from a single predicate in certain syntactic constructions (e.g., apposition, co-ordination or coreference). For instance, example (b) repeats the predicate **was born in** for the two components of the apposition *Barack Obama, a former U.S. president*.

To model these unique challenges, we introduce a custom BIO tagging scheme, shown in Table 2 below the dashed lines. Predicates are encoded using the P label type, while arguments are represented using Ai labels, where i represents the argument's position within the extracted Open IE tuple. While softer than SRL's predicate-specific argument roles (e.g., ARG0), these argument positions also capture semantic information because they are arranged such that the tuple can be naturally read as a standalone statement, regardless of the complications of the source text's syntax (such as reorderings and long-distance dependencies). For instance, in the last example in Table 2, the order of the arguments in the Open IE tuple deviates from the ordering in the original sentence due to a relative clause construction (headed by the word *Brexit*).

Finally, multiple extractions per predicate are encoded by assigning the same argument index to all arguments appearing in that position across all of the predicate's extractions. For example, note that the ***A0*** argument label appears twice for the apposition in example (b). To reconstruct the extractions from the BIO labels, we produce an extraction for every possible way of choosing one argument for each index.

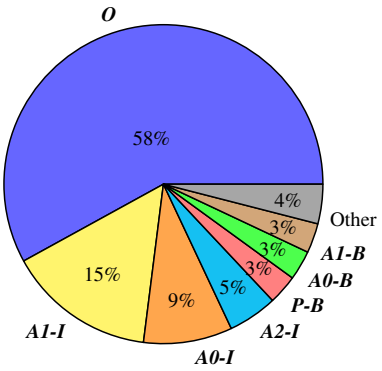

Figure 3: Word label distribution in the training set.

4 Supervised Open IE Model

Our model, named RnnOIE, is a bi-LSTM transducer, inspired by the state of the art deep learning approach for SRL suggested by Zhou and Xu (2015) and He et al. (2017). The architecture is shown in Figure 2.

Given an input instance of the form $(S,\ p)$, where S is the input sentence, and p is the word index of the predicate's syntactic head, we extract a feature vector $feat$ for every word $w_i \in S$:

$$feat(w_i,\ p) = emb(w_i) \oplus emb(pos(w_i)) \oplus \\ \oplus\ emb(w_p) \oplus emb(pos(w_p))$$

Here, $emb(w)$ is a d-dimensional word embedding, $emb(pos(w))$ is a 5-dimensional embedding of w's part of speech, and $\oplus$ denotes concatenation. We duplicate the predicate head's features on all words to allow the model to more directly access this information as it makes predicate-specific word label predictions.

The features are fed into a bi-directional deep LSTM transducer (Graves, 2012) which computes contextualized output embeddings. The outputs are used in softmaxes for each word, producing independent probability distributions over possible BIO tags.

The model is trained with gold predicate heads, using a per-word maximum likelihood objective. Figure 3 depicts the overall word label distribution within the training set. The large percentage of ***O*** labels demonstrates Open IE's tendency to shorten arguments, compared to SRL which considers full syntactic constitutes as arguments.

Inference At inference time, we first identify all verbs and nominal predicates in the sentence as candidate predicate heads. We use a Part Of Speech (POS) tagger to identify verbs, and Catvar's subcategorization frames (Habash and Dorr, 2003) for nominalizations, identifying nouns which share the same frame with a verbal equivalent (e.g., *acquisition* with *acquire*). We then generate an input instance for each candidate predicate head. For each instance, we tag each word with its most likely BIO label under the model, and reconstruct Open IE tuples from the resulting sequence according to the method described in Section 3, with the exception that we ignore malformed spans (i.e., if an ***A0-I*** label is not preceded by ***A0-I*** or ***A0-B***, we treat it as ***O***).

Assigning extraction confidence It is beneficial for an Open IE system to associate a confidence value with each predicted extraction to allow for tuning its precision-recall tradeoff. Our model does not directly produce confidence values for extractions, but it does assign probabilities to each BIO label that it predicts. We experimented with several heuristics to combine these predictions to an extraction-level confidence metric. The best performance on the development set was achieved by multiplying the probabilities of the B and I labels participating in the extraction.[4] This metric prefers shorter extractions, which correlates well with the requirements of Open IE (Bhutani et al., 2016).

Implementation details We implemented the model using the Keras framework (Chollet, 2015) with TensorFlow backend (Abadi et al., 2015). All

[4] We also tried taking the maximum or minimum observed single word-label probability.

Mercury filling, particularly prevalent in the USA, was banned in the EU, partly because it causes antibiotic resistance.

prevalent	-	What was **particularly prevalent in the USA**? mercury filling	(mercury filling; **particularly prevalent**; in the USA)
banned	What was **banned**? mercury filling Where was something **banned**? the EU Why was something **banned**? partly because it causes antibiotic resistance	What was **banned in the EU partly because it causes antibiotic resistance**? mercury filling	(mercury filling; **was banned**; in the EU; partly because it causes antibiotic resistance)
causes	What **caused** something? mercury filling What did something **cause**? antibiotic resistance	What did **mercury filling cause**? antibiotic resistance	(mercury filling; **caused**; antibiotic resistance)

Table 3: Comparison of QA-SRL, QAMR, and desired Open IE annotations for an example sentence, adapted from the QAMR corpus.

hyperparameters were tuned on the `OIE2016` development set. The bi-LSTM transducer has 3 layers and each LSTM cell uses 128 hidden units and a linear rectifier (ReLU) (Nair and Hinton, 2010) activation function. The model was trained for 100 epochs in mini batches of 50 samples, with 10% word-level dropout. The word-embeddings were initialized using the GloVe 300-dimensions pre-trained embeddings (Pennington et al., 2014) and were kept fixed during training. The part of speech embeddings were randomly initialized and updated during training. Finally, we use the average perceptron part-of-speech tagger (as implemented in spaCy[5]) to predict parts of speech for input features and verb predicate identification.

5 Open IE from QAMR

This section describes our approach for automatically extracting Open IE tuples from QAMR (Michael et al., 2018), a recent extension of QA-SRL. While QA-SRL uses question templates centered on verbs, QAMR annotates free-form questions over arbitrary predicate types. The QAMR corpus consists of annotations over $5,000$ sentences. By extending the `OIE2016` training set with extractions from QAMR, we more than triple the available amount of training data.

The extraction algorithm, as well as the resulting corpus, are made publicly available at `https://github.com/gabrielStanovsky/supervised-oie`.

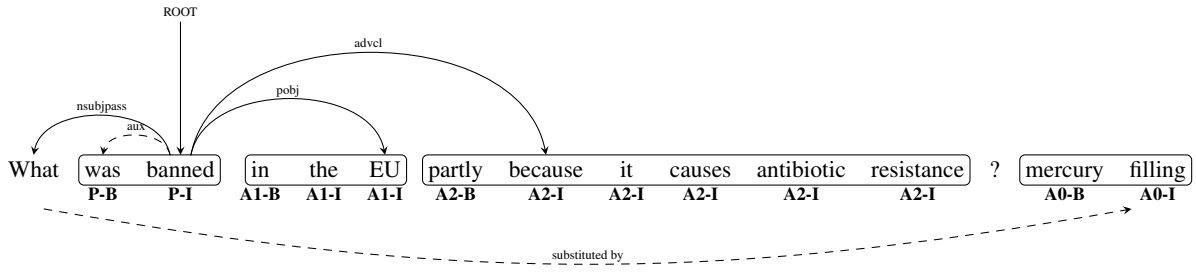
[5] `https://spacy.io`

5.1 The QAMR Corpus

Question-Answer Meaning Representation, or QAMR (Michael et al., 2018), was recently proposed as an extension of QA-SRL. Like QA-SRL, QAMR represents predicate-argument structure with a set of question-answer pairs about a sentence, where each answer is a span from the sentence. However, while QA-SRL restricts questions to fit into a particular verb-centric template, QAMR is more general, allowing any natural language question that begins with a *wh*-word and contains at least one word from the sentence. This allows QAMR to express richer, more complex relations. Consider, for example, the first two entries for QAMR in Table 3. The first explicates the implicit relation **made of** from the noun compound *mercury filling*, and the second identifies the adjectival predicate **prevalent**. Neither of these can be represented in QA-SRL.

5.2 Extraction Algorithm

While QAMR's broader scope presents an opportunity to vastly increase the number and coverage of annotated Open IE tuples, it also poses additional challenges for the extraction algorithm. The free-form nature of QAMR questions means that some are over-expressive for Open IE, while in many other cases it is less obvious how to extract a predicate and a list of arguments from a question-answer pair.



(mercury filling; **was banned**; in the EU; partly because it causes antibiotic resistance)

Figure 4: A QAMR (top) to Open IE (bottom) conversion example. The BIO labels for our encoding of the Open IE tuple appear below the text. The root of the question's dependency tree is the predicate, while its syntactic constituents are the arguments. The answer appears as the first argument of the Open IE tuple due to the passive construction.

Over-expressiveness The QAMR formalism allows many constructions that diverge from Open IE extractions, which generally are drawn verbatim from the source text. For example, the predicate **made** is introduced in the QAMR for the sentence in Table 3, despite not appearing in the sentence. To circumvent this issue, we filter out questions which: (1) introduce new content words,[6] (2) have more than one *wh*-word, (3) do not start with *who*, *what*, *when* or *where*, or (4) ask *what did X do?*, delegating the predicate to the answer.

Detecting predicates and arguments While a QA-SRL question has a designated predicate and a single argument as the answer, in QAMR, the predicate can appear anywhere in the question and its arguments are spread between the question and answer. For example, extracting an Open IE tuple for the predicate **banned** in Table 3 requires decoupling the predicate and its arguments *in the EU* and *partly because it causes antibiotic resistance*. Our solution to this problem is illustrated in Figure 4. We first run each question through a syntactic dependency parser. We then identify the predicate as the head of the question's dependency tree extended to include all dependents with an auxiliary relation (e.g., *aux*, *neg*, or *prt*). The predicted arguments are the predicate's constituent argument subtrees, while the answer to the question replaces the subtree headed by the wh-word. Finally, we employ similar heuristics to those used converting verbal QA-SRL to Open IE to find the correct argument position for the answer (Stanovsky and Dagan, 2016). For example, the passive construction in Figure 4 implies that the answer should be placed in the first argument position, while the existence of a prepositional object in, e.g., *What did he put **on the table**?* signals that the answer should be placed in the second argument position.

[6]We do not count inflected forms of verbs from the sentence, such as *caused* in the last entry of the table, as new words.

QAMR Open IE Tuples

Table 4: Tuples from the All Words Open IE Corpus, exemplifying n-ary extractions (top example), non-verbal predicates (middle), and multi-word predicates (bottom).

5.3 The All Words Open IE Corpus

As described by Michael et al. (2018), QAMR annotations were gathered via crowdsourcing in a two-stage pipeline over Wikipedia and Wikinews text. We use the training partition of the QAMR dataset, which consists of 51,063 QA pairs over 3,938 sentences. Our filtering and conversion from the QAMR corpus yields 12,952 Open IE tuples (2.5 times the size of `OIE2016`'s training corpus), composed of 7,470 (58%) verbal predicates, 4,952 (38%) nominal predicates, and 530 (4%) adjectival predicates. See Table 4 for example tuples, taken from the converted corpus.

Examining the results, we found that they are not accurate enough to constitute a gold test cor-

pus, partly because some relations were missed by the annotators of QAMR and partly because of noise introduced in the automatic extraction process. Instead, we use this corpus to extend the train partition of OIE2016. In the following section, we show its usefulness in significantly improving the precision and recall of our Open IE model.

6 Evaluation

We evaluate the performance of our model on the four test sets discussed in Section 2.

6.1 Experimental Setup

Metrics We evaluate each system according to three metrics. First, as is typical for Open IE, we compute a *precision-recall (PR) curve* by evaluating the systems' performance at different extraction confidence thresholds. This curve is useful for downstream applications which can set the threshold according to their specific needs (i.e., recall oriented versus precision oriented). Second, we compute the *area under the PR curve (AUC)* as a scalar measurement of the overall system performance. Finally, for each system, we report a single F1 score using a confidence threshold optimized on the development set. This can serve as a preset threshold for out-of-the-box use.

Matching function Similar to other cases in NLP, we would like to allow some variability in the predicted tuples. For example, for the sentence *The sheriff standing against the wall spoke in a very soft voice* we would want to treat both (The Sheriff; **spoke**; in a soft voice) and (The sheriff standing against the wall; **spoke**; in a very soft voice) as acceptable extractions. To that end, we follow He et al. (2015) which judge an argument as correct if and only if it includes the syntactic head of the gold argument (and similarly for predicates). For OIE2016, we use the available Penn Treebank gold syntactic trees (Marcus et al., 1993), while for the other test sets, we use predicted trees instead. While this metric may sometimes be too lenient, it does allow a more balanced and fair comparison between systems which can make different, but equally valid, span boundary decisions.

Baselines We compare our model (RnnOIE) against the top-performing systems of those evaluated most recently in Stanovsky and Dagan (2016) and in Schneider et al. (2017): Open IE4,[7] ClausIE (Del Corro and Gemulla, 2013), and PropS (Stanovsky et al., 2016).

6.2 Results

Table 5 reports the AUC and F1 scores of all of the systems on the 4 test sets. In addition, the PR curves for the two largest test sets (OIE2016 and WEB) are depicted in Figures 5a and 5b. We report results for two versions of our model: one trained on the OIE2016 training set containing only verbal predicates (*RnnOIE-verb*), and another on the extended training set that includes the automatic conversion of QAMR outlined in Section 5 (*RnnOIE-aw*).

Overall, RnnOIE-aw outperforms the other systems across the datasets. On the larger test sets (OIE2016 and WEB) it provides the best performance in terms of AUC and F1, with a superior precision-recall curve. On each of the smaller test sets, it performs best on one metric and competitively on the other.

Furthermore, on all of the test sets, extending the training set significantly improves our model's performance, showing that it benefits from the additional data and types of predicates available in the QAMR dataset. While this is most notable in the test sets which include nominalizations (WEB, NYT, and PENN), it also improves the performance on OIE2016, which is composed solely of verb predicates.

6.3 Performance Analysis

In our analysis, we find that RnnOIE generalizes to unseen predicates, produces more and shorter arguments on average than are in the gold extractions, and, like all of the systems we tested, struggles with nominal predicates.

Unseen predicates We split the propositions in the gold and predicted OIE2016 test set into two partitions, *seen* and *unseen*, based on whether the predicate head's lemma appears in the training set. The *unseen* part contains 145 unique predicate lemmas in 148 extractions, making up 24% out of the 590 unique predicate lemmas and 7% out of the 1993 total extractions in the test set. We then evaluated RnnOIE-aw on each part separately. The resulting PR curves (Figure 5c) depict overall good performance also on the unseen part, competitive with previous Open IE systems.

System	# Tuples	Args/Prop	Words/Arg
Gold	1730	2.45	5.38
ClausIE	2768	2.00	5.78
PropS	1551	2.68	5.8
Open IE4	1793	3.07	4.55
RnnOIE-aw	1993	3.19	4.68

Table 6: Output statistics of the different systems on OIE2016, versus the gold data.

This indicates that our model generalizes beyond memorization of specific predicate templates.

Argument length and number In Table 6 we compare statistics on the the outputs of the Open IE systems on OIE2016 and the gold data. The best performing systems, RnnOIE and OpenIE4, tend to produce more arguments, and each argument tends to be shorter on average, in comparison to other systems and gold.

Runtime analysis Since Open IE is intended to be usable at web scale, we timed the different Open IE systems on a batch of 3200 sentences from OIE2016, running on a Xeon 2.3GHz CPU. The results are presented in Table 8.[8] We find that our system fares well, processing only 12% fewer sentences per second than the fastest system, Open IE 4.0. Further, while these numbers are reported on CPU for the sake of fair comparison, running our neural model on a GPU (NVIDIA GeForce GTX 1080 Ti) boosts speed by a factor of more than 10 (149.25 sentences per second, on average).

Error analysis All of the systems still lack in recall across all tested corpora. We examined a random sample of 100 recall errors shared by all of the extractors across the tested datasets and found several common error types, shown in Table 7. Notably, noun and nominalized predicates still pose a challenge, appearing in 51% of the recall errors (whereas they make up 24% of all extractions). 19% of the examined errors required some

[8]PropS and ClausIE's relatively slow performance is in part due to their hard-coded use of the Stanford parser, which took on average 0.2 seconds per sentence. Using a faster parser (e.g., spaCy) may improve this performance.

Phenomenon	%	Example (sentence / gold tuple)
Noun	38	*Andre Agassi did a similar thing in his **hometown** of Las Vegas a few years ago.* (Andre Agassi; **hometown**; Las Vegas)

form of sentence level inference, such as determining event factuality or pronoun resolution. 14% of the errors involved long sentences with over 40 words (where the average word count per sentence is 29.4).

7 Conclusions and Future Work

We present a supervised model for Open IE, formulating it as a sequence tagging problem and applying a bi-LSTM transducer to produce a state-of-the-art Open IE system. Along the way, we address several task-specific challenges, including the BIO encoding of predicates with multiple extractions and confidence estimation in our sequence tagging model. To train the system, we leverage a recently published large scale corpus for Open IE (Stanovsky and Dagan, 2016), and further extend it using a novel conversion of the QAMR corpus (Michael et al., 2018), which covers a wider range of predicates.

In addition to these contributions, this work shows that Open IE can greatly benefit from future research into the QA-SRL paradigm. For example, Open IE would directly benefit from an automatic QA-SRL extractor, while a more exhaustive or extensive annotation of QAMR would improve Open IE's performance on a wider range of predicates.

Embedding Syntax and Semantics of Prepositions via Tensor Decomposition

Abstract

Prepositions are among the most frequent words in English and play complex roles in the syntax and semantics of sentences. Not surprisingly, they pose well-known difficulties in automatic processing of sentences (prepositional attachment ambiguities and idiosyncratic uses in phrases). Existing methods on preposition representation treat prepositions no different from content words (e.g., word2vec and GloVe). In addition, recent studies aiming at solving prepositional attachment and preposition selection problems depend heavily on external linguistic resources and use dataset-specific word representations. In this paper we use *word-triple* counts (one of the triples being a preposition) to capture a preposition's interaction with its attachment and complement. We then derive preposition embeddings via tensor decomposition on a large unlabeled corpus. We reveal a new geometry involving Hadamard products and empirically demonstrate its utility in paraphrasing phrasal verbs. Furthermore, our preposition embeddings are used as simple features in two challenging downstream tasks: preposition selection and prepositional attachment disambiguation. We achieve results comparable to or better than the state-of-the-art on multiple standardized datasets.

1 Introduction

Prepositions are a linguistically closed class comprising some of the most frequent words; they play an important role in the English language since they encode rich syntactic and semantic information. Many preposition-related tasks are challenging in computational linguistics because of their polysemous nature and flexible usage patterns. An accurate understanding and representation of prepositions' linguistic role is key to several important NLP tasks such as grammatical error correction and prepositional phrase attachment. A first-order approach is to represent prepositions as real-valued vectors via word embeddings such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014).

Word embeddings have brought a renaissance in NLP research; they have been very successful in capturing word similarities as well as analogies (both syntactic and semantic) and are now mainstream in nearly all downstream NLP tasks (such as question-answering (Chen et al., 2017)). Despite this success, available literature does not highlight any specific properties of word embeddings of prepositions. Indeed, many of the common prepositions have very similar vector representations as shown in Table 1 for preposition vectors trained using word2vec and GloVe (Tensor embedding is our proposed representation for prepositions). While this suggests that using available representations for prepositions diminishes the distinguishing aspect between prepositions, one could hypothesize that this is primarily because standard word embedding algorithms treat prepositions no different from other content words such as verbs and nouns, i.e., embeddings are created based on co-occurrences with other words. However, prepositions are very frequent and co-occur with nearly all words, which means that their co-occurrence ought to be treated differently.

Preposition pair	Word2vec	GloVe	Tensor
(above, below)	0.85	0.78	0.22
(above, beneath)	0.40	0.45	0.15
(after, before)	0.83	0.70	0.44
(after, during)	0.56	0.42	0.16
(amid, despite)	0.47	0.37	0.12
(amongst, besides)	0.46	0.37	0.21
(beneath, inside)	0.55	0.47	0.29

Table 1: Cosine similarity between pairs of centered prepositions using some word embeddings

Modern descriptive linguistic theory proposes

Proceedings of NAACL-HLT 2018, pages 896–906
New Orleans, Louisiana, June 1 - 6, 2018.

to understand a preposition via its interactions with *both* the head it attaches to (termed *head*) and its complement (Huddleston, 1984; DeCarrico, 2000). This theory naturally suggests that one should count co-occurrences of a given preposition with *pairs* of neighboring words. One way of achieving this would be by considering a *tensor* of triples ($word_1$, $word_2$, preposition), where we do not restrict $word_1$ and $word_2$ to be the head and complement words; instead we model a preposition's interaction with *all* pairs of neighboring words via a *slice* of a tensor X, where the slice is populated by word co-occurrences restricted to a context window of the specific preposition. Thus, the tensor dimension is $N \times N \times K$ where N is the vocabulary size and K is the number of prepositions; since $K \approx 50$, we note that $N \gg K$.

Using such a representation, we notice that the resulting tensor is low rank and use it to extract embeddings for both preposition and non-preposition words. In doing so, we use a combination of standard ideas from word representations (such as weighted spectral decomposition as in GloVe (Pennington et al., 2014)) and tensor decompositions (alternating least squares (ALS) methods (Sharan and Valiant, 2017)). We find that the preposition embeddings extracted in this manner are discriminative (see the preposition similarity of the tensor embedding in Table 1). Note that the smaller the cosine similarity is, the more distinct the representations are from each other. We demonstrate that the resulting preposition representation captures the core linguistic properties of prepositions–the attachment and the complement properties. Using both intrinsic evaluations and downstream tasks, we show this by providing new state-of-the-art results on well-known NLP tasks involving prepositions.

Intrinsic evaluations: We show that the *Hadamard* product of the embeddings of a verb and a preposition that together make a phrasal verb, closely approximates the representation of this phrasal verb's paraphrase as a single verb. Example: $v_{\text{made}} \odot v_{\text{from}} \approx v_{\text{produced}} \odot v$, where $\odot$ represents the Hadamard product (i.e., element-wise multiplication) of two vectors and v is a constant vector (not associated with a specific word and is defined later); this approximation validates that prepositional semantics are appropriately encoded into their trained embeddings. We provide a mathematical interpretation for this new geometry while empirically demonstrating the paraphrasing of compositional phrasal verbs.

Extrinsic evaluations: Our preposition embeddings are used as features for a simple classifier in two well-known challenging downstream NLP classification tasks. In both tasks, we perform as well as or strictly better than the state-of-the-art on multiple standardized datasets.

Preposition selection: While the context in which a preposition occurs governs the choice of the preposition, the specific preposition by itself significantly influences the semantics of the context in which it occurs. Furthermore, the choice of the right preposition for a given context can be very subtle. This idiosyncratic behavior of prepositions is the reason behind preposition errors being one of the most frequent error types made by second language English speakers (Leacock et al., 2010)). We demonstrate the utility of the preposition embeddings in the preposition selection task, which is to choose the correct preposition to a given sentence. We show this for a large set of contexts–$7,000$ combined instances from the CoNLL-2013 and the SE datasets (Prokofyev et al., 2014). Our approach achieves 6% and 2% absolute improvement over the previous state-of-the-art results on the respective datasets.

Prepositional phrase attachment disambiguation: Prepositional phrase attachment is a common cause of structural ambiguity in natural language. In the sentence "Pierre Vinken *joined the board as a voting member*", the prepositional phrase "as a voting member" can attach to either "joined" (the VP) or "the board" (the NP); in this case the VP attachment is correct. Despite being extensively studied over decades, prepositional attachment continues to be a major source of syntactic parsing errors (Brill and Resnik, 1994; Kummerfeld et al., 2012; de Kok and Hinrichs, 2016). We use our prepositional representations as simple features to a standard classifier on this task. Our approach tested on a widely studied standard dataset (Belinkov et al., 2015) achieves 89% accuracy and compares favorably with the state-of-the art. It is noteworthy that while the state-of-the-art results are obtained with significant linguistic resources, including syntactic parsers and the WordNet, our approach achieves a comparable performance without relying on such resources.

We emphasize two aspects of our contributions: (1) Word representations trained via *pairwise*

word counts are previously shown to capture much of the benefits of the unlabeled sentence-data; example: (Sharan and Valiant, 2017) reports that their word representations via word-triple counts are better than others, but still significantly worse than regular word2vec representations. One of our main observations is that considering word-triple counts makes most (linguistic) sense when one of the words is a preposition. Furthermore, the sparsity of the corresponding tensor is no worse than the sparsity of the regular word co-occurrence matrix (since prepositions are so frequent and co-occur with essentially every word). Taken together, these two points strongly suggest the benefits of tensor representations in the context for prepositions.

(2) The word and preposition representations via tensor decomposition are simple features leading to a standard classifier. In particular, we do not use dependency parsing (which many prior methods have relied on) or handcrafted features (Prokofyev et al., 2014) or train task-specific representations on the annotated training dataset (Belinkov et al., 2015). The simplicity of our approach, combined with the strong empirical results, lends credence to the strength of the prepositional representations found via tensor decompositions.

2 Method

We begin with a description of how the tensor with triples (word, word, preposition) is formed and empirically show that its slices are low-rank. Next, we derive low dimensional vector representations for words and prepositions via appropriate tensor decomposition methods.

Tensor creation: Suppose that K prepositions are in the preposition set $P = \{p_1, \ldots, p_K\}$; here K is 49 in our preposition selection task, and 76 in the attachment disambiguation task. We limited the number of prepositions to what was needed in the dataset. The vocabulary, the set of all words excluding the prepositions, contains N words, $V = \{w_1, \ldots, w_N\}$, and $N \approx 1M$. We generate a third order tensor $\mathbf{X}_{N \times N \times (K+1)}$ from the WikiCorpus (Al-Rfou et al., 2013) as follows. We say two words co-occur if they appear within a distance t of each other in a sentence. For $k \leq K$, the entry $\mathbf{X}_{ijk}$ is the number of occurrences where word w_i co-occurs with preposition p_k, and w_j also co-occurs with preposition p_k in the same sentence, and this is counted across all sentences in the WikiCorpus. For $0 \leq k \leq K$, $\mathbf{X}[:, :, k]$ is a matrix of the count of the word pairs that co-occur with the preposition k, and we call such a matrix a slice.

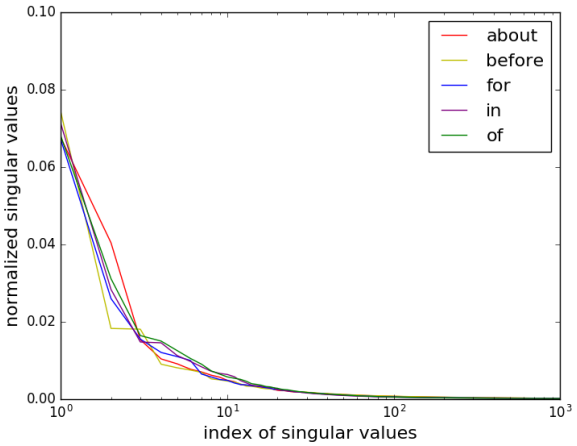

Figure 1: Decaying normalized singular values of slices.

Here we use a window of size $t = 3$. While prepositions co-occur with many words, there are also a number of other words which do not occur in the context of any preposition. In order to make the maximal use of the data, we add an extra slice $\mathbf{X}[:, :, K+1]$, where the entry $\mathbf{X}_{ij(K+1)}$ is the number of occurrences where w_i co-occurs with w_j (within distance $2t = 6$) but at least one of them is not within a distance of t of any preposition. Note that the preposition window of 3 is smaller than the word window of 6, since it is known that the interaction between prepositions and neighboring words usually weakens more sharply with distance when compared to that of content words (Hassani and Lee, 2017).

Empirical properties of X: We find that the tensor X is very sparse – only 1% of the tensor elements are non-zero. Furthermore, $\log(1 + \mathbf{X}[:, :, k])$ is low-rank (here the logarithm is applied component-wise to every entry of the tensor slice). Towards seeing this, we choose slices corresponding to the prepositions "about", "before","for", "in" and "of", and plot their normalized singular values in Figure 1. We see that the singular values decay dramatically, suggesting the low-rank structure in each slice.

Tensor decomposition: We combine standard ideas from word embedding algorithms and tensor decomposition algorithms to arrive at the low-rank approximation to the tensor $\log(1 + \mathbf{X})$. In

particular, we consider two separate methods:

1. *Alternating Least Squares (ALS)*. A generic method to decompose a tensor into its modes is via the CANDECOMP/PARAFAC (CP) decomposition (Kolda and Bader, 2009). The tensor $\log(1 + \mathbf{X})$ is decomposed into three modes: $\mathbf{U}_{d\times N}$, $\mathbf{W}_{d\times N}$ and $\mathbf{Q}_{d\times(K+1)}$, based on the solutions to the optimization problem (1). Here $\mathbf{u}_i$, $\mathbf{w}_i$ and $\mathbf{q}_i$ are the i-th column of U, W and Q, respectively.

$$L = \min_{\mathbf{U},\mathbf{W},\mathbf{Q}} \sum_{i=1}^{N}\sum_{j=1}^{N}\sum_{k=1}^{K+1} \big(\langle \mathbf{u}_i, \mathbf{w}_j, \mathbf{q}_k \rangle - \log(1 + \mathbf{X}_{ijk}) \big)^2, \quad (1)$$

where $\langle \mathbf{a}, \mathbf{b}, \mathbf{c} \rangle = \mathbf{1}^t(\mathbf{a} \odot \mathbf{b} \odot \mathbf{c})$ is the inner product of three vectors $\mathbf{a}, \mathbf{b}$ and $\mathbf{c}$. Here $\mathbf{1}$ is the column vector of all ones and $\odot$ refers to the Hadamard product. We can interpret the columns of U as the word representations and the columns of Q as the preposition representations, each of dimension d (equal to 200 in this paper). There are several algorithmic solutions to this optimization problem in the literature, most of which are based on alternating least squares methods (Kolda and Bader, 2009; Comon et al., 2009; Anandkumar et al., 2014) and we employ a recent one named Orth-ALS (Sharan and Valiant, 2017) in this paper. Orth-ALS periodically orthogonalizes the decomposed components while fixing two modes and updating the remaining one. It is supported by theoretical guarantees and empirically outperforms standard ALS methods in different applications.

2. *Weighted Decomposition (WD)*: Based on ideas from the literature on word embedding algorithms, we also consider weighting different elements of the tensors differently in order to reduce the effect of the large dynamic range of the tensor values. Specifically, we employ the GloVe objective function to our tensor model and minimize the objective function (2):

$$L_{\text{weighted}} = \min_{\mathbf{U},\mathbf{W},\mathbf{Q}} \sum_{i=1}^{N}\sum_{j=1}^{N}\sum_{k=1}^{K+1} \omega_{ijk} \big(\langle \mathbf{u}_i, \mathbf{w}_j, \mathbf{q}_k \rangle + b_{Ui} + b_{Wj} + b_{Qk} - \log(\mathbf{X}_{ijk} + 1) \big)^2, \quad (2)$$

where b_{Ui} is the scalar bias for the word i in the matrix U. Similarly, b_{Wj} is the bias for the word j in the matrix W, and b_{Qk} for preposition k in the matrix Q. Bias terms are learned in such a way as to minimize the loss function. Here ω_{ijk} is the weight assigned to each tensor element X_{ijk}, and we use the weighting proposed by GloVe:

$$\omega_{ijk} = \min\left(\left(\frac{\mathbf{X}_{ijk}}{x_{\max}} \right)^{\alpha}, 1 \right).$$

We set the hyperparameters to be $x_{\max} = 10$, and $\alpha = 0.75$ in this work. We solve this optimization problem via standard gradient descent, arriving at word representations $\mathbf{U}$ and tensor representations $\mathbf{Q}$.

3 Geometry of Phrasal Verbs

Representation Interpretation Suppose that we have a phrase (h, p_i, c) where h, p_i and c are the head word, the preposition $i (i \leq K)$ and the complement respectively. The inner product of the word vectors of h, p_i and c reflects how frequently h and c co-occur in the context of p. It also reflects how cohesive the triple is.

Recall that there is an extra $(K + 1)-$th slice that describes the word co-occurrences outside the preposition window, which considers cases such as the verb phrase (v, c) where v and c are the verb and its complement without a preposition in their shared context. Now consider a phrasal verb *sparked off* and a verb phrase with head *prompted*. For any complement word c that fits these two phrases–the phrasal verb having h as its head verb and p_i as its preposition, and the other, the verb phrase with v as its head–we can expect that

$$\langle \mathbf{u}_h, \mathbf{q}_i, \mathbf{w}_c \rangle \approx \langle \mathbf{u}_v, \mathbf{q}_{K+1}, \mathbf{w}_c \rangle.$$

In other words $\mathbf{u}_h \odot \mathbf{q}_i \approx \mathbf{u}_v \odot \mathbf{q}_{K+1}$, where $\mathbf{a} \odot \mathbf{b}$ denotes the pointwise multiplication (Hadamard product) of vectors $\mathbf{a}$ and $\mathbf{b}$. This suggests that: (1) The vector $\mathbf{q}_{K+1}$ is a constant vector for all (v, c) pairs, and that (2) we could paraphrase the verb phrase (h, p_i) by finding a verb v such that $\mathbf{u}_v \odot \mathbf{q}_{K+1}$ is closest to $\mathbf{u}_h \odot \mathbf{q}_i$.

$$\text{paraphrase} = \arg\min_v \|\mathbf{u}_v \odot \mathbf{q}_{K+1} - \mathbf{u}_h \odot \mathbf{q}_i\|. \quad (3)$$

This shows that well-trained embeddings are able to capture the relation between phrasal verbs and their equivalent single verb forms.

In Table 2, we list paraphrases of some verb phrases, which are generated from the weighted tensor decomposition. As can be seen, the tensor embedding gives reasonable paraphrasing, which

Phrase	replied to	blocked off	put in	pray for	dreamed of	sparked off
Paraphrase	answered	intercepted	place	hope	wanted	prompted
Phrase	stuck with	derived from	switched over	asked for	passed down	blend in
Paraphrase	stalled	generated	transferred	requested	delivered	mix

Table 2: Paraphrasing of prepositional phrases.

validates that the trained embedding is interpretable in terms of lexical semantics.

In the next two sections, we evaluate the proposed tensor-based preposition embeddings in the context of two important NLP downstream tasks: preposition selection and preposition attachment disambiguation. In this work, we use the English WikiCorpus (around 9 GB) as the training corpus for different sets of embeddings. We train tensor embeddings with both Orth-ALS and weighted decomposition. The implementation of Orth-ALS is built upon the SPLATT toolkit (Smith and Karypis, 2016). We perform orthogonalization in the first 5 iterations in Orth-ALS decomposition, and the training is completed when its performance stabilizes. As for the weighted decomposition, we train for 20 iterations, and its hyperparameters are set as $x_{\max} = 10$, and $\alpha = 0.75$.

We also include two baselines for comparison–word2vec's CBOW model and GloVe. We set 20 training iterations for both the models. The hyperparameters in word2vec are set as: window size=6, negative sampling=25 and downsampling=1e-4. The hyperparameters in GloVe are set as: window size=6, x_{max}=10, α=0.75 and minimum word count=5. We note that all the representations in this study–word2vec, GloVe and our tensor embedding–are of dimension 200.

4 Downstream Application: Preposition Selection

Grammatical error detection and correction constitute important tasks in NLP. Among grammatical errors, prepositional errors constitute about 13% of all errors, ranking second among the most common error types (Leacock et al., 2010). This is due to the fact that prepositions are highly polysemous and have idiosyncratic usage. Selecting a preposition depends on how well we can capture the interaction between a preposition and its context. Hence we choose this task to evaluate how well the lexical interactions are captured by different methods.

Task. Given a sentence in English containing a preposition, we either replace the preposition with the correct one or retain it. For example, in the sentence "It can save the effort to carrying a lot of cards," "to" should be corrected as "of." Formally, there is a closed set of preposition candidates $P = \{p_1, \ldots, p_m\}$. A preposition p is used in a sentence s consisting of words $s = \{\ldots, w_{-2}, w_{-1}, p, w_1, w_2, \ldots\}$. If used incorrectly, we need to replace p by another preposition $\hat{p} \in P$ based on the context.

	Error ratio	38.2

Table 3: Dataset statistics.

Dataset. For training, we use the data from the Cambridge First Certificate in English (FCE) exam, just as used by the state-of-the-art on preposition error correction (Prokofyev et al., 2014). As for test data, we use two the CoNLL-2013 and the Stack Exchange (SE) datasets. The CoNLL dataset on preposition error correction was published by the CoNLL 2013 shared task (Ng et al., 2014), collected from 50 essays written by 25 non-native English learners at a university. The SE dataset consists of texts generated by non-native speakers on the Stack Exchange website. Detailed statistics are shown in Table 3. We focus on the most frequent 49 prepositions listed in Appendix A.

Evaluation metric. Three metrics–precision, recall and F1 score–are used to evaluate the preposition selection performance.

Our algorithm. We first preprocess the dataset by removing articles, determiners and pronouns, and take a context window of 3. We divide the task into two steps: error detection and error cor-

Dataset	Method	Precision	Recall	F1 score

Table 4: Performance on preposition selection.

rection. Firstly, we decide whether a preposition is used correctly in the context. If not, we suggest another preposition as replacement in the second step. The detection step uses only three features: the cosine similarity between the the current preposition embedding and the average context embedding, the rank of the preposition in terms of this cosine similarity, and the probability that this preposition is not changed in the training corpus. We build a decision tree classifier with these three features and find that we can identify errors with 98% F1 score in the CoNLL dataset and 96% in the SE dataset.

For the error correction part, we only focus on the errors detected in the first stage. Suppose that the original preposition is q, and the candidate preposition is p with the embedding v_p. The word vectors in the left context window are averaged as the left context embedding v_ℓ, and the right vectors are averaged to give the right context embedding v_r. We have the following features:

1. Embedding features: $\mathbf{v}_\ell, \mathbf{v}_p$ and $\mathbf{v}_r$;
2. Pair similarity between the preposition and the context: maximum of the similarity of the preposition between the left and the right context, i.e., pair sim $= \max\left(\frac{\mathbf{v}_\ell^T \mathbf{v}_p}{\|\mathbf{v}_\ell\|_2 \cdot \|\mathbf{v}_p\|_2}, \frac{\mathbf{v}_r^T \mathbf{v}_p}{\|\mathbf{v}_r\|_2 \cdot \|\mathbf{v}_p\|_2}\right)$;
3. Triple similarity $= \frac{\langle \mathbf{v}_\ell, \mathbf{v}_p, \mathbf{v}_r \rangle}{\|\mathbf{v}_\ell\|_3 \cdot \|\mathbf{v}_p\|_3 \cdot \|\mathbf{v}_r\|_3}$;
4. Confusion probability: the probability that q is replaced by p in the training data.

A two-layer feed-forward neural network (FNN) with hidden layer sizes of 500 and 10 is trained with these features to score prepositions in each sentence. The preposition with the highest score is the suggested edit.

Baseline. The state-of-the-art on preposition selection uses n-gram statistics from a large corpus (Prokofyev et al., 2014). Features such as point-wise mutual information (PMI) and part-of-speech tags are fed into a supervised scoring system. Given a sentence with a preposition to either replace or retain, the preposition with the highest score is chosen.

The performance of the baseline is affected by both the system architecture and the features. To evaluate the benefits brought about by our tensor embedding-based features, we also consider other baselines which have the same two-step architecture whereas the features are generated from word2vec and GloVe embeddings. These baselines allow us to compare the representation power independent of the classifier.

Result. We compare our proposed embedding-based method against baselines mentioned in Table 4. We note that the proposed tensor embeddings achieve the best performance among all approaches. In particular, the tensor with weighted decomposition has the highest F1 score on the CoNLL dataset–a 6% improvement over the state-of-the-art. However, the tensor with ALS decomposition performs the best on the SE dataset, achieving a 2% improvement over the state-of-the art. We also note that with the same architecture, tensor embeddings perform much better than word2vec and GloVe embeddings on both the datasets. This validates the representation power of tensor embeddings of prepositions.

To get a deeper insight into the importance of the features in the preposition selection task, we also performed an ablation analysis of the tensor

Removed feature		Left context embedding	Prep embedding	Right context embedding	Pair similarity	Triple similarity	Confusion score
CoNLL	Precision	0.1558	0.2662	0.3117	0.3247	0.3247	0.3506
	Recall	0.1579	0.2697	0.3158	0.3289	0.3289	0.3553
	F1 score	0.1569	0.2680	0.3137	0.3268	0.3268	0.3529
SE	Precision	0.2587	0.2796	0.2649	0.2658	0.2647	0.1993
	Recall	0.2743	0.2964	0.2801	0.2818	0.2807	0.2114
	F1 score	0.2663	0.2877	0.2726	0.2735	0.2725	0.2052

Table 5: Ablation analysis in preposition selection.

method with weighted decomposition as shown in Table 5. We find that the left context is the most important feature in for the CoNLL dataset, whereas the confusion score is the most important for the SE dataset. Pair similarity and triple similarity are less important when compared with the other features. This is because the neural network was able to learn the lexical similarity from the embedding features, thus reducing the importance of the similarity features.

Discussion. Now we analyze different cases where our approach selects the wrong preposition. (1) *Limited context window*. We focus on the local context within a preposition's window. In some cases, we find that head words might be out of the context window. An instance of this is found in the sentence "prevent more of this kind of tragedy *to* happening" *to* should be corrected as *from*. Given the context window of 3, we cannot get the lexical clues provided by *prevent*, which leads to the selection error. (2) *Preposition selection requires more context*. Even when the context window contains all the words on which the preposition depends, it still may not be sufficient to select the right one. For example, in the sentence "it is controlled by some men *in* a bad purpose" where our approach replaces the preposition *in* with the preposition *on* given the high frequency of the phrase "on purpose". The correct preposition should be *for* based on the whole sentence.

5 Downstream Application: Prepositional Attachment

In this section, we discuss the task of prepositional phrase (PP) attachment disambiguation, a well-studied, but hard task in syntactic parsing. The PP attachment disambiguation inherently requires an accurate description of the interactions among the head, the preposition and the complement, which becomes an ideal task to evaluate our tensor-based embeddings.

Task. The English dataset used in this work is collected from a linguistic treebank by (Belinkov et al., 2015). It provides $35,359$ training and $1,951$ test instances. Each instance consists of several head candidates, a preposition and a complement word. The task is to pick the head to which the preposition attaches. In the example "he saw an elephant with long tusks", the words "saw" and "elephant" are the candidate head words.

Our algorithm. Let $\mathbf{v}_h, \mathbf{v}_p$ and $\mathbf{v}_c$ be embeddings for the head candidate h, preposition p and child c respectively. We then use the following features:

1. Embedding feature: candidate head, preposition and complement embedding;
2. Triple similarity: $\frac{\langle \mathbf{v}_h, \mathbf{v}_p, \mathbf{v}_c \rangle}{\|\mathbf{v}_h\|_3 \cdot \|\mathbf{v}_p\|_3 \cdot \|\mathbf{v}_c\|_3}$;
3. Head-preposition similarity: $\frac{\mathbf{v}_h^T \mathbf{v}_p}{\|\mathbf{v}_h\|_2 \cdot \|\mathbf{v}_p\|_2}$;
4. Head-child similarity: $\frac{\mathbf{v}_h^T \mathbf{v}_c}{\|\mathbf{v}_h\|_2 \cdot \|\mathbf{v}_c\|_2}$;
5. Part-of-speech (pos) tag of candidates and next words;
6. Distance between h and p.

We use a basic neural network, a two-layer feed-forward network (FNN) with hidden-layers of size 1000 and 20, to take the input features and predict the probability that a candidate is the head. The candidate with the highest likelihood is chosen as the head.

Baselines. For comparison, we include the following state-of-the-art approaches in preposition attachment disambiguation. The linguistic resources they used to enrich their features are listed in Table 6.

Classifier	HPCD (enriching)	LRFR	OntoLSTM	FNN	FNN	FNN	FNN
Embedding method	GloVe	Word2vec	Glove-extended	Word2vec	GloVe	Our method (ALS)	Our method (WD)
Resources	POS tag, WordNet, VerbNet	POS tag, WordNet, VerbNet	POS tag, WordNet	POS tag	POS tag	POS tag	POS tag
Accuracy	0.887	**0.903**	0.897	0.866	0.858	0.883	0.892

Table 6: Accuracy in prepositional attachment disambiguation.

(1) Head-Prep-Child-Dist (HPCD) Model (Belinkov et al., 2015): this compositional neural network is used to train task-specific representations of prepositions.
(2) Low-Rank Feature Representation (LRFR) (Yu et al., 2016): this method incorporates word parts, contexts and labels into a tensor, and uses decomposed vectors as features for disambiguation.
(3) Ontology LSTM (OntoLSTM) (Dasigi et al., 2017): the vectors are initialized with GloVe, extended by AutoExtend (Rothe and Schütze, 2015), and trained via LSTMs for head selection.

Similar to the experiments in the preposition selection task (see Section 4), we also include baselines which have the same feed-forward network architecture but generate features with vectors trained by word2vec and GloVe. They are denoted as FNN with different initializations in Table 6. Since the attachment disambiguation is a selection task, accuracy is a natural evaluation metric.

Result. We compare the results of the different approaches and the linguistic resources used in Table 6, where we see that our simple classifier built on the tensor representation is comparable in performance to the state-of-the-art (within 1% of the result). This result is notable considering that prior competitive approaches have used significant linguistic resources such as VerbNet and WordNet, whereas we use none. With the same feed-forward neural network as the classifier, our tensor-based approaches (both ALS and WD) achieve better performance than word2vec and GloVe.

An ablation analysis that is provided in Table 7 shows that the head vector feature affects the performance the most (indicating that heads interact more closely with prepositions), and the POS tag feature comes second. The similarity features appear less important since the classifier has access to the lexical relatedness via the embedding features. Prior works have reported the importance of the distance feature since 81.7% sentences take the word closest to the preposition as the head. In our experiments, the distance feature was found to be less important compared to the embedding features.

Discussion. We found that one source of attachment disambiguation error is the lack of a broader context in our features. A broader context is critical in examples such as "worked" and "system," which are head candidates of "for trades" in the sentence "worked on a system for trading". They are reasonable heads in the expressions "worked for trades" and "system for trades" and further disambiguation requires a context larger than what we considered.

6 Related Work

Word representation. Word embeddings have been successfully used in many NLP applications. Word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) show that embeddings can capture lexical semantics very well. Zhang et al. (2014) studied embeddings which can generalize different similarity perspectives when combined with corresponding linear transformations. Unlike other words, the crucial syntactic roles of prepositions in addition to their rich semantic meanings have been highlighted in prior works (Hovy et al., 2010; Schneider et al., 2015). Nevertheless, word representations specifically focused on prepositions are not available and to the best of our knowledge, ours is the first work exploring this intriguing direction.

Tensor Decomposition. Tensors embed higher order interaction among different modes, and the tensor decomposition captures this interaction via lower dimensional representations. There are several decomposition methods such as Alternating Least Square (ALS) (Kolda and Bader, 2009), Si-

Removed feature	Head vector	Prep vector	Child vector	Head-prep similarity	Head-child similarity	Triple similarity	POS	Distance
Accuracy	0.843	0.871	0.880	0.877	0.885	0.873	0.850	0.872

Table 7: Ablation analysis in preposition attachment disambiguation.

multaneous Diagonalization (SD) (Kuleshov et al., 2015) and optimization-based methods (Liu and Nocedal, 1989; Moré, 1978). Orthogonalized Alternating Least Square (Orth-ALS) adds the step of component orthogonalization to each update step in the ALS method (Sharan and Valiant, 2017). Owing to its theoretical guarantees and, more relevantly due to its good empirical performance, Orth-ALS is the algorithm of choice in this paper.

Preposition Selection. Preposition selection, an important area of study in computational linguistics, is also a very practical topic in the context of grammar correction and second language learning. Prior works have used hand-crafted heuristic rules (Xiang et al., 2013), n-gram features (Prokofyev et al., 2014; Rozovskaya et al., 2013), and by the use of POS tags and dependency relations to enrich other features (Kao et al., 2013)–all toward addressing preposition error correction.

Prepositional Attachment Disambiguation. There is a storied literature on prepositional attachment disambiguation, long recognized as an important part of syntactic parsing (Kiperwasser and Goldberg, 2016). Recent works, based on word embeddings have pushed the boundary of state of the art empirical results. A seminal work in this direction is the Head-Prep-Child-Dist Model, which trained embeddings in a compositional network to maximize the accuracy of head prediction (Belinkov et al., 2015). The performance has been further improved in conjunction with semantic and syntactic features. A recent work has proposed an initialization with semantics-enriched GloVe embeddings, and retrained representations with LSTM-RNNs (Dasigi et al., 2017). Another recent work has used tensor decompositions to capture the relation between word representations and their labels (Yu et al., 2016).

7 Conclusion

Co-occurrence counts of word pairs in sentences and the resulting word vector representations (embeddings) have revolutionalized NLP research. A natural generalization is to consider co-occurrence counts of word triples, resulting in a third order tensor. Partly due to the size of the tensor (a vocabulary of 1M, leads to a tensor with 10^{18} entries!) and partly due to the extreme dynamic range of entries (including sparsity), word vector representations via tensor decompositions have largely been inferior to their lower order cousins (i.e., regular word embeddings).

In this work, we trek this well-trodden but arduous terrain by restricting word triples to the scenario when one of the words is a preposition. This is linguistically justified, since prepositions are understood to model interactions between pairs of words. Numerically, this is also very well justified since the sparsity and dynamic range of the resulting tensor is no worse than the original matrix of pairwise co-occurrence counts; this is because prepositions are very frequent and co-occur with essentially every word in the vocabulary.

Our intrinsic evaluations and new state-of-the-art results in downstream evaluations lend strong credence to the tensor-based approach to prepositional representation. We expect our vector representations of prepositions to be widely used in more complicated downstream NLP tasks where prepositional role is crucial, including "text to programs" (Guu et al., 2017).

Abstract

A core part of linguistic typology is the classification of languages according to linguistic properties, such as those detailed in the World Atlas of Language Structure (WALS). Doing this manually is prohibitively time-consuming, which is in part evidenced by the fact that only 100 out of over 7,000 languages spoken in the world are fully covered in WALS.

We learn distributed language representations, which can be used to predict typological properties on a massively multilingual scale. Additionally, quantitative and qualitative analyses of these language embeddings can tell us how language similarities are encoded in NLP models for tasks at different typological levels. The representations are learned in an unsupervised manner alongside tasks at three typological levels: phonology (grapheme-to-phoneme prediction, and phoneme reconstruction), morphology (morphological inflection), and syntax (part-of-speech tagging).

We consider more than 800 languages and find significant differences in the language representations encoded, depending on the target task. For instance, although Norwegian Bokmål and Danish are typologically close to one another, they are phonologically distant, which is reflected in their language embeddings growing relatively distant in a phonological task. We are also able to predict typological features in WALS with high accuracies, even for unseen language families.

1 Introduction

For more than two and a half centuries, linguistic typologists have studied languages with respect to their structural and functional properties (Haspelmath, 2001; Velupillai, 2012). Although typology has a long history (Herder, 1772; Gabelentz, 1891; Greenberg, 1960, 1974; Dahl, 1985; Comrie, 1989; Haspelmath, 2001; Croft, 2002), computational approaches have only recently gained popularity (Dunn et al., 2011; Wälchli, 2014; Östling, 2015; Cotterell and Eisner, 2017; Asgari and Schütze, 2017; Malaviya et al., 2017; Bjerva and Augenstein, 2018). One part of traditional typological research can be seen as assigning sparse explicit feature vectors to languages, for instance manually encoded in databases such as the World Atlas of Language Structures (WALS, Dryer and Haspelmath, 2013). A recent development which can be seen as analogous to this is the process of learning distributed language representations in the form of dense real-valued vectors, often referred to as *language embeddings* (Tsvetkov et al., 2016; Östling and Tiedemann, 2017; Malaviya et al., 2017). We hypothesise that these language embeddings encode typological properties of language, reminiscent of the features in WALS, or even of parameters in Chomsky's Principles and Parameters framework (Chomsky, 1993).

In this paper, we model languages in deep neural networks using language embeddings, considering three typological levels: phonology, morphology and syntax. We consider four NLP tasks to be representative of these levels: grapheme-to-phoneme prediction and phoneme reconstruction, morphological inflection, and part-of-speech tagging. We pose three research questions (**RQ**s):

RQ 1 Which typological properties are encoded in task-specific distributed language representations, and can we predict phonological, morphological and syntactic properties of languages using such representations?

RQ 2 To what extent do the encoded properties change as the representations are fine tuned for tasks at different linguistic levels?

RQ 3 How are language similarities encoded in fine-tuned language embeddings?

Proceedings of NAACL-HLT 2018, pages 907–916
New Orleans, Louisiana, June 1 - 6, 2018.

One of our key findings is that language representations differ considerably depending on the target task. For instance, for grapheme-to-phoneme mapping, the differences between the representations for Norwegian Bokmål and Danish increase rapidly during training. This is due to the fact that, although the languages are typologically close to one another, they are phonologically distant.

2 Related work

Computational linguistics approaches to typology are now possible on a larger scale than ever before due to advances in neural computational models. Even so, recent work only deals with fragments of typology compared to what we consider here.

Computational typology has to a large extent focused on exploiting word or morpheme alignments on the massively parallel New Testament, in approximately 1,000 languages, in order to infer word order (Östling, 2015) or assign linguistic categories (Asgari and Schütze, 2017). Wälchli (2014) similarly extracts lexical and grammatical markers using New Testament data. Other work has taken a computational perspective on language evolution (Dunn et al., 2011), and phonology (Cotterell and Eisner, 2017; Alishahi et al., 2017).

Language embeddings In this paper, we follow an approach which has seen some attention in the past year, namely the use of distributed language representations, or *language embeddings*. Some typological experiments are carried out by Östling and Tiedemann (2017), who learn language embeddings via multilingual language modelling and show that they can be used to reconstruct genealogical trees. Malaviya et al. (2017) learn language embeddings via neural machine translation, and predict syntactic, morphological, and phonetic features.

Contributions Our work bears the most resemblance to Bjerva and Augenstein (2018), who fine-tune language embeddings on the task of PoS tagging, and investigate how a handful of typological properties are coded in these for four Uralic languages. We expand on this and thus contribute to previous work by: (i) introducing novel qualitative investigations of language embeddings, in addition to thorough quantitative evaluations; (ii) considering four tasks at three different typological levels; (iii) considering a far larger sample of several hundred languages; and (iv) grounding the language representations in linguistic theory.

3 Background

3.1 Distributed language representations

There are several methods for obtaining distributed language representations by training a recurrent neural language model (Mikolov et al., 2010) simultaneously for different languages (Tsvetkov et al., 2016; Östling and Tiedemann, 2017). In these recurrent multilingual language models with long short-term memory cells (LSTM, Hochreiter and Schmidhuber, 1997), languages are embedded into an n-dimensional space. In order for multilingual parameter sharing to be successful in this setting, the neural network is encouraged to use the language embeddings to encode features of language. In this paper, we explore the embeddings trained by Östling and Tiedemann (2017), both in their original state, and by further tuning them for our four tasks. These are trained by training a multilingual language model with language representations on a collection of texts from the New Testament, covering 975 languages. While other work has looked at the types of representations encoded in different layers of deep neural models (Kádár et al., 2017), we choose to look at the representations only in the bottom-most embedding layer. This is motivated by the fact that we look at several tasks using different neural architectures, and want to ensure comparability between these.

3.1.1 Language embeddings as continuous Chomskyan parameter vectors

We now turn to the theoretical motivation of the language representations. The field of NLP is littered with distributional word representations, which are theoretically justified by distributional semantics (Harris, 1954; Firth, 1957), summarised in the catchy phrase *You shall know a word by the company it keeps* (Firth, 1957). We argue that language embeddings, or distributed representations of language, can also be theoretically motivated by Chomsky's Principles and Parameters framework (Chomsky and Lasnik, 1993; Chomsky, 1993, 2014). Language embeddings encode languages as dense real-valued vectors, in which the dimensions are reminiscent of the parameters found in this framework. Briefly put, Chomsky argues that languages can be described in terms of principles

(abstract rules) and parameters (switches) which can be turned either on or off for a given language (Chomsky and Lasnik, 1993). An example of such a switch might represent the positioning of the head of a clause (i.e. either head-initial or head-final). For English, this switch would be set to the 'initial' state, whereas for Japanese it would be set to the 'final' state. Each dimension in an n-dimensional language embedding might also describe such a switch, albeit in a more continuous fashion. The number of dimensions used in our language representations, 64, is a plausible number of parameter vector dimensions (Dunn et al., 2011). If we were able to predict typological features using such representations, this lends support to the argument that languages, at the very least, *can* be represented by theoretically motivated parameter vectors, with the given dimensionality.

3.2 Typological features in the World Atlas of Language Structure

In the experiments for **RQ1** and **RQ2** we predict typological features extracted from WALS (Dryer and Haspelmath, 2013). We choose to investigate three linguistic levels of language: phonology, morphology, and syntax. This is motivated by three factors: (i) these features are related to NLP tasks for which data is available for a large language sample; (ii) the levels cover a range from basic phonological and morphological structure, to syntactic structure, allowing us to approach our research question from several angles; and (iii) the features in these categories are coded in WALS for a relatively large selection of languages. We extract the three feature sets which represent these typological levels of language from WALS.[1]

Phonological features cover 20 features ranging from descriptions of the consonant and vowel inventories of a particular language to presence of tone and stress markers. As an example, consider WALS feature 13A (Tone).[2] This feature takes three feature values: (i) *no tones*, (ii) *simple tone system*, and (iii) *complex tone system*. Most Indo-European languages, such as English, Spanish, and Russian, do not have any tones (i). Norwegian and Swedish are exceptions to this, as they both have simple tone systems (ii) similar to that in Japanese. Finally, complex tone systems (iii) are typically found in several African languages as well as languages in South-East Asia.

Morphological features cover a total of 41 features. We consider the features included in the Morphology chapter as well as those included in the Nominal Categories chapter to be morphological in nature.[3] This includes features such as the number of genders, usage of definite and indefinite articles and reduplication. As an example, consider WALS feature 37A (Definite Articles).[4] This feature takes five values: (i) *Definite word distinct from demonstrative*, (ii) *Demonstrative word used as definite article*, (iii) *Definite affix*, (iv) *No definite, but indefinite article*, and (v) *No definite or indefinite article*. Again, most Indo-European languages fall into category (i), with Norwegian, Swedish, and Danish as relative outliers in category (iii).

Word-order features cover 56 features, encoding properties such as the ordering of subjects, objects and verbs. As an example, consider WALS feature 81A (Order of Subject, Object and Verb).[5] This feature takes all possible combinations of the three word classes as its feature values, with the addition of a special class for *No dominant order*. Most languages in WALS fall into the categories SOV (41.0%) and SVO (35.4%).

4 Method

The general set-up of the experiments in this paper is as follows. We aim at answering our three research questions dealing with typological properties and similarities as encoded in language embeddings. In order to do this, we attempt to predict typological features as they are encoded in WALS, using language embeddings which have been fine-tuned during training on tasks related to different typological properties. The main interest in this paper is therefore not on how well each model performs on a given NLP task, but rather on what the resulting language embeddings encode.

Concretely, we use language embeddings $\vec{l}_i$ from a given training iteration of a given task as input to a k-NN classifier, which outputs the typological class a language belongs to (as coded in WALS). We train separate classifiers for each

[1] These are defined in the chapter structure in WALS: http://wals.info/chapter

[2] http://wals.info/feature/13A

[3] This choice was made as, e.g., feature 37A (Definite Articles) includes as a feature value whether a definite affix is used.

[4] http://wals.info/feature/37A

[5] http://wals.info/feature/81A

typological property and each target task. When $i = 0$, this indicates the pre-trained language embeddings as obtained from Östling and Tiedemann (2017). Increasing i indicates the number of iterations over which the system at hand has been trained. In each experiment, for a given iteration i, we consider each $\vec{l_i} \in L$ where L is the intersection $L_{task} \cap L_{pre}$, where L_{task} is the set of languages for a given task, and L_{pre} is the set of languages for which we have pre-trained embeddings.

All results in the following sections are the mean of three-fold cross-validation, and the mean over the WALS features in each given category.[6] We run the experiments in a total of three settings: (i) evaluating on randomly selected language/feature pairs from a task-related feature set; (ii) evaluating on an *unseen language family from a task-related feature set*; (iii) evaluating on randomly selected language/feature pairs from all WALS feature sets. This allows us to establish how well we can predict task-related features given a random sample of languages (i), and a sample from which a whole language family has been omitted (ii). Finally, (iii) allows us to compare the task-specific feature encoding with a general one.

A baseline reference is also included, which is defined as the most frequently occurring typological trait within each category.[7] For instance, in the morphological experiments, we only consider the 41 WALS features associated with the categories of morphology and nominal categories. The overlap between languages for which we have data for morphological inflection and languages for which these WALS features are coded is relatively small (fewer than 20 languages per feature). This small dataset size is why we have opted for a non-parametric k-Nearest Neighbours classifier for the typological experiments. We use $k = 1$, as several of the features take a large number of class values, and might only have a single instance represented in the training set.

Table 1 shows the datasets we consider (detailed in later sections), the typological class they are related to, the size of the language sample in the task, and the size of the intersection $L_{task} \cap L_{pre}$. The number of pre-trained language embeddings, $|L_{pre}|$, is 975 in all cases. We focus the evaluation for each task-specific language embedding set on the typological property relevant to that dataset. In addition, we also evaluate on a set of all typological properties in WALS. Note that the evaluation on all properties is only comparable to the evaluation on each specific property, as the set of languages under consideration differs between tasks.

Dataset	Class	$\lvert L_{task}\rvert$	$\lvert L_{task} \cap L_{pre}\rvert$
G2P	Phonology	311	102
ASJP	Phonology	4,664	824
SIGMORPHON	Morphology	52	29
UD	Syntax	50	27

Table 1: Overview of tasks and datasets.

5 Phonology

5.1 Grapheme-to-phoneme

We use grapheme-to-phoneme (G2P) as a proxy of a phonological task (Deri and Knight, 2016; Peters et al., 2017). The dataset contains over 650,000 such training instances, for a total of 311 languages (Deri and Knight, 2016). The task is to produce a phonological form of a word, given its orthographic form and the language in which it is written. Crucially, this mapping is highly different depending on the language at hand. For instance, take the word written *variation*, which exists in both English and French:

```
(English, variation) -> ˌvɛəriˈeɪʃən
(French,  variation) -> ˌvaʁjaˈsjɔ̃
```

5.1.1 Experiments and Analysis

We train a sequence-to-sequence model with attention for the task of grapheme-to-phoneme mapping.[8] The model takes as input the characters of each source form together with the language embedding for the language at hand and outputs a predicted phonological form. Input and output alphabets are shared across all languages. The system is trained over 3,000 iterations.

Quantitative results Since we consider Grapheme-to-Phoneme as a phonological task, we focus the quantitative evaluation on phonological features from WALS. We run experiments using the language embeddings as features for a simple

[6] The mean accuracy score is a harsh metric, as some features are very difficult to predict due to them, e.g., being very language specific or taking a large number of different values.

[7] The languages represented in several of the tasks under consideration have a high Indo-European bias. Hence, several of the properties have a relatively skewed distribution, providing us with a strong baseline.

[8] The system is described in detail in Section 8.

k-NN classifier. The results in Table 2 indicate that G2P is a poor proxy for language phonology, however, as typological properties pertaining to phonology are not encoded. That is to say, the k-NN results do not outperform the baseline, and performance is on par even after fine tuning (no significant difference, $p > 0.05$). In the unseen setting, however, we find that pre-trained language embeddings are significantly better ($p < 0.05$) at predicting the phonological features than both fine-tuned ones and the baseline.

System / features	Random phon.	Unseen phon.	All feat.
Most Frequent Class	*75.46%	65.57%	79.90%
k-NN (pre-trained)	71.45%	*86.54%	80.39%
k-NN (fine-tuned)	71.66%	82.36%	79.17%

Table 2: Accuracies on prediction of WALS features with language embeddings fine-tuned on Grapheme-to-Phoneme mapping. Asterisks indicate results significantly higher than both other conditions ($p < 0.05$).

Qualitative results We now turn to why this task is not a good proxy of phonology. The task of grapheme-to-phoneme is more related to the processes in the diachronic development of the writing system of a language than it is to the actual genealogy or phonology of the language. This is evident when considering the Scandinavian languages Norwegian and Danish which are typologically closely related, and have almost exactly the same orthography. In spite of this fact, the phonology of the two languages differs drastically due to changes in Danish phonology, which impacts the mapping from graphemes to phonemes severely. Hence, the written forms of the two languages should be very similar, which makes the language embeddings based on language modelling highly similar to one another. However, when the embeddings are fine-tuned on a task taking orthography as well as phonology into account, this is no longer the case. Figure 1 shows that the language embeddings of Norwegian Bokmål and Danish diverge from each other, which is especially striking when comparing to the converging with the typologically much more distant languages Tagalog and Finnish. However, the absolute difference between Norwegian Bokmål and both Tagalog/Finnish is still greater than that of Norwegian Bokmål and Danish even after 3,000 iterations.

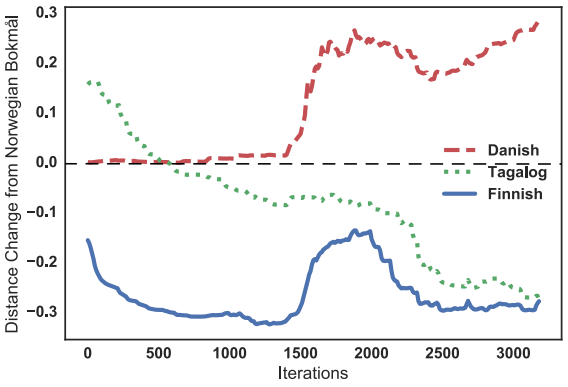

Figure 1: Language similarities between Norwegian, and Danish/Tagalog/Finnish, as G2P-based embeddings are fine-tuned.

5.2 Phonological reconstruction

As a second phonological task, we look at phonological reconstruction using word lists from the Automated Similarity Judgement Program (ASJP, Wichmann et al. (2016)). This resource contains word lists of at least 40 words per language for more than 4,500 languages. The task we consider is to reproduce a given source phonological form, also given the language, for instance:

```
(English, wat3r) -> wat3r
```

The intuition behind these experiments is that languages with similar phonetic inventories will be grouped together, as reflected in changes in the language embeddings.

5.2.1 Experiments and Analysis

We train a sequence-to-sequence model with attention, framed as an auto-encoding problem, using the same sequence-to-sequence architecture and setup as for the grapheme-to-phoneme task. The model takes as input the characters of each source form together with the language embedding for the language at hand and outputs the predicted target form which is identical to the source form.

Quantitative results Since we also consider phonological reconstruction to be a phonological task, we focus the quantitative evaluation on phonological features from WALS. As with the G2P experiments, Table 3 shows that the fine-tuned embeddings do not offer predictive power above the most frequent class baseline ($p > 0.05$). Observing the changes in the language embeddings reveals that the embeddings are updated to

a very small extent, indicating that these are not used by the model to a large extent. This can be explained by the fact that the task is highly similar for each language, and that the model largely only needs to learn to copy the input string.

We do, however find that evaluating on a set with an unseen language family does yield results significantly above baseline levels with the pre-trained embeddings ($p < 0.05$), which together with the G2P results indicate that the language modelling objective does encode features to some extent related to phonology.

System / features	Random phon.	Unseen phon.	All feat.
Most Frequent Class	***59.39%**	63.71%	***58.12%**
k-NN (pre-trained)	53.02%	***77.44%**	51.6%
k-NN (fine-tuned)	53.09%	***77.45%**	51.9%

Table 3: Accuracies on prediction of WALS features with language embeddings fine-tuned on Phonological Reconstruction. Asterisks indicate results significantly higher than non-bold conditions ($p < 0.05$).

6 Morphology

6.1 Morphological inflection

We use data from the Unimorph project, specifically the data released for the SIGMORPHON-2017 shared task (Cotterell et al., 2017).[9] This data covers 52 languages, thereby representing a relatively large typological variety. Whereas the shared task has two subtasks, namely inflection and paradigm cell filling, we only train our system using the inflection task. This was a choice of convenience, as we are not interested in solving the task of morphological paradigm cell filling, but rather observing the language embeddings as they are fine-tuned. Furthermore we focus on the high-resource setting in which we have access to 10,000 training examples per language. The inflection subtask is to generate a target inflected form given a lemma with its part-of-speech as in the following example:

```
(release, V;V.PTCP;PRS) -> releasing
```

6.1.1 Morphological experiments

We train a sequence-to-sequence model with attention over 600 iterations, using the same sequence-to-sequence architecture from the previous tasks.

[9] https://unimorph.github.io/

Quantitative results Since this is considered a morphological task, Table 4 contains results using the language embeddings to predict morphological properties. The fine-tuned language embeddings in this condition are able to predict morphological properties in WALS significantly above baseline levels and pre-trained embeddings ($p < 0.05$). We further also obtain significantly better results in the unseen setting ($p < 0.05$), in which the language family evaluated on is not used in training. This indicates that these properties are important to the model when learning the task at hand.

System / Features	Random morph.	Unseen morph.	All feat.
Most Frequent Class	77.98%	85.68%	84.12%
k-NN (pre-trained)	74.49%	88.83%	**84.97%**
k-NN (fine-tuned)	***82.91%**	***91.92%**	84.95%

Table 4: Accuracies on prediction of WALS features with language embeddings fine-tuned on morphological inflection. Asterisks indicate results significantly higher than both other conditions ($p < 0.05$).

Qualitative results The performance of the fine-tuned embeddings on prediction of morphological features is above baseline for most features. For 18 out of the 35 features under consideration both the baseline and k-NN performances are at 100% from the outset, so these are not considered here.[10] Figure 2 shows two of the remaining 17 features.[11] We can observe two main patterns: For some features such as 49A (Number of cases), fine-tuning on morphological inflection increases the degree to which the features are encoded in the language embeddings. This can be explained by the fact that the number of cases in a language is central to how morphological inflection is treated by the model. For instance, languages with the same number of cases might benefit from sharing certain parameters. On the other hand, the feature 38A (Indefinite Articles) mainly encodes whether the indefinite word is distinct or not from the word for *one*, and it is therefore not surprising that this is not learned in morphological inflection.

7 Word order

7.1 Part-of-speech tagging

We use PoS annotations from version 2 of the Universal Dependencies (Nivre et al., 2016). As

[10] This is partially explained by the fact that certain categories were completely uniform in the small sample as well as by the Indo-European bias in the sample.

[11] The full feature set is included in the Supplements.

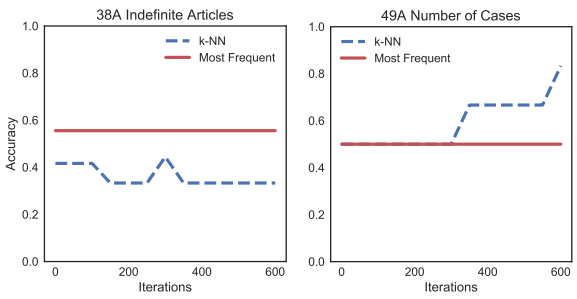

Figure 2: Prediction of two morphological features in WALS with morphological language embeddings, one data point per 50 iterations.

we are mainly interested in observing the language embeddings, we down-sample all training sets to 1,500 sentences (approximate number of sentences of the smallest data sets) so as to minimise any size-related effects.

7.1.1 Word-order experiments

We approach the task of PoS tagging using a fairly standard bi-directional LSTM architecture based on Plank et al. (2016), detailed in Section 8.

Quantitative results Table 5 contains results on WALS feature prediction using language embeddings fine-tuned on PoS tagging. We consider both the set of word order features, which are relevant for the dataset, and a set of all WALS features. Using the fine-tuned embeddings is significantly better than both the baseline and the pre-trained embeddings ($p < 0.05$), in both the random and the unseen conditions, indicating that the model learns something about word order typology. This can be expected, as word order features are highly relevant when assigning a PoS tag to a word.

System / features	Random W-Order	Unseen W-Order	All feat.
Most Frequent Class	76.81%	82.47%	82.93%
k-NN (pre-trained)	76.66%	92.76%	82.69%
k-NN (fine-tuned)	*80.81%	*94.48%	83.55%

Table 5: Accuracies on prediction of WALS features with language embeddings fine-tuned on PoS tagging. Asterisks indicate the result in bold significantly outperforming both other conditions ($p < 0.05$).

Qualitative results We now turn to the syntactic similarities between languages as encoded in the fine-tuned language embeddings. We consider a set of the North-Germanic languages Icelandic, Swedish, Norwegian Nynorsk, Danish, Norwegian Bokmål, the West-Germanic language English, and the Romance languages Spanish, French, and Italian. We apply hierarchical clustering using UPGMA (Michener and Sokal, 1957) to the pre-trained language embeddings of these languages.[12] Striking here is that English is grouped together with the Romance languages. This can be explained by the fact that English has a large amount of vocabulary stemming from Romance loan words, which under the task of language modelling results in a higher similarity with such languages. We then cluster the embeddings fine-tuned on PoS tagging in the same way. In this condition, English has joined the rest of the Germanic languages' cluster. This can be explained by the fact that, in terms of word ordering and morpho-syntax, English is more similar to these languages than it is to the Romance ones.

We can also observe that, whereas the orthographically highly similar Norwegian Bokmål and Danish form the first sub-cluster in the pre-trained condition, Norwegian Nynorsk replaces Danish in this pairing when fine-tuning on PoS tagging. This can be explained by the fact that morpho-syntactic similarities between the two written varieties of Norwegian are more similar to one another.

8 Implementation

8.1 Sequence-to-sequence modelling

The system architecture used in the sequence-to-sequence tasks, i.e., G2P, phonological reconstruction, and morphological inflection is depicted in Figure 3. The system is based on that developed by Östling and Bjerva (2017) and is implemented using Chainer (Tokui et al., 2015). We modify the architecture by concatenating a language embedding, $\vec{l}$, to the character embeddings before encoding. In the grapheme-to-phoneme and phonological reconstruction experiments, the one-hot feature mapping before decoding is irrelevant and therefore omitted. The rest of the hyperparameters are the same as in Östling and Bjerva (2017).

8.2 Sequence labelling

This system is based on Plank et al. (2016), and is implemented using DyNet (Neubig et al., 2017). We train using the Adam optimisation algorithm (Kingma and Ba, 2014) over a maximum of 10 epochs using early stopping. We make two modifications to the bi-LSTM architecture of Plank et al.

[12] Included in the Supplements due to space restrictions.

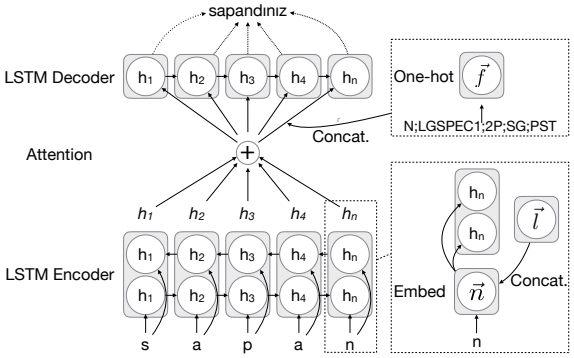

Figure 3: System architecture used in the seq-to-seq tasks (morphological inflection, G2P, and phonological reconstruction). Figure adapted with permission from Östling and Bjerva (2017).

(2016). First of all, we do not use any atomic embedded word representations, but rather use only character-based word representations. This choice was made so as to encourage the model not to rely on language-specific vocabulary. Additionally, we concatenate a pre-trained language embedding to each word representation. In our formulation, each word w is represented as $LSTM_c(w) + \vec{l}$, where $LSTM_c(w)$ is the final states of a character bi-LSTM running over the characters in a word and $\vec{l}$ is an embedded language representation. We use a two-layer deep bi-LSTM with 100 units in each layer, and 100-dimensional character embeddings. The rest of the hyper-parameters are the same as in Plank et al. (2016).[13]

9 Discussion and Conclusions

The language embeddings obtained by fine-tuning on linguistic tasks at various typological levels were found to include typological information somehow related to the task at hand. This lends some support to the theoretical foundations of such representations, in that it shows that it is possible to learn something akin to a vector of continuous Chomskyan parameters (Chomsky, 1993).

9.1 RQ1: Encoding of typological features in task-specific language embeddings

The features which are encoded depend to a large degree on the task at hand. The language embeddings resulting from the phonological tasks did not encode phonological properties in the sense of WALS features, whereas the pre-trained ones did.

[13]Both modified systems are included in the Supplements, and will be made publicly available.

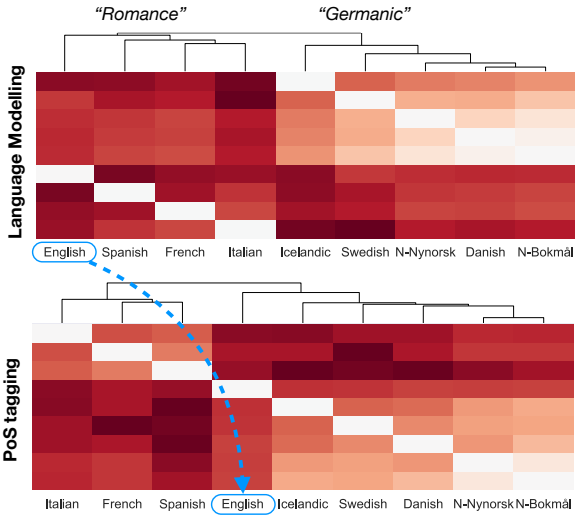

Figure 4: Language similarities changing during fine tuning.

The morphological language embeddings were found to encode morphological features, and the PoS language embeddings were similarly found to encode word order features.

A promising result is the fact that we were able to predict typological features for unseen language families. That is to say, without showing, e.g., a single Austronesian training instance to the k-NN classifier, typological features could still be predicted with high accuracies. This indicates that we can predict typological features with language embeddings, even for languages for which we have no prior typological knowledge.

Table 6 contains a comparison of the top five and bottom five feature prediction accuracies for the ASJP task.[14] In the case of the phonologically oriented ASJP task it is evident that the embeddings still encode something related to phonology, as four out of five best features are phonological.

9.2 RQ2: Change in encoding of typological features

The changes in the features encoded in language embeddings are relatively monotonic. Features are either learnt, forgotten, or remain static throughout training. This indicates that the language representations converge towards a single optimum.

9.3 RQ3: Language similarities

Training language embeddings in the task of multilingual language modelling has been found to reproduce trees which are relatively close matches

[14]See the Supplement for the remaining tasks.

to more traditional genealogical trees (Östling and Tiedemann, 2017). We show a similar analysis considering pre-trained and PoS fine-tuned embeddings, and it is noteworthy that fine-tuning on PoS tagging in this case yielded a tree more faithful to genealogical trees, such as those represented on glottolog.org. Figure 4 shows an example of this, in which a language modelling objective places English with Romance languages. This makes sense, as the English lexicon contains a large amount of Romance vocabulary. When fine-tuning on PoS tagging, however, English is placed among the Germanic languages, as it shares more syntactic similarities with these.

Another striking result in terms of language similarities in fine-tuned language embedding spaces was found in the G2P task. We here found that the phonological differences between some otherwise similar languages, such as Norwegian Bokmål and Danish, were accurately encoded.

Task	Feature	WALS Chapter	Accuracy
ASJP	6A	Phonology	89.45

Monte Carlo Syntax Marginals for Exploring and Using Dependency Parses

Katherine A. Keith, Su Lin Blodgett, and **Brendan O'Connor**
College of Information and Computer Sciences
University of Massachusetts Amherst
{kkeith,blodgett,brenocon}@cs.umass.edu

Abstract

Dependency parsing research, which has made significant gains in recent years, typically focuses on improving the accuracy of single-tree predictions. However, ambiguity is inherent to natural language syntax, and communicating such ambiguity is important for error analysis and better-informed downstream applications. In this work, we propose a *transition sampling* algorithm to sample from the full joint distribution of parse trees defined by a transition-based parsing model, and demonstrate the use of the samples in probabilistic dependency analysis. First, we define the new task of *dependency path prediction*, inferring syntactic substructures over part of a sentence, and provide the first analysis of performance on this task. Second, we demonstrate the usefulness of our *Monte Carlo syntax marginal* method for parser error analysis and calibration. Finally, we use this method to propagate parse uncertainty to two downstream information extraction applications: identifying persons killed by police and semantic role assignment.[1]

1 Introduction

Dependency parsers typically predict a single tree for a sentence to be used in downstream applications, and most work on dependency parsers seeks to improve accuracy of such single-tree predictions. Despite tremendous gains in the last few decades of parsing research, accuracy is far from perfect—but perfect accuracy may be impossible since syntax models by themselves do not incorporate the discourse, pragmatic, or world knowledge necessary to resolve many ambiguities.

In fact, although relatively unexamined, substantial ambiguity already exists within commonly used discriminative probabilistic parsing models,

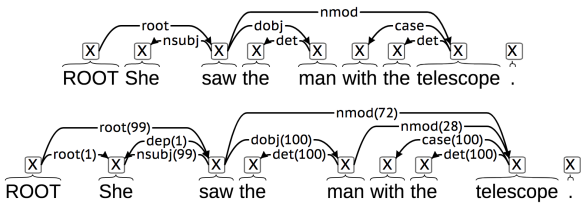

Figure 1: Example of a sentence with inherent ambiguity. **Top:** output from a greedy parser. **Bottom:** edge marginal probabilities from 100 samples in parentheses.

which define a parse forest—a probability distribution $p(y \mid x)$ over possible dependency trees $y \in \mathcal{Y}(x)$ for an input sentence x.

For example, the top of Figure 1 shows the predicted parse $y^{(greedy)}$ from such a parser (Chen and Manning, 2014), which resolves a prepositional (PP) attachment ambiguity in one manner; this prediction was selected by a standard greedy transition-based algorithm (§2.1). However, the bottom of Figure 1 shows *marginal* probabilities of individual (relation, governor, child) edges under this same model. These denote our estimated probabilities, across all possible parse structures, that a pair of words are connected with a particular relation (§2.4). For example, the two different PP attachment readings both exist within this parse forest with marginal probabilities

$$p(\ \text{nmod}(\text{saw}_2, \text{telescope}_7) \mid x) = 0.72 \quad (1)$$
$$p(\ \text{nmod}(\text{man}_4, \text{telescope}_7) \mid x) = 0.28, \quad (2)$$

where (1) implies she used a telescope to see the man, and (2) implies she saw a man who had a telescope.

These types of irreducible syntactic ambiguities exist and should be taken into consideration when analyzing syntactic information; for instance, one could transmit multiple samples (Finkel et al., 2006) or confidence scores (Bunescu, 2008) over

Proceedings of NAACL-HLT 2018, pages 917–928
New Orleans, Louisiana, June 1 - 6, 2018.

ambiguous readings to downstream analysis components.

In this work, we introduce a simple *transition sampling* algorithm for transition-based dependency parsing (§2.2), which, by yielding exact samples from the full joint distribution over trees, makes it possible to infer probabilities of long-distance or other arbitrary structures over the parse distribution (§2.4). We implement transition sampling—a very simple change to pre-existing parsing software—and use it to demonstrate several applications of probabilistic dependency analysis:

- Motivated by how dependency parses are typically used in feature-based machine learning, we introduce a new parsing-related task—*dependency path prediction*. This task involves inference over variable length *dependency paths*, syntactic substructures over only parts of a sentence.
- To accomplish this task, we define a *Monte Carlo syntax marginal* inference method which exploits information across samples of the entire parse forest. It achieves higher accuracy predictions than a traditional greedy parsing algorithm, and allows tradeoffs between precision and recall (§4).
- We provide a quantitative measure of the model's inherent uncertainty in the parse, *whole-tree entropy*, and show how it can be used for error analysis (§3).
- We demonstrate the method's (surprisingly) reasonable calibration (§5).
- Finally, we demonstrate the utility of our method to propagate uncertainty to downstream applications. Our method improves performance for giving probabilistic semantics to a rule-based event extractor to identify civilians killed by police (§6), as well as semantic role assignment (§7).

2 Monte Carlo dependency analysis

2.1 Overview of transition-based dependency parsing

We examine the *basic* form of the Universal Dependencies formalism (Nivre et al., 2016), where, for a sentence x of length N, a possible dependency parse y is a set of (relation, governorToken, childToken) edges, with a tree constraint that every token in the parse has exactly one governor—that is, for every token $w \in \{1..N\}$, there is exactly one triple $(r, g, w) \in y$ where it participates as a child. The governor is either one of the observed tokens, or a special ROOT vertex.

There exist a wide variety of approaches to machine learned, discriminative dependency parsing, which often define a probability distribution $p(y \mid x)$ over a domain of formally legal dependency parse trees $y \in \mathcal{Y}(x)$. We focus on *transition-based* dependency parsers (Nivre, 2003; Kübler et al., 2009), which (typically) use a stack-based automaton to process a sentence, incrementally building a set of edges. Transition-based parsers are very fast, have runtimes linear in sentence length, feature high performance (either state-of-the-art, or nearly so), and are easier to implement than other modeling paradigms (§2.5).

A probabilistic transition-based parser assumes the following stochastic process to generate a parse tree:

- Initialize state S_0
- For $n = 1, 2, \ldots$:
  - (A) $a_n \sim p(a_n \mid S_{n-1})$
  - (B) $S_n := \text{Update}(S_{n-1}, a_n)$
  - (C) Break if $\text{InEndState}(S_n)$

Most state transition systems (Bohnet et al., 2016) use shift and reduce actions to sweep through tokens from left to right, pushing and popping them from a stack to create the edges that populate a new parse tree y. The action decision probability, $p(a_{next} \mid S_{current})$, is a softmax distribution over possible next actions. It can be parameterized by any probabilistic model, such as log-linear features of the sentence and current state (Zhang and Nivre, 2011), multilayer perceptrons (Chen and Manning, 2014), or recurrent neural networks (Dyer et al., 2015; Kiperwasser and Goldberg, 2016).

To predict a single parse tree on new data, a common inference method is *greedy decoding*, which runs a close variant of the above transition model as a deterministic automaton, replacing stochastic step (A) with a best-action decision, $a_n := \arg\max_{a_n} p(a_n \mid S_{n-1})$.[2] An inferred ac-

[2]Since greedy parsing does not require probabilistic semantics for the action model—the softmax normalizer does not need to be evaluated—non-probabilistic training, such as with hinge loss (SVMs), is a common alternative, including in some of the cited work.

tion sequence $a_{1:n}$ determines the resulting parse tree (edge set) y; the relationship can be denoted as $y(a_{1:n})$.

2.2 Transition sampling

In this work, we propose to analyze the full joint posterior $p(y \mid x)$, and use *transition sampling*, a very simple forward/ancestral sampling algorithm,[3] to draw parse tree samples from that distribution. To parse a sentence, we run the automaton stochastically, sampling the action probability in step (A). This yields one action sequence $a_{1:n}$ from the full joint distribution of action sequences, and therefore a parse $y(a_{1:n})$ from the distribution of parses. We can obtain as many parse samples as desired by running the transition sampler S times, yielding a collection (multiset) of parse structures $\{y^{(s)} \mid s \in \{1..S\}\}$, where each $y^{(s)} \sim p(y \mid x)$ is a full dependency parse tree.[4] Runtime to draw one parse sample is very similar to the greedy algorithm's runtime. We denote the set of unique parses in the sample $\tilde{\mathcal{Y}}(x)$.

We implement a transition sampler by modifying an implementation of Chen and Manning's multilayer perceptron transition-based parser[5] and use it for all subsequent experiments.

2.3 MC-MAP single parse prediction

One minor use of transition sampling is a method for predicting a single parse, by selecting the most probable (common) parse tree in the sample,

$$\hat{y}^{\text{MC-MAP}} = \arg\max_{y \in \tilde{\mathcal{Y}}} \tilde{p}(y \mid x) \quad (3)$$

$$= \arg\max_{y \in \tilde{\mathcal{Y}}} \frac{c(y)}{S} \quad (4)$$

where $\tilde{p}(y \mid x)$ denotes the Monte Carlo estimate of a parse's probability, which is proportional to how many times it appears in the sample: $c(y) \equiv \sum_s^S 1\{y = y^{(s)}\}$. Note that $\tilde{p}(y \mid x)$ correctly accounts for the case of an ambiguous transition system where multiple different action sequences can yield the same tree—i.e., $y(a_{1:n})$ is not one-to-one—since the transition sampler can sample the multiple different paths.

This "MC-MAP" method is asymptotically guaranteed to find the model's most probable parse ($\arg\max_y p(y \mid x)$) given enough samples.[6] By contrast, greedy decoding and beam search have no theoretical guarantees. MC-MAP's disadvantage is that it may require a large number of samples, depending on the difference between the top parse's probability compared to other parses in the domain.

2.4 Monte Carlo Syntax Marginal (MCSM) inference for structure queries

Beyond entire tree structures, parse posteriors also define marginal probabilities of particular events in them. Let $f(y) \to \{0, 1\}$ be a boolean-valued *structure query* function of a parse tree—for example, whether the tree contains a particular edge:

$$f(y) = 1\{\text{dobj(kill,Smith)} \in y\}$$

or more complicated structures, such as a length-2 dependency path:

$$f(y) = 1\{\text{nsubj(kill, cop)} \wedge \text{dobj(kill, Smith)} \in y\}.$$

More precisely, these queries are typically formulated to check for edges between specific tokens, and may check tokens' string forms.

Although $f(y)$ is a deterministic function, since the parsing model is uncertain of the correct parse, we find the *marginal probability*, or expectation, of a structure query by integrating out the posterior parse distribution—that is, the predicted probability that the parse has the property in question:

$$p(f(y) \mid x) = \sum_{y \in \mathcal{Y}(x)} f(y)\, p(y \mid x) \quad (5)$$

$$\approx \tilde{p}(f(y) \mid x) = \sum_{y \in \tilde{\mathcal{Y}}(x)} f(y) \frac{c(y)}{S}. \quad (6)$$

Eq. 5 is the expectation with regard to the model's true probability distribution (p) over parses from the domain of all possible parse trees $\mathcal{Y}(x)$ for a sentence, while Eq. 6 is a Monte Carlo estimate of the query's marginal probability—the fraction of parse tree samples where the structure query is true. We use this simple method for all inference

[3] "Ancestral" refers to a directed Bayes net (e.g. Barber (2012)) of action decisions, each conditioned on the full history of previous actions—not ancestors in a parse tree.

[4] Dyer et al. (2016) use the same algorithm to draw samples from a transition-based constituency parsing model, as an importance sampling proposal to support parameter learning and single-tree inference.

[5] CoreNLP 3.8.0 with its 'english_UD' pretrained model.

[6] This holds since the Monte Carlo estimated probability of any tree converges to its true probability, according to, e.g., Hoeffding's inequality or the central limit theorem. Thus, with enough samples, the tree with the highest true probability will have estimated probability higher than any other tree's.

in this work, though importance sampling (Dyer et al., 2016), particle filters (Buys and Blunsom, 2015), or diverse k-best lists (Zhang and McDonald, 2014) could support more efficient inference in future work.

2.5 Probabilistic inference for dependencies: related work

Our transition sampling method aims to be an easy-to-implement algorithm for a highly performant class of dependency models, that conducts exact probabilistic inference for arbitrary structure queries in a reasonable amount of time. A wide range of alternative methods have been proposed for dependency inference that cover some, but perhaps not all, of these goals.

For transition-based parsing, beam search is a commonly used inference method that tries to look beyond a single structure. Beam search can be used to yield an approximate K-best list by taking resulting structures on the beam, though there are no theoretical guarantees about the result, and runtime is no better than the transition sampler.[7] Finkel et al. (2006) further discuss tradeoffs between beam search and sampling, and find they give similar performance when propagating named entity recognition and PCFG parse information to downstream tasks.

Graph-based parsers are the major alternative modeling paradigm for dependency parsing; instead of a sequence of locally normalized decisions, they directly parameterize an entire tree's globally normalized probability. Parse samples could be drawn from a graph-based model via Markov chain Monte Carlo (Zhang et al., 2014), which is asymptotically correct, but may require a large amount of time to obtain non-autocorrelated parses. A range of methods address inference for specific queries in graph-based models—for example, edge marginals for edge-factored models via the matrix-tree theorem (Koo et al., 2007), or approximate marginals with loopy belief propagation (Smith and Eisner, 2008).[8] By contrast, our method is guaranteed to give correct marginal inferences for arbitrary, potentially long-distance, queries.

Given the strong performance of graph-based parsers in the single-structure prediction setting (e.g. Zeman et al. (2017); Dozat et al. (2017)), it may be worthwhile to further explore probabilistic inference for these models. For example, Niculae et al. (2018) present an inference algorithm for a graph-based parsing model that infers a weighted, sparse set of highly-probable parse trees, and they illustrate that it can infer syntactic ambiguities similar to Figure 1.

Dynamic programming for dependency parsing, as far as we are aware, has only been pursued for single-structure prediction (e.g. Huang and Sagae (2010)), but in principle could be generalized to calculate local structure query marginals via an inside-outside algorithm, or to sample entire structures through an inside-outside sampler (Eisner, 2016), which Finkel et al. (2006) use to propagate parse uncertainty for downstream analysis.

3 Exploratory error analysis via whole-tree entropy calculations

In this section we directly explore the model's intrinsic uncertainty, while §5 conducts a quantitative analysis of model uncertainty compared to gold standard structures. Parse samples are able to both pass on parse uncertainty and yield useful insights that typical error analysis approaches cannot. For a sentence x, we can calculate the *whole-tree entropy*, the model's uncertainty of whole-tree parse frequencies in the samples:

$$\begin{aligned} H(p) &= -\sum_{y \in \mathcal{Y}(x)} p(y \mid x) \log p(y \mid x) \\ &\approx H(\tilde{p}) = -\sum_{y \in \tilde{\mathcal{Y}}(x)} \frac{c(y)}{S} \log \frac{c(y)}{S}. \end{aligned} \tag{7}$$

Since this entropy estimate is only based on an S-sample approximation of p, it is upper bounded at $\log(S)$ in the case of a uniform MC distribution. Another intuitive measure of uncertainty is simply the number of unique parses, that is, the cardinality of the MC distribution's domain ($|\tilde{\mathcal{Y}}|$); this quantity is not informative for the true distribution p, but in the MC distribution it is intuitively upper bounded by S.[9]

[7] Loosely, if it takes N transitions to complete a parse, and B possible actions at each transition must be evaluated, our method evaluates KNB actions to obtain K trees. Beam search evaluates a similar number of actions when using a K-sized beam, but also requires non-parallelizable management of the beam's priority queue.

[8] These papers infer marginals to support parameter learning, but we are not aware of previous work that directly analyzes or uses dependency parse marginals.

[9] Shannon entropy, domain support cardinality, and top probability ($\max_{y \in \tilde{Y}} \tilde{p}(y)$), which we show in Table 1, are all instances of the more general Renyi entropy (Smith and Eisner, 2007).

Sentence	Domain Size	Top 3 Freq.	Entropy
In Ramadi , there was a big demonstration .	3	[98, 1, 1]	0.112
US troops there clashed with guerrillas in a fight that left one Iraqi dead .	40	[33, 11, 6]	2.865
The sheikh in wheel - chair has been attacked with a F - 16 - launched bomb .	98	[2, 2, 1]	4.577

Table 1: Example sentences from the UD development set and summaries of their Monte Carlo parse distributions. *Domain Size* gives $|\tilde{\mathcal{Y}}_{100}|$, the number of unique parse structures in 100 samples. *Top 3 Freq.* gives the frequencies of the 3 most probable structures in $\tilde{\mathcal{Y}}_{100}$. *Entropy* is calculated according to Eq. 7; its upper bound is $\log(100) = 4.605$.

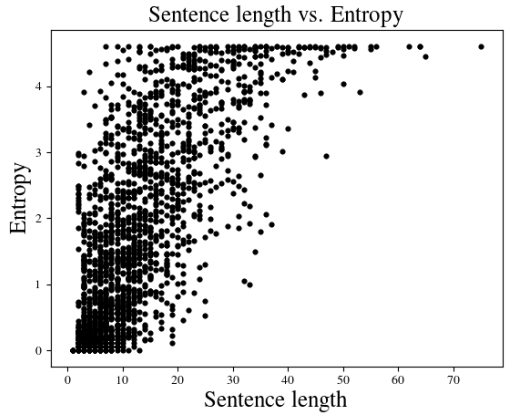

Figure 2: Length of sentences (in number of tokens in UD development set) against entropy (100 samples per sentence).

We run our dependency sampler on the 2002 sentences in the Universal Dependencies 1.3 English Treebank development set, generating 100 samples per sentence; Table 1 shows example sentences along with $|\tilde{\mathcal{Y}}|$ and entropy statistics for each sentence. We find that in general, as sentence length increases, so does the entropy of the parse distribution (Fig. 2). Moreover, we find that entropy is a useful diagnostic tool. For example, 7% of sentences in the UD development corpus with fewer than 15 tokens and $H(\tilde{p}) \geq 2$ exhibit uncertainty around the role of '-' (compare *Sciences - principally biology* and *thought-provoking*), and another 7% of such sentences exhibit uncertainty around 's' (potentially representing a plural or a possessive).

4 Monte Carlo Syntax Marginals for partial dependency parsing

Here we examine the utility of marginal inference for predicting parts of dependency parses, using the UD 1.3 Treebank's English development set to evaluate.[10]

4.1 Greedy decoding

Using its off-the-shelf pretrained model with greedy decoding, the CoreNLP parser achieves 80.8% labeled attachment score (LAS). LAS is equivalent to both the precision and recall of predicting (rel,gov,child) triples in the parse tree.[11]

4.2 Minimum Bayes risk (MBR) decoding

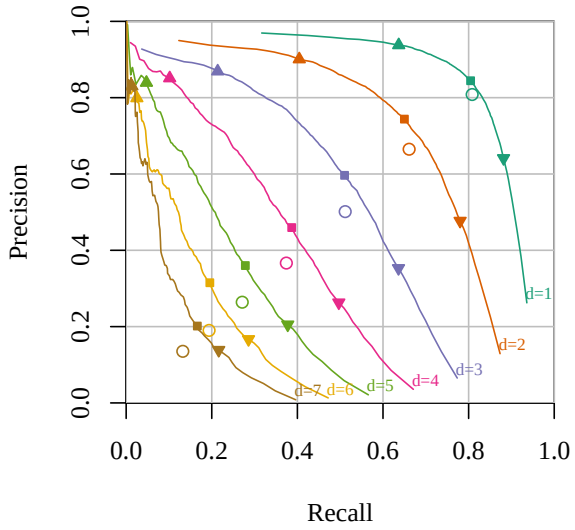
A simple way to use marginal probabilities for parse prediction is to select, for each token, the governor and relation that has the highest marginal probability. This method gives a minimum Bayes risk (MBR) prediction of the parse, minimizing the model's expected LAS with regards to local uncertainty; similar MBR methods have been shown to improve accuracy in tagging and constituent parsing (e.g. Goodman (1996); Petrov and Klein (2007)). This method yields 81.4% LAS, outperforming greedy parsing, though it may yield a graph that is not a tree.

4.3 Syntax marginal inference for dependency paths

An alternative view on dependency parsing is to consider what structures are needed for downstream applications. One commonly used parse substructure is the *dependency path* between two words, which is widely used in unsupervised lexical semantics (Lin and Pantel, 2001), distantly supervised lexical semantics (Snow et al., 2005), relation learning (Riedel et al., 2013), and supervised semantic role labeling (Hacioglu, 2004; Das et al., 2014), as well as applications in economics (Ghose et al., 2007), political science (O'Connor et al., 2013), biology (Fundel et al., 2006), and the humanities (Bamman et al., 2013, 2014).

[10]UD 1.3 is the UD version that this parsing model is most similar to: https://mailman.stanford.edu/pipermail/parser-user/2017-November/003460.html

[11]LAS is typically defined as proportion of tokens whose governor (and relation on that governor-child edge) are correctly predicted; this is equivalent to precision and recall of edges if all observed tokens are evaluated. If, say, punctuation is excluded from evaluation, this equivalence does not hold; in this work we always use all tokens for simplicity.



Path Len.	Greedy F1	Marginal Max F1	Marginal Thresh.	MC-MAP F1

▲ Conf≥0.9 ▼ Conf≥0.1

Figure 3: Precision-recall analysis against gold UD 1.3 English dev (§4.1) set for all dependency paths of lengths 1 to 7. **Left:** Each path length is a different color (1 in top-right, 7 in bottom-left), with greedy performance (◯) as well as the marginal path predictions' PR curve, with points at confidence thresholds 0.9 (▲), 0.1 (▼), and where F1 is highest (■). **Right:** F1 for each method, as well as the confidence threshold for the marginal PR curve's max-F1 point. For path length 1, Greedy and MC-MAP F1 are the same as labeled attachment score (LAS).

In this work, we consider a dependency path to be a set of edges from the dependency parse; for example, a length-2 path $p = \{\text{nsubj}(3,1), \text{dobj}(3,4)\}$ connects tokens 1 and 4. Let $\mathcal{P}_d(y)$ be the set of all length-d paths from a parse tree y.[12] Figure 3's "Greedy" table column displays the F-scores for the precision and recall of retrieving $\mathcal{P}_d(y^{(gold)})$ from the prediction $\mathcal{P}_d(y^{(greedy)})$ for a series of different path lengths. $\mathcal{P}_1$ gives individual edges, and thus is the same as LAS (80.8%). Longer length paths see a rapid decrease in performance; even length-2 paths are retrieved with only $\approx 66\%$ precision and recall.[13] We are not aware of prior work that evaluates dependency parsing beyond single edge or whole sentence accuracy.

We define *dependency path prediction* as the task of predicting a set of dependency paths for a sentence; the paths do not necessarily have to come from the same tree, nor even be consistent with a single syntactic analysis. We approach this task with our Monte Carlo syntax marginal method, by predicting paths from the transition sampling parser. Here we treat each possible path as a structure query (§2.4) and return all paths whose marginal probabilities are at least threshold t. Varying t trades off precision and recall.

We apply this method to 100 samples per sentence in the UD treebank. When we take all length-1 paths that appear in every single sample (i.e., estimated marginal probability 1.0), precision greatly increases to 0.969, while recall drops to 0.317 (the top-left point on Figure 3's **teal** length-1 curve.) We can also accommodate applications which may prefer to have a higher recall: predicting all paths with at least 0.01 probability results in 0.936 recall (the bottom-right point on the curve in Figure 3).[14]

This marginal path prediction method dominates the greedy parser: for length-1 paths, there are points on the marginal decoder's PR curve that achieve both higher precision and recall than the greedy decoder, giving F1 of 82.4% when accepting all edges with marginal probability at least 0.45. Furthermore, these advantages are more prominent for longer dependency paths. For example, for length-3 paths, the greedy parser only achieves 50.6% F1, while the marginal parser im-

[12] Path construction may traverse both up and down directed edges; we represent a path as an edge set to evaluate its existence in a parse. A path may not include the same vertex twice. The set of all paths for a parse includes all paths from all pairs of vertexes (observed tokens and ROOT).

[13] For length 1 paths, precision and recall are identical; this does not hold for longer paths, though precision and recall from a single parse prediction are similar.

[14] The 6.4% of gold-standard edges with predicted 0 probability often correspond to inconsistencies in the formalism standards between the model and UD; for example, 0.7% of the gold edges are 'name' relations among words in a name, which the model instead analyzes as 'compound'. Inspecting gold edges' marginal probabilities helps error analysis, since when one views a single predicted parse, it is not always clear whether observed errors are systematic, or a fluke for that one instance.

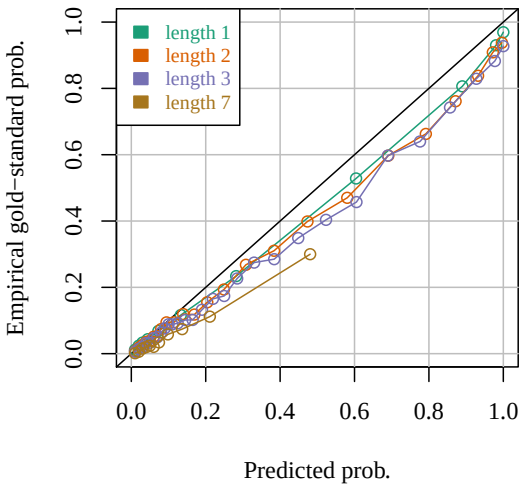

Figure 4: Calibration curves for marginal predictions for several path lengths. Predictions below the $y = x$ line indicate overconfidence. Points denote the average predicted probability versus empirical (gold) probability among predicted paths within each dynamically allocated bin.

proves a bit to 55.0% F1; strikingly, it is possible to select high-confidence paths to get much higher 90.1% precision (at recall 11.6%, with confidence threshold $t = 0.95$). Figure 3 also shows the precision/recall points on each curve for thresholds $t = 0.9$ and $t = 0.1$.

We also evaluated the MC-MAP single-parse prediction method (§2.3), which slightly, but consistently, underperforms the greedy decoder at all dependency lengths. More work is required to understand whether this is is an inference or modeling problem: for example, we may not have enough samples to reliably predict a high-probability parse; or, as some previous work finds in the context of beam search, the label bias phenomenon in this type of locally-normalized transition-based parser may cause it to assign higher probability to non-greedy analyses that in fact have lower linguistic quality (Zhang and Nivre, 2012; Andor et al., 2016).

5 Calibration

The precision-recall analysis shows that the predicted marginal probabilities are meaningful in a ranking sense, but we can also ask whether they are meaningful in a sense of *calibration*: predictions are calibrated if, among all structures with predicted probability $q \pm \epsilon$, they exist in the gold parses with probability q. That is, predictions with confidence q have precision q.[15] If probabilities are calibrated, that implies expectations with regard to their distribution are unbiased, and may also justify intuitive interpretations of probabilities in exploratory analysis (§3). Calibration may also have implications for joint inference, EM, and active learning methods that use confidence scores and confidence-based expectations.

We apply Nguyen and O'Connor (2015)'s adaptive binning method to analyze the calibration of structure queries from an NLP system, by taking the domain of all seen length-d paths from the 100 samples' parse distribution for the treebank, grouping by ranges of predicted probabilities to have at least 5000 paths per bin, to ensure stability of the local precision estimate.[16]

We find that probabilities are reasonably well calibrated, if slightly overconfident—Figure 4 shows the average predicted probability per bin, compared to how often these paths appear in the gold standard (local precision). For example, for edges (length-1 paths), predictions near 60% confidence (the average among predictions in range $[0.42, 0.78]$) correspond to edges that are actually in the gold standard tree only 52.8% of the time. The middle confidence range has worse calibration error, and longer paths perform worse. Still, this level of calibration seems remarkably good, considering there was no attempt to re-calibrate predictions (Kuleshov and Liang, 2015) or to use a model that specifically parameterizes the energy of dependency paths (Smith and Eisner, 2008; Martins et al., 2010)—these predictions are simply a side effect of the overall joint model for incremental dependency parsing.

6 Probabilistic rule-based IE: classifying police fatalities

Supervised learning typically gives the most accurate information extraction or semantic parsing systems, but for many applications where train-

[15] This is a *local* precision, as opposed to the more usual tail probability of measuring precision of all predictions *higher* than some t—the integral of local precision. For example, Figure 3's length-1 $t = 0.9$ precision of 0.942 (△) is the average y value of several rightmost bins in Figure 4. This contrast corresponds to Efron (2010)'s dichotomy of local versus global false discovery rates.

[16] This does not include gold-standard paths with zero predicted probability. As Nguyen and O'Connor found for sequence tagging and coreference, we find the prediction distribution is heavily skewed to near 0 and 1, necessitating adaptive bins, instead of fixed-width bins, for calibration analysis (Niculescu-Mizil and Caruana, 2005; Bennett, 2000).

ing data is scarce, Chiticariu et al. (2013) argue that rule-based systems are useful and widespread in practice, despite their neglect in contemporary NLP research. Syntactic dependencies are a useful abstraction with which to write rule-based extractors, but they can be brittle due to errors in the parser. We propose to integrate over parse samples to infer a *marginal* probability of a rule match, increasing robustness and allowing for precision-recall tradeoffs.

6.1 Police killings victim extraction

We examine the task of extracting the list of names of persons killed by police from a test set of web news articles in Sept–Dec 2016. We use the dataset released by Keith et al. (2017), consisting of 24,550 named entities $e \in \mathcal{E}$ and sentences from noisy web news text extractions (that can be difficult to parse), each of which contains at least one e (on average, 2.8 sentences/name) as well as keywords for both police and killing/shooting. The task is to classify whether a given name is a person who was killed by police, given 258 gold-standard names that have been verified by journalists.

6.2 Dependency rule exractor

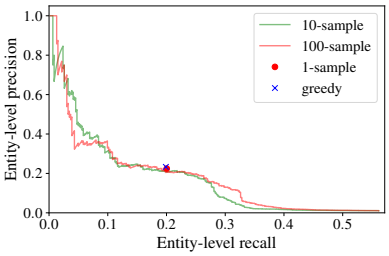
Keith et al. present a baseline rule-based method that uses Li and Ji (2014)'s off-the-shelf RPI-JIE ACE event parser to extract (event type, agent, patient) tuples from sentences, and assigns $f_{\text{JIE}}(x_i, e) = 1$ iff the event type was a killing, the agent's span included a police keyword, and the patient was the candidate entity e. An entity is classified as a victim if at least one sentence is classified as true, resulting in a 0.17 F1 score (as reported in previous work).[17]

We define a similar syntactic dependency rule system using a dependency parse as input: our extractor $f(x, e, y)$ returns 1 iff the sentence has a killing keyword k,[18] which both

1. has an agent token a (defined as, governed by *nsubj* or *nmod*) which is a police keyword, or a has a (*amod* or *compound*) modifier that is a police keyword; and,
2. has a patient token p (defined as, governed by *nsubjpass* or *dobj*) contained in the candidate name e's span.

[17]This measures recall of the entire gold-standard victim database, though the corpus only includes 57% of the victims.

[18]Police and killing/shooting keywords are from Keith et al.'s publicly released software.



Method	F1
RPI-JIE	0.170
Greedy	0.215
1 samp.	0.212
10 samp.	0.219
100 samp.	**0.222**

Figure 5: **Left:** Rule-based entity precision and recall for police fatality victims, with greedy parsing and Monte Carlo inference. **Right:** F1 scores for RPI-JIE, Greedy, and 1-sample methods, and maximum F1 on PR curve for probabilistic (multiple sample) inference.

Applying this $f(x, e, y)$ classifier to greedy parser output, it performs better than the RPI-JIE-based rules (Figure 5, right), perhaps because it is better customized for the particular task.

Treating f as a structure query, we then use our Monte Carlo marginal inference (§2) method to calculate the probability of a rule match for each sentence—that is, the fraction of parse samples where $f(x, e, y^{(s)})$ is true—and infer the entity's probability with the *noisy-or* formula (Craven and Kumlien, 1999; Keith et al., 2017). This gives soft classifications for entities.

6.3 Results

The Monte Carlo method achieves slightly higher F1 scores once there are at least 10 samples (Fig. 5, right). More interestingly, the soft entity-level classifications also allow for precision-recall tradeoffs (Fig. 5, left), which could be used to prioritize the time of human reviewers updating the victim database (filter to higher precision), or help ensure victims are not missed (with higher recall). We found the sampling method retrieved several true-positive entities where only a single sentence had a non-zero rule prediction at probability 0.01—that is, the rule was only matched in one of 100 sampled parses. Since current practitioners are already manually reviewing millions of news articles to create police fatality victim databases, the ability to filter to high recall—even with low precision—may be useful to help ensure victims are not missed.

6.4 Supervised learning

Sampling also slightly improves supervised learning for this problem. We modify Keith et al.'s logistic regression model based on a dependency

path feature vector $f(x_i, y)$, instead creating feature vectors that average over multiple parse samples ($E_{\tilde{p}(y)}[f(x_i, y)]$) at both train and test time. With the greedy parser, the model results in 0.229 F1; using 100 samples slightly improves performance to 0.234 F1.

7 Semantic role assignment

Semantic role labeling (SRL), the task to predict argument structures (Gildea and Jurafsky, 2002), is tightly tied to syntax, and previous work has found it beneficial to conduct it with joint inference with constituency parsing, such as with top-k parse trees (Toutanova et al., 2008) or parse tree samples (Finkel et al., 2006). Since §4 shows that Monte Carlo marginalization improves dependency edge prediction, we hypothesize dependency sampling could improve SRL as well.

SRL includes both identifying argument spans, and assigning spans to specific semantic role labels (argument types). We focus on just the second task of semantic role assignment: assuming argument spans are given, to predict the labels. We experiment with English OntoNotes v5.0 annotations (Weischedel et al., 2013) according to the CoNLL 2012 test split (Pradhan et al., 2013). We focus only on predicting among the five core arguments (Arg0 through Arg4) and ignore spans with gold-standard adjunct or reference labels. We fit a separate model for each predicate[19] among the 2,160 predicates that occur at least once in both the training and test sets (115,811 and 12,216 sentences respectively).

Our semantic model of label $z_t \in \{A0..A4\}$ for argument head token t and predicate token p, $p_{\text{sem}}(z_t \mid p, y)$, is simply the conditional probability of the label, conditioned on y's edge between t and p if one exists.[20] (If they are not directly connected, the model instead conditions on a 'no edge' feature.) Probabilities are maximum likelihood estimates from the training data's (predicate, argument label, path) counts, from either greedy parses, or averaged among parse samples. To predict at test time, the greedy parsing model simply uses $p(z_t \mid p, y^{(greedy)})$. The Monte Carlo model, by contrast, treats it as a directed joint model and marginalizes over syntactic analyses:

$$p_{MC}(z_t \mid p, x) = \sum_{y \in \tilde{\mathcal{Y}}(x)} p_{\text{sem}}(z_t \mid p, y)\, \tilde{p}_{\text{syn}}(y \mid x).$$

Method	Accuracy
Baseline (most common)	0.393
Greedy	0.496
MCSM method, 100-samples	**0.529**

Table 2: Semantic role assignment accuracy on English OntoNotes v5.0. The baseline is for each unique predicate, predict the argument that was seen the most at training time.

The baseline accuracy of predicting the predicate's most common training-time argument label yields 0.393 accuracy, and the greedy parser performs at 0.496. The Monte Carlo method (with 100 samples) improves accuracy to 0.529 (Table 2). Dependency samples' usefulness in this limited case suggests they may help systems that use dependency parses more broadly for SRL (Hacioglu, 2004; Das et al., 2014).

8 Conclusion

In this work, we introduce a straightforward algorithm for sampling from the full joint distribution of a transition-based dependency parser. We explore using these parse samples to discover both parsing error and structural ambiguities. Moreover, we find that our Monte Carlo syntax marginal method not only dominates the greedy method for dependency path prediction (especially for longer paths), but also allows for control of precision-recall tradeoffs. Propagating dependency uncertainty can potentially help a wide variety of semantic analysis and information extraction tasks.

[19] That is, for each unique (lemma, framesetID) pair, such as (view, view-02).

[20] The dataset's argument spans must be reconciled with predicted parse structures to define the argument head t; 90% of spans are consistent with the greedy parser in that all the span's tokens have the same highest ancestor contained with the span, which we define as the argument head. For inconsistent cases, we select the largest subtree (that is, highest within-span ancestor common to the largest number of the span's tokens). It would be interesting to modify the sampler to restrict to parses that are consistent with the span, as a form of rejection sampling.

Neural Particle Smoothing for Sampling from Conditional Sequence Models

Chu-Cheng Lin and **Jason Eisner**
Center for Language and Speech Processing
Johns Hopkins University, Baltimore MD, 21218
{kitsing,jason}@cs.jhu.edu

Abstract

We introduce *neural particle smoothing*, a sequential Monte Carlo method for sampling annotations of an input string from a given probability model. In contrast to conventional particle filtering algorithms, we train a proposal distribution that *looks ahead* to the end of the input string by means of a right-to-left LSTM. We demonstrate that this innovation can improve the quality of the sample. To motivate our formal choices, we explain how our neural model and neural sampler can be viewed as low-dimensional but nonlinear approximations to working with HMMs over very large state spaces.

1 Introduction

Many structured prediction problems in NLP can be reduced to labeling a length-T input string $\mathbf{x}$ with a length-T sequence $\mathbf{y}$ of tags. In some cases, these tags are annotations such as syntactic parts of speech. In other cases, they represent actions that incrementally build an output structure: IOB tags build a chunking of the input (Ramshaw and Marcus, 1999), shift-reduce actions build a tree (Yamada and Matsumoto, 2003), and finite-state transducer arcs build an output string (Pereira and Riley, 1997).

One may wish to score the possible taggings using a recurrent neural network, which can learn to be sensitive to complex patterns in the training data. A globally normalized conditional probability model is particularly valuable because it quantifies uncertainty and does not suffer from label bias (Lafferty et al., 2001); also, such models often arise as the predictive conditional distribution $p(\mathbf{y} \mid \mathbf{x})$ corresponding to some well-designed generative model $p(\mathbf{x}, \mathbf{y})$ for the domain. In the neural case, however, inference in such models becomes intractable. It is hard to know what the model actually predicts and hard to compute gradients to improve its predictions.

In such intractable settings, one generally falls back on approximate inference or sampling. In the NLP community, beam search and importance sampling are common. Unfortunately, beam search considers only the approximate-top-k taggings from an exponential set (Wiseman and Rush, 2016), and importance sampling requires the construction of a good proposal distribution (Dyer et al., 2016).

In this paper we exploit the sequential structure of the tagging problem to do *sequential* importance sampling, which resembles beam search in that it constructs its proposed samples incrementally—one tag at a time, taking the actual model into account at every step. This method is known as particle filtering (Doucet and Johansen, 2009). We extend it here to take advantage of the fact that the sampler has access to the entire input string as it constructs its tagging, which allows it to look ahead or—as we will show—to use a neural network to approximate the effect of lookahead. Our resulting method is called *neural particle smoothing*.

1.1 What this paper provides

For $\mathbf{x} = x_1 \cdots x_T$, let $\mathbf{x}_{:t}$ and $\mathbf{x}_{t:}$ respectively denote the prefix $x_1 \cdots x_t$ and the suffix $x_{t+1} \cdots x_T$.

We develop *neural particle smoothing*—a sequential importance sampling method which, given a string $\mathbf{x}$, draws a sample of taggings $\mathbf{y}$ from $p_\theta(\mathbf{y} \mid \mathbf{x})$. Our method works for any conditional probability model of the quite general form[1]

$$p_\theta(\mathbf{y} \mid \mathbf{x}) \stackrel{\text{def}}{\propto} \exp G_T \tag{1}$$

where G is an *incremental stateful global scoring model* that recursively defines scores G_t of prefixes of $(\mathbf{x}, \mathbf{y})$ at all times $0 \le t \le T$:

$$G_t \stackrel{\text{def}}{=} G_{t-1} + g_\theta(\mathbf{s}_{t-1}, x_t, y_t) \quad \text{(with } G_0 \stackrel{\text{def}}{=} 0\text{)} \tag{2}$$

$$\mathbf{s}_t \stackrel{\text{def}}{=} f_\theta(\mathbf{s}_{t-1}, x_t, y_t) \quad \text{(with } \mathbf{s}_0 \text{ given)} \tag{3}$$

These quantities implicitly depend on $\mathbf{x}, \mathbf{y}$ and θ. Here $\mathbf{s}_t$ is the model's *state* after observing the pair of length-t prefixes $(\mathbf{x}_{:t}, \mathbf{y}_{:t})$. G_t is the *score-so-far*

[1] A model may require for convenience that each input end with a special end-of-sequence symbol: that is, $x_T = \text{EOS}$.

Proceedings of NAACL-HLT 2018, pages 929–941
New Orleans, Louisiana, June 1 - 6, 2018.

of this prefix pair, while $G_T - G_t$ is the *score-to-go*. The state $\mathbf{s}_t$ summarizes the prefix pair in the sense that the score-to-go depends only on $\mathbf{s}_t$ and the length-$(T-t)$ suffixes $(\mathbf{x}_{t:}, \mathbf{y}_{t:})$. The *local scoring function* g_θ and *state update function* f_θ may be any functions parameterized by θ—perhaps neural networks. We assume θ is fixed and given.

This model family is expressive enough to capture any desired $p(\mathbf{y} \mid \mathbf{x})$. Why? Take any distribution $p(\mathbf{x}, \mathbf{y})$ with this desired conditionalization (e.g., the true joint distribution) and factor it as

$$\begin{aligned}\log p(\mathbf{x}, \mathbf{y}) &= \textstyle\sum_{t=1}^{T} \log p(x_t, y_t \mid \mathbf{x}_{:t-1}, \mathbf{y}_{:t-1}) \\ &= \textstyle\sum_{t=1}^{T} \underbrace{\log p(x_t, y_t \mid \mathbf{s}_{t-1})}_{\text{use as } g_\theta(\mathbf{s}_{t-1}, x_t, y_t)} = G_T \quad (4)\end{aligned}$$

by making $\mathbf{s}_t$ include as much information about $(\mathbf{x}_{:t}, \mathbf{y}_{:t})$ as needed for (4) to hold (possibly $\mathbf{s}_t = (\mathbf{x}_{:t}, \mathbf{y}_{:t})$).[2] Then by defining g_θ as shown in (4), we get $p(\mathbf{x}, \mathbf{y}) = \exp G_T$ and thus (1) holds for each $\mathbf{x}$.

1.2 Relationship to particle filtering

Our method is spelled out in §4 (one may look now). It is a variant of the popular *particle filtering* method that tracks the state of a physical system in discrete time (Ristic et al., 2004). Our particular *proposal distribution* for y_t can be found in equations (5), (6), (25) and (26). It considers not only past observations $\mathbf{x}_{:t}$ as reflected in $\mathbf{s}_{t-1}$, but also future observations $\mathbf{x}_{t:}$, as summarized by the state $\bar{\mathbf{s}}_t$ of a right-to-left recurrent neural network $\bar{f}$ that we will train:

$$\hat{H}_t \stackrel{\text{def}}{=} h_\phi(\bar{\mathbf{s}}_{t+1}, x_{t+1}) + \hat{H}_{t+1} \quad (5)$$

$$\bar{\mathbf{s}}_t \stackrel{\text{def}}{=} \bar{f}_\phi(\bar{\mathbf{s}}_{t+1}, x_{t+1}) \quad \text{(with } \mathbf{s}_T \text{ given)} \quad (6)$$

Conditioning the distribution of y_t on future observations $\mathbf{x}_{t:}$ means that we are doing "smoothing" rather than "filtering" (in signal processing terminology). Doing so can reduce the bias and variance of our sampler. It is possible so long as $\mathbf{x}$ is provided in its entirety before the sampler runs—which is often the case in NLP.

1.3 Applications

Why sample from p_θ at all? Many NLP systems instead simply search for the *Viterbi sequence* $\mathbf{y}$ that maximizes G_T and thus maximizes $p_\theta(\mathbf{y} \mid \mathbf{x})$. If the space of states $\mathbf{s}$ is small, this can be done efficiently by dynamic programming (Viterbi, 1967); if not, then A^* may be an option (see §2). More common is to use an approximate method: beam search, or perhaps a sequential prediction policy trained with reinforcement learning. Past work has already shown how to improve these approximate search algorithms by conditioning on the future (Bahdanau et al., 2017; Wiseman and Rush, 2016).

Sampling is essentially a generalization of maximization: sampling from $\exp \frac{G_T}{\text{temperature}}$ approaches maximization as $\text{temperature} \to 0$. It is a fundamental building block for other algorithms, as it can be used to take expectations over the whole space of possible $\mathbf{y}$ values. For unfamiliar readers, Appendix E reviews how sampling is crucially used in minimum-risk decoding, supervised training, unsupervised training, imputation of missing data, pipeline decoding, and inference in graphical models.

2 Exact Sequential Sampling

To develop our method, it is useful to first consider exact samplers. Exact sampling is tractable for only some of the models allowed by §1.1. However, the form and notation of the exact algorithms in §2 will guide our development of approximations in §3.

An *exact sequential sampler* draws y_t from $p_\theta(y_t \mid \mathbf{x}, \mathbf{y}_{:t-1})$ for each $t = 1, \ldots, T$ in sequence. Then $\mathbf{y}$ is exactly distributed as $p_\theta(\mathbf{y} \mid \mathbf{x})$.

For each given $\mathbf{x}, \mathbf{y}_{:t-1}$, observe that

$$\begin{aligned}&p_\theta(y_t \mid \mathbf{x}, \mathbf{y}_{:t-1}) && (7)\\ &\propto p_\theta(\mathbf{y}_{:t} \mid \mathbf{x}) = \textstyle\sum_{\mathbf{y}_{t:}} p_\theta(\mathbf{y} \mid \mathbf{x}) && (8)\\ &\propto \textstyle\sum_{\mathbf{y}_{t:}} \exp G_T && (9)\\ &= \exp\,(G_t + \underbrace{\log \textstyle\sum_{\mathbf{y}_{t:}} \exp\,(G_T - G_t)}_{\text{call this } H_t}) && (10)\\ &= \exp\,(G_{t-1} + g_\theta(\mathbf{s}_{t-1}, x_t, y_t) + H_t) && (11)\\ &\propto \exp\,(g_\theta(\mathbf{s}_{t-1}, x_t, y_t) + H_t) && (12)\end{aligned}$$

Thus, we can easily construct the needed distribution (7) by normalizing (12) over all possible values of y_t. The challenging part of (12) is to compute H_t: as defined in (10), H_t involves a sum over exponentially many futures $\mathbf{y}_{t:}$. (See Figure 1.)

We chose the symbols G and H in homage to the A^* search algorithm (Hart et al., 1968). In that algorithm (which could be used to find the Viterbi sequence), g denotes the score-so-far of a partial solution $\mathbf{y}_{:t}$, and h denotes the optimal score-to-go. Thus, $g + h$ would be the score of the *best* sequence with prefix $\mathbf{y}_{:t}$. Analogously, our $G_t +$

[2] Furthermore, $\mathbf{s}_t$ could even depend on all of $\mathbf{x}$ (if $\mathbf{s}_0$ does), allowing direct expression of models such as stacked BiRNNs.

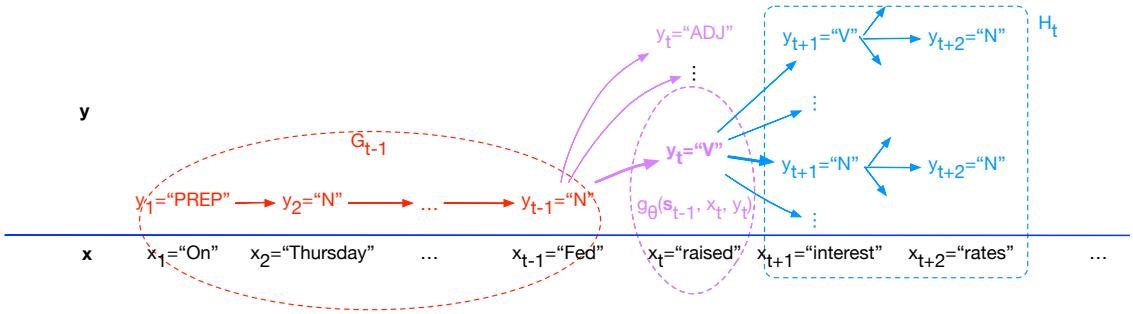

Figure 1: Sampling a single particle from a tagging model. $y_1, \ldots, y_{t-1}$ (orange) have already been chosen, with a total model score of G_{t-1}, and now the sampler is constructing a proposal distribution q (purple) from which the next tag y_t will be sampled. Each y_t is evaluated according to its contribution to G_t (namely g_θ) and its future score H_t (blue). The figure illustrates quantities used throughout the paper, beginning with exact sampling in equations (7)–(12). Our main idea (§3) is to *approximate* the H_t computation (a log-sum-exp over exponentially many sequences) when exact computation by dynamic programming is not an option. The form of our approximation uses a right-to-left recurrent neural network but is *inspired* by the exact dynamic programming algorithm.

H_t is the log of the total exponentiated scores of *all* sequences with prefix $\mathbf{y}_{:t}$. G_t and H_t might be called the *logprob-so-far* and *logprob-to-go* of $\mathbf{y}_{:t}$.

Just as A^* approximates h with a "heuristic" $\hat{h}$, the next section will approximate H_t using a neural estimate $\hat{H}_t$ (equations (5)–(6)). However, the specific form of our approximation is inspired by cases where H_t can be computed exactly. We consider those in the remainder of this section.

2.1 Exact sampling from HMMs

A *hidden Markov model* (HMM) specifies a normalized *joint* distribution $p_\theta(\mathbf{x}, \mathbf{y}) = \exp G_T$ over state sequence $\mathbf{y}$ and observation sequence $\mathbf{x}$,[3] Thus the posterior $p_\theta(\mathbf{y} \mid \mathbf{x})$ is proportional to $\exp G_T$, as required by equation (1).

The HMM specifically defines G_T by equations (2)–(3) with $\mathbf{s}_t = y_t$ and $g_\theta(\mathbf{s}_{t-1}, x_t, y_t) = \log p_\theta(y_t \mid y_{t-1}) + \log p_\theta(x_t \mid y_t)$.[4]

In this setting, H_t can be computed exactly by the *backward algorithm* (Rabiner, 1989). (Details are given in Appendix A for completeness.)

2.2 Exact sampling from OOHMMs

For sequence tagging, a weakness of (first-order) HMMs is that the model state $\mathbf{s}_t = y_t$ may contain little information: only the most recent tag y_t is remembered, so the number of possible model states $\mathbf{s}_t$ is limited by the vocabulary of output tags.

We may generalize so that the data generating process is in a latent state $u_t \in \{1, \ldots, k\}$ at each time t, and the observed y_t—along with x_t—is generated from u_t. Now k may be arbitrarily large. The model has the form

$$p_\theta(\mathbf{x}, \mathbf{y}) = \exp G_T \tag{13}$$
$$= \sum_{\mathbf{u}} \prod_{t=1}^{T} p_\theta(u_t \mid u_{t-1}) \cdot p_\theta(x_t, y_t \mid u_t)$$

This is essentially a pair HMM (Knudsen and Miyamoto, 2003) without insertions or deletions, also known as an "ϵ-free" or "same-length" probabilistic finite-state transducer. We refer to it here as an *output-output HMM* (OOHMM).[5]

Is this still an example of the general model architecture from §1.1? Yes. Since u_t is latent and evolves stochastically, it cannot be used as the state $\mathbf{s}_t$ in equations (2)–(3) or (4). However, we *can* define $\mathbf{s}_t$ to be the model's *belief state* after observing $(\mathbf{x}_{:t}, \mathbf{y}_{:t})$. The belief state is the posterior probability distribution over the underlying state u_t of the system. That is, $\mathbf{s}_t$ deterministically keeps track of all possible states that the OOHMM might be in—just as the state of a determinized FSA keeps track of all possible states that the original nondeterministic FSA might be in.

We may compute the belief state in terms of a vector of *forward probabilities* that starts at $\boldsymbol{\alpha}_0$,

$$(\boldsymbol{\alpha}_0)_u \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } u = \text{BOS (see footnote 4)} \\ 0 & \text{if } u = \text{any other state} \end{cases} \tag{14}$$

and is updated deterministically for each $0 < t \leq T$ by the *forward algorithm* (Rabiner, 1989):

$$(\boldsymbol{\alpha}_t)_u \stackrel{\text{def}}{=} \sum_{u'=1}^{k} (\boldsymbol{\alpha}_{t-1})_{u'} \cdot p_\theta(u \mid u') \cdot p_\theta(x_t, y_t \mid u) \tag{15}$$

[3] The HMM actually specifies a distribution over a pair of infinite sequences, but here we consider the marginal distribution over just the length-T prefixes.

[4] It takes $\mathbf{s}_0 = \text{BOS}$, a beginning-of-sequence symbol, so $p_\theta(y_1 \mid \text{BOS})$ specifies the initial state distribution.

[5] This is by analogy with the *input-output HMM* (IOHMM) of Bengio and Frasconi (1996), which defines $p(\mathbf{y} \mid \mathbf{x})$ directly and conditions the transition to u_t on x_t. The OOHMM instead defines $p(\mathbf{y} \mid \mathbf{x})$ by conditionalizing (13)—which avoids the *label bias* problem (Lafferty et al., 2001) that in the IOHMM, y_t is independent of future input $\mathbf{x}_{t:}$ (given the past input $\mathbf{x}_{:t}$).

$(\boldsymbol{\alpha}_t)_u$ can be interpreted as the logprob-so-far *if* the system is in state u after observing $(\mathbf{x}_{:t}, \mathbf{y}_{:t})$. We may express the update rule (15) by $\boldsymbol{\alpha}_t^\top = \boldsymbol{\alpha}_{t-1}^\top P$ where the matrix P depends on (x_t, y_t), namely $P_{u'u} \stackrel{\text{def}}{=} p_\theta(u \mid u') \cdot p_\theta(x_t, y_t \mid u)$.

The belief state $\mathbf{s}_t \stackrel{\text{def}}{=} [\![\boldsymbol{\alpha}_t]\!] \in \mathbb{R}^k$ simply normalizes $\boldsymbol{\alpha}_t$ into a probability vector, where $[\![\mathbf{u}]\!] \stackrel{\text{def}}{=} \mathbf{u}/(\mathbf{u}^\top \mathbf{1})$ denotes the *normalization operator*. The state update (15) now takes the form (3) as desired, with f_θ a normalized vector-matrix product:

$$\mathbf{s}_t^\top = f_\theta(\mathbf{s}_{t-1}, x_t, y_t) \stackrel{\text{def}}{=} [\![\mathbf{s}_{t-1}^\top P]\!] \tag{16}$$

As in the HMM case, we define G_t as the log of the generative prefix probability,

$$G_t \stackrel{\text{def}}{=} \log p_\theta(\mathbf{x}_{:t}, \mathbf{y}_{:t}) = \log \textstyle\sum_u (\boldsymbol{\alpha}_t)_u \tag{17}$$

which has the form (2) as desired if we put

$$\begin{aligned} g_\theta(\mathbf{s}_{t-1}, x_t, y_t) &\stackrel{\text{def}}{=} G_t - G_{t-1} \qquad (18)\\ &= \log \frac{\boldsymbol{\alpha}_{t-1}^\top P \mathbf{1}}{\boldsymbol{\alpha}_{t-1}^\top \mathbf{1}} = \log (\mathbf{s}_{t-1}^\top P \mathbf{1}) \end{aligned}$$

Again, exact sampling is possible. It suffices to compute (9). For the OOHMM, this is given by

$$\textstyle\sum_{\mathbf{y}_{t:}} \exp G_T = \boldsymbol{\alpha}_t^\top \boldsymbol{\beta}_t \tag{19}$$

where $\boldsymbol{\beta}_T \stackrel{\text{def}}{=} \mathbf{1}$ and the *backward algorithm*

$$\begin{aligned} (\boldsymbol{\beta}_t)_v &\stackrel{\text{def}}{=} p_\theta(\mathbf{x}_{t:} \mid u_t = u) \qquad (20)\\ &= \sum_{\mathbf{u}_{t:}, \mathbf{y}_{t:}} p_\theta(\mathbf{u}_{t:}, \mathbf{x}_{t:}, \mathbf{y}_{t:} \mid u_t = u)\\ &= \sum_{u'} \underbrace{p_\theta(u' \mid u) \cdot p(x_{t+1} \mid u')}_{\text{call this } \overline{P}_{uu'}} \cdot (\boldsymbol{\beta}_{t+1})_{u'} \end{aligned}$$

for $0 \le t < T$ uses dynamic programming to find the total probability of all ways to generate the future observations $\mathbf{x}_{t:}$. Note that $\boldsymbol{\alpha}_t$ is defined for a *specific prefix* $\mathbf{y}_{:t}$ (though it sums over all $\mathbf{u}_{:t}$), whereas $\boldsymbol{\beta}_t$ sums over *all suffixes* $\mathbf{y}_{t:}$ (and over all $\mathbf{u}_{t:}$), to achieve the asymmetric summation in (19).

Define $\bar{\mathbf{s}}_t \stackrel{\text{def}}{=} [\![\boldsymbol{\beta}_t]\!] \in \mathbb{R}^k$ to be a normalized version of $\boldsymbol{\beta}_t$. The $\boldsymbol{\beta}_t$ recurrence (20) can clearly be expressed in the form $\bar{\mathbf{s}}_t = [\![\overline{P} \bar{\mathbf{s}}_{t+1}]\!]$, much like (16).

2.3 The logprob-to-go for OOHMMs

Let us now work out the definition of H_t for OOHMMs (cf. equation (35) in Appendix A for HMMs). We will write it in terms of $\hat{H}_t$ from §1.2. Let us define $\hat{H}_t$ symmetrically to G_t (see (17)):

$$\hat{H}_t \stackrel{\text{def}}{=} \log \sum_u (\boldsymbol{\beta}_t)_u \;\; (= \log \mathbf{1}^\top \boldsymbol{\beta}_t) \tag{21}$$

which has the form (5) as desired if we put

$$h_\phi(\bar{\mathbf{s}}_{t+1}, x_{t+1}) \stackrel{\text{def}}{=} \hat{H}_t - \hat{H}_{t+1} = \log (\mathbf{1}^\top \overline{P} \bar{\mathbf{s}}_{t+1}) \tag{22}$$

From equations (10), (17), (19) and (21), we see

$$\begin{aligned} H_t &= \log \big(\sum_{\mathbf{y}_{t:}} \exp G_T \big) - G_t\\ &= \log \frac{\boldsymbol{\alpha}_t^\top \boldsymbol{\beta}_t}{(\boldsymbol{\alpha}_t^\top \mathbf{1})(\mathbf{1}^\top \boldsymbol{\beta}_t)} + \log (\mathbf{1}^\top \boldsymbol{\beta}_t)\\ &= \underbrace{\log \mathbf{s}_t^\top \bar{\mathbf{s}}_t}_{\text{call this } C_t} + \hat{H}_t \qquad (23) \end{aligned}$$

where $C_t \in \mathbb{R}$ can be regarded as evaluating the *compatibility* of the state distributions $\mathbf{s}_t$ and $\bar{\mathbf{s}}_t$.

In short, the generic strategy (12) for exact sampling says that for an OOHMM, y_t is distributed as

$$\begin{aligned} p_\theta(y_t \mid \mathbf{x}, \mathbf{y}_{:t-1}) &\propto \exp\, (g_\theta(\mathbf{s}_{t-1}, x_t, y_t) + H_t)\\ &\propto \exp\, \big(\underbrace{g_\theta(\mathbf{s}_{t-1}, x_t, y_t)}_{\text{depends on } \mathbf{x}_{:t}, \mathbf{y}_{:t}} + \underbrace{C_t}_{\text{on } \mathbf{x}, \mathbf{y}_{:t}} + \underbrace{\hat{H}_t}_{\text{on } \mathbf{x}_{t:}} \big)\\ &\propto \exp\, (g_\theta(\mathbf{s}_{t-1}, x_t, y_t) + C_t) \qquad (24) \end{aligned}$$

This is equivalent to choosing y_t in proportion to (19)—but we now turn to settings where it is infeasible to compute (19) exactly. There we will use the formulation (24) but approximate C_t. For completeness, we will also consider how to approximate $\hat{H}_t$, which dropped out of the above distribution (because it was the same for all choices of y_t) but may be useful for other algorithms (see §4).

3 Neural Modeling as Approximation

3.1 Models with large state spaces

The expressivity of an OOHMM is limited by the number of states k. The state $u_t \in \{1, \ldots, k\}$ is a bottleneck between the past $(\mathbf{x}_{:t}, \mathbf{y}_{:t})$ and the future $(\mathbf{x}_{t:}, \mathbf{y}_{t:})$, in that past and future are *conditionally independent* given u_t. Thus, the mutual information between past and future is at most $\log_2 k$ bits.

In many NLP domains, however, the past seems to carry substantial information about the future. The first half of a sentence greatly reduces the uncertainly about the second half, by providing information about topics, referents, syntax, semantics, and discourse. This suggests that an accurate HMM language model $p(\mathbf{x})$ would require *very large* k—as would a generative OOHMM model $p(\mathbf{x}, \mathbf{y})$ of *annotated* language. The situation is perhaps better for discriminative models $p(\mathbf{y} \mid \mathbf{x})$, since much of

the information for predicting $\mathbf{y}_{t:}$ might be available in $\mathbf{x}_{t:}$. Still, it is important to let $(\mathbf{x}_{:t}, \mathbf{y}_{:t})$ contribute enough additional information about $\mathbf{y}_{t:}$: even for short strings, making k too small (giving $\leq \log_2 k$ bits) may harm prediction (Dreyer et al., 2008).

Of course, (4) says that an OOHMM can express any joint distribution for which the mutual information is finite,[6] by taking k large enough for v_{t-1} to capture the relevant info from $(\mathbf{x}_{:t-1}, \mathbf{y}_{:t-1})$.

So why not just take k to be large—say, $k = 2^{30}$ to allow 30 bits of information? Unfortunately, evaluating G_T then becomes very expensive—both computationally and statistically. As we have seen, if we define $\mathbf{s}_t$ to be the belief state $[\![\boldsymbol{\alpha}_t]\!] \in \mathbb{R}^k$, updating it at each observation (x_t, y_t) (equation (3)) requires multiplication by a $k \times k$ matrix P. This takes time $O(k^2)$, and requires enough data to learn $O(k^2)$ transition probabilities.

3.2 Neural approximation of the model

As a solution, we might hope that for the inputs $\mathbf{x}$ observed in practice, the very high-dimensional belief states $[\![\boldsymbol{\alpha}_t]\!] \in \mathbb{R}^k$ might tend to lie near a d-dimensional manifold where $d \ll k$. Then we could take $\mathbf{s}_t$ to be a vector in $\mathbb{R}^d$ that compactly encodes the approximate coordinates of $[\![\boldsymbol{\alpha}_t]\!]$ relative to the manifold: $\mathbf{s}_t = \nu([\![\boldsymbol{\alpha}_t]\!])$, where ν is the encoder.

In this new, nonlinearly warped coordinate system, the functions of $\mathbf{s}_{t-1}$ in (2)–(3) are no longer the simple, essentially linear functions given by (16) and (18). They become nonlinear functions operating on the manifold coordinates. (f_θ in (16) should now ensure that $\mathbf{s}_t^\top \approx \nu([\![(\nu^{-1}(\mathbf{s}_{t-1}))^\top P]\!])$, and g_θ in (18) should now estimate $\log\, (\nu^{-1}(\mathbf{s}_{t-1}))^\top P\mathbf{1}$.) In a sense, this is the reverse of the "kernel trick" (Boser et al., 1992) that converts a low-dimensional nonlinear function to a high-dimensional linear one.

Our hope is that $\mathbf{s}_t$ has enough dimensions $d \ll k$ to capture the useful information from the true $[\![\boldsymbol{\alpha}_t]\!]$, **and** that θ has enough dimensions $\ll k^2$ to capture most of the dynamics of equations (16) and (18). We thus proceed to fit the neural networks f_θ, g_θ directly to the data, *without ever knowing* the true k or the structure of the original operators $P \in \mathbb{R}^{k \times k}$.

We regard this as the implicit justification for various published probabilistic sequence models $p_\theta(\mathbf{y} \mid \mathbf{x})$ that incorporate neural networks. These models usually have the form of §1.1. Most simply, (f_θ, g_θ) can be instantiated as one time step in an RNN (Aharoni and Goldberg, 2017), but it is common to use enriched versions such as deep LSTMs. It is also common to have the state $\mathbf{s}_t$ contain not only a vector of manifold coordinates in $\mathbb{R}^d$ but also some unboundedly large representation of $(\mathbf{x}, \mathbf{y}_{:t})$ (cf. equation (4)), so the f_θ neural network can refer to this material with an attentional (Bahdanau et al., 2015) or stack mechanism (Dyer et al., 2015).

A few such papers have used *globally* normalized conditional models that can be viewed as approximating some OOHMM, e.g., the parsers of Dyer et al. (2016) and Andor et al. (2016). That is the case (§1.1) that particle smoothing aims to support. Most papers are *locally* normalized conditional models (e.g., Kann and Schütze, 2016; Aharoni and Goldberg, 2017); these simplify supervised training and can be viewed as approximating IOHMMs (footnote 5). For locally normalized models, $H_t = 0$ by construction, in which case particle filtering (which estimates $H_t = 0$) is just as good as particle smoothing. Particle filtering is still useful for these models, but lookahead's inability to help them is an expressive limitation (known as *label bias*) of locally normalized models. We hope the existence of particle smoothing (which learns an estimate H_t) will make it easier to adopt, train, and decode globally normalized models, as discussed in §1.3.

3.3 Neural approximation of logprob-to-go

We can adopt the same neuralization trick to approximate the OOHMM's logprob-to-go $H_t = C_t + \hat{H}_t$. We take $\bar{\mathbf{s}}_t \in \mathbb{R}^d$ on the same theory that it is a low-dimensional reparameterization of $[\![\beta_t]\!]$, and define $(\bar{f}_\phi, h_\phi)$ in equations (5)–(6) to be neural networks. Finally, we must replace the definition of C_t in (23) with another neural network c_ϕ that works on the low-dimensional approximations:[7]

$$C_t \stackrel{\text{def}}{=} c_\phi(\mathbf{s}_t, \bar{\mathbf{s}}_t) \quad \text{(except that } C_T \stackrel{\text{def}}{=} 0) \tag{25}$$

The resulting approximation to (24) (which does not actually require h_ϕ) will be denoted $q_{\theta,\phi}$:

$$q_{\theta,\phi}(y_t \mid \mathbf{x}, \mathbf{y}_{:t-1}) \stackrel{\text{def}}{\propto} \exp\, (g_\theta(\mathbf{s}_{t-1}, x_t, y_t) + C_t) \tag{26}$$

The neural networks in the present section are all parameterized by ϕ, and are intended to produce an estimate of the logprob-*to-go* H_t—a function of $\mathbf{x}_{t:}$, which sums over all possible $\mathbf{y}_{t:}$.

By contrast, the OOHMM-inspired neural networks suggested in §3.2 were used to specify an

[6] This is not true for the language of balanced parentheses.

[7] $C_T = 0$ is correct according to (23). Forcing this ensures $H_T = 0$, so our approximation becomes exact as of $t = T$.

actual model of the logprob-*so-far* G_t—a function of $\mathbf{x}_{:t}$ and $\mathbf{y}_{:t}$—using separate parameters θ.

Arguably ϕ has a harder modeling job than θ because it must implicitly sum over possible futures $\mathbf{y}_{t:}$. We now consider how to get corrected samples from $q_{\theta,\phi}$ even if ϕ gives poor estimates of H_t, and then how to train ϕ to improve those estimates.

4 Particle smoothing

In this paper, we assume nothing about the given model G_T except that it is given in the form of equations (1)–(3) (including the parameter vector θ).

Suppose we run the exact sampling strategy but approximate p_θ in (7) with a *proposal distribution* $q_{\theta,\phi}$ of the form in (25)–(26). Suppressing the subscripts on p and q for brevity, this means we are effectively drawing $\mathbf{y}$ not from $p(\mathbf{y} \mid \mathbf{x})$ but from

$$q(\mathbf{y} \mid \mathbf{x}) = \prod_{t=1}^{T} q(y_t \mid \mathbf{x}, \mathbf{y}_{:t-1}) \tag{27}$$

If $C_t \approx H_t + \text{const}$ within each y_t draw, then $q \approx p$.

Normalized importance sampling corrects (mostly) for the approximation by drawing *many* sequences $\mathbf{y}^{(1)}, \ldots \mathbf{y}^{(M)}$ IID from (27) and assigning $\mathbf{y}^{(m)}$ a relative *weight* of $w^{(m)} \stackrel{\text{def}}{=} \frac{p(\mathbf{y}^{(m)} \mid \mathbf{x})}{q(\mathbf{y}^{(m)} \mid \mathbf{x})}$. This *ensemble of weighted particles* yields a distribution

$$\hat{p}(\mathbf{y}) \stackrel{\text{def}}{=} \frac{\sum_{m=1}^{M} w^{(m)} \mathbb{I}(\mathbf{y}=\mathbf{y}^{(m)})}{\sum_{m=1}^{M} w^{(m)}} \approx p(\mathbf{y} \mid \mathbf{x}) \tag{28}$$

that can be used as discussed in §1.3. To compute $w^{(m)}$ in practice, we replace the numerator $p(\mathbf{y}^{(m)} \mid \mathbf{x})$ by the unnormalized version $\exp G_T$, which gives the same $\hat{p}$. Recall that each G_T is a sum $\sum_{t=1}^{T} g_\theta(\cdots)$.

Sequential importance sampling is an equivalent implementation that makes t the *outer* loop and m the *inner* loop. It computes a *prefix ensemble*

$$Y_t \stackrel{\text{def}}{=} \{(\mathbf{y}_{:t}^{(1)}, w_t^{(1)}), \ldots, (\mathbf{y}_{:t}^{(M)}, w_t^{(M)})\} \tag{29}$$

for each $0 \leq t \leq T$ in sequence. Initially, $(\mathbf{y}_{:0}^{(m)}, w_0^{(m)}) = (\epsilon, \exp C_0)$ for all m. Then for $0 < t \leq T$, we extend these particles in parallel:

$$\mathbf{y}_{:t}^{(m)} = \mathbf{y}_{:t-1}^{(m)} y_t^{(m)} \quad \text{(concatenation)} \tag{30}$$

$$w_t^{(m)} = w_{t-1}^{(m)} \frac{\exp\left(g_\theta(\mathbf{s}_{t-1}, x_t, y_t) + C_t - C_{t-1}\right)}{q(y_t \mid \mathbf{x}, \mathbf{y}_{:t-1})} \tag{31}$$

where each $y_t^{(m)}$ is drawn from (26). Each Y_t yields a distribution $\hat{p}_t$ over prefixes $\mathbf{y}_{:t}$, which estimates the distribution $p_t(\mathbf{y}_{:t}) \stackrel{\text{def}}{\propto} \exp\left(G_t + C_t\right)$. We return $\hat{p} \stackrel{\text{def}}{=} \hat{p}_T \approx p_T = p$. This gives the same $\hat{p}$ as in (28): the final $\mathbf{y}_T^{(m)}$ are the same, with the same final weights $w_T^{(m)} = \frac{\exp G_T}{q(\mathbf{y}^{(m)} \mid \mathbf{x})}$, where G_T was now summed up as $C_0 + \sum_{t=1}^{T} g_\theta(\cdots) + C_t - C_{t-1}$.

That is our basic *particle smoothing* strategy. If we use the naive approximation $C_t = 0$ everywhere, it reduces to *particle filtering*. In either case, various well-studied improvements become available, such as various resampling schemes (Douc and Cappé, 2005) and the particle cascade (Paige et al., 2014).[8]

An easy improvement is *multinomial resampling*. After computing each $\hat{p}_t$, this replaces Y_t with a set of M new draws from $\hat{p}_t$ ($\approx p_t$), each of weight 1—which tends to drop low-weight particles and duplicate high-weight ones.[9] For this to usefully focus the ensemble on good prefixes $\mathbf{y}_{:t}$, p_t should be a good approximation to the true marginal $p(\mathbf{y}_{:t} \mid \mathbf{x}) \propto \exp\left(G_t + H_t\right)$ from (10). That is why we arranged for $p_t(\mathbf{y}_{:t}) \propto \exp\left(G_t + C_t\right)$. Without C_t, we would have only $p_t(\mathbf{y}_{:t}) \propto \exp G_t$—which is fine for the traditional particle filtering setting, but in our setting it ignores future information in $\mathbf{x}_{t:}$ (which we have assumed is available) and also favors sequences $\mathbf{y}$ that happen to accumulate most of their global score G_T early rather than late (which is possible when the globally normalized model (1)–(2) is *not* factored in the generative form (4)).

5 Training the Sampler Heuristic

We now consider training the parameters ϕ of our sampler. These parameters determine the updates $\bar{f}_\phi$ in (6) and the compatibility function c_ϕ in (25). As a result, they determine the proposal distribution q used in equations (27) and (31), and thus determine the stochastic choice of $\hat{p}$ that is returned by the sampler on a given input $\mathbf{x}$.

In this paper, we simply try to tune ϕ to yield good proposals. Specifically, we try to ensure that $q_\phi(\mathbf{y} \mid \mathbf{x})$ in equation (27) is close to $p(\mathbf{y} \mid \mathbf{x})$ from equation (1). While this may not be necessary for the sampler to perform well downstream,[10] it does

[8] The particle cascade would benefit from an estimate of $\hat{H}_t$, as it (like A* search) compares particles of different lengths.

[9] While resampling mitigates the degeneracy problem, it could also reduce the diversity of particles. In our experiments in this paper, we only do multinomial resampling when the effective sample size of $\hat{p}_t$ is lower than $\frac{M}{2}$. Doucet and Johansen (2009) give a more thorough discussion on when to resample.

[10] In principle, one could attempt to train ϕ "end-to-end" on some downstream objective by using reinforcement learning or the Gumbel-softmax trick (Jang et al., 2017; Maddison et al., 2017). For example, we might try to ensure that $\hat{p}$ closely matches the model's distribution p (equation (28))—the "na-

guarantee it (assuming that the model p is correct). Specifically, we seek to minimize

$$(1-\lambda)\mathrm{KL}(p||q_\phi) + \lambda\mathrm{KL}(q_\phi||p) \quad (\text{with } \lambda \in [0,1]) \tag{32}$$

averaged over examples $\mathbf{x}$ drawn from a training set.[11] (The training set need not provide true $\mathbf{y}$'s.)

The *inclusive KL divergence* $\mathrm{KL}(p||q_\phi)$ is an expectation under p. We estimate it by replacing p with a sample $\hat{p}$, which in practice we can obtain with our sampler under the current ϕ. (The danger, then, is that $\hat{p}$ will be biased when ϕ is not yet well-trained; this can be mitigated by increasing the sample size M when drawing $\hat{p}$ for training purposes.)

Intuitively, this term tries to encourage q_ϕ in future to re-propose those $\mathbf{y}$ values that turned out to be "good" and survived into $\hat{p}$ with high weights.

The *exclusive KL divergence* $\mathrm{KL}(q_\phi||p)$ is an expectation under q_ϕ. Since we can sample from q_ϕ exactly, we can get an unbiased estimate of $\nabla_\phi \mathrm{KL}(q_\phi||p)$ with the likelihood ratio trick (Glynn, 1990).[12] (The danger is that such "REINFORCE" methods tend to suffer from very high variance.)

This term is a popular objective for variational approximation. Here, it tries to discourage q_ϕ from re-proposing "bad" $\mathbf{y}$ values that turned out to have low $\exp G_T$ relative to their proposal probability.

Our experiments balance "recall" (inclusive) and "precision" (exclusive) by taking $\lambda = \frac{1}{2}$ (which Appendix F compares to $\lambda \in \{0, 1\}$). Alas, because of our approximation to the inclusive term, neither term's gradient will "find" and directly encourage good $\mathbf{y}$ values that have never been proposed. Appendix B gives further discussion and formulas.

6 Models for the Experiments

To evaluate our methods, we needed pre-trained models p_θ. We experimented on several models. In each case, we trained a *generative* model $p_\theta(\mathbf{x}, \mathbf{y})$, so that we could try sampling from its posterior distribution $p_\theta(\mathbf{y} \mid \mathbf{x})$. This is a very common setting where particle smoothing should be able to help. Details for replication are given in Appendix C.

tural" goal of sampling. This objective can tolerate inaccurate local proposal distributions in cases where the algorithm could recover from them through resampling. Looking even farther downstream, we might merely want $\hat{p}$—which is typically used to compute expectations—to provide accurate guidance to some decision or training process (see Appendix E). This might not require fully matching the model, and might even make it desirable to deviate from an inaccurate model.

[11] Training a single approximation q_ϕ for all $\mathbf{x}$ is known as *amortized inference*.

[12] The normalizing constant of p from (1) can be ignored because the gradient of a constant is 0.

6.1 Tagging models

We can regard a tagged sentence $(\mathbf{x}, \mathbf{y})$ as a string over the "pair alphabet" $\mathcal{X} \times \mathcal{Y}$. We train an RNN language model over this "pair alphabet"—this is a neuralized OOHMM as suggested in §3.2:

$$\log p_\theta(\mathbf{x}, \mathbf{y}) = \sum_{t=1}^{T} \log p_\theta(x_t, y_t \mid \mathbf{s}_{t-1}) \tag{33}$$

This model is locally normalized, so that $\log p_\theta(\mathbf{x}, \mathbf{y})$ (as well as its gradient) is straightforward to compute for a given training pair $(\mathbf{x}, \mathbf{y})$. Joint sampling from it would also be easy (§3.2).

However, $p(\mathbf{y} \mid \mathbf{x})$ is globally renormalized (by an unknown partition function that depends on $\mathbf{x}$, namely $\exp H_0$). Conditional sampling of $\mathbf{y}$ is therefore potentially hard. Choosing y_t optimally requires knowledge of H_t, which depends on the future $\mathbf{x}_{t:}$.

As we noted in §1, many NLP tasks can be seen as tagging problems. In this paper we experiment with two such tasks: **English stressed syllable tagging**, where the stress of a syllable often depends on the number of remaining syllables,[13] providing good reason to use the *lookahead* provided by particle smoothing; and **Chinese NER**, which is a familiar textbook application and reminds the reader that our formal setup (tagging) provides enough machinery to treat other tasks (chunking).

English stressed syllable tagging This task tags a sequence of phonemes $\mathbf{x}$, which form a word, with their stress markings $\mathbf{y}$. Our training examples are the stressed words in the CMU pronunciation dictionary (Weide, 1998). We test the sampler on held-out unstressed words.

Chinese social media NER This task does named entity recognition in Chinese, by tagging the characters of a Chinese sentence in a way that marks the named entities. We use the dataset from Peng and Dredze (2015), whose tagging scheme is a variant of the BIO scheme mentioned in §1. We test the sampler on held-out sentences.

6.2 String source separation

This is an artificial task that provides a discrete analogue of speech source separation (Zibulevsky and Pearlmutter, 2001). The generative model is that J strings (possibly of different lengths) are generated

[13] English, like many other languages, assigns stress from right to left (Hayes, 1995).

IID from an RNN language model, and are then combined into a single string $\mathbf{x}$ according to a random *interleaving* string $\mathbf{y}$.[14] The posterior $p(\mathbf{y} \mid \mathbf{x})$ predicts the interleaving string, which suffices to reconstruct the original strings. The interleaving string is selected from the uniform distribution over all possible interleavings (given the J strings' lengths). For example, with $J = 2$, a possible generative story is that we first sample two strings Foo and Bar from an RNN language model. We then draw an interleaving string 112122 from the aforementioned uniform distribution, and interleave the J strings deterministically to get FoBoar.

$p(\mathbf{x}, \mathbf{y})$ is proportional to the product of the probabilities of the J strings. The only parameters of p_θ, then, are the parameters of the RNN language model, which we train on clean (non-interleaved) samples from a corpus. We test the sampler on random interleavings of held-out samples.

The state $\mathbf{s}$ (which is provided as an input to c_θ in (25)) is the concatenation of the J states of the language model as it independently generates the J strings, and $g_\theta(\mathbf{s}_{t-1}, x_t, y_t)$ is the log-probability of generating x_t as the next character of the $y_t{}^{\text{th}}$ string, given that string's language model state within $\mathbf{s}_{t-1}$. As a special case, $\mathbf{x}_T = \text{EOS}$ (see footnote 1), and $g_\theta(\mathbf{s}_{T-1}, \text{EOS}, \text{EOS})$ is the total log-probability of termination in all J language model states.

String source separation has good reason for lookahead: appending character "o" to a reconstructed string "␣gh" is only advisable if "s" and "t" are coming up soon to make "ghost." It also illustrates a powerful application setting—posterior inference under a generative model. This task conveniently allowed us to construct the generative model from a pre-trained language model. Our constructed generative model illustrates that the state $\mathbf{s}$ and transition function f can reflect interesting problem-specific structure.

CMU Pronunciation dictionary The CMU pronunciation dictionary (already used above) provides sequences of phonemes. Here we use words no longer than 5 phonemes. We interleave the (unstressed) phonemes of $J = 5$ words.

Penn Treebank The PTB corpus (Marcus et al., 1993) provides English sentences, from which we use only the sentences of length ≤ 8. We interleave the words of $J = 2$ sentences.

[14] We formally describe the generative process in Appendix G.

7 Experiments

In our experiments, we are given a pre-trained scoring model p_θ, and we train the parameters ϕ of a particle smoothing algorithm.[15]

We now show that our proposed neural particle smoothing sampler does better than the particle filtering sampler. To define "better," we evaluate samplers on the *offset KL divergence* from the true posterior.

7.1 Evaluation metrics

Given $\mathbf{x}$, the "natural" goal of conditional sampling is for the sample distribution $\hat{p}(\mathbf{y})$ to approximate the true distribution $p_\theta(\mathbf{y} \mid \mathbf{x}) = \exp G_T / \exp H_0$ from (1). We will therefore report—averaged over all held-out test examples $\mathbf{x}$—the KL divergence

$$\begin{aligned} \mathrm{KL}(\hat{p}||p) = \mathbb{E}_{\mathbf{y}\sim\hat{p}}\left[\log \hat{p}(\mathbf{y})\right] \qquad (34) \\ - \left(\mathbb{E}_{\mathbf{y}\sim\hat{p}}\left[\log \tilde{p}(\mathbf{y} \mid \mathbf{x})\right] - \log Z(\mathbf{x})\right), \end{aligned}$$

where $\tilde{p}(\mathbf{y} \mid \mathbf{x})$ denotes the *unnormalized* distribution given by $\exp G_T$ in (2), and $Z(\mathbf{x})$ denotes its normalizing constant, $\exp H_0 = \sum_{\mathbf{y}} \tilde{p}(\mathbf{y} \mid \mathbf{x})$.

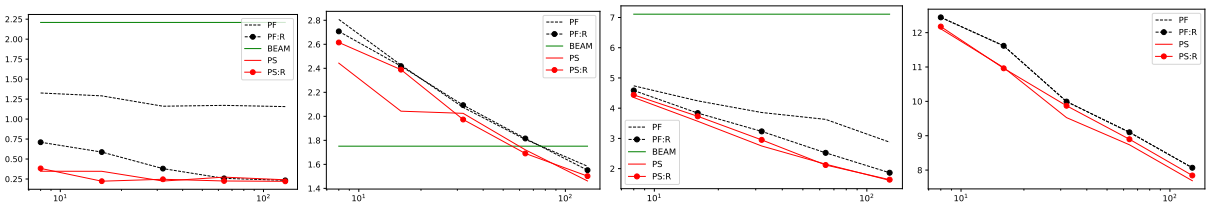
As we are unable to compute $\log Z(\mathbf{x})$ in practice, we replace it with an estimate $z(\mathbf{x})$ to obtain an *offset KL divergence*. This change of constant does not change the measured difference between two samplers, $\mathrm{KL}(\hat{p}_1||p) - \mathrm{KL}(\hat{p}_2||p)$. Nonetheless, we try to use a reasonable estimate so that the reported KL divergence is interpretable in an absolute sense. Specifically, we take $z(\mathbf{x}) = \log \sum_{\mathbf{y}\in\mathcal{Y}} \tilde{p}(\mathbf{y} \mid \mathbf{x}) \leq \log Z$, where $\mathcal{Y}$ is the full set of distinct particles $\mathbf{y}$ that we ever drew for input $\mathbf{x}$, including samples from the beam search models, while constructing the experimental results graph.[16] Thus, the offset KL divergence is a "best effort" lower bound on the true exclusive KL divergence $\mathrm{KL}(\hat{p}||p)$.

7.2 Results

In all experiments we compute the offset KL divergence for both the particle filtering samplers and the particle smoothing samplers, for varying ensemble sizes M. We also compare against a beam search baseline that keeps the highest-scoring M particles at each step (scored by $\exp G_t$ with no lookahead). The results are in Figures 2a–2d.

[15] For the details of the training procedures and the specific neural architectures in our models, see Appendices C and D.

[16] Thus, $\mathcal{Y}$ was collected across all samplings, iterations,and ensemble sizes M, in an attempt to make the summation over $\mathcal{Y}$ as complete as possible. For good measure, we added some extra particles: whenever we drew M particles via particle smoothing, we drew an additional $2M$ particles by particle filtering and added them to $\mathcal{Y}$.



(a) tagging: stressed syllables (b) tagging: Chinese NER (c) source separation: PTB (d) source separation: CMUdict

Figure 2: Offset KL divergences for the tasks in §§ 6.1 and 6.2. The logarithmic x-axis is the size of particles M ($8 \leq M \leq 128$). The y-axis is the offset KL divergence described in §7.1 (in bits per sequence). The smoothing samplers offer considerable speedup: for example, in Figure 2a, the non-resampled smoothing sampler achieves comparable offset KL divergences with only $1/4$ as many particles as its filtering counterparts. Abbreviations in the legend: PF=particle filtering. PS=particle smoothing. BEAM=beam search. ':R' suffixes indicate resampled variants. For readability, beam search results are omitted from Figure 2d, but appear in Figure 3 of the appendices.

Given a fixed ensemble size, we see the smoothing sampler consistently performs better than the filtering counterpart. It often achieves comparable performance at a fraction of the ensemble size.

Beam search on the other hand falls behind on three tasks: stress prediction and the two source separation tasks. It does perform better than the stochastic methods on the Chinese NER task, but only at small beam sizes. Varying the beam size barely affects performance at all, across all tasks. This suggests that beam search is unable to explore the hypothesis space well.

We experiment with resampling for both the particle filtering sampler and our smoothing sampler. In source separation and stressed syllable prediction, where the right context contains critical information about how viable a particle is, resampling helps particle filtering *almost* catch up to particle smoothing. Particle smoothing itself is not further improved by resampling, presumably because its effective sample size is high. The goal of resampling is to kill off low-weight particles (which were overproposed) and reallocate their resources to higher-weight ones. But with particle smoothing, there are fewer low-weight particles, so the benefit of resampling may be outweighted by its cost (namely, increased variance).

8 Related Work

Much previous work has employed sequential importance sampling for approximate inference of intractable distributions (e.g., Thrun, 2000; Andrews et al., 2017). Some of this work learns adaptive proposal distributions in this setting (e.g. Gu et al., 2015; Paige and Wood, 2016). The key difference in our work is that we consider future inputs, which is impossible in online decision settings such as robotics. Klaas et al. (2006) did do particle smoothing, like us, but they did not learn adaptive proposal distributions.

Just as we use a right-to-left RNN to guide *posterior sampling* of a left-to-right generative model, Krishnan et al. (2017) employed a right-to-left RNN to guide *posterior marginal inference* in the same sort of model. Serdyuk et al. (2018) used a right-to-left RNN to regularize training of such a model.

9 Conclusion

We have described neural particle smoothing, a sequential Monte Carlo method for approximate sampling from the posterior of incremental neural scoring models. Sequential importance sampling has arguably been underused in the natural language processing community. It is quite a plausible strategy for dealing with rich, globally normalized probability models such as neural models—particularly if a good sequential proposal distribution can be found. Our contribution is a neural proposal distribution, which goes beyond particle filtering in that it uses a right-to-left recurrent neural network to "look ahead" to future symbols of $\mathbf{x}$ when proposing each symbol y_t. The form of our distribution is well-motivated.

There are many possible extensions to the work in this paper. For example, we can learn the generative model and proposal distribution jointly; we can also infuse them with hand-crafted structure, or use more deeply stacked architectures; and we can try training the proposal distribution end-to-end (footnote 10). Another possible extension would be to allow each step of q to propose a *sequence* of actions, effectively making the tagset size ∞. This extension relaxes our $|\mathbf{y}| = |\mathbf{x}|$ restriction from §1 and would allow us to do general sequence-to-sequence transduction.
