Specifically, linguistic phenomena like *alphabetisms*, *blending*, *clippings*, and *reduplicatives* abound in slang (see Table 1)[2]. Note the rich and varied word formation patterns ranging from simple abbreviations like `dink` to more complex combinations like `lambortini`, a blend of `lamborghini` and `martini`. Note further, that even within a particular class like BLENDS there are variations in what portions of the components are retained.

Word	Derived From	Type
dink	double income no kids	alphabetism
lambortini	lamborghini + martini	blend
diamat	dialectical + materialism	blend
tude	attitude	clipping (fore)
brill	brilliant	clipping (back)
yik-yak	yik	reduplicative

Table 1: Sample words depicting word formation in slang. Note the rich variation across different types.

These word formation mechanisms are not only attractive from a linguistic standpoint in deepening our understanding of slang but also have applications spanning the development of rich conversational agents and tools like brand name generators (Özbal and Strapparava, 2012). While such phenomena have been qualitatively studied by Mattiello (2008, 2013), computational models for their generation have not been proposed.

In this paper, we propose the first simple models for generating blends, clippings, and reduplicatives[3]. Our models incorporate linguistic insights coupled with data-driven analysis to model the above phenomena. In line with "Occam's razor", we strive for simplicity. The simplicity of our models not only implies better generalization, more robust estimation of parameters in the wake of small dataset sizes, and better interpret-ability but also yields state of the art performance.

Specifically, we show that by exploiting structural constraints, blend formation can be modeled as a simple *sequence labeling* problem as opposed to prior work which models it as a *general sequence to sequence* problem. This view enables the use of

[1] While the definition of slang is a controversial issue, we adopt a broad definition including non-standard expressions.

[2] While such phenomena are likely present in several languages, in this work we restrict ourselves to slang in English.

[3] While there has been some prior work on computationally modeling blends, generative models for clippings and reduplicatives have not been outlined.

Proceedings of NAACL-HLT 2018, pages 1424–1434
New Orleans, Louisiana, June 1 - 6, 2018.

a simple LSTM model to yield competitive performance. Similarly, we propose the first probabilistic generative models for clippings and reduplicatives effectively incorporating phonetic constraints. In a nutshell, our contributions are:

1. **Generative models.** We propose simple models for generating blends, clippings and, reduplicatives with state of the art performance.

2. **Linguistic Insights.** We reveal linguistic insights into these phenomena which we incorporate into the generative models.

3. **Resources.** We release all our models and the compiled datasets to aid further research [4].

2 Datasets and Definitions

Here, we define the extra-grammatical morphological phenomena modeled and describe the datasets used for our experiments and analysis. Mattiello (2013) argues that slang exhibits extra-grammatical morphological properties that distinguish them from the standard variety and identified four broad word formation phenomena[5] described below:

1. **Alphabetisms** are shortenings of a multiword sequence. Examples include `lol` from `laugh out loud` or `YOLO` from `you only live once`. They can be further sub-categorized into two types based on their pronunciation although the distinction may not always be clear: (a) *Acronyms* are pronounced using the regular reading rules (for example. YOLO) (b) *Initialisms* are pronounced letter by letter (for example. BBC).

2. **Blends** or portmanteaus, are formed by merging parts of existing words. For example, `edutainment` is a blend of `education` and `entertainment`. Prior work notes that blend formation does not exhibit rigid rules but only demonstrates affinities towards certain patterns of formation (Mattiello, 2013) suggesting learning based approaches to modeling blends (Deri and Knight, 2015; Gangal et al., 2017).

3. **Clippings** are constructed by shortening words (lexemes). For example, `berg` is a clipping of `iceberg`, `gym` is a clipping of `gymnasium` and `ammo` is a clipping of `ammunition`. Based on the portion that is being clipped, clippings are sub-categorized into three types: (a) BACK clipping where the beginning of the word (lexeme) is retained (like `brill` from `brilliant`) (b) a FORE clipping, where the end of a word is retained (like `choke` from `artichoke`) and (c) A COMPOUND clipping (`adman`), a clipping of a compound word (`advertisment man`).

4. **Reduplicatives** are word pairs constructed by either repeating a word (`boo boo`) or by alternating certain vowels or consonants so that they are phonologically similar (`clickety-clackety`, `teenie-weenie`, `itsy-bitsy`).

In our work, we propose generative models using a data-driven approach towards generating blends, clippings ,and reduplicatives. We do not consider generative models for alphabetisms since a majority of them can be trivially generated by picking the first letter of each word making up the acronym (for example. `laugh out loud` → `lol`). We now outline the datasets considered:

1. **Blends.** We consider a gold standard dataset $\mathcal{D}_{knight}$ of 400 blends constructed by (Deri and Knight, 2015) from Wikipedia as well as a larger list of 1624 blends manually compiled by (Gangal et al., 2017) called $\mathcal{D}_{large}$, a superset of $\mathcal{D}_{knight}$. We define $\mathcal{D}_{blind} = \mathcal{D}_{large} - \mathcal{D}_{knight}$.

2. **Clippings.** We consider a list of 576 human curated clippings constructed by Mattiello (2013) for our analysis of clippings. These were manually collected from a variety of sources including prior work and dictionaries like the *Oxford English Dictionary* and the *Merriam-Webster online dictionary*.

3. **Reduplicatives.** We consider a dataset of a total of 337 reduplicatives manually constructed by Mattiello (2013) also collected from prior work and online dictionaries[6].

[4] Code and data with reproducible results is available at `https://github.com/viveksck/simplicity`

[5] These categories are not exhaustive and several slang words and non-standard expressions do not fall into any of the above categories.

[6] We note that the dataset released by (Mattiello, 2013) is the largest human curated dataset of slang word formation we are aware of. Furthermore, large crowd sourced data-sets like Urban Dictionary are a poor fit for such modeling since they do not explicitly contain annotations by linguistic experts.

3 Models and Methods

We now describe our proposed models to generate blends, clippings, and reduplicatives. We precisely formulate the problem, specify our models and comprehensively outline our evaluation.

3.1 Blends

Problem Formulation Given a string $C = C_1\#C_2$, consisting of components C_1 and C_2, we seek to combine them to yield the blend B. For example, given $C_1 =$ `brad` and $C_2 =$ `angelina` such that $C =$ `brad#angelina`, we seek to generate the blend `brangelina`.

Existing Models (Deri and Knight, 2015) proposed a model to generate blends using multi-tape finite state transducers. Most recently, (Gangal et al., 2017) (the current state of the art) model this as a general sequence to sequence learning problem and propose a neural encoder-decoder architecture with attention to outperform the model by (Deri and Knight, 2015). However, this model fails to effectively exploit the inherent structure and linguistic constraints of blending. One implication is an exploration of an overly complex hypothesis space with a small amount of training data making it harder to generalize. A second implication is that the decoding phase uses exhaustive generation. In fact, the best model *exhaustively* generates all candidate strings, where the first part is a prefix of C_1 and the second part is a suffix of C_2 and scores them to pick the best candidate while using a backward model learned to generate the components given the blend. In contrast, we propose a more straightforward model that explicitly incorporates inherent linguistic constraints entirely obviating the need for decoding using exhaustive candidate generation yet yielding competitive performance.

3.1.1 Linguistic Insights into Blend Formation

While one can model the problem of learning to blend as a variable length sequence to sequence learning problem (akin to machine translation), we argue that incorporating structural constraints yields a different view of modeling the problem that can enable better generalization given the small amount of training data. We motivate this by observing the following constraints:

1. **Blend length and vocabulary constraints.** First, we observe that a majority of blends (99.0% in D_{knight} and 92.4% in D_{blind}) are formed by using only characters present in the original components. Second, the length of the blends in these cases is at-most the length of the components.

2. **Fixed length input output representation.** The blend B can thus be encoded as a string of the exact same length as C by noting that B only contains characters copied from C or deleted from C. Specifically, we represent B by $E(B)$ denoting the sequence of *copy* (**C**) and *delete* (**D**) operations needed to transform C to B. $E(B)$ can easily be computed by the edit distance function between C and B. For example, `brangelina` is encoded as `CCCDDDCCCCCCC`. Since $E(B)$ has the same length of C, we can now model this as a *fixed length sequence labeling* problem rather than a variable length sequence to sequence learning problem completely obviating the need for the *"encoder-decoder"* architecture for this large class of blends.

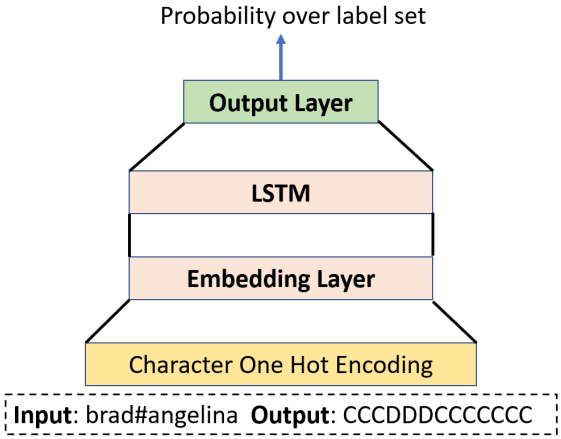

Figure 1: Our simple LSTM sequence labeling model for blends. Our model is considerably simpler both in complexity of the parameter space and in terms of implementation compared to the encoder-decoder model proposed by (Gangal et al., 2017) which modeled the problem as a machine translation problem.

Equivalent Problem Definition Given a string $C = C_1\#C_2$, consisting of components C_1 and C_2, learn $E(B)$, a labeling of each character in C from the label set $\{\mathbf{C}, \mathbf{D}\}$.

3.1.2 Proposed model: CopyCat

Model Architecture Inline with work on neural sequence labeling (Wang et al., 2015; Plank et al., 2016), our model uses a single layer long

short term memory (LSTM) (Graves et al., 2012) and an embedding layer as depicted in Figure 1. Since the size of the training set is relatively small, we reduce the number of learn-able parameters by using pre-trained character embeddings frozen during training. In particular, we use 50 dimensional character embeddings from (Gangal et al., 2017) obtained by training an LSTM language model on an English Dictionary. The implementation of the LSTM layer is described by (Graves et al., 2012; Wang et al., 2015) and therefore omitted here. The output layer is a soft-max over the label set $\{\mathbf{C}, \mathbf{D}\}$.

Candidate Generation Our model outputs probability scores over the label set for each element in the sequence. As in previous works (Gangal et al., 2017), we use the output to generate an ordered candidate set $\mathcal{T}$. To construct $\mathcal{T}$, we use a simple top-K decoder which selects the k most probable label sequences. Finding the k most probable tag sequences from the soft-max outputs can be cast as finding the top k shortest simple paths in a directed acyclic graph which can be efficiently solved using (Yen, 1971; Eppstein, 1998). Note that the greedy decoder which just picks the most likely label at each position is a special case with $k = 1$. While the number of candidates generated by (Gangal et al., 2017) depends on the size of C, our model generates a constant number of candidates ($k = 5$) regardless of the input C.

Candidate Ranking and Selection While the list of candidates in $\mathcal{T}$, can be used to make a prediction we note that re-ranking these candidates can result in better performance and thus consider multiple ranking strategies:

1. **LSTM.** We consider only the scores as obtained by the LSTM with no re-ranking.

2. **LSTM + LM.** We augment the score of each candidate to include both the score of the LSTM as well as its score according to a character level language model where the language model is trained on a large amount of unsupervised text [7].

3. **LSTM + LM + LEN.** Figure 2 shows a least squares fit to the length of the blends versus the length of its component, suggesting a strong correlation between these two variables. We capture this notion through a probabilistic model. Specifically, we model $\mathbf{Pr}(Blend_{len}|Component_{len})$ by fitting a Bayesian Ridge Regression model to the training data and score each candidate on this model as well. Finally, we combine the scores obtained for the LSTM, the language model and the length model uniformly to yield the final score for each candidate.

In each of the above cases, we pick the topmost candidate as our prediction.

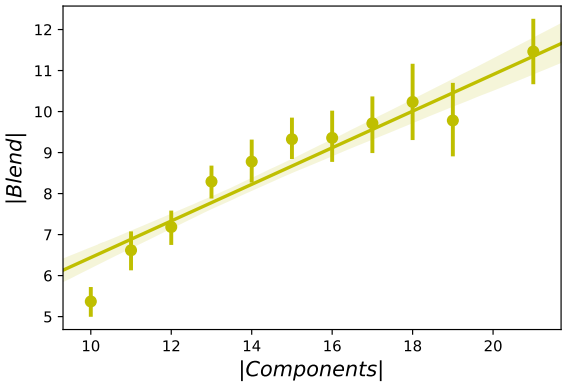

Figure 2: Best fit between blend length and the length of the input string, implying that one can infer the length of the blend from the length of the components using a regression model.

Table 2 illustrates the effects of each of these ranking strategies on an exemplary set of strings. While ranking using the raw scores of the LSTM yields blends which are close, observe that the LSTM alone does not capture ease of pronunciation effectively. For example, the top ranking candidate `brngelina` is relatively unlikely under both a character language model and a phoneme language model. Incorporating scores from the language model results in much more natural blends like `brangelina`. To observe the effect of the length model, note that for `kentucky#indiana` the blends obtained by LSTM and LSTM + LM are too short (`keiana` and `keana`). Incorporating the length model boosts scores for candidates closer to the target length yielding `keniana` which is closer to the target `kentuckiana`.

3.1.3 Evaluation

We compare our model to previous methods namely (Deri and Knight, 2015) and (Gangal et al., 2017). Inline with (Gangal et al., 2017), we evaluate our model on $\mathcal{D}_{knight}$ and $\mathcal{D}_{blind}$ (consisting of 1078

[7] We use words from the CMU pronouncing dictionary.

Input	LSTM	LSTM + LM	LSTM + LM + LEN	Gold standard
brad#angelina	brngelina	brangelina	brangelina	brangelina
animated#matrix	animtrix	animatrix	animatrix	animatrix
merkel#sarkozy	merkrkozy	merkkozy	merkkozy	merkozy
dramatic#drastic	draastic	drastic	dramastic	dramastic
kentucky#indiana	keiana	keana	keniana	kentuckiana
employability#agility	emplglity	emplgility	employgility	employagility

Table 2: Set of examples demonstrating the effect of incorporating the language model and length model when ranking candidates revealing insights into blend formation. Incorporating the language model generally improves the fluency of the blend while the length model helps generate blends with lengths close to the target.

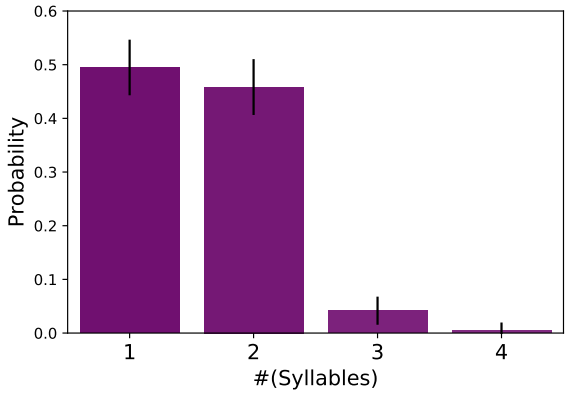

Figure 3: Distribution of the number of syllables in clippings. Most clippings have at-most 2 syllables but it is a challenge to infer whether a given word has a one or two syllable clipping.

instances)[8]. For evaluating on $\mathcal{D}_{knight}$, we use 10-fold cross-validation. For evaluating on $\mathcal{D}_{blind}$ we train our model on $\mathcal{D}_{knight}$ and report the mean score on the test-set obtained using 10 random splits of the training data. As in previous work, our metric is the edit distance between the predicted blend and the true blend.

3.2 Clippings

Problem Formulation Given a word w, learn a model that can generate its clipping c. For example, given the word `administration` we would like the model to output the clipping `admin`.

Proposed Models We motivate our models by presenting two insights into linguistic properties of clippings first noted by (Mattiello, 2013). First, most clippings are back clippings while fore clippings are relatively rare. Second, most clippings tend to have at most two syllables (see Figure 3). The first insight guides our model in determining whether to retain a prefix or a suffix of the original word. The second insight guides our model in determining how much to retain (or clip). In particular, we can capture this in two ways: (a) Working in the phoneme space and (b) Learn a function to predict the length of the clipping (which encodes the number of syllables implicitly).

3.2.1 CLIPPHONE

CLIPPHONE operates by mapping the word w to a sequence of phonemes, explicitly clipping in the phoneme space and mapping the phoneme sequence back to the grapheme space. In particular, the model can be described as follows: **(1)** Let θ and π represent multinomial distributions over clipping types and the number of syllables respectively. **(2)** Represent the word w as a sequence of phonemes $\mathcal{P}$ and identify each syllable. **(3)** Draw a sample l from π to represent the number of syllables in the clipping and the type t by drawing a sample from θ. **(4)** If $t \in \{\text{BACK}, \text{FORE}\}$, clip $\mathcal{P}$ to have exactly l syllables by selecting the appropriate length prefix or suffix depending on clipping type t to make exactly l syllables represented by $\mathcal{P}_{clip}$. If t is a COMPOUND, clip each word recursively and concatenate the outputs. **(5)** Map P_{clip} back to grapheme space to yield the clipping. **(6)** The parameters of θ and π, both multinomial distributions can be estimated from observed data via maximum likelihood estimators.

Phoneme-based representation Given w, we obtain its phoneme representation using the pretrained state-of-art neural model G2PSEQ2SEQ (Yao and Zweig, 2015)[9]. For example, the word `captain` is mapped to the following sequence of phonemes $\mathcal{P}$ given by `K AE P T AH N`.

Clipping in the phoneme space We identify the syllable boundaries in $\mathcal{P}$ by looking for vowel phonemes and clip $\mathcal{P}$ until it contains the desired number of syllables. For example, a one syllable clipping of `K AE P T AH N` is `K AE P T`

[8] We discard relatively rare instances with insertions.

[9] G2PSeq2Seq has a PER of 5.45% on CMUDict.

since AH is the beginning of the second syllable ($\mathcal{P}_{clip}$ = K AE P T).

Mapping clipping back to graphemes Finally, given the clipped phoneme sequence $\mathcal{P}_{clip}$, we map it back to the grapheme space by learning a sequence to sequence model to map a phoneme sequence to its grapheme sequence. We follow the same model architecture as used in G2PSEQ2SEQ (Yao and Zweig, 2015) but just flip the input and output sequences, thus learning a model to map phonemes back to graphemes. Finally, we quantify the effectiveness of this model explicitly in our evaluation by establishing an upper-bound on the expected performance using this model.

3.2.2 CLIPGRAPH

As we will demonstrate empirically, CLIPPHONE poses the following challenges: Since a given phoneme sequence can map to multiple grapheme sequences, explicitly mapping to phoneme space and back introduces errors and loss of fidelity [10]. This is compounded by noting that whether w's clipping should have one or two syllables is hard to predict (since both occur in almost equal proportions empirically, see Figure 3). Furthermore, deciding whether the clipping should end in a vowel or a consonant and determining the length is yet another challenge. As an alternative, we propose CLIPGRAPH where we seek to directly learn a model to predict the length of the clipping directly given w, obviating the need to work in phoneme space. CLIPGRAPH works as follows: **(1)** Let θ represent multinomial distributions over clipping types and let π be a model that predicts the length l of the clipping w_{clip} given w. **(2)** Draw a sample from θ to get the type of clipping t. **(3)** Retain the appropriate l-length prefix or suffix of w based on the type t handling compound words recursively. **(4)** We use Ridge regression to learn π from the training data and estimate θ using its maximum likelihood estimator.

Evaluation To evaluate our models, we consider a naive baseline NAIVE which clips w to one of its prefixes or suffixes randomly. For CLIPPHONE, we also consider one (CLIPPHONE-1SYL) and two (CLIPPHONE-2SYL) syllable clippings. Since (Jamet, 2009) notes that determining whether a word has a one or two syllable clipping is extremely challenging, we also consider a model with an oracle (CLIPPHONE(O)) on the number of syllables in the clipping to quantify this. Finally, we establish an upper bound (G2P-GOLD) on the performance of any method using our learned P2G model. G2P-GOLD maps the gold standard G to phoneme space and maps the resulting phoneme sequence back to yield $\hat{G}$ as the predicted clipping. We use the edit distance between the predicted clipping and the gold standard as the evaluation metric.

[10] K AE P T can be mapped to capped or capt.

3.3 Reduplicatives

Problem Formulation Given a word v, we seek to generate a word w such that $v.w$ is a reduplicative. For example, given the word flip, we would like to generate flop or flap to yield the reduplicatives flip-flop or flip-flap.

Proposed Model We motivate our model from a linguistic standpoint by referring to observations by (Mattiello, 2013) that a large fraction of reduplicatives can be formed by either (a) Duplicating the word DUPLICATE (boo-boo) (b) Exchanging the initial vowel VOWELEX (bing-bong) and (c) Exchanging the initial consonant CONEX (teenie-weenie). Other patterns include adding a consonant (artsy-fartsy) or adding schm/shm (moodle-schmoodle). In our work, we propose a generative model for the three dominant forms of reduplication mentioned above. Broadly, our model captures the notion that vowels and consonants display strong replacement preferences. For example, the vowel i is much more likely to be replaced with a than u (instances like clip-clap, wishy-washy). Similarly the consonant t is much more likely to be replaced by w (as in teenie-weenie, tinky-winky). We incorporate these insights into our generative model as follows: **(1)** Let θ be a distribution over the three different types of reduplicatives. Let ϕ_v, ψ_c be distributions over letters that replace vowel v and consonant c respectively. **(2)** Sample the type of reduplicative t generated from θ. **(3)** If t is DUPLICATE, set w to v and return w as the reduplicative component. **(4)** If t is VOWELEX, find the first vowel x with non-zero replacement probability. Sample the replacement z from ϕ_x and replace x with z. If t is CONEX, find the first consonant c with non-zero replacement probability and sample the replacement z from ψ_c. Replace c with z. **(5)** Return the edited string as the second component of the reduplicative. **(6)** The parame-

ters of multinomial distributions θ, ϕ_v, and ψ_c are estimated via MLE estimates from the data.

Evaluation We consider two baseline models (a) **LET** Uniformly replace a letter with another letter in v to return w. (b) **LET(COND)** Uniformly replace a letter (vowel or consonant) with a letter from its class. Since reduplicatives are characterized by phonologically similar sounds, merely using edit distance as a metric for evaluation would be ineffective. For example, even the ill-rhyming `flip-flsp` has the same edit distance as the correct reduplicative `flip-flop`. Thus, we use a distance measure (MIR) defined over the phoneme space (Hixon et al., 2011) which effectively captures the similarity of two phonetic sequences by modeling the affinities between pairs of phonemes using a point access mutation matrix and is superior over metrics like PER (phoneme error rate).

4 Experiments

Having described our models and evaluation metrics in the previous section, we proceed to evaluate our models empirically and describe our results.

Blends We train our model on $\mathcal{D}_{knight}$ and evaluate on the $\mathcal{D}_{blind}$ dataset as in (Gangal et al., 2017) comparing against previous methods (Deri and Knight, 2015; Gangal et al., 2017). We set the number of hidden units to 50 with a dropout probability of 0.5[11]. We use ADAM (Kingma and Ba, 2014) optimizer with an initial learning rate of 0.001 to train the model for 500 epochs with early stopping over a validation set.

Tables 3 and 4 show the mean edit distance of our predictions from the target blend. First, the evaluation on the $\mathcal{D}_{knight}$ dataset compares the performance of our models against previous baselines. Note that just using our basic model COPYCAT -(LSTM + LM) outperforms the baseline proposed by (Deri and Knight, 2015) (1.59 vs 1.49). Furthermore, observe that even our vanilla model (LSTM) significantly outperforms the equivalent "FORWARD" models by (Gangal et al., 2017)[12] that use greedy and beam-search decoding (1.90 and 2.37 vs 1.75). Moreover, observe that our model even achieves almost equivalent performance to the "FORWARD" state-of-art model which uses exhaustive decoding (1.37 vs 1.33). Furthermore, our model achieves competitive performance with the more complex models proposed by GANGAL-BACKWARD which use exhaustive decoding. We emphasize that we can achieve competitive performance using a simpler model without using exhaustive decoding. Similar observations can also be made for the evaluation of the $\mathcal{D}_{blind}$ data set (our best model yields a score of 1.91 vs 1.77). Altogether these observations suggest that even simple models with effective modeling of linguistic structure can perform competitively and even outperform overly complex models (see Table 6 for a few example predictions).

Model	Distance
KNIGHT	1.59
GANGAL-FORWARD (GREEDY)	1.90
GANGAL-FORWARD (BEAM)	2.37
GANGAL-FORWARD (SOTA)†	1.33
GANGAL-BACKWARD (SOTA)†	1.12
COPYCAT-(LSTM)	1.75
COPYCAT-(LSTM + LM)	1.49
COPYCAT-(LSTM + LM + LEN)	**1.40**
COPYCAT-(LSTM + LM + LEN)†	**1.37**

Table 3: 10-fold cross validation performance of our blending model COPYCAT in terms of edit distance (lower is better) on $\mathcal{D}_{knight}$ dataset. † indicates ensemble approach using sub-samples of training data consistent with previous work. Our simpler model yields competitive performance (especially compared to the state of art forward model) without the need for exhaustive decoding (which the state of art uses), uses a smaller learn-able parameter set while effectively using linguistic insights into the blending process.

Clippings We consider the dataset of clippings introduced by (Mattiello, 2013) and report the mean edit distance (μ) on a set of 173 clippings in Figure 4 (see Table 5 as well). First, both CLIPPHONE ($\mu = 3.39$) and CLIPGRAPH ($\mu = 2.65$) outperform the naive baseline ($\mu = 4.6$). Second, based on the empirical distribution, it is almost impossible to predict whether a word has a one or two syllables (0.49 vs 0.46 significant only at $\alpha > 0.2$) clipping and incorrect guesses critically affect the downstream performance. In the absence of such information, just clipping to one syllable yields better performance. However, when this information is exactly known (CLIPPHONE(O)), we note an improvement as expected ($\mu = 2.79$). Finally, CLIPGRAPH shows a small but not signif-

[11] All hyper-parameters were chosen using a validation set.

[12] We obtain the numbers for these baselines from the latest released data and predictions at https://github.com/vgtomahawk/Charmanteau-CamReady.

Model	Distance

GANGAL-BACKWARD (SOTA)†	1.77
COPYCAT-(LSTM)	2.27
COPYCAT-(LSTM + LM)	2.13
COPYCAT-(LSTM + LM + LEN)	**1.98**
COPYCAT-(LSTM + LM + LEN)†	**1.91**

Table 4: Performance of our blending model COPYCAT in terms of edit distance (lower is better) on $\mathcal{D}_{blind}$ dataset. † indicates ensemble approach using sub-samples of training data consistent with previous work. Our simpler model yields competitive performance without the need for exhaustive decoding, uses a smaller learn-able parameter set while effectively using linguistic insights into the blending process. To ensure fair comparison, numbers for the baselines were obtained by filtering the released predictions for these models to the same set of words our models were evaluated on.

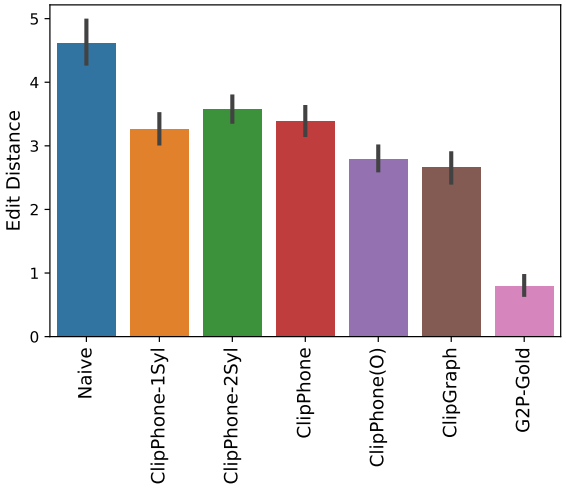

Figure 4: **Evaluation of clipping models** (lower is better). The NAIVE model is the performance lower bound. Both CLIPPHONE and CLIPGRAPH substantially outperform the baseline. Estimating whether a given word has one or two syllable clipping is a major challenge hindering CLIPPHONE since both cases are equally likely from empirical estimation. Using an oracle on the number of syllables (CLIPPHONE(O)) improves performance. CLIPGRAPH which operates purely in grapheme space performs as well as CLIPPHONE(O). G2PGOLD denotes a upper bound when using our P2G model.

icant advantage over methods working explicitly in the phoneme space which are prone to errors by imperfect conversion. Finally, the upper bound on the performance is substantially better than our models ($\mu = 0.79$) suggesting scope for future improvements.

Input	Our models		Gold
	CLIPPHONE	CLIPGRAPH	Clipping
cocaine	coke	coca	coke
juvenile	juve	juve	juvey
amelia	umm	amel	mel
alfred	fred	fred	fred
kid video	kidvid	kivid	kidvid

Table 5: Exemplary predictions from clippings models. We can generate one/two syllable clippings, as well as compound clippings. Note the effect of incorrect P2G conversion for `amelia` as `umm` which is pronounced similar to `ame`. The current G2P model does not incorporate stress. It is possible that incorporating stress into the model can address this scenario.

Input	Prediction	Gold	Dist

Table 6: Exemplary predictions from our simple blends model which suggests our model effectively captures blending phenomena by incorporating linguistic constraints.

Reduplicatives We evaluate our model on a held-out test set of 50 reduplicatives obtained using the manually compiled dataset by (Mattiello, 2013). We evaluate two flavors of our model: (a) OUR(NODUP) where we disallow generating duplicates (which are trivial to generate) and (b) OUR, the full-fledged model where duplicate reduplicatives are allowed. We report the mean MIR for each model over 10 independent runs in Figure 5. Our model consistently outperforms the baselines (LET, and LET(COND)) by at-least 8 percentage points suggesting it adeptly captures patterns in reduplicative formation. Finally, we examine the inferred probability distributions to gain insights into the linguistic phenomena in reduplicative formation few of which we outline: (a) The most common reduplicative types are DUPLICATE, VOWELEX followed by CONEX. (b) Vowel `i` is more likely to be replaced by `a` and `o` and (c) Consonant `t` is much more likely to be replaced by `w` and `l` (like

in `teenie-weenie`). We leave a comprehensive analysis of these patterns to future work.

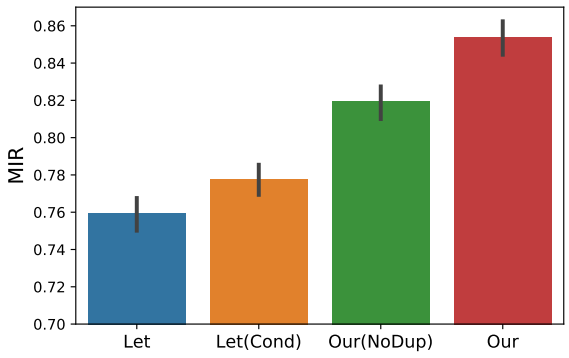

Figure 5: Performance of our reduplicative models based on the MIR metric (higher is better). Our models OUR(NODUP) and OUR consistently outperform baselines by at-least 8 percentage points (0.86 vs. 0.78).

5 Related Work

Blends, clippings and reduplicatives have been studied from a linguistic standpoint (Thun, 1963; Murata, 1990; Merlini Barbaresi, 2008; Hladky, 1998; Hamans, 1997; Fandrych, 2008; Moehkardi, 2016; Ungerer, 2007; Beal, 1991; Algeo, 1977; Smith et al., 2014; Shaw et al., 2014; Beliaeva, 2014; Broad et al., 2016; Renner et al., 2013; Gries, 2004a,b). Most relevant is the work of (Mattiello, 2005, 2008, 2013) who argues that slang is pervasive on the Internet, suggests its extra-grammatical nature and outlines some phonological and morphological properties. Specifically, these phenomena are discussed followed by a qualitative analysis on a manually compiled dataset of 1580 words from various sources. Recently (Deri and Knight, 2015) and (Gangal et al., 2017) study the problem of learning to blend and derive data-driven computational models for the task. (Deri and Knight, 2015) propose a model based on finite state transducers. (Gangal et al., 2017) outperform (Deri and Knight, 2015) by modeling the problem of generating blends as a variable length sequence to sequence learning problem and propose a neural encoder-decoder based model. We differ from all of these works in several ways. In contrast to the blending model proposed by Gangal et al. (2017), our model is simpler with lesser parameters, does not require using an encoder-decoder framework, or exhaustive decoding and yet yields competitive performance on a large class of blends. We also propose the first computational generative data-driven models for clippings and reduplicatives while capturing phonetic similarity as well and evaluate our models quantitatively.

6 Conclusion

We proposed generative models for blends, clippings, and reduplicatives, three dominant word-formation phenomena in slang. Our models are distinguished by their simplicity, adept use of linguistic and structural constraints, easy to implement and yield state of the art performance.

Our work suggests several directions for future research. First, our blending model can be extended to handle relatively rare insertions, incorporate the language model and the length model in a unified reinforcement learning framework optimizing a joint reward. Second, we do not investigate the complementary problem of de-blending. Moreover, we note that our evaluation of blends is based on an assumed gold standard. It would be useful to also characterize our blending model based on a human evaluation. Third, the gap between the performance of our clipping model and the upper bound (by the oracle) opens up the question of developing more nuanced models for clipping perhaps using deeper linguistic cues like stress patterns. Fourth, our models do not incorporate relatively rare types of reduplicative formation (like *schm* reduplicatives) suggesting yet another direction for research. Yet another open question is whether a global model can effectively model all the above phenomena. Finally, in our work, we focus on only developing models for word formation in English slang. However, such word formation patterns are also evident in other languages (Štekauer et al., 2012) and it is an open question as to whether similar models generalize to other languages as well.

Finally, our work potentially enables the development of several applications some of which include brand name generators, and rich conversational agents that are not only passive agents but can actively contribute to the evolution of language varieties.

Altogether our work has implications for the broader fields of Internet Linguistics and natural language understanding especially in the context of slang formation.

Abstract

Languages with productive morphology pose problems for language models that generate words from a fixed vocabulary. Although character-based models allow any possible word type to be generated, they are linguistically naïve: they must discover that words exist and are delimited by spaces—basic linguistic facts that are built in to the structure of word-based models. We introduce an open-vocabulary language model that incorporates more sophisticated linguistic knowledge by predicting words using a mixture of three generative processes: (1) by generating words as a sequence of characters, (2) by directly generating full word forms, and (3) by generating words as a sequence of morphemes that are combined using a hand-written morphological analyzer. Experiments on Finnish, Turkish, and Russian show that our model outperforms character sequence models and other strong baselines on intrinsic and extrinsic measures. Furthermore, we show that our model learns to exploit morphological knowledge encoded in the analyzer, and, as a byproduct, it can perform effective unsupervised morphological disambiguation.

1 Introduction

Language modelling of morphologically rich languages is particularly challenging due to the vast set of potential word forms and the sparsity with which they appear in corpora. Traditional *closed vocabulary* models are unable to produce word forms unseen in training data and unable to generalize sub-word patterns found in data.

The most straightforward solution is to treat language as a sequence of characters (Sutskever et al., 2011). However, models that operate at two levels—a character level and a word level—have better performance (Chung et al., 2016). Another solution is to use morphological information, which has shown benefits in non-neural models (Chahuneau et al., 2013). In this paper, we present a model that combines these approaches in a fully neural framework.

Our model incorporates explicit morphological knowledge (e.g. from a finite-state morphological analyzer/generator) into a neural language model, combining it with existing word- and character-level modelling techniques, in order to create a model capable of successfully modelling morphologically complex languages. In particular, our model achieves three desirable properties.

First, it conditions on all available (intra-sentential) context, allowing it, in principle, to capture long-range dependencies, such as that the verb agreement between "students" and "are" in the sentence "The students who studied the hardest are getting the highest grades". While traditional n-gram based language models lack this property, RNN-based language models fulfill it.

Second, it explicitly captures morphological variation, allowing sharing of information between variants of the same word. This allows faster, smoother training as well as improved predictive generalization. For example, if the model sees the phrase "gorped the ball" in data, it is able to infer that "gorping the ball" is also likely to be valid. Similarly, the model is capable of understanding that morphological consistency within noun phrases is important. For example in Russian, one might say *malen'kaya chërniya koshka* ("small black cat", nominative), or *malen'kuyu chërniyu koshku* (accusative), but *malen'kiy chërnuyu koshke* (mixing nominative, accusative and dative) would have much lower probability.

Third, the language model seamlessly handles out of vocabulary items and their morphological variants. For example, even if the word *Obama* was never seen in a Russian corpus, we expect *Ya dal eto prezidentu Obame* ("I gave it to presi-

Proceedings of NAACL-HLT 2018, pages 1435–1445
New Orleans, Louisiana, June 1 - 6, 2018.

dent Obama") to have higher probability using the dative *Obame* than *Ya dal eto prezidentu Obama*, which uses the nominative. The model can also learn to decline proper nouns, including OOVs. Here it can recognize that *dal* ("gave") requires a dative, and that nouns ending with "a" generally do not meet that requirement.

In order to capture these properties, our model combines two pieces: an alternative embedding module that uses sub-word information such as character and morpheme-level information, and a generation module that allows us to output words at the word, morpheme, or character-level. The embedding module allows for the model to share information between morphological variants of surface forms, and produce sensible word embeddings for tokens never seen during training. The generation model allows us to emit tokens never seen during training, either by combining a lemma and a sequence of affixes to create a novel surface form, or by directly spelling out the desired word character by character. We then demonstrate the effectiveness both intrinsically, showing reduced perplexity on several morphologically rich languages, and extrinsically on machine translation and morphological disambiguation tasks.

2 Multi-level RNNLMs

Recurrent neural network language models are composed of three parts: (a) an encoder, which turns a context word into a vector, (b) a recurrent backbone that turns a sequence of word vectors that represent the ordered sequence of context vectors into a single vector, and (c) a generator, which assigns a probability to each word that could follow the given context. RNNLMs often use the same process for (a) and (c), but there is no reason why these processes cannot be decoupled. For example, Kim et al. (2016) and Ling et al. (2015) compose character-level representations for their word encoder, but generate words using a softmax whose probabilities rely on inner products between the current context vector and type-specific word embeddings.

In our model both the word generator (§2.1) and the word encoder (§2.2) compute representations that leverage three different views of words: frequent words have their own parameters, words that can be analyzed/generated by an analyzer are represented in terms of sequences of abstract morphemes, and all words are represented as a sequence of characters.

2.1 Word generation mixture model

In typical RNNLMs the probability of the ith word in a sentence, w_i given the preceding words is computed by using an RNN to encode the context followed by a softmax:

$$\begin{aligned} p(w_i \mid \boldsymbol{w}_{<i}) &= p(w_i \mid \mathbf{h}_i = \boldsymbol{\varphi}_{\text{RNN}}(w_1, \ldots, w_{i-1})) \\ &= \text{softmax}(\mathbf{W}\mathbf{h}_i + \mathbf{b}) \end{aligned}$$

where $\boldsymbol{\varphi}_{\text{RNN}}$ is an RNN that reads a sequence of words and returns a fixed sized vector encoding, $\mathbf{W}$ is a weight matrix, and $\mathbf{b}$ is a bias.

In this work, we will use a mixture model over M different models for generating words in place of the single softmax over words (Miyamoto and Cho, 2016; Neubig and Dyer, 2016):

$$\begin{aligned} p(w_i \mid \mathbf{h}_i) &= \sum_{m_i=1}^{M} p(w_i, m_i \mid \mathbf{h}_i) \\ &= \sum_{m_i=1}^{M} p(m_i \mid \mathbf{h}_i) p(w_i \mid \mathbf{h}_i, m_i), \end{aligned}$$

where $m_i \in [1, M]$ indicates the model used to generate word w_i. To ensure tractability for training and inference, we assume that m_i is conditionally independent of all $\boldsymbol{m}_{<i}$, given the sequence of word forms $\boldsymbol{w}_{<i}$.

We use three ($M = 3$) component models: (1) directly sampling a word from a finite vocabulary ($m_i = \text{WORD}$), (2) generating a word as a sequence of characters ($m_i = \text{CHARS}$), and (3) generating as a sequence of (abstract) morphemes which are then stitched together using a hand-written morphological transducer that maps from abstract morpheme sequences to surface forms ($m_i = \text{MORPHS}$). Figure 1 illustrates the model components, and we describe in more detail here:

Word generator. Select a word by directly sampling from a multinomial distribution over surface form words. Here the vocabulary is the $|V_w|$ most common full-form words seen during training. All less frequent words are assigned zero probability by this model, and must be generated by one of the remaining models.

Character sequence generator. Generate a word as a sequence of characters. Each character is predicted conditioned on the LM hidden state $\mathbf{h}_i$ and the partial word generated so far, encoded

with an RNN. The product of these probabilities is the total probability assigned to a full word form.

Morpheme sequence generator. Similarly to the character sequence generator, we can generate a word as a sequence of morphemes. We first generate a root r, followed by a sequence of affixes $a_1, a_2, \ldots$. For example the word "devours" might be generated as devour+3P+SG+EOW. Since multiple sequences of abstract morphemes may in general give rise to a single output form,[1] we marginalize these, i.e.,

$$p(w_i \mid \mathbf{h}_i, m_i = \text{MORPHS}) = \sum_{\boldsymbol{a}_i \in \{\boldsymbol{a} \mid \text{GEN}(\boldsymbol{a}) = w_i\}} p_{morphs}(\boldsymbol{a}_i \mid \mathbf{h}_i).$$

where $\text{GEN}(\boldsymbol{a})$ gives the surface word form produced from the morpheme sequence $\boldsymbol{a}$.

Due to the model's ability to produce output at the character level, it is able to produce any output sequence at all within the language's alphabet. This is critical as it allows the model to generate unknown words, such as novel names or declensions thereof. Furthermore, the morphological level facilitates the model's generation of word forms whose lemmas may be known, but whose surface form was nevertheless unattested in the training data. Finally the word-level generation model handles generating words that the model has seen many times during training.

2.2 Morphologically aware context vectors

Word vectors are typically learned with a single, independent vector for each word type. This independence means, for example, that the vectors for the word "apple" and the word "apples" are completely unrelated. Seeing the word "apple" gives no information at all about the word "apples".

Ideally we would like to share information between such related words. Nevertheless, sometimes words have idiomatic usage, so we'd like not to tie them together too tightly.

We accomplish this by again using three different types of word vectors for each word in the vocabulary. The first is a standard per-type word vector. The second is the output of a character-level RNN using Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997). The third is the output of a morphology-level LSTM over a lemma and a sequence of affixes, as output by a morphological analyzer.

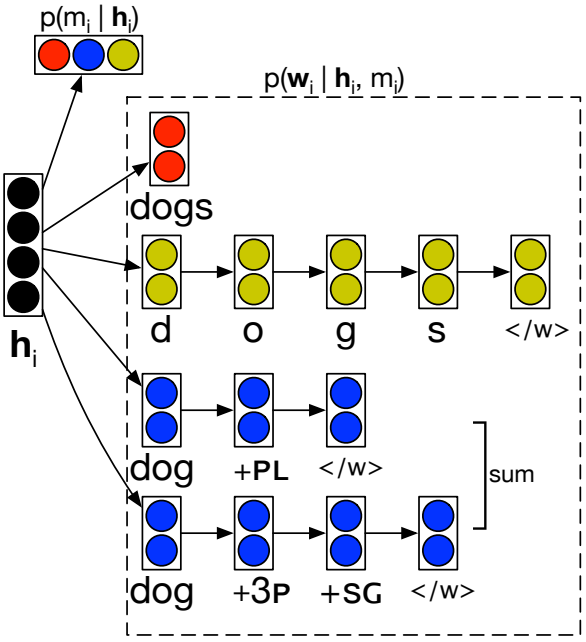

Figure 1: We allow the model to generate an output word at the word, morpheme, or character level, and marginalize over these three options to find the total probability of a word.

Typically language models first generate a word w_i given some (initially empty) prior context c_{i-1}, and then that word is combined with the context to generate a new context c_i that includes the new word. Since we have just used one or more of our three modes to generate each word, intuitively we would like to use the same mode(s) to generate the embedding used to progress the context.

Unfortunately, doing so introduces dependencies among the latent variables $p(\text{mode} \mid c_i)$ in our model, making exact inference intractable. As such, we instead drop the dependency on how a word was generated and instead represent the word at all three levels, regardless of the mode(s) actually used to generate it, and combine them by concatenating the three representations. A visual representation of the embedding process is shown in Figure 2.

Additionally, should a morphological analyzer produce more than one valid analysis for a surface form, we independently produce embeddings for each candidate analysis, and combine them using a per-dimension maximum operation. Mathemati-

[1] In general analyzers encode many-to-many relations, but our model assumes that any sequence of morphs in the underlying language generates a single surface form. This is generally true, although free spelling variants of a morph (e.g., American *-ize* vs. British *-ise* as well as alternative realizations like *shined/shone* and *learned/learnt*) violate this assumption.

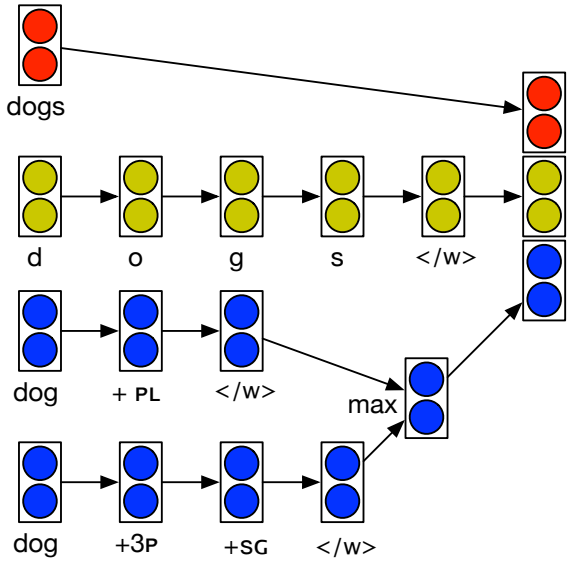

Figure 2: We concatenate word- morpheme- and character-level vectors to build a better input vector for our RNNLM.

cally, the ith dimension of the morphological embedding e_m is given by

$$e_{mi} = \max_j e_{a_j i}$$

where e_{a_j} is the embedding of the jth possible analysis, as computed by the LSTM over the lemma and its sequence of affixes.

The intuition behind the use of all analyses plus a pooling operation can be seen by observing the case of the word "does", which could be *do+3-person+singular* or *doe+plural*. If this word appears after the word "he", what we care about more is whether "does" could feasibly be a third person singular verb, thus agreeing with the subject. The max-pooling operation captures this intuition by ensuring that if a feature is active for one of these two analyses, it will also be active in the pooled representation. This procedure affords us the capability to efficiently marginalize over all three possible values of the latent variable at each step, and compute the full marginal of the word w_i given the context c_{i-1} during generation.

This formulation allows words with the same stem to share vector information through the character or morphological embeddings, but still affords each word the ability to capture idiomatic usages of individual words through the word embeddings. Furthermore, it allows a language model to explicitly capture morphological information, for example that third person singular subjects should co-occur with third person singular verbs. Finally, the character-level segment of the embedding allows the model to at least attempt to build sensible embeddings for completely unknown words. For example in Russian where names can decline with case this formulation allows the model to know that *Obame* is probably dative, even if it's an OOV at the word level, and even if the morphological analyzer is unable to produce any valid analyses.

We combine our three-layer input vectors, our factored output model, and a standard LSTM backbone to create a morphologically-enabled RNNLM that, as we will see in the next section, performs well on morphologically complex languages.

3 Intrinsic Evaluation

We demonstrate the effectiveness of our model by experimenting on three languages: Finnish, Turkish, and Russian. For Finnish we use version 8 of the Europarl corpus, for Turkish we use the SETIMES2 corpus, and for Russian we use version 12 of the News Commentary corpus. Statistics of our experimental corpora can be found in Table 1.

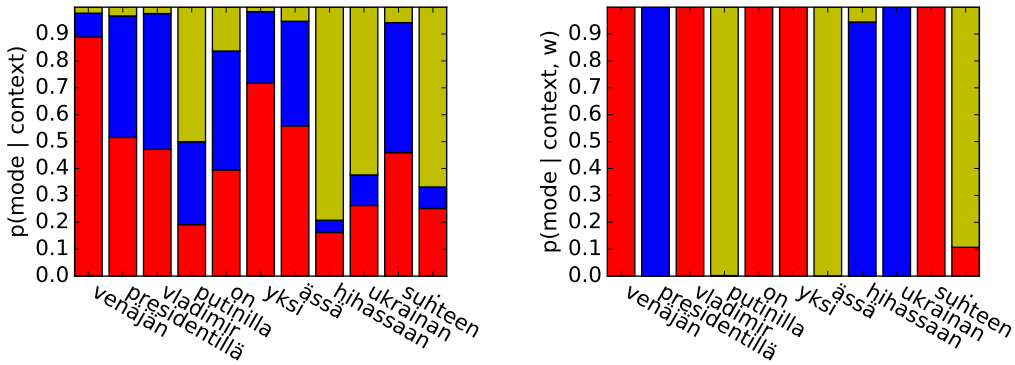
Each data set was pre-processed by UNKing all but the top ≈20k words and lemmas by frequency. No characters or affixes were UNKed. This step is not strictly required—our model is, after all, capable of producing arbitrary words— but it speeds up training immensely by reducing the size of the word and lemma softmaxes. Since the morphology and/or character-level embeddings can still capture information about the original forms of these words, the degradation in modelling performance is minimal.

For morphological analysis we use Omorfi[2] for Finnish, the analyzer of Oflazer (1994) for Turkish, and PyMorphy[3] for Russian.

3.1 Baseline Models

Since models are not accurately comparable unless they share output vocabularies, our baselines must also allow for the generation of arbitrary word forms, including out-of-vocabulary items. We compare to three such models: an improved Kneser-Ney (Kneser and Ney, 1995) 4-gram baseline, with an additional character-level backoff model for OOVs, an RNNLM with character-level backoff, and a pure character-based RNN language model (Sutskever et al., 2011).

[2] https://github.com/flammie/omorfi
[3] https://github.com/kmike/pymorphy



Finnish: "Russian President Vladimir Putin has an ace up his sleeve in the Ukrainian relationship."

Figure 3: An example of the priors (left) and posteriors (right) over modes used to generate each word in a sample sentences. Probability given to the word-, morpheme-, and character-level models are shown in red, blue, and gold respectively. More examples can be found in the appendix.

Since Kneser-Ney language models (and other count-based models) are typically word-level and do not model out-of-vocabulary items, we employ a two-level approach with separate Kneser-Ney models at the word and character levels. We train the word-level model after UNKing low frequency words, and we train the character-level model on the same list of low frequency words. Now when we want to predict a word w_i given some context c we can use the word-level model to directly predict $p(w_i|c)$ unless w_i is an out-of-vocabulary item. In that case we model $p(w_i \mid c)$ as

$$p(w_i \mid c) = p(\text{UNK} \mid c) \cdot p(w_i \mid \text{UNK})$$

where the first factor is the probability of the word-level model emitting UNK, and the second is the probability of the actual out-of-vocabulary word form under the character-level model.

Secondly we compare to a similar hybrid RNN model that first predicts the word-level probability for each word, and if it predicted UNK then also predicts a sequence of characters using a separate network. This model uses 256-dimensional character and word embeddings, and a 1024-dimensional recurrent hidden layer.

Finally we also compare to a standard RNN language model trained purely on the character level. For this baseline we also use 256-dimensional character embeddings and a 1024-dimensional recurrent hidden layer.

3.2 Multi-factored Models

For our model we use 128-dimensional word and root embeddings, 64-dimensional affix and character embeddings, 128-dimensional word-internal recurrent hidden layers for characters and morphemes, and a 256-dimensional recurrent hidden layer for the main inter-word LSTM.

The network is trained to stochastically optimize the log likelihood of the training data using Adam (Kingma and Ba, 2014). After each 10k training examples (Finnish, Turkish) or 100k training examples (Russian) we evaluate the model on a development set.[4] If the perplexity on the development set represents a new best, we save the current model to disk, thereby mitigating overfitting via early stopping. No other regularization is used.

For each language we run four variants of our model. In order to preserve the ability to model and emit any word in the modelled language, it is essential that we keep the character-level part of our model intact. The morpheme- and word-level models, however, may be removed without compromising the generality of the model. As such, we present our model using only character-level input and outputs (C), using character- and morpheme-level inputs and outputs (CM), using character- and word-level inputs, but no morphology (CW), and using all three levels as per the full model (CMW).

3.3 Results and Analysis

Our experimental results (Table 2) show that our multi-modal model significantly outperforms all three baselines: a naïve n-gram model, a purely character-level RNNLM, and a hybrid RNNLM

[4] We evaluate less frequently on Russian since the dev set is much larger.

	Finnish	Russian	Turkish
Train Sents	2.1M	1.1M	188K
Train Words	38M	26M	3.9M
Dev Sents	1K	38K	1K

Affix Vocab	140	34	180
Char Vocab	229	150	80

Table 1: Details of our data sets. Each cell indicates the number of sentences and the number of words in each set.

for open-vocabulary language models. Furthermore, they confirm that morphological analyzers can improve performance of such language models on particularly morphologically rich languages. We observe that across all three languages the space-aware character-level model outperforms the purely character-based model that treats spaces just as any other character. Furthermore we see that the Kneser-Ney language model performs admirably well on this task, underscoring the difference in setting between the familiar, traditional closed-vocabulary LMs, and the open-vocabulary language modelling task. Additionally we find that the relative success of the n-gram model and the hybrid model over the character only models underscores the importance of access to word-level information, even when using a less sophisticated model.

Table 3 shows some examples of sentences on which our model heavily outperforms the RNN baseline and vice-versa. We find that the sentences on which our model peforms well contain much less frequent word forms. For each sentence we examine the frequency with which each token appears in our training corpus. The sentences on which our model performs best have a median token frequency of 305 times, while the sentences where the RNN performs better has an average token frequency of 3031 times. Overall our model has better log-likelihood than the RNN baseline on 88.1% of sentences.

Our methods outperform the n-gram model in all languages with either set of just two models, CM or CW. The same models outperform the hybrid baseline in Turkish and Russian, and achieves comparable results in Finnish. Finally, in the agglutinative languages, using all three modes performs best, while in Russian, a fusional language, characters and words alone edge out the model with morphology. We hypothesize that our morphology model is better able to model the long strings of morphemes found in Turkish and Finnish, but gains little from the more idiosyncratic fusional morphemes of Russian.

Some examples of the priors and posteriors of the modes used to generate some randomly selected sentences from the held out test set can be seen in Figure 3 and the appendix (Figure 4). The figures show that all of the models tend a priori to prefer to generate words directly when possible, but that context can certainly influence its priors. In Finnish, after seeing the word *Vladmir*, the model suddenly assigns significantly more weight to the character-level model to generate the following word, which is likely to be a surname. In Russian, after the preposition *o*, the following noun is required to be in a rare case. As such, the model suddenly assigns more probability mass to the following word being generated using the morpheme-level model.

The posteriors tell a similarly encouraging story. In Finnish we see that the word *presidentillä* is overwhelmingly likely to be produced by the morphology model due to its peculiar adessive ("at") case marking. *Vladmir* is common enough in the data that it can be generated wholly, but the last name *Putin* is again inflected into the adessive case, forming *Putinilla*. Unfortunately the morphological analyzer is unfamiliar with the stem *Putin*, forcing the word to be generated by the character-level model. In our Turkish example, all of the short words are generated at the word level, while the primary nouns *internetten* ("internet") and *ders* ("lecture") are possible to generate either as words or as a sequence of morphemes. The verb, which has much more complex morphology (progressive past tense with a third person singular agent), is generated via the morphological model.

4 Extrinsic Evaluation

In addition to evaluating our model intrinsically using perplexity, we evaluate it on two downstream tasks. The first is machine translation between English and Turkish. The second is Turkish morphological analysis disambiguation.

Table 3: Some examples of Turkish sentence on which our morphological model heavily outperforms the baseline RNNLM (top) and some examples of the opposite (bottom). The sentences that our model performs well on have many particularly rare words, whereas the sentences the RNNLM performs well on were seen hundreds or thousands of times in the training corpus. Words in bold were seen fewer than 25 times in the training corpus. Arrows indicate line wrapping.

4.1 Machine Translation

As an extrinsic evaluation we test whether our language model improves machine translation between Turkish and English. While we could transform our model into a source-conditioned translation model, we choose here to focus on testing our model as an external unconditional language model, leaving the conditional version for future work. Since neural machine translation systems struggle with low-resource languages (Koehn and Knowles, 2017), we choose to introduce the score of our LM as an additional feature to a cdec (Dyer et al., 2010) hierarchical MT system. We train on the WMT 2016 Turkish–English data set, and perform n-best reranking after re-tuning weights with the new feature.

The results, shown in Table 4 demonstrate small but significant gains in both directions, particularly into Turkish, where modelling productive morphology should be more important.

Lang. Pair	System	BLEU
TR-EN	Baseline	15.0
	Morph. Input	**15.2**
EN-TR	Baseline	10.1
	Morph. Output	**10.5**

4.2 Morphological Disambiguation

Our model is a joint model over words and the latent processes giving rise to those words (i.e., which generation process was selected and, for the morpheme process, which morpheme sequence was generated). While our model is not directly trained to perform morphological disambiguation, it still performs this task quite admirably. Given a trained morphological language model, a sentence $\mathbf{s}$, and a set of morphological analyses $\mathbf{z}$, we can query the model to find $p(\mathbf{s}, \mathbf{z}) = p(w_1, w_2, \ldots, w_N)$ for a given sentence. Most notably, each w_i may have a set of possible morphological analyses $\{a_1, a_2, \ldots a_{M_i}\}$ from which we would like to choose the most likely *a posteriori*. To perform this task, we simply query the model M_i times, each time hiding all but the jth possible analysis from the model. We can then re-normalize the resulting probabilities to find $p(a_j|\mathbf{s})$ for each $j \in 1 \ldots M_i$.

To make training and inference with our model

Model	Supervised?	Ambiguous Words	All words

Bidirectional	no	**63.85%**	**84.11%**
Shen et. al	yes	91.03%	96.43%

Table 5: Morphological disambiguation accuracy results for Turkish.

tractable, we have assumed independence between previous adjacent events and the next word generation given the previous surface word forms (§2.1). Thus, the posterior probability over the analysis is only determined by the left context—subsequent decisions are independent of the process used to generate a word at time t. However, since disambiguating information may be present in either direction, we introduce a model variant that conditions on information in both directions. Bidirectional dependencies mean that we can no longer use the chain rule to factor the probability distribution from left-to-right. Rather we have to switch to a globally normalized, undirected model (i.e., a Markov random field) to define the probabilities of selecting the mode of generation and generation probability (conditional on the mode). The factors used to parameterize the model are defined in terms of two LSTMs, one encoding from left-to-right the prefix of the ith word ($\mathbf{h}_i$, defined exactly as above), and a second encoding from right-to-left its suffix ($\mathbf{h}'_i$). These two vector representations are used to compute a score using a locally normalized mixture model for each word. Intuitively, the morphological analysis generated at each time step should be compatible with both the preceding words and the following words.

Optimizing this model with the same MLE criterion we used in the direct model is, unfortunately, intractable since a normalizer would need to be computed. Instead, we use a pseudo-likelihood objective (Besag, 1975).

$$\begin{aligned}\mathcal{L}_{\text{PL}} &= \prod_i p(w_i \mid \boldsymbol{w}_{-i}) \\ &= \prod_i \sum_m p(m_i = m \mid \boldsymbol{w}_{-i}) p(w_i \mid m, \boldsymbol{w}_{-i})\end{aligned}$$

We note that although this model has a very different semantics from the directed one, the PL training objective is identical to the directed model's, the only difference is that features are based both on the past and future, rather than only the past.

Similarly to training, evaluating sentence likelihoods using this model is intractable, but posterior inference over m_i and a_i is feasible since the normalization factors cancel and therefore do not need to be computed.

For our experiments we use the data set of Yuret and Türe (2006) who manually disambiguated from among the possible forms identified by an FST. We significantly out-perform the simple baseline of randomly guessing, and our results are competitive with Yatbaz and Yuret (2009), although they evaluated on a different dataset so they are not directly comparable. Furthermore, we also compare to a supervised model (Shen et al., 2016). While unsupervised techniques can't hope to exceed supervised accuracies, this comparison provides insight into the difficulty of the problem. See Table 5 for results.

5 Related Work

Purely Character-based or Subword-based LMs have a rich history going all the way back to Markov (1906)'s work modelling Russian character-by-character with his namesake models. More recently Sutskever et al. (2011) were the first to apply RNNs to character-level language modelling, leveraging their ability to handle the long-range dependencies required to model language at the character level. It is also possible to alleviate the closed vocabulary problem by training models on automatically acquired subword units (Mikolov et al., 2012; Sennrich et al., 2015). While these approaches allow for an open vocabulary (or nearly open, in the case of subwords) they discard a large amount of higher-level information, inhibiting learning.

Character-aware language models, which combine character- and word-level information have shown promise (Kang et al., 2011; Ling et al., 2015; Kim et al., 2016). Unsupervised morphology has also been shown to improve the representations used by a log-bilinear LM (Botha and Blunsom, 2014). Jozefowicz et al. (2016) explore many interesting such architectures, and compare with fully character-based models.

While these models allow for the elegant encoding of novel word forms they lack an open vocabulary.

Open-vocabulary hybrid models alleviate this problem, extending the benefits of character-level representations to the generation. Such hybrid models with open vocabularies have been around since Brown et al. (1992). More recently, Chung et al. (2016) and Hwang and Sung (2016) describe methods of modelling sentences at both the word and character levels, using mechanisms to allow both a word-internal model that captures short-range dependencies and a word-external model to capture longer-range dependencies. These models have been successfully applied to machine translation by Luong and Manning (2016), who use a character-level model to predict translations of out of vocabulary words. Our work falls in this category—we combine multiple representation levels while maintaining the ability to generate any character sequence. In contrast to these previous works, we demonstrate the utility of incorporating morphological information in these open-vocabulary models.

Mixture model language generation where the mixture coefficients are predicted by a neural net are becoming quite common. Neubig and Dyer (2016) use this strategy to combine a count-based model and a neural language model. Ling et al. (2016) interpolate between character- and word-based models to translate between natural language text and computer code. Merity et al. (2016) also use multiple output models, allowing a word to either be generated by a standard softmax or by copying a word from earlier in the input sentence.

6 Conclusion

We have demonstrated a technique for language modelling that works particularly well on morphologically rich languages where having an open vocabulary is desirable. We achieve this by using a multi-modal architecture that allows words to be input and output at the word, morpheme, or character levels. We show that knowledge of the existence of word boundaries is of critical importance for language modelling tasks, even when otherwise operating entirely at the character level, resulting in a surprisingly large reduction in per-character entropy across all languages studied.

Furthermore, we demonstrate that if we have access to a morphological analyzer we can leverage it to further improve our LM, reinforcing the notion that the explicit inclusion of linguistic information can indeed aid learning of neural models.

Abstract

Entity mentions embedded in longer entity mentions are referred to as nested entities. Most named entity recognition (NER) systems deal only with the flat entities and ignore the inner nested ones, which fails to capture finer-grained semantic information in underlying texts. To address this issue, we propose a novel neural model to identify nested entities by dynamically stacking flat NER layers. Each flat NER layer is based on the state-of-the-art flat NER model that captures sequential context representation with bidirectional long short-term memory (LSTM) layer and feeds it to the cascaded CRF layer. Our model merges the output of the LSTM layer in the current flat NER layer to build new representation for detected entities and subsequently feeds them into the next flat NER layer. This allows our model to extract outer entities by taking full advantage of information encoded in their corresponding inner entities, in an inside-to-outside way. Our model dynamically stacks the flat NER layers until no outer entities are extracted. Extensive evaluation shows that our dynamic model outperforms state-of-the-art feature-based systems on nested NER, achieving 74.7% and 72.2% on GENIA and ACE2005 datasets, respectively, in terms of F-score.[1]

1 Introduction

The task of named entity recognition (NER) involves the extraction from text of names of entities pertaining to semantic types such as *person (PER)*, *location (LOC)* and *geo-political entity (GPE)*. NER has drawn the attention of many researchers as the first step towards NLP applications such as entity linking (Gupta et al., 2017), relation extraction (Miwa and Bansal, 2016), event extraction (Feng et al., 2016) and co-reference resolution (Fragkou, 2017; Stone and Arora, 2017).

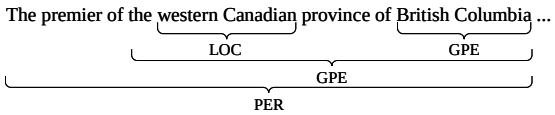

Figure 1: A sentence from ACE2005 (Walker et al., 2006) containing the nested 4 entities nested 3 levels deep.

Due to the properties of natural language, many named entities contain *nested entities*: embedded names which are included in other entities, illustrated in Figure 1. This phenomenon is quite common in many domains (Alex et al., 2007; Byrne, 2007; Wang, 2009; Màrquez et al., 2007). However, much of the work on NER copes only with non-nested entities which are also called *flat entities* and neglects nested entities. This leads to loss of potentially important information, with negative impacts on subsequent tasks.

Traditional approaches to NER mainly involve two types of approaches: supervised learning (Ling and Weld, 2012; Marcińczuk, 2015; Leaman and Lu, 2016) and hybrid approaches (Bhasuran et al., 2016; Rocktäschel et al., 2012; Leaman et al., 2015) that combine supervised learning with rules. Such approaches require either domain knowledge or heavy feature-engineering. Recent advances in neural networks enable NER without depending on external knowledge resources through automated learning high-level and abstract features from text (Lample et al., 2016; Ma and Hovy, 2016; Pahuja et al., 2017; Strubell et al., 2017).

In this paper, we propose a novel dynamic neural model for nested entity recognition, without relying on any external knowledge resources or linguistics features. Our model enables sequentially

[1]Code is available at https://github.com/meizhiju/layered-bilstm-crf

Proceedings of NAACL-HLT 2018, pages 1446–1459
New Orleans, Louisiana, June 1 - 6, 2018.

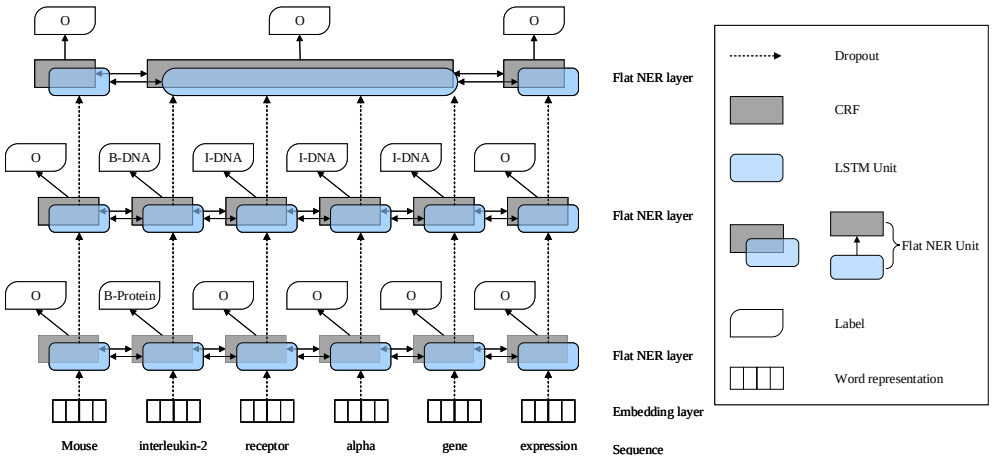

Figure 2: Overview of our layered model architecture. "interleukin-2" and "interleukin-2 receptor alpha gene" are nested entities.

stacking flat NER layers from bottom to up and identifying entities in an end-to-end manner. The number of stacked layers depends on the level of entity nesting and dynamically adjusts to the input sequences as the nested level varies from different sequences.

Given a sequence of words, our model first represents each word using a low-dimensional vector concatenated from its corresponding word and character sequence embeddings. Taking the sequence of the word representation as input, our flat NER layer enables capturing context representation by a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) layer. The context representation is then fed to a CRF layer for label prediction. Subsequently, the context representation from the LSTM layer is merged to build representation for each detected entity, which is used as the input for the next flat NER layer. Our model stops detecting entities if no entities are predicted by the current flat NER layer. Through stacking flat NER layers in order, we are able to extract entities from inside to outside with sharing parameters among the different LSTM layers and CRF layers.

We gain 3.9 and 9.1 percentage point improvements regarding F-score over the state-of-the-art feature-based model on two nested entity corpora: GENIA (Kim et al., 2003) and ACE2005 (Walker et al., 2006), and analyze contributions of inner entities to outer entity detection, drawing several key conclusions.

In addition, experiments are conducted on a flatly annotated corpora JNLPBA (Kim et al., 2004). Our model can be a complete NER model as well for flat entities, on the condition that it is trained on annotations that do not account for nested entities. We obtain 75.55% in terms of F-score that is comparable to the state-of-the-art performance.

2 Neural Layered Model

Our nested NER model is designed based on a sequential stack of flat NER layers that detects nested entities in an end-to-end manner. Figure 2 provides the overview of our model. Our flat NER layers are inspired by the state-of-the-art model proposed in Lample et al. (2016). The layer utilizes one single bidirectional LSTM layer to represent word sequences and predict flat entities by putting one single CRF layer on top of the LSTM layer. Therefore, we refer to our model as Layered-BiLSTM-CRF model. If any entities are predicted, a new flat NER layer is introduced and the word sequence representation of each detected entity by the current flat NER layer is merged to compose a representation for the entity, which is then passed on to the new flat NER layer as its input. Otherwise, the model terminates stacking and hence finishes entity detection.

In this section, we provide a brief description of the model architecture: the flat NER layers and their stacking, the embedding layer and their training.

2.1 Flat NER layer

A flat NER layer consists of an LSTM layer and a CRF layer. The LSTM layer captures the bidi-

rectional context representation of sequences and subsequently feeds it to the CRF layer to globally decode label sequences.

LSTM is a variant of recurrent neural networks (RNNs) (Goller and Kuchler, 1996) that incorporates a memory cell to remember the past information for a long period of time. This enables capturing long dependencies, thus reducing the gradient vanishing/explosion problem existing in RNNs. We employ bidirectional LSTM with no peephole connection. We refer the readers to Hochreiter and Schmidhuber (1997) for more details of LSTM used in our work.

CRFs are used to globally predict label sequences for any given sequences. Given an input sequence $X = (x_1, x_2, \ldots, x_n)$ which is the output from the LSTM layer, we maximize the log-probability during training. In decoding, we set transition costs between illegal transitions, e.g., transition from O to I-PER, as infinite to restrict illegal labels. The expected label sequence $y = (y_1, y_2, \ldots, y_n)$ is predicted based on maximum scores in decoding.

2.2 Stacking flat NER layers

We stack a flat NER layer on the top of the current flat NER layer, aiming to extract outer entities. Concretely, we merge and average current context representation of the regions composed in the detected entities, as described in the following equation:

$$m_i = \frac{1}{end - start + 1} \sum_{i=start}^{end} z_i, \qquad (1)$$

where z_i denotes the representation of the i-th word from the flat NER layer, and m_i is the merged representation for an entity. The region starts from a position $start$ and ends at a position end of the sequence. This merged representation of detected entities allows us to treat each detected entity as a single token, and hence we are able to make the most of inner entity information to encourage outer entity recognition. If the region is detected as a non-entity, we keep the representation without any processing. The processed context representation of the flat NER layer is used as the input for the next flat NER layer.

2.3 Embedding layer

The input for the first NER layer is different from the remaining flat NER layers since the first layer has no previous layers. We thus represent each word by concatenating character sequence embeddings and word embeddings for the first flat NER layer. Figure 3 describes the architecture of the embedding layer to produce word representation.

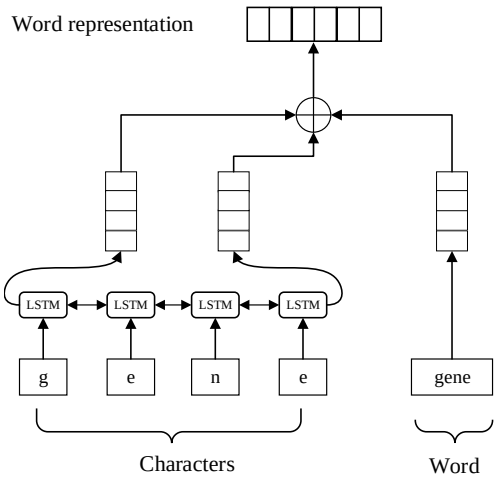

Figure 3: Word representation of a word 'gene'. We concatenate the outputs of character embedding from LSTM and word embedding to obtain its final word representation.

Following the successes of Ma and Hovy (2016) and Lample et al. (2016) in utilizing character embeddings on the flat NER task, we also represent each word with its character sequence to capture the orthographic and morphological features of the word. Each character is mapped to a randomly initialized vector through a character lookup table. We feed the character vectors comprising a word to a bidirectional LSTM layer and concatenate the forward and backward representation to obtain the word-level embedding.

Differently from the character sequence embeddings, the pretrained word embeddings are used to initialize word embeddings. When evaluating or applying the model, words that are outside of the pretrained embeddings and training dataset are mapped to an *unknown* (UNK) embedding, which is randomly initialized during training. To train the UNK embedding, we replace words whose frequency is 1 in the training dataset with the UNK embedding with a probability 0.5.

2.4 Training

We prepare the gold labels based on the conventional BIO (Beginning, Inside, Out of entities) tagging scheme to represent a label attached to each word.

As our model detects entities from inside to outside, we keep the same order in preparing the gold labels for each word sequence. We call it the *detection order rule*. Meantime, we define that each entity region in the sequence can only be tagged once with the same entity type, referred to as the *non-duplicate rule*. For instance, in Figure 2, "interleukin-2" is tagged first while "interleukin-2 receptor alpha gene" is subsequently tagged following the above two rules. When assigning the label *O* to non-entity regions, we only follow the detection order rule. As a result, two gold label sequences {O, B-Protein, O, O, O, O} and {O, B-DNA, I-DNA, I-DNA, I-DNA, O} are assigned to the given word sequence "Mouse interleukin-2 receptor alpha gene expression" as shown in Figure 2. With these rules, the number of labels for each word equals the nested level of entities in the given word sequence.

We employ mini-batch training and update the model parameters using back-propagation through time (BPTT) (Werbos, 1990) with Adam (Kingma and Ba, 2014). The model parameters include weights, bias, transition costs, and embeddings of characters. We disable updating the word embeddings.[2] During training, early stopping, L2-regularization and dropout (Hinton et al., 2012) are used to prevent overfitting. Dropout is employed to the input of each flat NER layer. Hyperparameters including batch size, number of hidden units in LSTM, character dimensions, dropout rate, Adam learning rate, gradient clipping and weight decay (L2) are all tuned with Bayesian optimization (Snoek et al., 2012).

3 Evaluation Settings

We employed three datasets for evaluation: GENIA[3] (Kim et al., 2003), ACE2005[4] (Walker et al., 2006) and JNLPBA[5] (Kim et al., 2004). We briefly explain the data and task settings and then introduce model and experimental settings.

3.1 Data and Task Settings

We performed nested entity extraction experiments on GENIA and ACE2005 while we conducted flat entity extraction on the JNLPBA dataset. For the details of data statistics and preprocessing, please refer to the supplementary materials.

GENIA involves 36 fine-grained entity categories among total 2,000 MEDLINE abstracts. Following the same task settings as in Finkel and Manning (2009) and Lu and Roth (2015), we collapsed all DNA subcategories as DNA. The same setting was applied to RNA, protein, cell line and cell type categories. We used same test portion as Finkel and Manning (2009), Lu and Roth (2015) and Muis and Lu (2017) for the direct comparison.

ACE2005 contains 7 fine-grained entity categories. We made same modifications described in Lu and Roth (2015) and Muis and Lu (2017) by keeping files from bn, bw, nw and wl and spitting them into training, development and testing datasets at random following same ratio 8:1:1, respectively.

JNLPBA defines both training and testing datasets. These two datasets are composed of 2,000 and 404 MEDLINE abstracts, respectively. JNLPBA is originally from the GENIA corpus. However, only flat and topmost entities in JNLPBA are kept while nested and discontinuous entities are removed. Like our preprocessing on the GENIA corpus, subcategories are collapsed and only 5 entity types are finally reserved. We randomly chose the 90% sentences of the original training dataset as our training dataset and the remaining as our development dataset.

Precision (P), recall (R) and F-score (F) were used for the evaluation metrics in our tasks. We define that if the numbers of gold entities and predictions are all zeros, the evaluation metrics all equal one hundred percent.

3.2 Model and Experimental Settings

Our model was implemented with Chainer[6] (Tokui et al., 2015). We initialized word embeddings in GENIA and JNLPBA with the pretrained embeddings trained on MEDLINE abstracts (Chiu et al., 2016). For ACE2005, we initialized each word with the pretrained embeddings which are trained by Miwa and Bansal (2016). Except for the word embeddings, parameters of word embeddings were initialized with a normal distribution. For LSTM, we initialized hidden states, cell state and all the bias terms as 0 except for the forget gate

[2] We tried updating and disabling updating word embeddings. The former trial did not work.

[6] https://chainer.org/

bias that was set as 1. For other hyper-parameters, we chose the best hyper-parameters via Bayesian optimization. We refer the readers to the supplemental material for the settings of the hyper-parameters of the models and Bayesian optimization.

For ablation tests, we compared with our layered-BiLSTM-CRF model with two models that produce the input for next flat NER layer in different ways. The first model is called *layered-BiLSTM-CRF w/o layered out-of-entities* which uses the input of the current flat NER layer for out-of-entity words. We name the second model as *layered-BiLSTM-CRF w/o layered LSTM* as it skips all intermediate LSTM layers and only uses output of embedding layer to build the input for the next flat NER layer. Please refer to supplemental material for the introduced two models.[7]

To investigate the effectiveness of our model on different nested levels of entities, we evaluated the model performance on each flat NER layer on GENIA and ACE2005 test datasets.[8] When calculating precision and recall measurements, we collected the predictions and gold entities from the corresponding flat NER layer. Since predicted entities on a specific flat NER layer might be from other flat NER layers, we defined extended precision (EP), extended recall (ER) and extended F-score (EF) to measure the performance. We calculated EP by comparing the predicted entities in a specific flat NER layer with all the gold entities, and ER by comparing the gold entities in a specific flat NER layer with all the predicted entities. EF was calculated in the same way with F.

In addition to experiments on nested GENIA and ACE2005 datasets, flat entity recognition was conducted on the JNLPBA dataset. We trained our flat model that only kept the first flat NER layer and removed the following stacking layers. We follow the hyper-parameters settings by Lample et al. (2016) for this evaluation.

[7]We examined the contributions of predicted labels of the current flat NER layer to the next flat NER layer. For this, we introduced label embeddings into each test by combining the embedding with context representation. Experiments show that appending label embedding hurts the performance of our model while gain slight improvements in the rest 2 models on development datasets.

[8]We removed entities which were predicted in previous flat NER layers during evaluation.

4 Results and Analysis

4.1 Nested NER

Table 1 presents the comparisons of our model with related work including the state-of-the-art feature-based model by Muis and Lu (2017). Our model outperforms the state-of-the-art models with 74.7% and 72.2% in terms of F-score, achieving the new state-of-the-art in the nested NER tasks. For GENIA, our model gained more improvement in terms of recall with enabling extract more nested entities without reducing precision. On ACE2005, we improved recall with 12.2 percentage points and obtained 5.1% relative error reductions. Compared with GENIA, our model gained more improvements in ACE2005 in terms of F-score. Two possible reasons account for it. One reason is that ACE2005 contains more deeper nested entities (maximum nested level is 5) than GENIA (maximum nested level is 3) on the test dataset. This allows our model to capture the potentially 'nested' relations among nested entities. The other reason is that ACE2005 has more nested entities (37.45%) compared with GENIA (21.56%).

Table 2 shows the results of models on the development datasets of GENIA and ACE2005, respectively. From this table, we can see that our model, which only utilizes context representation for preparation of input for the next flat NER layer, performs better than the rest two models. This demonstrates that introducing input of the current flat NER layer such as skipping either representation for any non-entity or words or all intermediate LSTM layers hurts performance. Compared with the layered-BiLSTM-CRF model, the drop of the performance in the layered-BiLSTM-CRF w/o layered out-of-entities model reflects the skip of representation for out-of-entity words leads to the decline in performance. This is because the representation of non-entity words didn't incorporate the current context representation as we used the input rather than the output to represent them. By analogy, the layered BiLSTM-CRF w/o layer LSTM model skips representation for both entities and non-entity words, resulting in worse performance. This is because, when skipping all intermediate LSTM layers, input of the first flat NER layer, i.e., word embeddings, is passed to the remaining flat NER layers. Since word embeddings do not contain context representation, we fail to incorporate the context representation when we use

the word embeddings as the input for the flat NER layers. Therefore, we have no chance to take advantage of the context representation and instead we only manage to use the word embeddings as the input for flat NER layers in this case.

Table 3 and Table 4 describe the performance for each entity type in GENIA and ACE2005 test datasets, respectively. In GENIA, our model performed best in recognizing entities with type *RNA*. This is because most of the entities pertaining to *RNA* mainly end up either with "mRNA" or *RNA*. These two words are informative indicators of *RNA* entities. For entities in rest entity types, their performances are close to the overall performance. One possible reason is that there are many instances to model them. This also accounts for the high performances of entity types such as *PER*, *GPE* in ACE2005. The small amounts of instances of entity types like *FAC* in ACE2005 is one reason for their under overall performances. We refer readers to supplemental material for statistics details.

When evaluating our model on top level which contains only outermost entities, the precision, recall and F-score were 78.19%, 75.17% and 76.65% on GENIA test dataset. For ACE2005, the corresponding precision, recall and F-score were 68.37%, 68.57% and 68.47%. Compared with the overall performance listed in Table 1, we obtained higher top level performance on GENIA but lower performance in ACE2005. We discuss details of this phenomena in the following tables.

Table 5 shows the performances of each flat NER layer in GENIA test dataset. Among all the stacking flat NER layers, our model resulted in the best performance regarding standard evaluation metrics on the first flat NER layer which contains the predictions for the gold innermost entities. When the model went to deeper flat NER layers, the performance dropped gradually as the number of gold entities decreased. However, the performance for predictions on each flat

Layer	P (%)	R (%)	F (%)	EP (%)	ER (%)	EF (%)	#Predictions	#Gold Entities
Layer 1	72.86	69.82	71.31	78.46	71.06	74.57	4,783	4,991

Layer 5	0.00	0.00	0.00	0.00	0.00	0.00	0	1

Table 6: Results of layer evaluation on ACE2005 test dataset.

NER layer was different in terms of extended evaluation metrics. For the first two flat NER layers, performance of extended evaluation is better than the performance of standard evaluation. It indicates that gold entities correspond to some of the predictions on the specific flat NER layer are from other flat NER layers. This may lead to the zero performances for the last flat NER layer. In addition, performance on the second flat NER layer was higher than it was on the first flat NER layer in terms of extended F-score. This demonstrates that our model is able to obtain higher performance on top level of entities than innermost entities.

Table 6 lists the results of each flat NER layer on ACE2005 test dataset. Similar to GENIA, the first flat NER layer achieved better performance than the rest flat NER layers. Performances decreased in a bottom-to-up manner regarding model architecture. This phenomena was the same with the extended evaluation performances, which reflects that some of the predictions in a specific flat NER layer were detected in other flat NER layers. Unlike rising tendency (except last flat NER layer) regarding extend F-score in GENIA, performance in ACE2005 was in downtrend. This accounts for the fact that F-score on top level was lower than it on the fist flat NER layer. Even though the decline trend in extended F-score, the first flat NER layer contained the largest proportion of predictions for the gold entities, the overall performance on all nested entities showed in Table 1 was still high. Unlike GENIA, our model in ACE2005 stopped before reaching the maximum nested level of entities. It indicates our model failed to model the appropriate nested levels. This is one of the reasons that account for the zero predictions on the last flat NER layer. One reason is that our model The sparse instances on the high nested levels could be another reason that resulted in the zero performances on the last flat NER layer.

4.2 Flat NER

Compared with the state-of-the-art work on JNLPBA (Gridach, 2017) which achieved 75.87% in terms of F-score, our model obtained 75.55% in F-score. Since both the model by Gridach (2017) and our flat model are based on Lample et al. (2016), so it is reasonable that both models were able to get comparable performance.

4.3 Error analysis

We showed the error types and their statistics both for all nested entities and each flat NER layer on GENIA and ACE2005 test datasets. From ACE2005 test dataset, 28% of predictions were incorrect in 200 sentences which were selected at random. Among these errors, 39% of them were because their text spans were assigned with other entity types. We call this type of errors *type error*. The main reason is that most of them are pronouns and co-refer to other entities which are absent in the sentence. Taking this sentence "whether that is true now, we can not say" as an example, "we" is annotated as *ORG* while our model labeled it as *PER*. Lack of context information such as the absence of co-referent entities leads our model to make the wrong decisions. In addition, 30% of the errors were caused by that incorrect predictions were predicted as only parts of gold entities with correct entity types. This error type is referred to as *partial prediction error*. This might be due to these gold entities tend to clauses or inde-

pendent sentences, thus possibly containing many modifiers. For example, in this sentence "A man who has been to Baghdad many times and can tell us with great knowledge exactly what it's going to be like to fight on those avenues in that sprawling city of Baghdad - Judy .", "A man who has been to Baghdad many times and can tell us with great knowledge exactly what it's going to be like to fight on those avenues in that sprawling city of Baghdad" is annotated as *PER* while our model could only extract "A man who has been to Baghdad many times" and predicted it as *PER*.

Errors on the first flat NER layer, we got 41% in type error and 11% of partial prediction error, respectively. Apart from this, our model recognized predictions from other flat NER layers, leading to 5% errors. We define this error type as *layer error*. Unlike the first flat NER layer, 26% of errors were caused by layer error. Additionally, 17% of the errors belong to type error. In particular, 22% errors were due to the type error. As for the last flat NER layer, 40% errors were caused by partial prediction error. The rest errors were different from the mentioned error types. One possible reason is that we have less gold entities to train this flat NER layer compared with previous flat NER layers. Another reason might be the error propagation.

Similarly, 200 sentences were randomly selected from GENIA test dataset. We got 20% errors of predictions in the subset. Among these errors, 17% and 24% of errors were separately due to type error and partial prediction error. In addition, 24% of the predictions on the first flat NER layer were incorrect. Among them, the top error types were layer error, partial prediction error and type error, accounting for 21%, 18% and 13%, respectively. Errors on the second flat NER layer were mainly caused by type error and the and partial prediction error.

5 Related Work

The success of neural networks has boosted the performance of flat named NER in different domains (Lample et al., 2016; Ma and Hovy, 2016; Gridach, 2017; Strubell et al., 2017). Such models achieved the state of the art without any handcrafted features and external knowledge resources.

Contrary to flat NER, much fewer attempts have emphasized the nested entity recognition. Existing approaches to nested NER (Shen et al., 2003; Alex et al., 2007; Finkel and Manning, 2009; Lu and Roth, 2015; Xu and Jiang, 2016; Muis and Lu, 2017) mainly rely on hand-crafted features. They also failed to take advantage of the dependencies among nested entities. Our model enables capturing dependencies and automatic learning high-level abstract features from texts.

Early work regarding nested NER involve mainly hybrid systems that combined rules with supervised learning algorithms. For example, Shen et al. (2003), Zhou et al. (2004) and Zhang et al. (2004) employed a Hidden Markov Model to GENIA to extract inner entities and then used rule-based methods to obtain the outer entities. Furthermore, Gu (2006) extracted nested entities based on SVM which were trained separately on both inner entities and outermost entities without putting the hidden relations between nested entities into consideration. All these methods failed to capture the dependencies between nested entities. One trial work is that Alex et al. (2007) separately built a inside-out and outside-in layered CRFs which were able to use the current guesses as the input for next layer. They also cascaded separate CRFs of each entity type by using output from previous CRFs as features of current CRFs, yielding best performance in their work. One of the main drawbacks in the cascading approach was that it failed to handle nested entities sharing the same entity type, which were quite common in natural languages.

Finkel and Manning (2009) proposed a discriminative constituency tree to represent each sentence where the root node was used for connection. All entities were treated as phrases and represented as subtrees following the whole tree structure. Unlike our linguistic features independent model, Finkel and Manning (2009) used a CRF-based approach driven by entity-level features to detect nested entities

Later on, Lu and Roth (2015) built hyper-graphs that allow edges to connect multiple nodes to represent both the nested entities and their references (a.k.a. mentions). One issue in their approach is the spurious structures of hyper-graphs as they enumerate combinations of nodes, types and boundaries to represent entities. In addition, they fail to encode the dependencies among embedded entities using hyper-graphs. In contrast, our model enables nested entity representation by merging representation of multiple tokens composed in the entity and considers it as the longer

entity representation. This allows us to represent outer entities based on inner entity representation, thus managing to capture the relations between inner and outer entities, and hence overcoming the spurious entity structure problem.

As an improvement in overcoming spurious structure issue in Lu and Roth (2015), Muis and Lu (2017) further incorporated mention separators along with features to yield better performance on nested entities. Both Lu and Roth (2015) and Muis and Lu (2017) rely on hand-crafted features to extract nested entities without incorporating hidden dependencies in nested entities. In contrast, we make the most of dependencies of nested entities in our model to encourage outer entity recognition by automatic learning of high-level and abstract features from sequences.

Shared tasks dealing with nested entities like SemEval-2007 Task 9[9] and GermEval-2014[10] were held in order to advance the state-of-the-art on this issue. Additionally, as subtasks in KBP 2015[11] and KBP 2016[12], one of the aims in tri-lingual Entity Discovery and Linking Track (EDL) track was extracting nested entities from textual documents varying from English, Chinese and Spanish. Following this task, Xu and Jiang (2016) firstly developed a new tagging scheme which is based on fixed-size ordinally-forgetting encoding (FOFE) method for text fragment representation. All the entities along their contexts were represented using this novel tagging scheme. Different from the extensively used LSTM-RNNs in sequence labeling task, a feed-forward neural network was used to predict labels on entity level for each fragment in any of given sequences. Additionally, Li et al. (2017) used the model proposed in Lample et al. (2016) to the extract both flat entities and components composed in nested and discontinuous entities. Another BiLSTM was applied to combine the components to get nested and discontinuous entities. However, these methods failed to capture and utilize the inner entity representation to facilitate outer entity detection.

6 Conclusion

This paper presented a dynamic layered model which takes full advantage of inner entity information to encourage outer entity recognition in an end-to-end manner. Our model is based on a flat NER layer consisting of LSTM and CRF, so our model is able to capture context representation of input sequences and globally decode predicted labels at a flat NER layer without relying on feature-engineering. Our model automatically stacks the flat NER layers with sharing the parameters of LSTM and CRF in the layers. The stacking continues until the current flat NER layer predicts sequences as all outside of entities, which enables stopping dynamically stacked flat NER layers. Each flat NER layer receives the merged context representation as input for outer entity recognition, based on the predicted entities from the previous flat NER layer. With this dynamic end-to-end model, our model is able to outperform existing models, achieving the-state-of-art on two nested NER tasks. In addition, the model can be flexibly simplified as a flat NER model by removing components cascaded after the first NER layer.

Extensive evaluation shows that utilization of inner entities significantly encourages outer entities detection with improvements of 3.9 and 9.1 percentage points in F-score on GENIA and ACE2005, respectively. Additionally, utilization of only current context representation contributes to the performance improvement than use of context representation from multi-layers.

A Data Statistics and Preprocessing

Statistics of GENIA, ACE2005 and JNLPBA are described in Tables 7, 8 and 9, respectively.

We used NERSuite (Cho et al., 2010) for GENIA to perform tokenization while Stanford CoreNLP (Manning et al., 2014) was used for ACE2005. The JNLPBA dataset has already been went through tokenization and sentence splitting, so we did not apply any preprocessing.

For GENIA, we had to manually revolve the following two issues, in addition to the above preprocessing.

One of the issues we had in this corpus is the removal of discontinuous entities during parsing. In provided GENIA XML file, each flat entity is annotated with 'lex' (lexical) and 'sem' (semantics) attributes while discontinuous and nested entities may have none, one or two attributes when these entities embed with each other, making it difficult to extract the strictly nested ones. Taken the text "recombinant human nm23-H1, -H2, mouse nm23-M1, and -M2 proteins" as an example, there are six discontinuous entities, "recombinant human nm23-H1 protein", "recombinant human H2 protein", "recombinant mouse nm23-M1 protein", "recombinant mouse nm23-M2 protein", "mouse nm23-M2" and "human nm23-H2", and two nested entities, "mouse nm23-M1" and "human nm23-H1". We extract these nested entities based on symbol * appeared 'lex' attribute which

is an connection indicator of the separated texts in discontinuous entities. Meanwhile, each of the separated texts has no 'sem' attribute unless itself is an innermost entity. Unfortunately, there are some inconsistent cases such as "c-fos and c-jun transcripts" where symbol * should be in the 'lex' attribute as the discontinuous entity "c-fos transcript" is connected by "c-fos" and "transcript" while "c-jun transcript" is connected by "c-jun" and "transcript". These two entities share the same text "transcript". However, each of them is annotated with two attributes: 'lex' and 'sem', following the same annotation for flat entities. Although it is possible to ignore the latter entity based on 'lex' attribute and its belonging sentence, this rule fails to deal with entity "c-jun gene" in the example of "c-fos and c-jun genes" as the 'lex' of "c-jun gene" is mistaken as "c-jun genes". Therefore, in this case, we ignored "c-fos transcript" and instead kept the "c-jun transcripts" as a flat entity.

Another issue is the incomplete tokenization. The label assignment to one word was conducted on the word-level instead of character level, but there are entities that correspond to parts of words. An example is "NF-YA subunit", which contains two protein entities: "NF-Y" and "A subunit". To cope with this problem, we treat both two entities as false negative entities in training dataset as there are only 13 such entities in the training data set.

B Bayesian Optimization Setting

The hyper-parameters which were tuned for our model are listed in Table 10 and Table 11. These hyper-parameters are tuned by Bayesian optimization with the hyper parameters listed in Table 12.

C Model Structure

Figure 4 shows the model architecture when we skip all intermediate LSTM layers and only word embeddings are used to produce the input for the next flat NER layer.

Figure 5 describes the model architecture when we skip the representation of non-entity words to prepare the input for the next flat NER layer. Concretely, we merge and average representation following Equation 1. For the predicted non-entity words, however, we skip the LSTM layer and directly use their corresponding representation from the input rather than the output context representation.

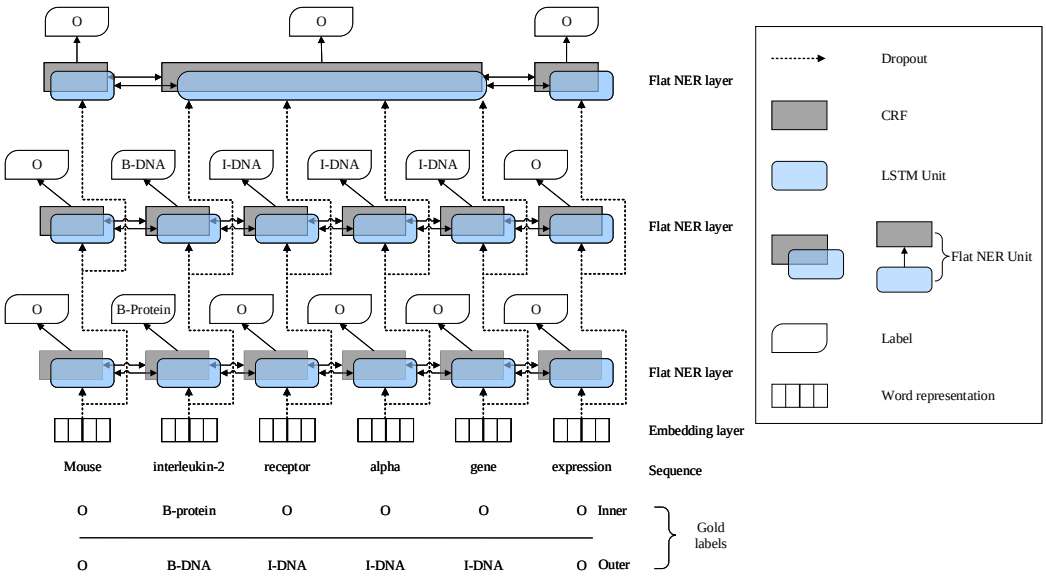

Figure 4: Overview of the model architecture with skipping representation for non-entity words. “interleukin-2” and “interleukin-2 receptor alpha gene” are nested entities.

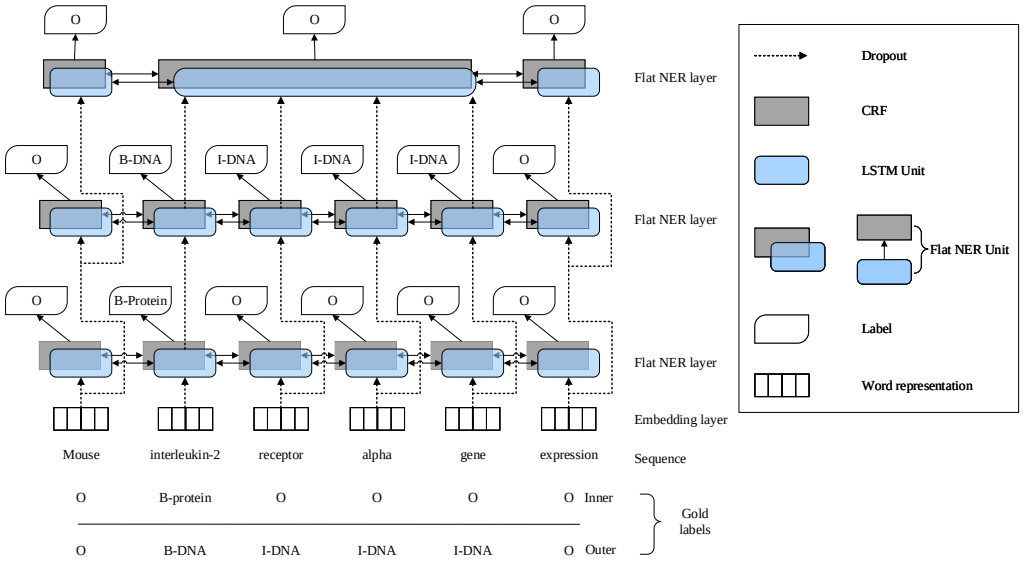

Figure 5: Overview of the model architecture with skipping representation for whole sequence. “interleukin-2” and “interleukin-2 receptor alpha gene” are nested entities.

Abstract

We present a novel deep learning architecture to address the natural language inference (NLI) task. Existing approaches mostly rely on simple reading mechanisms for independent encoding of the premise and hypothesis. Instead, we propose a novel *dependent reading* bidirectional LSTM network (DR-BiLSTM) to efficiently model the relationship between a premise and a hypothesis during encoding and inference. We also introduce a sophisticated ensemble strategy to combine our proposed models, which noticeably improves final predictions. Finally, we demonstrate how the results can be improved further with an additional preprocessing step. Our evaluation shows that DR-BiLSTM obtains the best single model and ensemble model results achieving the new state-of-the-art scores on the Stanford NLI dataset.

1 Introduction

Natural Language Inference (NLI; a.k.a. Recognizing Textual Entailment, or RTE) is an important and challenging task for natural language understanding (MacCartney and Manning, 2008). The goal of NLI is to identify the logical relationship (*entailment*, *neutral*, or *contradiction*) between a premise and a corresponding hypothesis. Table 1 shows few example relationships from the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015).

Recently, NLI has received a lot of attention from the researchers, especially due to the availability of large annotated datasets like SNLI (Bowman et al., 2015). Various deep learning models have been proposed that achieve successful results for this task (Gong et al., 2017; Wang et al., 2017; Chen et al., 2017; Yu and Munkhdalai, 2017a; Parikh et al., 2016; Zhao et al., 2016; Sha et al., 2016). Most of these existing NLI models use attention mechanism to jointly interpret and align the premise and hypothesis. Such models use simple reading mechanisms to encode the premise and hypothesis independently. However, such a complex task require explicit modeling of dependency relationships between the premise and the hypothesis during the encoding and inference processes to prevent the network from the loss of relevant, contextual information. In this paper, we refer to such strategies as *dependent reading*.

P[a]	A senior is waiting at the window of a restaurant that serves sandwiches.	Relationship
H[b]	A person waits to be served his food.	Entailment
	A man is looking to order a grilled cheese sandwich.	Neutral
	A man is waiting in line for the bus.	Contradiction
[a]**P**, Premise. [b]**H**, Hypothesis.		

Table 1: Examples from the SNLI dataset.

There are some alternative reading mechanisms available in the literature (Sha et al., 2016; Rocktäschel et al., 2015) that consider dependency aspects of the premise-hypothesis relationships. However, these mechanisms have two major limitations:

- So far, they have only explored dependency aspects during the encoding stage, while ignoring its benefit during inference.
- Such models only consider encoding a hy-

Proceedings of NAACL-HLT 2018, pages 1460–1469
New Orleans, Louisiana, June 1 - 6, 2018.

pothesis depending on the premise, disregarding the dependency aspects in the opposite direction.

We propose a dependent reading bidirectional LSTM (DR-BiLSTM) model to address these limitations. Given a premise u and a hypothesis v, our model first encodes them considering dependency on each other ($u|v$ and $v|u$). Next, the model employs a soft attention mechanism to extract relevant information from these encodings. The augmented sentence representations are then passed to the inference stage, which uses a similar dependent reading strategy in both directions, i.e. $u \rightarrow v$ and $v \rightarrow u$. Finally, a decision is made through a multi-layer perceptron (MLP) based on the aggregated information.

Our experiments on the SNLI dataset show that DR-BiLSTM achieves the best single model and ensemble model performance obtaining improvements of a considerable margin of 0.4% and 0.3% over the previous state-of-the-art single and ensemble models, respectively.

Furthermore, we demonstrate the importance of a simple preprocessing step performed on the SNLI dataset. Evaluation results show that such preprocessing allows our single model to achieve the same accuracy as the state-of-the-art ensemble model and improves our ensemble model to outperform the state-of-the-art ensemble model by a remarkable margin of 0.7%. Finally, we perform an extensive analysis to clarify the strengths and weaknesses of our models.

2 Related Work

Early studies use small datasets while leveraging lexical and syntactic features for NLI (MacCartney and Manning, 2008). The recent availability of large-scale annotated datasets (Bowman et al., 2015; Williams et al., 2017) has enabled researchers to develop various deep learning-based architectures for NLI.

Parikh et al. (2016) propose an attention-based model (Bahdanau et al., 2014) that decomposes the NLI task into sub-problems to solve them in parallel. They further show the benefit of adding intra-sentence attention to input representations. Chen et al. (2017) explore sequential inference models based on chain LSTMs with attentional input encoding and demonstrate the effectiveness of syntactic information. We also use similar attention mechanisms. However, our model is distinct from these models as they do not benefit from dependent reading strategies.

Rocktäschel et al. (2015) use a word-by-word neural attention mechanism while Sha et al. (2016) propose re-read LSTM units by considering the dependency of a hypothesis on the information of its premise ($v|u$) to achieve promising results. However, these models suffer from weak inferencing methods by disregarding the dependency aspects from the opposite direction ($u|v$). Intuitively, when a human judges a premise-hypothesis relationship, s/he might consider back-and-forth reading of both sentences before coming to a conclusion. Therefore, it is essential to encode the premise-hypothesis dependency relations from both directions to optimize the understanding of their relationship.

Wang et al. (2017) propose a bilateral multi-perspective matching (BiMPM) model, which resembles the concept of matching a premise and hypothesis from both directions. Their matching strategy is essentially similar to our attention mechanism that utilizes relevant information from the other sentence for each word sequence. They use similar methods as Chen et al. (2017) for encoding and inference, without any dependent reading mechanism.

Although NLI is well studied in the literature, the potential of dependent reading and interaction between a premise and hypothesis is not rigorously explored. In this paper, we address this gap by proposing a novel deep learning model (DR-BiLSTM). Experimental results demonstrate the effectiveness of our model.

3 Model

Our proposed model (DR-BiLSTM) is composed of the following major components: input encoding, attention, inference, and classification. Figure 1 demonstrates a high-level view of our proposed NLI framework.

Let $u = [u_1, \cdots, u_n]$ and $v = [v_1, \cdots, v_m]$ be the given premise with length n and hypothesis with length m respectively, where $u_i, v_j \in \mathbb{R}^r$ is an word embedding of r-dimensional vector. The task is to predict a label y that indicates the logical relationship between premise u and hypothesis v.

3.1 Input Encoding

RNNs are the natural solution for variable length sequence modeling, consequently, we utilize a

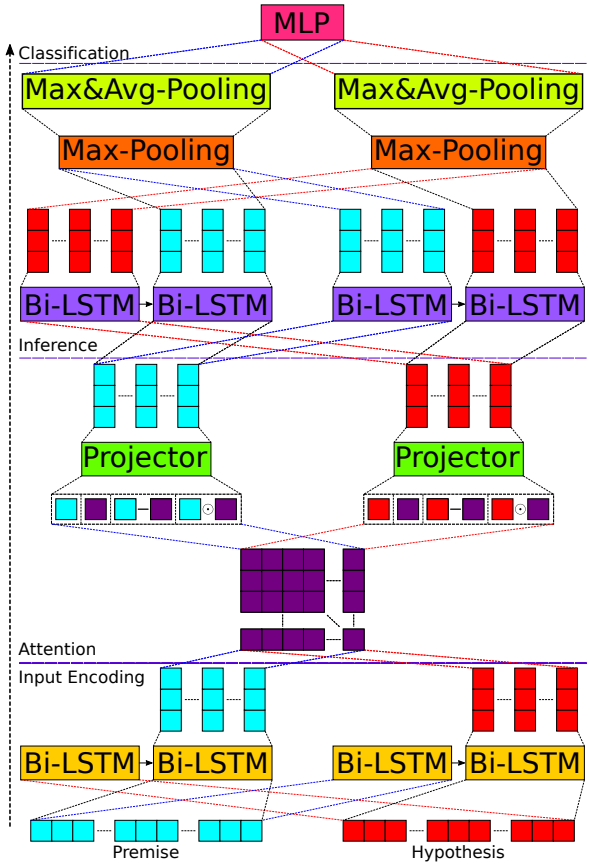

Figure 1: A high-level view of DR-BiLSTM. The data (premise u and hypothesis v, depicted with cyan and red tensors respectively) flows from bottom to top. Relevant tensors are shown with the same color and elements with the same colors share parameters.

bidirectional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) for encoding the given sentences. For ease of presentation, we only describe how we encode u depending on v. The same procedure is utilized for the reverse direction $(v|u)$.

To dependently encode u, we first process v using the BiLSTM. Then we read u through the BiLSTM that is initialized with previous reading final states (memory cell and hidden state). Here we represent a word (e.g. u_i) and its context depending on the other sentence (e.g. v). Equations 1 and 2 formally represent this component.

$$\begin{aligned} \bar{v}, s_v &= \textit{BiLSTM}(v, 0) \\ \hat{u}, - &= \textit{BiLSTM}(u, s_v) \end{aligned} \tag{1}$$

$$\begin{aligned} \bar{u}, s_u &= \textit{BiLSTM}(u, 0) \\ \hat{v}, - &= \textit{BiLSTM}(v, s_u) \end{aligned} \tag{2}$$

where $\{\bar{u} \in \mathbb{R}^{n \times 2d}, \hat{u} \in \mathbb{R}^{n \times 2d}, s_u\}$ and $\{\bar{v} \in \mathbb{R}^{m \times 2d}, \hat{v} \in \mathbb{R}^{m \times 2d}, s_v\}$ are the independent reading sequences, dependent reading sequences, and BiLSTM final state of independent reading of u and v respectively. Note that, "$-$" in these equations means that we do not care about the associated variable and its value. BiLSTM inputs are the word embedding sequences and initial state vectors. $\hat{u}$ and $\hat{v}$ are passed to the next layer as the output of the input encoding component.

The proposed encoding mechanism yields a richer representation for both premise and hypothesis by taking the history of each other into account. Using a max or average pooling over the independent and dependent readings does not further improve our model. This was expected since dependent reading produces more promising and relevant encodings.

3.2 Attention

We employ a soft alignment method to associate the relevant sub-components between the given premise and hypothesis. In deep learning models, such purpose is often achieved with a soft attention mechanism. Here we compute the unnormalized attention weights as the similarity of hidden states of the premise and hypothesis with Equation 3 (energy function).

$$e_{ij} = \hat{u}_i \hat{v}_j^T, \quad i \in [1, n], j \in [1, m] \tag{3}$$

where $\hat{u}_i$ and $\hat{v}_j$ are the dependent reading hidden representations of u and v respectively which are computed earlier in Equations 1 and 2. Next, for each word in either premise or hypothesis, the relevant semantics in the other sentence is extracted and composed according to e_{ij}. Equations 4 and 5 provide formal and specific details of this procedure.

$$\tilde{u}_i = \sum_{j=1}^{m} \frac{\exp(e_{ij})}{\sum_{k=1}^{m} \exp(e_{ik})} \hat{v}_j, \quad i \in [1, n] \tag{4}$$

$$\tilde{v}_j = \sum_{i=1}^{n} \frac{\exp(e_{ij})}{\sum_{k=1}^{n} \exp(e_{kj})} \hat{u}_i, \quad j \in [1, m] \tag{5}$$

where $\tilde{u}_i$ represents the extracted relevant information of $\hat{v}$ by attending to $\hat{u}_i$ while $\tilde{v}_j$ represents the extracted relevant information of $\hat{u}$ by attending to $\hat{v}_j$.

To further enrich the collected attentional information, a trivial next step would be to pass the concatenation of the tuples $(\hat{u}_i, \tilde{u}_i)$ or $(\hat{v}_j, \tilde{v}_j)$ which provides a linear relationship between them. However, the model would suffer from the absence of *similarity* and *closeness* measures. Therefore, we calculate the difference and element-wise product for the tuples $(\hat{u}_i, \tilde{u}_i)$ and $(\hat{v}_j, \tilde{v}_j)$ that represent the similarity and closeness information respectively (Chen et al., 2017; Kumar et al., 2016).

The difference and element-wise product are then concatenated with the computed vectors, $(\hat{u}_i, \tilde{u}_i)$ or $(\hat{v}_j, \tilde{v}_j)$, respectively. Finally, a feed-forward neural layer with ReLU activation function projects the concatenated vectors from $8d$-dimensional vector space into a d-dimensional vector space (Equations 6 and 7). This helps the model to capture deeper dependencies between the sentences besides lowering the complexity of vector representations.

$$\begin{aligned} a_i &= [\hat{u}_i, \tilde{u}_i, \hat{u}_i - \tilde{u}_i, \hat{u}_i \odot \tilde{u}_i] \\ p_i &= \textit{ReLU}(W_p a_i + b_p) \end{aligned} \tag{6}$$

$$\begin{aligned} b_j &= [\hat{v}_j, \tilde{v}_j, \hat{v}_j - \tilde{v}_j, \hat{v}_j \odot \tilde{v}_j] \\ q_j &= \textit{ReLU}(W_p b_j + b_p) \end{aligned} \tag{7}$$

Here $\odot$ stands for element-wise product while $W_p \in \mathbb{R}^{8d \times d}$ and $b_p \in \mathbb{R}^d$ are the trainable weights and biases of the projector layer respectively.

3.3 Inference

During this phase, we use another BiLSTM to aggregate the two sequences of computed matching vectors, p and q from the attention stage (Section 3.2). This aggregation is performed in a sequential manner to avoid losing effect of latent variables that might rely on the sequence of matching vectors.

Instead of aggregating the sequences of matching vectors individually, we propose a similar dependent reading approach for the inference stage. We employ a BiLSTM reading process (Equations 8 and 9) similar to the input encoding step discussed in Section 3.1. But rather than passing just the dependent reading information to the next step, we feed both independent reading ($\bar{p}$ and $\bar{q}$) and dependent reading ($\hat{p}$ and $\hat{q}$) to a max pooling layer, which selects maximum values from each sequence of independent and dependent readings ($\bar{p}_i$ and $\hat{p}_i$) as shown in Equations 10 and 11. The main intuition behind this architecture is to maximize the inferencing ability of the model by considering both independent and dependent readings.

$$\begin{aligned} \bar{q}, s_q &= \textit{BiLSTM}(q, 0) \\ \hat{p}, - &= \textit{BiLSTM}(p, s_q) \end{aligned} \tag{8}$$

$$\begin{aligned} \bar{p}, s_p &= \textit{BiLSTM}(p, 0) \\ \hat{q}, - &= \textit{BiLSTM}(q, s_p) \end{aligned} \tag{9}$$

$$\tilde{p} = \textit{MaxPooling}(\bar{p}, \hat{p}) \tag{10}$$

$$\tilde{q} = \textit{MaxPooling}(\bar{q}, \hat{q}) \tag{11}$$

Here $\{\bar{p} \in \mathbb{R}^{n \times 2d}, \hat{p} \in \mathbb{R}^{n \times 2d}, s_p\}$ and $\{\bar{q} \in \mathbb{R}^{m \times 2d}, \hat{q} \in \mathbb{R}^{m \times 2d}, s_q\}$ are the independent reading sequences, dependent reading sequences, and BiLSTM final state of independent reading of p and q respectively. BiLSTM inputs are the word embedding sequences and initial state vectors.

Finally, we convert $\tilde{p} \in \mathbb{R}^{n \times 2d}$ and $\tilde{q} \in \mathbb{R}^{m \times 2d}$ to fixed-length vectors with pooling, $U \in \mathbb{R}^{4d}$ and $V \in \mathbb{R}^{4d}$. As shown in Equations 12 and 13, we employ both max and average pooling and describe the overall inference relationship with concatenation of their outputs.

$$U = [\textit{MaxPooling}(\tilde{p}), \textit{AvgPooling}(\tilde{p})] \tag{12}$$

$$V = [\textit{MaxPooling}(\tilde{q}), \textit{AvgPooling}(\tilde{q})] \tag{13}$$

3.4 Classification

Here, we feed the concatenation of U and V ($[U, V]$) into a multilayer perceptron (MLP) classifier that includes a hidden layer with *tanh* activation and *softmax* output layer. The model is trained in an end-to-end manner.

$$\textit{Output} = \textit{MLP}([U, V]) \tag{14}$$

4 Experiments and Evaluation

4.1 Dataset

The Stanford Natural Language Inference (SNLI) dataset contains $570K$ human annotated sentence pairs. The premises are drawn from the Flickr30k (Plummer et al., 2015) corpus, and then the hypotheses are manually composed for each relationship class (*entailment*, *neutral*, *contradiction*, and -). The "-" class indicates that there is no consensus decision among the annotators, consequently, we remove them during the training and evaluation following the literature. We use the same data split as provided in Bowman et al. (2015) to report comparable results with other models.

4.2 Experimental Setup

We use pre-trained 300-D Glove $840B$ vectors (Pennington et al., 2014) to initialize our word embedding vectors. All hidden states of BiLSTMs during input encoding and inference have 450 dimensions ($r = 300$ and $d = 450$). The weights are learned by minimizing the log-loss on the training data via the Adam optimizer (Kingma and Ba, 2014). The initial learning rate is 0.0004. To avoid overfitting, we use dropout (Srivastava et al., 2014) with the rate of 0.4 for regularization, which is applied to all feedforward connections. During training, the word embeddings are updated to learn effective representations for the NLI task. We use a fairly small batch size of 32 to provide more exploration power to the model. Our observation indicates that using larger batch sizes hurts the performance of our model.

4.3 Ensemble Strategy

Ensemble methods use multiple models to obtain better predictive performance. Previous works typically utilize trivial ensemble strategies by either using majority votes or averaging the probability distributions over the same model with different initialization seeds (Wang et al., 2017; Gong et al., 2017).

By contrast, we use weighted averaging of the probability distributions where the weight of each model is learned through its performance on the SNLI development set. Furthermore, the differences between our models in the ensemble originate from: 1) variations in the number of dependent readings (i.e. 1 and 3 rounds of dependent reading), 2) projection layer activation (*tanh* and *ReLU* in Equations 6 and 7), and 3) different initialization seeds.

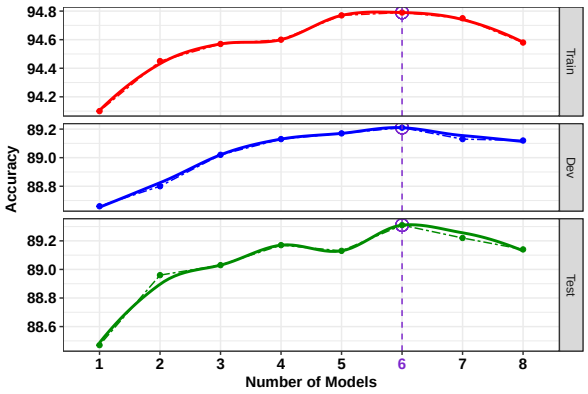

Figure 2: Performance of n ensemble models reported for training (red, top), development (blue, middle), and test (green, bottom) sets of SNLI. For n number of models, the best performance on the development set is used as the criteria to determine the final ensemble. The best performance on development set (89.22%) is observed using 6 models and is henceforth considered as our final DR-BiLSTM (Ensemble) model.

The main intuition behind this design is that the effectiveness of a model may depend on the complexity of a premise-hypothesis instance. For a simple instance, a simple model could perform better than a complex one, while a complex instance may need further consideration toward disambiguation. Consequently, using models with different rounds of dependent readings in the encoding stage should be beneficial.

Figure 2 demonstrates the observed performance of our ensemble method with different number of models. The performance of the models are reported based on the best obtained accuracy on the development set. We also study the effectiveness of other ensemble strategies e.g. majority voting, and averaging the probability distributions. But, our ensemble strategy performs the best among them (see Section 1 in the supplementary material for additional details).

4.4 Preprocessing

We perform a trivial preprocessing step on SNLI to recover some out-of-vocabulary words found in the development set and test set. Note that our vocabulary contains all words that are seen in the training set, so there is no out-of-vocabulary word in it. The SNLI dataset is not immune to human

errors, specifically, misspelled words. We noticed that misspelling is the main reason for some of the observed out-of-vocabulary words. Consequently, we simply fix the unseen misspelled words using Microsoft spell-checker (other approaches like edit distance can also be used). Moreover, while dealing with an unseen word during evaluation, we try to: 1) replace it with its lower case, or 2) split the word when it contains a "-" (e.g. "marsh-like") or starts with "un" (e.g. "unloading"). If we still could not find the word in our vocabulary, we consider it as an *unknown* word. In the next subsection, we demonstrate the importance and impact of such trivial preprocessing (see Section 2 in the supplementary material for additional details).

4.5 Results

Table 2 shows the accuracy of the models on training and test sets of SNLI. The first row represents a baseline classifier presented by Bowman et al. (2015) that utilizes handcrafted features. All other listed models are deep-learning based. The gap between the traditional model and deep learning models demonstrates the effectiveness of deep learning methods for this task. We also report the estimated human performance on the SNLI dataset, which is the average accuracy of five annotators in comparison to the gold labels (Gong et al., 2017). It is noteworthy that recent deep learning models surpass the human performance in the NLI task.

As shown in Table 2, previous deep learning models (rows 2-19) can be divided into three categories: 1) sentence encoding based models (rows 2-7), 2) single inter-sentence attention-based models (rows 8-16), and 3) ensemble inter-sentence attention-based models (rows 17-19). We can see that inter-sentence attention-based models perform better than sentence encoding based models, which supports our intuition. Natural language inference requires a deep interaction between the premise and hypothesis. Inter-sentence attention-based approaches can provide such interaction while sentence encoding based models fail to do so.

To further enhance the modeling of interaction between the premise and hypothesis for efficient disambiguation of their relationship, we introduce the dependent reading strategy in our proposed DR-BiLSTM model. The results demonstrate the effectiveness of our model. DR-BiLSTM (Single) achieves 88.5% accuracy on the test set which is noticeably the best reported result among the existing single models for this task. Note that the difference between DR-BiLSTM and Chen et al. (2017) is statistically significant with a p-value of < 0.001 over the *Chi-square* test[1].

Model	Accuracy	
	Train	Test
(Bowman et al., 2015) (Feature)	99.7%	78.2%
(Bowman et al., 2015)	83.9%	80.6%
(Vendrov et al., 2015)	98.8%	81.4%
(Mou et al., 2016)	83.3%	82.1%
(Bowman et al., 2016)	89.2%	83.2%
(Liu et al., 2016b)	84.5%	84.2%
(Yu and Munkhdalai, 2017a)	86.2%	84.6%
(Rocktäschel et al., 2015)	85.3%	83.5%
(Wang and Jiang, 2016)	92.0%	86.1%
(Liu et al., 2016a)	88.5%	86.3%
(Parikh et al., 2016)	90.5%	86.8%
(Yu and Munkhdalai, 2017b)	88.5%	87.3%
(Sha et al., 2016)	90.7%	87.5%
(Wang et al., 2017) (Single)	90.9%	87.5%
(Chen et al., 2017) (Single)	92.6%	88.0%
(Gong et al., 2017) (Single)	91.2%	88.0%
(Chen et al., 2017) (Ensemble)	93.5%	88.6%
(Wang et al., 2017) (Ensemble)	93.2%	88.8%
(Gong et al., 2017) (Ensemble)	92.3%	88.9%
Human Performance (Estimated)	97.2%	87.7%
DR-BiLSTM (Single)	94.1%	**88.5%**
DR-BiLSTM (Single)+Process	94.1%	**88.9%**
DR-BiLSTM (Ensemble)	94.8%	**89.3%**
DR-BiLSTM (Ensem.)+Process	94.8%	**89.6%**

Table 2: Accuracies of the models on the training set and test set of SNLI. DR-BiLSTM (Ensemble) achieves the accuracy of 89.3%, the best result observed on SNLI, while DR-BiLSTM (Single) obtains the accuracy of 88.5%, which considerably outperforms the previous non-ensemble models. Also, utilizing a trivial preprocessing step yields to further improvements of 0.4% and 0.3% for single and ensemble DR-BiLSTM models respectively.

To further improve the performance of NLI systems, researchers have built ensemble models. Previously, ensemble systems obtained the best performance on SNLI with a huge margin. Table 2 shows that our proposed single model achieves competitive results compared to these reported ensemble models. Our ensemble model considerably outperforms the current state-of-the-art by obtaining 89.3% accuracy.

Up until this point, we discussed the performance of our models where we have not con-

[1]Chi-square test (χ^2 test) is used to determine if there is a significant difference between two categorical variables (i.e. models' outputs).

sidered preprocessing for recovering the out-of-vocabulary words. In Table 2, "DR-BiLSTM (Single) + Process", and "DR-BiLSTM (Ensem.) + Process" represent the performance of our models on the preprocessed dataset. We can see that our preprocessing mechanism leads to further improvements of 0.4% and 0.3% on the SNLI test set for our single and ensemble models respectively. In fact, our single model ("DR-BiLSTM (Single) + Process") obtains the state-of-the-art performance over both reported single and ensemble models by performing a simple preprocessing step. Furthermore, "DR-BiLSTM (Ensem.) + Process" outperforms the existing state-of-the-art remarkably (0.7% improvement). For more comparison and analyses, we use "DR-BiLSTM (Single)" and "DR-BiLSTM (Ensemble)" as our single and ensemble models in the rest of the paper.

4.6 Ablation and Configuration Study

We conducted an ablation study on our model to examine the importance and effect of each major component. Then, we study the impact of BiLSTM dimensionality on the performance of the development set and training set of SNLI. We investigate all settings on the development set of the SNLI dataset.

Model	Dev Acc[a]	p-value
DR-BiLSTM	**88.69%**	-
DR-BiLSTM - hidden MLP	88.45%	<0.001
DR-BiLSTM - average pooling	88.50%	<0.001
DR-BiLSTM - max pooling	88.39%	<0.001
DR-BiLSTM - elem. prd[b]	88.51%	<0.001
DR-BiLSTM - difference	88.24%	<0.001
DR-BiLSTM - diff[c] & elem. prd	87.96%	<0.001
DR-BiLSTM - inference pooling	88.46%	<0.001
DR-BiLSTM - dep. infer[d]	88.43%	<0.001
DR-BiLSTM - dep. enc[e]	88.26%	<0.001
DR-BiLSTM - dep. enc & infer	88.20%	<0.001

[a] Dev Acc, Development Accuracy.
[b] elem. prd, element-wise product.
[c] diff, difference.
[d] dep. infer, dependent reading inference.
[e] dep. enc, dependent reading encoding.

Table 3: Ablation study results. Performance of different configurations of the proposed model on the development set of SNLI along with their p-values in comparison to DR-BiLSTM (Single).

Table 3 shows the ablation study results on the development set of SNLI along with the statistical significance test results in comparison to the proposed model, DR-BiLSTM. We can see that all modifications lead to a new model and their differences are statistically significant with a p-value of < 0.001 over *Chi square* test.

Table 3 shows that removing any part from our model hurts the development set accuracy which indicates the effectiveness of these components. Among all components, three of them have noticeable influences: max pooling, difference in the attention stage, and dependent reading.

Most importantly, the last four study cases in Table 3 (rows 8-11) verify the main intuitions behind our proposed model. They illustrate the importance of our proposed dependent reading strategy which leads to significant improvement, specifically in the encoding stage. We are convinced that the importance of dependent reading in the encoding stage originates from its ability to focus on more important and relevant aspects of the sentences due to its prior knowledge of the other sentence during the encoding procedure.

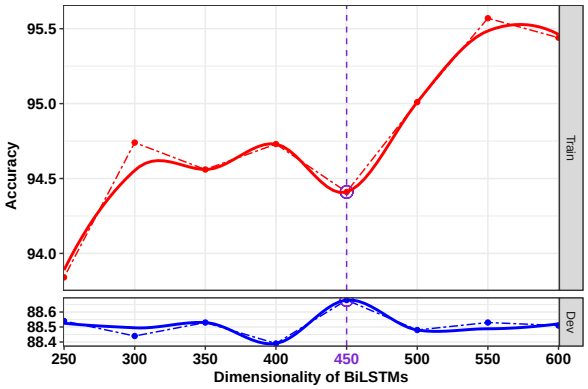

Figure 3: Impact of BiLSTM dimensionality in the proposed model on the training set (red, top) and development set (blue, bottom) accuracies of the SNLI dataset.

Figure 3 shows the behavior of the proposed model accuracy on the training set and development set of SNLI. Since the models are selected based on the best observed development set accuracy during the training procedure, the training accuracy curve (red, top) is not strictly increasing. Figure 3 demonstrates that we achieve the best performance with 450-dimensional BiLSTMs. In other words, using BiLSTMs with lower dimensionality causes the model to suffer from the lack of space for capturing proper information and dependencies. On the other hand, using higher dimensionality leads to overfitting which hurts the performance on the development set. Hence, we use 450-dimensional BiLSTM in our proposed

model.

4.7 Analysis

We first investigate the performance of our models categorically. Then, we show a visualization of the energy function in the attention stage (Equation 3) for an instance from the SNLI test set.

To qualitatively evaluate the performance of our models, we design a set of annotation tags that can be extracted automatically. This design is inspired by the reported annotation tags in Williams et al. (2017). The specifications of our annotation tags are as follows:

- **High Overlap:** premise and hypothesis sentences share more than 70% tokens.
- **Regular Overlap:** sentences share between 30% and 70% tokens.
- **Low Overlap:** sentences share less than 30% tokens.
- **Long Sentence:** either sentence is longer than 20 tokens.
- **Regular Sentence:** premise or hypothesis length is between 5 and 20 tokens.
- **Short Sentence:** either sentence is shorter than 5 tokens.
- **Negation:** negation is present in a sentence.
- **Quantifier:** either of the sentences contains one of the following quantifiers: much, enough, more, most, less, least, no, none, some, any, many, few, several, almost, nearly.
- **Belief:** either of the sentences contains one of the following belief verbs: know, believe, understand, doubt, think, suppose, recognize, forget, remember, imagine, mean, agree, disagree, deny, promise.

Table 4 shows the frequency of aforementioned annotation tags in the SNLI test set along with the performance (accuracy) of ESIM (Chen et al., 2017), DR-BiLSTM (Single), and DR-BiLSTM (Ensemble). Table 4 can be divided into four major categories: 1) gold label data, 2) word overlap, 3) sentence length, and 4) occurrence of special words. We can see that DR-BiLSTM (Ensemble) performs the best in all categories which matches our expectation. Moreover, DR-BiLSTM (Single) performs noticeably better than ESIM in most of the categories except "Entailment", "High Overlap", and "Long Sentence", for which our model is not far behind (gaps of 0.2%, 0.5%, and 0.9%, respectively). It is noteworthy that DR-BiLSTM (Single) performs better than ESIM in more frequent categories. Specifically, the performance of our model in "Neutral", "Negation", and "Quantifier" categories (improvements of 1.4%, 3.5%, and 1.9%, respectively) indicates the superiority of our model in understanding and disambiguating complex samples. Our investigations indicate that ESIM generates somewhat uniform attention for most of the word pairs while our model could effectively attend to specific parts of the given sentences and provide more meaningful attention. In other words, the dependent reading strategy enables our model to achieve meaningful representations, which leads to better attention to obtain further gains on such categories like Negation and Quantifier sentences (see Section 3 in the supplementary material for additional details).

Annotation Tag	Freq[a]	ESIM	DR(S)[b]	DR(E)[c]
Entailment	34.3%	90.0%	89.8%	90.9%
Neutral	32.8%	83.7%	85.1%	85.6%
Contradiction	32.9%	90.0%	90.5%	91.4%
High Overlap	24.3%	91.2%	90.7%	92.1%
Reg. Overlap	33.7%	87.1%	87.9%	88.8%
Low Overlap	45.4%	87.0%	87.8%	88.4%
Long Sentence	6.4%	92.2%	91.3%	91.9%
Reg. Sentence	74.9%	87.8%	88.4%	89.2%
Short Sentence	19.9%	87.6%	88.1%	89.3%
Negation	2.1%	82.2%	85.7%	87.1%
Quantifier	8.7%	85.5%	87.4%	87.6%
Belief	0.2%	78.6%	78.6%	78.6%

[a]Freq, Frequency.
[b]DR(S), DR-BiLSTM (Single).
[c]DR(E), DR-BiLSTM (Ensemble).

Table 4: Categorical performance analyses (accuracy) of ESIM (Chen et al., 2017), DR-BiLSTM (DR(S)) and Ensemble DR-BiLSTM (DR(E)) on the SNLI test set.

Finally, we show a visualization of the normalized attention weights (energy function, Equation 3) of our model in Figure 4. We show a sentence pair, where the premise is "*Male in a blue jacket decides to lay the grass.*", and the hypothesis is "*The guy in yellow is rolling on the grass.*", and its logical relationship is *contradiction*. Figure 4 indicates the model's ability in attending to critical pairs of words like <Male, guy>, <decides, rolling>, and <lay, rolling>. Finally, high attention between {decides, lay} and

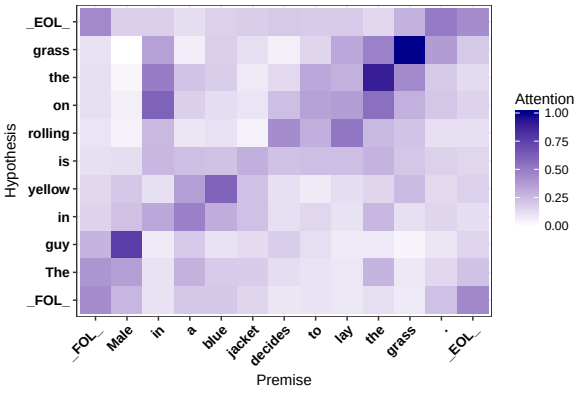

Figure 4: Normalized attention weights for a sample from the SNLI test set. Darker color illustrates higher attention.

{rolling}, and {Male} and {guy} leads the model to correctly classify the sentence pair as *contradiction* (for more samples with attention visualizations, see Section 4 in the supplementary material).

5 Conclusion

We propose a novel natural language inference model (DR-BiLSTM) that benefits from a dependent reading strategy and achieves the state-of-the-art results on the SNLI dataset. We also introduce a sophisticated ensemble strategy and illustrate its effectiveness through experimentation. Moreover, we demonstrate the importance of a simple preprocessing step on the performance of our proposed models. Evaluation results show that the preprocessing step allows our DR-BiLSTM (single) model to outperform all previous single and ensemble methods. Similar superior performance is also observed for our DR-BiLSTM (ensemble) model. We show that our ensemble model outperforms the existing state-of-the-art by a considerable margin of 0.7%. Finally, we perform an extensive analysis to demonstrate the strength and weakness of the proposed model, which would pave the way for further improvements in this domain.

Abstract

We introduce KBGAN, an adversarial learning framework to improve the performances of a wide range of existing knowledge graph embedding models. Because knowledge graphs typically only contain positive facts, sampling useful negative training examples is a non-trivial task. Replacing the head or tail entity of a fact with a uniformly randomly selected entity is a conventional method for generating negative facts, but the majority of the generated negative facts can be easily discriminated from positive facts, and will contribute little towards the training. Inspired by generative adversarial networks (GANs), we use one knowledge graph embedding model as a negative sample generator to assist the training of our desired model, which acts as the discriminator in GANs. This framework is independent of the concrete form of generator and discriminator, and therefore can utilize a wide variety of knowledge graph embedding models as its building blocks. In experiments, we adversarially train two translation-based models, TRANSE and TRANSD, each with assistance from one of the two probability-based models, DISTMULT and COMPLEX. We evaluate the performances of KBGAN on the link prediction task, using three knowledge base completion datasets: FB15k-237, WN18 and WN18RR. Experimental results show that adversarial training substantially improves the performances of target embedding models under various settings.

1 Introduction

Knowledge graph (Dong et al., 2014) is a powerful graph structure that can provide direct access of knowledge to users via various applications such as structured search, question answering, and intelligent virtual assistant. A common representation of knowledge graph beliefs is in the form of a discrete relational triple such as *LocatedIn(NewOrleans,Louisiana)*.

A main challenge for using discrete representation of knowledge graph is the lack of capability of accessing the similarities among different entities and relations. Knowledge graph embedding (KGE) techniques (e.g., RESCAL (Nickel et al., 2011), TRANSE (Bordes et al., 2013), DISTMULT (Yang et al., 2015), and COMPLEX (Trouillon et al., 2016)) have been proposed in recent years to deal with the issue. The main idea is to represent the entities and relations in a vector space, and one can use machine learning technique to learn the continuous representation of the knowledge graph in the latent space.

However, even steady progress has been made in developing novel algorithms for knowledge graph embedding, there is still a common challenge in this line of research. For space efficiency, common knowledge graphs such as Freebase (Bollacker et al., 2008), Yago (Suchanek et al., 2007), and NELL (Mitchell et al., 2015) by default only stores beliefs, rather than disbeliefs. Therefore, when training the embedding models, there is only the natural presence of the positive examples. To use negative examples, a common method is to remove the correct tail entity, and randomly sample from a uniform distribution (Bordes et al., 2013). Unfortunately, this approach is not ideal, because the sampled entity could be completely unrelated to the head and the target relation, and thus the quality of randomly generated negative examples is often poor (e.g, *LocatedIn(NewOrleans,BarackObama)*). Other approach might leverage external ontological constraints such as entity types (Krompaß et al., 2015) to generate negative examples, but such resource does not always exist or accessible.

In this work, we provide a generic solution to improve the training of a wide range of knowl-

Table 1: Some selected knowledge graph embedding models. The four models above the double line are considered in this paper. Except for COMPLEX, all boldface lower case letters represent vectors in $\mathbb{R}^k$, and boldface upper case letters represent matrices in $\mathbb{R}^{k\times k}$. $\mathbf{I}$ is the identity matrix.

edge graph embedding models. Inspired by the recent advances of generative adversarial deep models (Goodfellow et al., 2014), we propose a novel adversarial learning framework, namely, KBGAN, for generating better negative examples to train knowledge graph embedding models. More specifically, we consider probability-based, log-loss embedding models as the generator to supply better quality negative examples, and use distance-based, margin-loss embedding models as the discriminator to generate the final knowledge graph embeddings. Since the generator has a discrete generation step, we cannot directly use the gradient-based approach to back-propagate the errors. We then consider a one-step reinforcement learning setting, and use a variance-reduction REINFORCE method to achieve this goal. Empirically, we perform experiments on three common KGE datasets (FB15K-237, WN18 and WN18RR), and verify the adversarial learning approach with a set of KGE models. Our experiments show that across various settings, this adversarial learning mechanism can significantly improve the performance of some of the most commonly used translation based KGE methods. Our contributions are three-fold:

- We are the first to consider adversarial learning to generate useful negative training examples to improve knowledge graph embedding.
- This adversarial learning framework applies to a wide range of KGE models, without the need of external ontologies constraints.
- Our method shows consistent performance gains on three commonly used KGE datasets.

2 Related Work

2.1 Knowledge Graph Embeddings

A large number of knowledge graph embedding models, which represent entities and relations in a knowledge graph with vectors or matrices, have been proposed in recent years. RESCAL (Nickel et al., 2011) is one of the earliest studies on matrix factorization based knowledge graph embedding models, using a bilinear form as score function. TRANSE (Bordes et al., 2013) is the first model to introduce translation-based embedding. Later variants, such as TRANSH (Wang et al., 2014), TRANSR (Lin et al., 2015) and TRANSD (Ji et al., 2015), extend TRANSE by projecting the embedding vectors of entities into various spaces. DISTMULT (Yang et al., 2015) simplifies RESCAL by only using a diagonal matrix, and COMPLEX (Trouillon et al., 2016) extends DISTMULT into the complex number field. (Nickel et al., 2015) is a comprehensive survey on these models.

Some of the more recent models achieve strong performances. MANIFOLDE (Xiao et al., 2016) embeds a triple as a manifold rather than a point. HOLE (Nickel et al., 2016) employs circular correlation to combine the two entities in a triple. CONVE (Dettmers et al., 2017) uses a convolutional neural network as the score function. However, most of these studies use uniform sampling to generate negative training examples (Bordes et al., 2013). Because our framework is independent of the concrete form of models, all these models can be potentially incorporated into our framework, regardless of the complexity. As a proof of principle, our work focuses on simpler models. Table 1 summarizes the score functions and dimensions of all models mentioned above.

2.2 Generative Adversarial Networks and its Variants

Generative Adversarial Networks (GANs) (Goodfellow et al., 2014) was originally proposed for generating samples in a continuous space such as images. A GAN consists of two parts, the *generator* and the *discriminator*. The generator accepts a noise input and outputs an image. The discriminator is a classifier which classifies images as "true" (from the ground truth set) or "fake" (generated by the generator). When training a GAN, the generator and the discriminator play a minimax game, in which the generator tries to generate "real" images to deceive the discriminator, and the discriminator tries to tell them apart from ground truth images. GANs are also capable of generating samples satisfying certain requirements, such as conditional GAN (Mirza and Osindero, 2014).

It is not possible to use GANs in its original form for generating discrete samples like natural language sentences or knowledge graph triples, because the discrete sampling step prevents gradients from propagating back to the generator. SeqGAN (Yu et al., 2017) is one of the first successful solutions to this problem by using reinforcement learning—It trains the generator using policy gradient and other tricks. IRGAN (Wang et al., 2017) is a recent work which combines two categories of information retrieval models into a discrete GAN framework. Likewise, our framework relies on policy gradient to train the generator which provides discrete negative triples.

The discriminator in a GAN is not necessarily a classifier. Wasserstein GAN or WGAN (Arjovsky et al., 2017) uses a regressor with clipped parameters as its discriminator, based on solid analysis about the mathematical nature of GANs. GoGAN (Juefei-Xu et al., 2017) further replaces the loss function in WGAN with marginal loss. Although originating from very different fields, the form of loss function in our framework turns out to be more closely related to the one in GoGAN.

3 Our Approaches

In this section, we first define two types of training objectives in knowledge graph embedding models to show how KBGAN can be applied. Then, we demonstrate a long overlooked problem about negative sampling which motivates us to propose KBGAN to address the problem. Finally, we dive into the mathematical, and algorithmic details of KBGAN.

3.1 Types of Training Objectives

For a given knowledge graph, let $\mathcal{E}$ be the set of entities, $\mathcal{R}$ be the set of relations, and $\mathcal{T}$ be the set of ground truth triples. In general, a knowledge graph embedding (KGE) model can be formulated as a *score function* $f(h,r,t), h,t \in \mathcal{E}, r \in \mathcal{R}$ which assigns a score to every possible triple in the knowledge graph. The estimated likelihood of a triple to be true depends only on its score given by the score function.

Different models formulate their score function based on different designs, and therefore interpret scores differently, which further lead to various training objectives. Two common forms of training objectives are particularly of our interest:

Marginal loss function is commonly used by a large group of models called translation-based models, whose score function models distance between points or vectors, such as TransE, TransH, TransR, TransD and so on. In these models, smaller distance indicates a higher likelihood of truth, but only qualitatively. The marginal loss function takes the following form:

$$L_m = \sum_{(h,r,t)\in\mathcal{T}} [f(h,r,t) - f(h',r,t') + \gamma]_+ \quad (1)$$

where γ is the margin, $[\cdot]_+ = \max(0,\cdot)$ is the hinge function, and (h',r,t') is a negative triple. The negative triple is generated by replacing the head entity or the tail entity of a positive triple with a random entity in the knowledge graph, or formally $(h',r,t') \in \{(h',r,t)|h' \in \mathcal{E}\} \cup \{(h,r,t')|t' \in \mathcal{E}\}$.

Log-softmax loss function is commonly used by models whose score function has probabilistic interpretation. Some notable examples are RESCAL, DistMult, ComplEx. Applying the softmax function on scores of a given set of triples gives the probability of a triple to be the best one among them: $p(h,r,t) = \frac{\exp f(h,r,t)}{\sum_{(h',r,t')} \exp f(h',r,t')}$. The loss function is the negative log-likelihood of this probabilistic model:

$$L_l = \sum_{(h,r,t)\in\mathcal{T}} -\log \frac{\exp f(h,r,t)}{\sum \exp f(h',r,t')}$$
$$(h',r,t') \in \{(h,r,t)\} \cup Neg(h,r,t) \quad (2)$$

where $Neg(h,r,t) \subset \{(h',r,t)|h' \in \mathcal{E}\} \cup \{(h,r,t')|t' \in \mathcal{E}\}$ is a set of sampled corrupted triples.

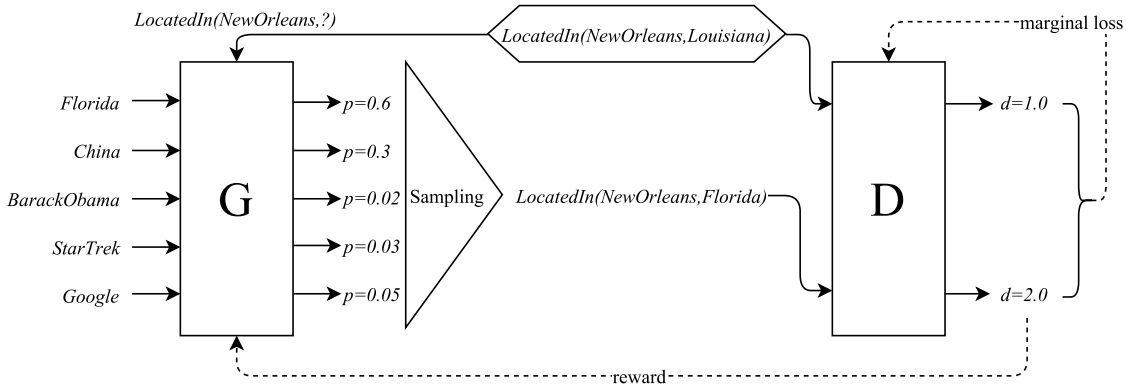

Figure 1: An overview of the KBGAN framework. The generator (G) calculates a probability distribution over a set of candidate negative triples, then sample one triples from the distribution as the output. The discriminator (D) receives the generated negative triple as well as the ground truth triple (in the hexagonal box), and calculates their scores. G minimizes the score of the generated negative triple by policy gradient, and D minimizes the marginal loss between positive and negative triples by gradient descent.

Other forms of loss functions exist, for example ConvE uses a triple-wise logistic function to model how likely the triple is true, but by far the two described above are the most common. Also, softmax function gives an probabilistic distribution over a set of triples, which is necessary for a generator to sample from them.

3.2 Weakness of Uniform Negative Sampling

Most previous KGE models use *uniform negative sampling* for generating negative triples, that is, replacing the head or tail entity of a positive triple with any of the entities in $\mathcal{E}$, all with equal probability. Most of the negative triples generated in this way contribute little to learning an effective embedding, because they are too obviously false.

To demonstrate this issue, let us consider the following example. Suppose we have a ground truth triple *LocatedIn(NewOrleans,Louisiana)*, and corrupt it by replacing its tail entity. First, we remove the tail entity, leaving *LocatedIn(NewOrleans,?)*. Because the relation *LocatedIn* constraints types of its entities, "?" must be a geographical region. If we fill "?" with a random entity $e \in \mathcal{E}$, the probability of e having a wrong type is very high, resulting in ridiculous triples like *LocatedIn(NewOrleans,BarackObama)* or *LocatedIn(NewOrleans,StarTrek)*. Such triples are considered "too easy", because they can be eliminated solely by types. In contrast, *LocatedIn(NewOrleans,Florida)* is a very useful negative triple, because it satisfies type constraints, but it cannot be proved wrong without detailed knowledge of American geography. If a KGE model is fed with mostly "too easy" negative examples, it would probably only learn to represent types, not the underlying semantics.

The problem is less severe to models using log-softmax loss function, because they typically samples tens or hundreds of negative triples for one positive triple in each iteration, and it is likely to have a few useful negatives among them. For instance, (Trouillon et al., 2016) found that a 100:1 negative-to-positive ratio results in the best performance for ComplEx. However, for marginal loss function, whose negative-to-positive ratio is always 1:1, the low quality of uniformly sampled negatives can seriously damage their performance.

3.3 Generative Adversarial Training for Knowledge Graph Embedding Models

Inspired by GANs, we propose an adversarial training framework named KBGAN which uses a KGE model with **softmax probabilities** to provide high-quality negative samples for the training of a KGE model whose training objective is **marginal loss function**. This framework is independent of the score functions of these two models, and therefore possesses some extent of universality. Figure 1 illustrates the overall structure of KBGAN.

In parallel to terminologies used in GAN literature, we will simply call these two models *generator* and *discriminator* respectively in the rest of this paper. We use softmax probabilistic models as the generator because they can adequately model the "sampling from a probability distribu-

Algorithm 1: The KBGAN algorithm

Data: training set of positive fact triples $\mathcal{T} = \{(h, r, t)\}$
Input: Pre-trained generator G with parameters θ_G and score function $f_G(h, r, t)$, and pre-trained discriminator D with parameters θ_D and score function $f_D(h, r, t)$
Output: Adversarially trained discriminator

$b \longleftarrow 0$; // baseline for policy gradient
repeat
  Sample a mini-batch of data $\mathcal{T}_{batch}$ from $\mathcal{T}$;
  $G_G \longleftarrow 0, G_D \longleftarrow 0$; // gradients of parameters of G and D
  $r_{sum} \longleftarrow 0$; // for calculating the baseline
  for $(h, r, t) \in \mathcal{T}_{batch}$ **do**
    Uniformly randomly sample N_s negative triples $Neg(h, r, t) = \{(h'_i, r, t'_i)\}_{i=1...N_s}$;
    Obtain their probability of being generated: $p_i = \frac{\exp f_G(h'_i, r, t'_i)}{\sum_{j=1}^{N_s} \exp f_G(h'_j, r, t'_j)}$;
    Sample one negative triple (h'_s, r, t'_s) from $Neg(h, r, t)$ according to $\{p_i\}_{i=1...N_s}$. Assume its probability to be p_s;
    $G_D \longleftarrow G_D + \nabla_{\theta_D}[f_D(h, r, t) - f_D(h'_s, r, t'_s) + \gamma]_+$; // accumulate gradients for D
    $r \longleftarrow -f_D(h'_s, r, t'_s), r_{sum} \longleftarrow r_{sum} + r$; // r is the reward
    $G_G \longleftarrow G_G + (r - b)\nabla_{\theta_G} \log p_s$; // accumulate gradients for G
  end
  $\theta_G \longleftarrow \theta_G + \eta_G G_G, \theta_D \longleftarrow \theta_D - \eta_D G_D$; // update parameters
  $b \leftarrow r_{sum}/|\mathcal{T}_{batch}|$; // update baseline
until *convergence*;

tion" process of discrete GANs, and we aim at improving discriminators based on marginal loss because they can benefit more from high-quality negative samples. Note that a major difference between GAN and our work is that, the ultimate goal of our framework is to produce a good discriminator, whereas GANS are aimed at training a good generator. In addition, the discriminator here is not a classifier as it would be in most GANs.

Intuitively, the discriminator should assign a relatively small distance to a high-quality negative sample. In order to encourage the generator to generate useful negative samples, the objective of the generator is to minimize the distance given by discriminator for its generated triples. And just like the ordinary training process, the objective of the discriminator is to minimize the marginal loss between the positive triple and the generated negative triple. In an adversarial training setting, the generator and the discriminator are alternatively trained towards their respective objectives.

Suppose that the generator produces a probability distribution on negative triples $p_G(h', r, t'|h, r, t)$ given a positive triple (h, r, t), and generates negative triples (h', r, t') by sampling from this distribution. Let $f_D(h, r, t)$ be the score function of the discriminator. The objective of the discriminator can be formulated as minimizing the following marginal loss function:

$$L_D = \sum_{(h,r,t)\in\mathcal{T}} [f_D(h, r, t) - f_D(h', r, t') + \gamma]_+ \quad (h', r, t') \sim p_G(h', r, t'|h, r, t) \quad (3)$$

The only difference between this loss function and Equation 1 is that it uses negative samples from the generator.

The objective of the generator can be formulated as maximizing the following expectation of negative distances:

$$R_G = \sum_{(h,r,t)\in\mathcal{T}} \mathbb{E}[-f_D(h', r, t')] \quad (h', r, t') \sim p_G(h', r, t'|h, r, t) \quad (4)$$

R_G involves a discrete sampling step, so we cannot find its gradient with simple differentiation. We use a simple special case of Policy Gradient Theorem[1] (Sutton et al., 2000) to obtain the gradient of R_G with respect to parameters of the generator:

$$\begin{aligned}\nabla_G R_G &= \sum_{(h,r,t)\in\mathcal{T}} \mathbb{E}_{(h',r,t')\sim p_G(h',r,t'|h,r,t)} \\ &[-f_D(h', r, t')\nabla_G \log p_G(h', r, t'|h, r, t)] \\ &\simeq \sum_{(h,r,t)\in\mathcal{T}} \frac{1}{N} \sum_{(h'_i,r,t'_i)\sim p_G(h',r,t'|h,r,t), i=1...N} \\ &[-f_D(h', r, t')\nabla_G \log p_G(h', r, t'|h, r, t)] \quad (5)\end{aligned}$$

[1] A proof can be found in the supplementary material

Model	Hyperparameters	Constraints or Regularizations
TRANSE	L_1 distance, $k = 50, \gamma = 3$	$\|\|\mathbf{e}\|\|_2 \leq 1, \|\|\mathbf{r}\|\|_2 \leq 1$
TRANSD	L_1 distance, $k = 50, \gamma = 3$	$\|\|\mathbf{e}\|\|_2 \leq 1, \|\|\mathbf{r}\|\|_2 \leq 1, \|\|\mathbf{e_p}\|\|_2 \leq 1, \|\|\mathbf{r_p}\|\|_2 \leq 1$
DISTMULT	$k = 50, \lambda = 1/0.1$	L2 regularization: $L_{reg} = L + \lambda\|\|\Theta\|\|_2^2$
COMPLEX	$2k = 50, \lambda = 1/0.1$	L2 regularization: $L_{reg} = L + \lambda\|\|\Theta\|\|_2^2$

Table 2: Hyperparameter settings of the 4 models we used. For DISTMULT and COMPLEX, $\lambda = 1$ is used for FB15k-237 and $\lambda = 0.1$ is used for WN18 and WN18RR. All other hyperparameters are shared among all datasets. L is the global loss defined in Equation (2). Θ represents all parameters in the model.

Dataset	#r	#ent.	#train	#val	#test

WN18	18	40,943	141,442	5,000	5,000
WN18RR	11	40,943	86,835	3,034	3,134

Table 3: Statistics of datasets we used in the experiments. "r": relations.

where the second approximate equality means we approximate the expectation with sampling in practice. Now we can calculate the gradient of R_G and optimize it with gradient-based algorithms.

Policy Gradient Theorem arises from reinforcement learning (RL), so we would like to draw an analogy between our model and an RL model. The generator can be viewed as an *agent* which interacts with the *environment* by performing *actions* and improves itself by maximizing the *reward* returned from the environment in response of its actions. Correspondingly, the discriminator can be viewed as the environment. Using RL terminologies, (h, r, t) is the *state* (which determines what actions the actor can take), $p_G(h', r, t'|h, r, t)$ is the *policy* (how the actor choose actions), (h', r, t') is the *action*, and $-f_D(h', r, t')$ is the *reward*. The method of optimizing R_G described above is called REINFORCE (Williams, 1992) algorithm in RL. Our model is a simple special case of RL, called one-step RL. In a typical RL setting, each action performed by the agent will change its state, and the agent will perform a series of actions (called an *epoch*) until it reaches certain states or the number of actions reaches a certain limit. However, in the analogy above, actions does not affect the state, and after each action we restart with another unrelated state, so each epoch consists of only one action.

To reduce the variance of REINFORCE algorithm, it is common to subtract a *baseline* from the reward, which is an arbitrary number that only depends on the state, without affecting the expectation of gradients.[2] In our case, we replace $-f_D(h', r, t')$ with $-f_D(h', r, t') - b(h, r, t)$ in the equation above to introduce the baseline. To avoid introducing new parameters, we simply let b be a constant, the average reward of the whole training set: $b = \sum_{(h,r,t)\in\mathcal{T}} \mathbb{E}_{(h',r,t')\sim p_G(h',r,t'|h,r,t)}[-f_D(h', r, t')]$. In practice, b is approximated by the mean of rewards of recently generated negative triples.

Let the generator's score function to be $f_G(h, r, t)$, given a set of candidate negative triples $Neg(h, r, t) \subset \{(h', r, t)|h' \in \mathcal{E}\} \cup \{(h, r, t')|t' \in \mathcal{E}\}$, the probability distribution p_G is modeled as:

$$p_G(h', r, t'|h, r, t) = \frac{\exp f_G(h', r, t')}{\sum \exp f_G(h^*, r, t^*)} \quad (h^*, r, t^*) \in Neg(h, r, t) \quad (6)$$

Ideally, $Neg(h, r, t)$ should contain all possible negatives. However, knowledge graphs are usually highly incomplete, so the "hardest" negative triples are very likely to be false negatives (true facts). To address this issue, we instead generate $Neg(h, r, t)$ by uniformly sampling of N_s entities (a small number compared to the number of all possible negatives) from $\mathcal{E}$ to replace h or t. Because in real-world knowledge graphs, true negatives are usually far more than false negatives, such set would be unlikely to contain any false negative, and the negative selected by the generator would likely be a true negative. Using a small $Neg(h, r, t)$ can also significantly reduce computational complexity.

Besides, we adopt the "bern" sampling technique (Wang et al., 2014) which replaces the "1" side in "1-to-N" and "N-to-1" relations with higher probability to further reduce false negatives.

Algorithm 1 summarizes the whole adversarial training process. Both the generator and the dis-

[2] A proof of such fact can also be found in the supplementary material

criminator require pre-training, which is the same as conventionally training a single KBE model with uniform negative sampling. Formally speaking, one can pre-train the generator by minimizing the loss function defined in Equation (1), and pre-train the discriminator by minimizing the loss function defined in Equation (2). Line 14 in the algorithm assumes that we are using the vanilla gradient descent as the optimization method, but obviously one can substitute it with any gradient-based optimization algorithm.

4 Experiments

To evaluate our proposed framework, we test its performance for the link prediction task with different generators and discriminators. For the generator, we choose two classical probability-based KGE model, DISTMULT and COMPLEX, and for the discriminator, we also choose two classical translation-based KGE model, TRANSE and TRANSD, resulting in four possible combinations of generator and discriminator in total. See Table 1 for a brief summary of these models.

4.1 Experimental Settings

4.1.1 Datasets

We use three common knowledge base completion datasets for our experiment: FB15k-237, WN18 and WN18RR. FB15k-237 is a subset of FB15k introduced by (Toutanova and Chen, 2015), which removed redundant relations in FB15k and greatly reduced the number of relations. Likewise, WN18RR is a subset of WN18 introduced by (Dettmers et al., 2017) which removes reversing relations and dramatically increases the difficulty of reasoning. Both FB15k and WN18 are first introduced by (Bordes et al., 2013) and have been commonly used in knowledge graph researches. Statistics of datasets we used are shown in Table 3.

4.1.2 Evaluation Protocols

Following previous works like (Yang et al., 2015) and (Trouillon et al., 2016), for each run, we report two common metrics, mean reciprocal ranking (MRR) and hits at 10 (H@10). We only report scores under the *filtered* setting (Bordes et al., 2013), which removes all triples appeared in training, validating, and testing sets from candidate triples before obtaining the rank of the ground truth triple.

4.1.3 Implementation Details

[3] In the pre-training stage, we train every model to convergence for 1000 epochs, and divide every epoch into 100 mini-batches. To avoid overfitting, we adopt early stopping by evaluating MRR on the validation set every 50 epochs. We tried $\gamma = 0.5, 1, 2, 3, 4, 5$ and L_1, L_2 distances for TRANSE and TRANSD, and $\lambda = 0.01, 0.1, 1, 10$ for DISTMULT and COMPLEX, and determined the best hyperparameters listed on table 2, based on their performances on the validation set after pre-training. Due to limited computation resources, we deliberately limit the dimensions of embeddings to $k = 50$, similar to the one used in earlier works, to save time. We also apply certain constraints or regularizations to these models, which are mostly the same as those described in their original publications, and also listed on table 2.

In the adversarial training stage, we keep all the hyperparamters determined in the pre-training stage unchanged. The number of candidate negative triples, N_s, is set to 20 in all cases, which is proven to be optimal among the candidate set of $\{5, 10, 20, 30, 50\}$. We train for 5000 epochs, with 100 mini-batches for each epoch. We also use early stopping in adversarial training by evaluating MRR on the validation set every 100 epochs.

We use the self-adaptive optimization method Adam (Kingma and Ba, 2015) for all trainings, and always use the recommended default setting $\alpha = 0.001, \beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 10^{-8}$.

4.2 Results

Results of our experiments as well as baselines are shown in Table 4. All settings of adversarial training bring a pronounced improvement to the model, which indicates that our method is consistently effective in various cases. TRANSE performs slightly worse than TRANSD on FB15k-237 and WN18, but better on WN18RR. Using DISTMULT or COMPLEX as the generator does not affect performance greatly.

TRANSE and TRANSD enhanced by KBGAN can significantly beat their corresponding baseline implementations, and outperform stronger baselines in some cases. As a prototypical and proof-of-principle experiment, we have never expected state-of-the-art results. Being simple models pro-

[3] The KBGAN source code is available at https://github.com/cai-lw/KBGAN

Method	FB15k-237 MRR	FB15k-237 H@10	WN18 MRR	WN18 H@10	WN18RR MRR	WN18RR H@10

Table 4: Experimental results. Results of KBGAN are results of its discriminator (on the left of the "+" sign). Underlined results are the best ones among our implementations. Results marked with † are produced by running Fast-TransX (Lin et al., 2015) with its default parameters. Results marked with ‡ are copied from (Dettmers et al., 2017). All other baseline results are copied from their original papers.

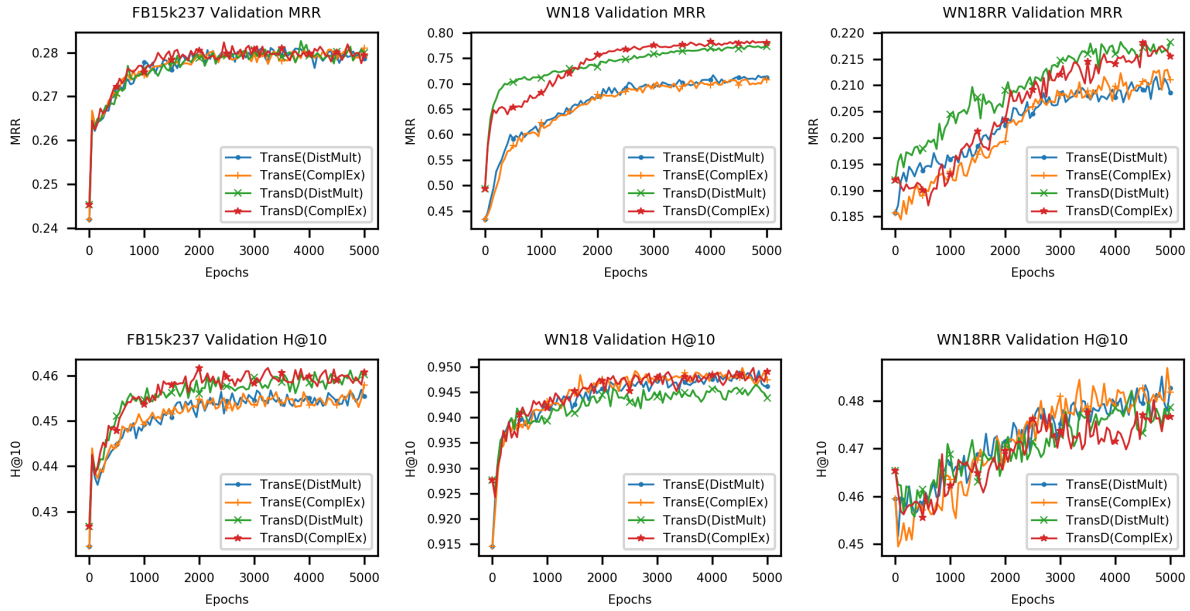

Figure 2: Learning curves of KBGAN. All metrics improve steadily as training proceeds.

posed several years ago, TRANSE and TRANSD has their limitations in expressiveness that are unlikely to be fully compensated by better training technique. In future researches, people may try employing more advanced models into KBGAN, and we believe it has the potential to become state-of-the-art.

To illustrate our training progress, we plot performances of the discriminator on validation set over epochs, which are displayed in Figure 2. As all these graphs show, our performances are always in increasing trends, converging to its maximum as training proceeds, which indicates that KBGAN is a robust GAN that can converge to good results in various settings, although GANs are well-known for difficulty in convergence. Fluctuations in these graphs may seem more prominent than other KGE models, but is considered normal for an adversially trained model. Note that in some cases the curve still tends to rise after 5000 epochs. We do not have sufficient computation resource to train for more epochs, but we believe that they will also eventually converge.

Positive fact	Uniform random sample	Trained generator

Table 5: Examples of negative samples in WN18 dataset. The first column is the positive fact, and the term in bold is the one to be replaced by an entity in the next two columns. The second column consists of random entities drawn from the whole dataset. The third column contains negative samples generated by the generator in the last 5 epochs of training. Entities in italic are considered to have semantic relation to the positive one

4.3 Case study

To demonstrate that our approach does generate better negative samples, we list some examples of them in Table 5, using the KBGAN (TRANSE + DISTMULT) model and the WN18 dataset. All hyperparameters are the same as those described in Section 4.1.3.

Compared to uniform random negatives which are almost always totally unrelated, the generator generates more *semantically* related negative samples, which is different from type relatedness we used as example in Section 3.2, but also helps training. In the first example, two of the five terms are physically related to the process of distilling liquids. In the second example, three of the five entities are geographical objects. In the third example, two of the five entities express the concept of "gather".

Because we deliberately limited the strength of generated negatives by using a small N_s as described in Section 3.3, the semantic relation is pretty weak, and there are still many unrelated entities. However, empirical results (when selecting the optimal N_s) shows that such situation is more beneficial for training the discriminator than generating even stronger negatives.

5 Conclusions

We propose a novel adversarial learning method for improving a wide range of knowledge graph embedding models—We designed a generator-discriminator framework with dual KGE components. Unlike random uniform sampling, the generator model generates higher quality negative examples, which allow the discriminator model to learn better. To enable backpropagation of error, we introduced a one-step REINFORCE method to seamlessly integrate the two modules. Experimentally, we tested the proposed ideas with four commonly used KGE models on three datasets, and the results showed that the adversarial learning framework brought consistent improvements to various KGE models under different settings.

Abstract

An essential step in FrameNet Semantic Role Labeling is the Frame Identification (FrameId) task, which aims at disambiguating a situation around a predicate. Whilst current FrameId methods rely on textual representations only, we hypothesize that FrameId can profit from a richer understanding of the situational context. Such contextual information can be obtained from common sense knowledge, which is more present in images than in text. In this paper, we extend a state-of-the-art FrameId system in order to effectively leverage multimodal representations. We conduct a comprehensive evaluation on the English FrameNet and its German counterpart SALSA. Our analysis shows that for the German data, textual representations are still competitive with multimodal ones. However on the English data, our multimodal FrameId approach outperforms its unimodal counterpart, setting a new state of the art. Its benefits are particularly apparent in dealing with ambiguous and rare instances, the main source of errors of current systems. For research purposes, we release *(a)* the implementation of our system, *(b)* our evaluation splits for SALSA 2.0, and *(c)* the embeddings for synsets and IMAGINED words.[1]

1 Introduction

FrameNet Semantic Role Labeling analyzes sentences with respect to frame-semantic structures based on FrameNet (Fillmore et al., 2003). Typically, this involves two steps: First, Frame Identification (FrameId), capturing the context around a predicate (*frame evoking element*) and assigning a frame, basically a word sense label for a prototypical situation, to it. Second, Role Labeling, i.e. identifying the participants (*fillers*) of the predicate and connecting them with predefined frame-specific role labels. FrameId is crucial to the success of Semantic Role Labeling as FrameId errors account for most wrong predictions in current systems (Hartmann et al., 2017). Consequently, improving FrameId is of major interest.

The main challenge and source of prediction errors of FrameId systems are ambiguous predicates, which can evoke several frames, e.g., the verb *sit* evokes the frame *Change_posture* in a context like *'a person is sitting back on a bench'*, while it evokes *Being_located* when *'a company is sitting in a city'*. Understanding the predicate context, and thereby the context of the situation (here, *'Who / what is sitting where?'*), is crucial to identifying the correct frame for ambiguous cases.

State-of-the-art FrameId systems model the situational context using pretrained distributed word embeddings (see Hermann et al., 2014). Hence, it is assumed that the context of the situation is explicitly expressed in words. However, language understanding involves implicit knowledge, which is not mentioned but still seems obvious to humans, e.g., *'people can sit back on a bench, but companies cannot'*, *'companies are in cities'*. Such implicit common sense knowledge is obvious enough to be rarely expressed in sentences, but is more likely to be present in images. Figure 1 takes the ambiguous predicate *sit* to illustrate

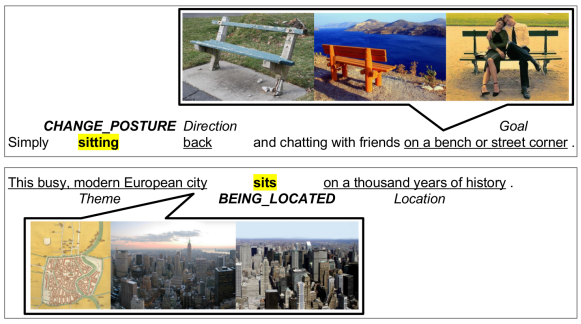

Figure 1: Example sentences demonstrating the potential benefit of images for ambiguous predicates.

how images can provide access to implicit common sense knowledge crucial to FrameId.

When looking at the semantics of events, FrameId has commonalities with event prediction tasks. These aim at linking events and their participants to script knowledge and at predicting events in narrative chains. Ahrendt and Demberg (2016) argue that knowing about the participants helps to identify the event, which suggests the need for implicit context knowledge also for FrameId. This specifically applies to images, which can reflect properties of the participants of a situation in a inherently different way, see Fig. 1.

We analyze whether multimodal representations grounded in images can encode common sense knowledge to improve FrameId. To that end, we extend SimpleFrameId (Hartmann et al., 2017), a recent FrameId model based on distributed word embeddings, to the multimodal case and evaluate for English and German. Note that there is a general lack of evaluation of FrameId systems for languages other than English. This is problematic as they yield different challenges; German, for example, due to long distance dependencies. Also, word embeddings trained on different languages have different strengths in ambiguous words. We elaborate on insights from using different datasets by language.

Contributions. *(1)* We propose a pipeline and architecture of a FrameId system, extending state-of-the-art methods with the option of using implicit multimodal knowledge. It is flexible toward modality and language, reaches state-of-the-art accuracy on English FrameId data, clearly outperforming several baselines, and sets a new state of the art on German FrameId data. *(2)* We discuss properties of language and meaning with respect to implicit knowledge, as well as the potential of multimodal representations for FrameId. *(3)* We perform a detailed analysis of FrameId systems. First, we develop a new strong baseline. Second, we suggest novel evaluation metrics that are essential for assessing ambiguous and rare frame instances. We show our system's advantage over the strong baseline in this regard and by this improve upon the main source of errors. Third, we analyze gold annotated datasets for English and German showing their different strengths. Finally, we release the implementation of our system, our evaluation splits for SALSA 2.0, and the embeddings for synsets and IMAGINED words.

2 Related Work

2.1 Frame identification

State-of-the-art FrameId systems rely on pretrained word embeddings as input (Hermann et al., 2014). This proved to be helpful: those systems consistently outperform the previously leading FrameId system SEMAFOR (Das et al., 2014), which is based on a handcrafted set of features. The open source neural network-based FrameId system SimpleFrameId (Hartmann et al., 2017) is conceptually simple, yet yields competitive accuracy. Its input representation is a concatenation of the predicate's pretrained embedding and an embedding of the predicate context. The dimension-wise mean of the pretrained embeddings of all words in the sentence is taken as the context. In this work, we first aim at improving the representation of the predicate context using multimodal embeddings, and second at assessing the applicability to another language, namely German.

Common sense knowledge for language understanding. Situational background knowledge can be described in terms of frames (Fillmore, 1985) and scripts (Schank and Abelson, 2013). Ahrendt and Demberg (2016) report that knowing about a script's participants aids in predicting events linked to script knowledge. Transferring this insight to FrameId, we assume that a rich context representation helps to identify the sense of ambiguous predicates. Addressing ambiguous predicates where participants have different properties depending on the context, Feizabadi and Padó (2012) give some examples where the location plays a discriminating role as participant: motion verbs that have both a concrete motion sense and a more abstract sense in the cognitive domain, e.g., *struggle*, *lean*, *follow*.

Frame identification in German. Shalmaneser (Erk and Pado, 2006) is a toolbox for semantic role assignment on FrameNet schemata of English and German (integrated into the SALSA project for German). Shalmaneser uses a Naive Bayes classifier to identify frames, together with features for a bag-of-word context with a window over sentences, bigrams, and trigrams of the target word and dependency annotations. They report an F1 of 75.1 % on FrameNet 1.2 and 60 % on SALSA 1.0. These scores are difficult to compare against more recent work as the evaluation uses older versions of datasets and custom splits. Shalmaneser

requires software dependencies that are not available anymore, hindering application to new data. To the best of our knowledge, there is no FrameId system evaluated on SALSA 2.0.

Johannsen et al. (2015) present a simple, but weak translation baseline for cross-lingual FrameId. A SEMAFOR-based system is trained on English FrameNet and tested on German Wikipedia sentences, translated word-by-word to English. This translation baseline reaches an F1 score of 8.5 % on the German sentences when translated to English. The performance of this weak translation baseline is worse than that of another simple baseline: a 'most frequent sense baseline' – computing majority votes for German (and many other languages) – reaches an F1 score of 53.0 % on the German sentences. This shows that pure translation does not help with FrameId and, furthermore, indicates a large room for improvement for FrameId in languages other than English.

2.2 Multimodal representation learning

There is a growing interest in Natural Language Processing for enriching traditional approaches with knowledge from the visual domain, as images capture qualitatively different information compared to text. Regarding FrameId, to the best of our knowledge, multimodal approaches have not yet been investigated. For other tasks, multimodal approaches based on pretrained embeddings are reported to be superior to unimodal approaches. Textual embeddings have been enriched with information from the visual domain, e.g., for Metaphor Identification (Shutova et al., 2016), Question Answering (Wu et al., 2017), and Word Pair Similarity (Collell et al., 2017). The latter presents a simple, but effective way of extending textual embeddings with so-called multimodal IMAGINED embeddings by a learned mapping from language to vision. We apply the IMAGINED method to our problem.

In this work, we aim to uncover whether representations that are grounded in images can help to improve the accuracy of FrameId. Our application case of FrameId is more complex than a comparison on the word-pair level as it considers a whole sentence in order to identify the predicate's frame. However, we see a potential for multimodal IMAGINED embeddings to help: their mapping from text to multimodal representations is learned from images for nouns. Such nouns, in turn, are candidates for role fillers of predicates. In order to identify the correct sense of an ambiguous predicate, it could help to enrich the representation of the context situation with multimodal embeddings for the entities that are linked by the predicate.

3 Our Multimodal FrameId Model

Our system builds upon the SimpleFrameId (Hartmann et al., 2017) system for English FrameId based on textual word embeddings. We extend it to multimodal and multilingual use cases; see Fig. 2 for a sketch of the system pipeline. Same as SimpleFrameId, our system is based on pretrained embeddings to build the input representation out of the predicate context and the predicate itself.

However, different to SimpleFrameId, our representation of the predicate context is multimodal: beyond textual embeddings we also use IMAGINED and visual embeddings. More precisely, we concatenate all unimodal representations of the predicate context, which in turn are the unimodal mean embeddings of all words in the sentence. We use concatenation for fusing the different embeddings as it is the simplest yet successful fusion approach (Bruni et al., 2014; Kiela and Bottou, 2014). The input representation is processed by a two-layer Multilayer Perceptron (MLP, Rosenblatt, 1958), where we adapt the number of hidden nodes to the increased input size and apply dropout to all hidden layers to prevent overfitting (Srivastava et al., 2014). Each node in the output layer corresponds to one frame-label class. We use rectified linear units (Nair and Hinton, 2010) as activation function for the hidden layers, and a soft-

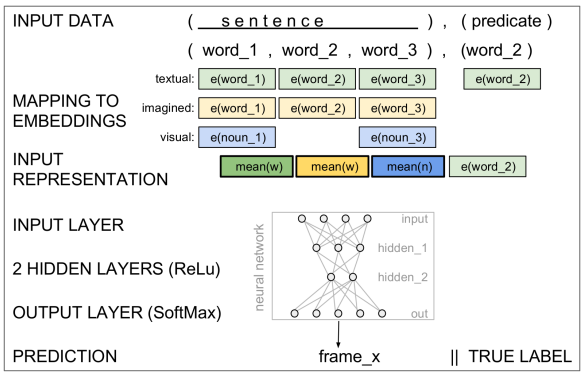

Figure 2: Sketch of the pipeline. *(1)* Data: sentence with predicate. *(2)* Mapping: words to embeddings. *(3)* Representation: concatenation of modality-specific means. *(4)* Classifier: neural network predicting frame.

max for the output layer yielding a multinomial distribution over frames. We take its $\arg\max$ as the final prediction at test time. Optionally, filtering based on the lexicon can be performed on the predicted probabilities for each frame label. The development set was used to determine the architecture and hyperparameters, see Sec. 6.

Majority baselines. We propose a new strong baseline based on a combination of two existing ones. These are: first, the most-frequent-sense baseline using the data majority (Data Baseline) to determine the most frequent frame for a predicate; second, the baseline introduced by Hartmann et al. (2017) using a lexicon (Lexicon Baseline) to consider the data counts of the Data Baseline only for those frames available for a predicate. We propose to combine them into a Data-Lexicon Baseline, which uses the lexicon for unambiguous predicates and for ambiguous ones it uses the data majority. This way, we trust the lexicon for unambiguous predicates but not for ambiguous ones, there we rather consider the data majority. Comparing a system to these baselines helps to see whether it just memorizes the data majority or the lexicon, or actually captures more.

All majority baselines strongly outperform the weak translation baseline of Johannsen et al. (2015) when training the system on English data and evaluating it on German data.

4 Preparation of Input Embeddings

Textual embeddings for words. We use the 300-dimensional GloVe embeddings (Pennington et al., 2014) for English, and the 100-dimensional embeddings of Reimers et al. (2014) for German. GloVe and Reimers have been trained on the Wikipedia of their targeted language and on additional newswire text to cover more domains, resulting in similarly low out-of-vocabulary scores.

Visual embeddings for synsets. We obtain visual embeddings for WordNet synsets (Fellbaum, 1998; , Ed.): we apply the pretrained VGG-m-128 Convolutional Neural Network model (Chatfield et al., 2014) to images for synsets from ImageNet (Deng et al., 2009), we extract the 128-dimensional activation of the last layer (before the softmax) and then we L_2-normalize it. We use the images of the WN9-IMG dataset (Xie et al., 2017), which links WordNet synsets to a collection of ten ImageNet images. We average the embeddings of all images corresponding to a synset, leading to a vocabulary size of 6555 synsets. All synsets in WN9-IMG are part of triples of the form entity-relation-entity, i.e. synset-relation-synset. Such synset entities that are participants of relations with other synset entities are candidates for incorporating the role fillers for predicates and, therefore, may help to find the correct frame for a predicate (see Sec. 5 for details about sense-disambiguation.)

Linguistic embeddings for synsets. We obtain 300-dimensional linguistic synset embeddings: we apply the AutoExtend approach (Rothe and Schütze, 2015) to GloVe embeddings and produce synset embeddings for all synsets having at least one synset lemma in the GloVe embeddings. This leads to a synset vocabulary size of 79 141. Linguistic synset embeddings are based on textual word embeddings and the synset information known by the knowledge base WordNet, thus they complement the visual synset embeddings.

IMAGINED embeddings for words. We use the IMAGINED method (Collell et al., 2017) for learning a mapping function: it maps from the word embedding space to the visual embedding space given those words that occur in both pretrained embedding spaces (7220 for English and 7739 for German). To obtain the English synset lemmas, we extract all lemmas of a synset and keep those that are nouns. We automatically translate English nouns to German nouns using the Google Translate API to obtain the corresponding German synset lemmas. The IMAGINED method is promising for cases where one embedding space (here, the textual one) has many instances without correspondence in the other embeddings space (here, the visual one), but the user still aims at obtaining instances of the first in the second space. We aim to obtain visual correspondences for the textual embeddings in order to incorporate regularities from images into our system. The mapping is a nonlinear transformation using a simple neural network. The objective is to minimize the cosine distance between each mapped representation of a word and the corresponding visual representation. Finally, a multimodal representation for any word can be obtained by applying this mapping to the word embedding.

5 Data and Preparation of Splits

English FrameId: Berkeley FrameNet. The Berkeley FrameNet (Baker et al., 1998; Ruppenhofer et al., 2016) is an ongoing project for building a large lexical resource for English with expert annotations based on frame semantics (Fillmore, 1976). It consists of two parts, a manually created lexicon that maps predicates to the frames they can evoke, and fully annotated texts (fulltext). The mapping can be used to facilitate the frame identification for a predicate in a sentence, e.g., a sentence in the fulltext corpus. Table 1 contains the lexicon statistics, Table 2 (top left) the dataset statistics. In this work, we use FrameNet 1.5 to ensure comparability with the previous state of the art, with the common evaluation split for FrameId systems introduced by Das and Smith (2011) (with the development split of Hermann et al., 2014). Due to having a single annotation as consent of experts, it is hard to estimate a performance bound of a single human for the fulltext annotation.

German FrameId: SALSA. The SALSA project (Burchardt et al., 2006; Rehbein et al., 2012) is a completed annotation project, which serves as the German counterpart to FrameNet. Its annotations are based on FrameNet up to version 1.2. SALSA adds proto-frames to properly annotate senses that are not covered by the English FrameNet. For a more detailed description of differences between FrameNet and SALSA, see Ellsworth et al. (2004); Burchardt et al. (2009). SALSA also provides a lexicon (see Table 1 for statistics) and fully annotated texts. There are two releases of SALSA: 1.0 (Burchardt et al., 2006) used for Shalmaneser (Erk and Pado, 2006) (cf. Sec. 2.1), and the final release 2.0 (Rehbein et al., 2012), which contains more annotations and adds nouns as predicates. We use the final release.

SALSA has no standard evaluation split; Erk and Pado (2006) used an undocumented random split. Also, it is not possible to follow the splitting method of Das and Smith (2011), as SALSA project distributions do not map to documents. We suggest splitting based on sentences, i.e. all annotations of a sentence are in the same set to avoid mixing training and test sets. We assign sentences to 100 buckets based on their IDs and create a 70/15/15 split for training, development, and test sets based on the bucket order. This procedure allows future work to be evaluated on the same data. Table 2 (bottom left) shows the dataset statistics.

Synsets in FrameNet and SALSA. To prepare the datasets for working with the synset embeddings, we sense-disambiguate all sentences using the API of BabelNet (Navigli and Ponzetto, 2010), which returns multilingual synsets. We thus depend on the state-of-the-art accuracy of BabelNet (Navigli and Ponzetto, 2012) when using synset embeddings on sense-disambiguated sentences. However, this dependence does not hold when applying IMAGINED embeddings to sentences, as the mapping from words to IMAGINED embeddings does not need any synsets labeled in the sentences. After sense-disambiguation some sentences do not contain any synset available in our synset embeddings. The statistics of those sentences that have at least one synset embedding (visual or linguistic AutoExtend) is given in Table 2 (right).

6 Experimental Setup

We contrast our system's performance for context representations based on unimodal (textual) versus multimodal (textual and visual) embeddings. Also, we compare English against German data. We run the prediction ten times to reduce noise in

lexicon	**frames**	**LUs**	**avg**(fr/pred)	**%amb.pred.**
FrameNet	1020	11 942	1.26	17.32
SALSA	1023	1827	2.82	57.56

Table 1: Lexicon statistics for FrameNet 1.5 and for SALSA 2.0: the total number of distinct **frames** and lexical units **LUs** (distinct predicate-frame combinations), the number of frames a predicate can evoke on average **avg**, and the % of **amb**iguous **pred**icates.

		sentences	**frames**	reduced sentences	
				syns-Vis	syns-AutoExt
FrameN	train	2819	15 406	1310	2714
	dev	707	4593	320	701
	test	2420	4546	913	2318
SALSA	train	16 852	26 081	4707	16 736
	dev	3561	5533	1063	3540
	test	3605	5660	1032	3570

Table 2: Dataset statistics for FrameNet 1.5 fulltext with Das split and for SALSA 2.0 with our split: number of **sentences** and **frames** (as used in our experiments). Right half (only used in further investigations): number of sentences when reduced to only those having synsets in the visual and in the linguistic AutoExtend embeddings.

the evaluation (cf. Reimers and Gurevych, 2017) and report the mean for each metric.

Use of lexicon. We evaluate our system in two settings: with and without lexicon, as suggested by Hartmann et al. (2017). In the with-lexicon setting, the lexicon is used to reduce the choice of frames for a predicate to only those listed in the lexicon. If the predicate is not in the lexicon, it corresponds to the without-lexicon setting, where the choice has to be done amongst all frames.

Evaluation metrics. FrameId systems are usually compared in terms of *accuracy*, which we adopt for comparability. As a multiclass classification problem, FrameId has to cope with a strong variation in the annotation frequency of frame classes. Minority classes are frames that occur only rarely; majority classes occur frequently. Note that the accuracy is biased toward majority classes, explaining the success of majority baselines on imbalanced datasets such as FrameNet.

Alternatively, the *F1 score* is sometimes reported as it takes a complementary perspective. The F-measure is the harmonic mean of precision and recall, measuring exactness and completeness of a model, respectively. In previous work, micro-averaging is used to compute F1 scores. Yet, similar to the accuracy, micro-averaging introduces a bias toward majority classes. We compute *F1-macro* instead, for which precision and recall are computed for each class and averaged afterwards, giving equal weight to all classes.

Taken together, this yields scores that underestimate (F1-macro) and overestimate (average accuracy) on imbalanced datasets. Previous work just used the overestimate such that a comparison is possible in terms of accuracy in the with-lexicon setting. We suggest to use F1-macro additionally to analyze rare, but interesting classes. Thus, a comparison within our work is possible for both aspects, giving a more detailed picture. Note that previous work reports one score whilst we report the mean score of ten runs.

Hyperparameters. We identified the best hyperparameters for the English and German data based on the respective development sets.[2] The Multilayer Perceptron architecture performed consistently better than a more complex Gated Recurrent Unit model (Cho et al., 2014). We found that more than two hidden layers did not bring any improvement over two layers; using dropout on the hidden layers helped to increase the accuracy. Among the various input representations, a concatenation of the representations of context and predicate was the best amongst others, including dependencies, lexicon indicators, and part-of-speech tags. Training is done using Nesterov-accelerated Adam (Nadam, Dozat, 2016) with default parameters. A batch size of 128 is used. Learning stops if the development accuracy has not improved for four epochs, and the learning rate is reduced by factor of two if there has not been any improvement for two epochs.

[2]Differences in hyperparameters to SimpleFrameId: 'nadam' as optimizer instead of 'adagrad', dropout on hidden layers and early stopping to regularize training. Different number of hidden units, optimized by grid search.

7 Results

First, we report our results on English data (see Table 3, top) and then, we compare against German data (see Table 3, bottom).

7.1 English FrameNet data

Baseline. Our new strong Data-Lexicon Baseline reaches a considerable accuracy of 86.32 %, which is hard to beat by trained models. Even the most recent state of the art only beats it by about two points: 88.41 % (Hermann et al., 2014). However, the accuracy of the baseline drops for ambiguous predicates (69.73 %) and the F1-macro score reveals its weakness toward minority classes (drop from 64.54 % to 37.42 %).

Unimodal. Our unimodal system trained and evaluated on English data slightly exceeds the accuracy of the previous state of the art (88.66 % on average versus 88.41 % for Hermann et al., 2014); our best run's accuracy is 89.35 %. Especially on ambiguous predicates, i.e. the difficult and therefore interesting cases, our average accuracy surpasses that of previous work by more than one point (the best run by almost three points). Considering the proposed F1-macro score for an assessment of the performance on minority classes and ambiguous predicates reveals our main improvement: Our system substantially outperforms the strong Data-Lexicon Baseline, demonstrating that our system differs from memorizing majorities and actually improves minority cases.

Multimodal. From a range of multimodal context representations as extensions to our system,

	model	with lexicon acc	with lexicon acc_amb	with lexicon F1-m	with lexicon F1-m_amb	without lexicon acc	without lexicon acc_amb	without lexicon F1-m	without lexicon F1-m_amb
FrameNet	Data Baseline	79.06	69.73	33.00	37.42	79.06	69.73	33.00	37.42
	Lexicon Baseline	79.89	55.52	65.61	30.95	–	–	–	–
	Data-Lexicon Baseline	86.32	69.73	64.54	37.42	–	–	–	–
	Hermann et al. (2014)	88.41	73.10	–	–	–	–	–	–
	Hartmann et al. (2017)	87.63	73.80	–	–	77.49	–	–	–
	our_uni	88.66	74.92	76.65	53.86	79.96	71.70	57.07	47.40
	our_mm (im, synsV)	**88.82**	**75.28**	**76.77**	**54.80**	**81.21**	**72.51**	**57.81**	**49.38**
SALSA	Data Baseline	77.00	70.51	37.40	28.87	77.00	70.51	37.40	28.87
	Lexicon Baseline	61.57	52.5	19.36	15.68	–	–	–	–
	Data-Lexicon Baseline	77.16	70.51	38.48	28.87	–	–	–	–
	our_uni	**80.76**	**75.59**	**48.42**	**41.38**	**80.59**	**75.52**	**47.64**	**41.17**
	our_mm (im)	80.71	75.58	48.29	41.19	80.51	75.51	47.36	40.93

Table 3: FrameId results (in %) on English (upper) and German (lower) with and without using the lexicon. Reported are **acc**uracy and **F1-m**acro, both also for **amb**iguous predicates (mean scores over ten runs). Models: *(a)* Data, Lexicon, and Data-Lexicon Baselines. *(b)* Previous models for English. *(c)* Ours: unimodal **our**-uni, multimodal on top of our-uni – **our**-mm – with IMAGINED embeddings (and synset visual embeddings for English). Best results highlighted in bold. The best run's results for English were:
our_uni: **acc**: 89.35 ; **acc_amb**: 76.45 ; **F1-m**: 76.95 ; **F1-m_amb**: 54.02 (with lexicon)
our_mm (im, synsV): **acc**: 89.09 ; **acc_amb**: 75.86 ; **F1-m**: 78.17 ; **F1-m_amb**: 57.48 (with lexicon)

the most helpful one is the concatenation of IMAGINED embeddings and visual synset embeddings: it outperforms the unimodal approach slightly in all measurements. We observe that the improvements are more pronounced for difficult cases, such as for rare and ambiguous cases (one point improvement in F1-macro), as well as in the absence of a lexicon (up to two points improvement).

Significance tests. We conduct a single sample t-test to judge the difference between previous state-of-the-art accuracy (Hermann et al., 2014) and our unimodal approach. The null hypothesis (expected value of our sample of ten accuracy scores equals previous state-of-the-art accuracy) is rejected at a significance level of $\alpha = 0.05$ ($p = 0.0318$). In conclusion, even our unimodal approach outperforms prior state of the art in terms of accuracy.

To judge the difference between our unimodal and our multimodal approach, we conduct a t-test for the means of the two independent samples. The null hypothesis states identical expected values for our two samples of ten accuracy scores. Regarding the setting with lexicon, the null hypothesis cannot be rejected at a significance level of $\alpha = 0.05$ ($p = 0.2181$). However, concerning accuracy scores without using the lexicon, the null hypothesis is rejected at a significance level of $\alpha = 0.05$ ($p < 0.0001$). In conclusion, the multimodal approach has a slight overall advantage and, interestingly, has a considerable advantage over the unimodal one when confronted with a more difficult setting of not using the lexicon.

7.2 German SALSA versus English data

German results. Our system evaluated on German data sets a new state of the art on this corpus with 80.76 % accuracy, outperforming the baselines (77.16 %; no other system evaluated on this dataset). The difference in F1-macro between the majority baselines and our system is smaller than for the English FrameNet. This indicates that the majorities learned from data are more powerful in the German case with SALSA than in the English case, when comparing against our system. Multimodal context representations cannot show an improvement for SALSA with this general dataset.

Lexicon. We report results achieved without the lexicon to evaluate independently of its quality (Hartmann et al., 2017). On English data, our systems outperforms Hartmann et al. (2017) by more than two points in accuracy and we achieve a large improvement over the Data Baseline. Comparing the F1-macro with and without lexicon, it can be seen that the additional information stored in the lexicon strongly increases the score by about 20 points for English data. For German data, the increase of F1-macro with lexicon versus without is small (one point).

8 Discussion

8.1 English data

Insights from the baseline. Many indicators point to our approach not just learning the data majority: our trained models have better F1-macro and especially much higher ambiguous F1-macro scores with lexicon. This clearly suggests that our system is capable of acquiring more expressiveness than the baselines do by counting majorities.

Impact of multimodal representations. Multimodal context representations improve results compared to unimodal ones. It helps to incorporate visual common sense knowledge about the situation's participants. Referring back to our example of the ambiguous predicate *sit*, the multimodal approach is able to transfer the knowledge to the test sentence *'Al-Anbar in general, and Ramadi in particular, are sat with the Americans in Jordan.'* by correctly identifying the frame *Being_located* whilst the unimodal approach fails with predicting *Change_posture*. The increase in performance when adding information from visual synset embeddings is not simply due to higher dimensionality of the embedding space. To verify, we further investigate extending the unimodal system with random word embeddings. This leads to a drop in performance compared to using just the unimodal representations or using these in combination with the proposed multimodal embeddings, especially in the setting without lexicon. Interestingly, replacing visual synset embeddings with linguistic synset embeddings (AutoExtend by Rothe and Schütze (2015), see Sec. 4) in further investigations also showed that visual embeddings yield better performance. This points out the potential for incorporating even more image evidence to extend our approach.

8.2 German versus English data

Difficulties for German data. The impact of multimodal context representations is more difficult to interpret for the German dataset. The fact that they have not helped here may be due to mismatches when translating the English nouns of a synset to German in order to train the IMAGINED embeddings. Here, we see room for future work to improve on simple translation by sense-based translations. In SALSA, a smaller portion of sentences has at least one synset embedding, see Table 2. For further investigations, we reduced the dataset to only sentences actually containing a synset embedding. Then, minor improvements of the multimodal approach were visible for SALSA. This points out that a dataset containing more words linking to implicit knowledge in images (visual synset embeddings) can profit more from visual and IMAGINED embeddings.

Impact of lexicon: English versus German. Even if both lexica approximately define the same number of frames (see Table 1), the number of defined lexical units (distinct predicate-frame combinations) in SALSA is smaller. This leads to a lexicon that is a magnitude smaller than the FrameNet lexicon. Thus, the initial situation for the German case is more difficult. The impact of the lexicon for SALSA is smaller than for FrameNet (best visible in the increase of F1-macro with using the lexicon compared to without), which can be explained by the larger percentage of ambiguous predicates (especially evoking proto-frames) and the smaller size of the lexicon. The evaluation on two different languages highlights the impact of an elaborate, manually created lexicon: it boosts the performance on frame classes that are less present in the training data. English FrameId benefits from the large high-quality lexicon, whereas German FrameId currently lacks a high-quality lexicon that is large enough to benefit the FrameId task.

Dataset properties: English versus German. To better understand the influence of the dataset on the prediction errors, we further analyze the errors of our approach (see Table 4) following Palmer

		with lexicon				without lexicon			
	model	**correct**	**e**_uns	**e**_unsLab	**e**_n	**correct**	**e**_uns	**e**_unsLab	**e**_n
FrameN	**our**_uni	89.35	0.40	3.04	7.22	80.36	1.32	7.68	10.65
	our_mm (im, synsV)	89.79	0.58	3.55	6.08	80.63	1.91	8.50	8.96

	our_mm (im)	81.24	1.94	1.88	14.94	80.96	1.94	2.05	15.05

Table 4: Error analysis of best uni- and multimodal systems. **correct**, **e**rrors: unseen, unseen label and normal.

and Sporleder (2010). A wrong prediction can either be a normal classification error, or it can be the result of an instance that was unseen at training time, which means that the error is due to the training set. The instance can either be completely unseen or unseen with the target label. We observe that FrameNet has larger issues with unseen data compared to SALSA, especially data that was unseen with one specific label but seen with another label. This is due to the uneven split of the documents in FrameNet, leading to data from different source documents and domains in the training and test split. SALSA does not suffer from this problem as much since the split was performed differently. It would be worth considering the same splitting method for FrameNet.

8.3 Future work

As stated previously, FrameId has commonalities with event prediction. Since identifying frames is only one way of capturing events, our approach is transferable to other schemes of event prediction and visual knowledge about participants of situations should be beneficial there, too. It would be interesting to evaluate the multimodal architecture on other predicate-argument frameworks, e.g., script knowledge or VerbNet style Semantic Role Labeling. In particular the exploration our findings on visual contributions to FrameId in the context of further event prediction tasks forms an interesting next step.

More precisely, future work should consider using implicit knowledge not only from images of the participants of the situation, but also from the entire scene in order to directly capture relations between the participants. This could provide access to a more holistic understanding of the scene. The following visual tasks with accompanying datasets could serve as a starting point: (a) visual Verb Sense Disambiguation with the VerSe dataset (Gella et al., 2016) and (b) visual SRL with several datasets, e.g., imSitu (Yatskar et al., 2016) (linked to FrameNet), V-COCO (Gupta and Malik, 2015) (verbs linked to COCO), VVN (Ronchi and Perona, 2015) (visual VerbNet) or even SRL grounded in video clips for the cooking-domain (Yang et al., 2016) and visual Situation Recognition (Mallya and Lazebnik, 2017). Such datasets could be used for extracting visual embeddings for verbs or even complex situations in order to improve the visual component in the embeddings for our FrameId system. Vice versa: visual tasks could profit from multimodal approaches (Baltrušaitis et al., 2017) in a similar sense as our textual task, FrameId, profits from additional information encoded in further modalities. Moreover, visual SRL might profit from our multimodal FrameId system to a similar extend as any FrameNet SRL task profits from correctly identified frames (Hartmann et al., 2017).

Regarding the combination of embeddings from different modalities, we suggest to experiment with different fusion strategies complementing the middle fusion (concatenation) and the mapping (IMAGINED method). This could be a late fusion at decision level operating like an ensemble.

9 Conclusion

In this work, we investigated multimodal representations for Frame Identification (FrameId) by incorporating implicit knowledge, which is better reflected in the visual domain. We presented a flexible FrameId system that is independent of modality and language in its architecture. With this flexibility it is possible to include textual and visual knowledge and to evaluate on gold data in different languages. We created multimodal representations from textual and visual domains and showed that for English FrameNet data, enriching the textual representations with multimodal ones improves the accuracy toward a new state of the art. For German SALSA data, we set a new state of the art with textual representations only and discuss why incorporating multimodal information is more difficult. For both datasets, our system is particularly strong with respect to ambiguous and rare classes, considerably outperforming our new Data-Lexicon Baseline and thus addressing a key challenge in FrameId.

Abstract

We present a new approach to learning semantic parsers from multiple datasets, even when the target semantic formalisms are drastically different, and the underlying corpora do not overlap. We handle such "disjoint" data by treating annotations for unobserved formalisms as latent structured variables. Building on state-of-the-art baselines, we show improvements both in frame-semantic parsing and semantic dependency parsing by modeling them jointly. Our code is open-source and available at https://github.com/Noahs-ARK/NeurboParser.

1 Introduction

Semantic parsing aims to automatically predict formal representations of meaning underlying natural language, and has been useful in question answering (Shen and Lapata, 2007), text-to-scene generation (Coyne et al., 2012), dialog systems (Chen et al., 2013) and social-network extraction (Agarwal et al., 2014), among others. Various formal meaning representations have been developed corresponding to different semantic theories (Fillmore, 1982; Palmer et al., 2005; Flickinger et al., 2012; Banarescu et al., 2013). The distributed nature of these efforts results in a set of annotated resources that are similar in spirit, but not strictly compatible. A major axis of structural divergence in semantic formalisms is whether based on *spans* (Baker et al., 1998; Palmer et al., 2005) or *dependencies* (Surdeanu et al., 2008; Oepen et al., 2014; Banarescu et al., 2013; Copestake et al., 2005, *inter alia*). Depending on application requirements, either might be most useful in a given situation.

Learning from a union of these resources seems promising, since more data almost always translates into better performance. This is indeed the case for two prior techniques—parameter sharing (FitzGerald et al., 2015; Kshirsagar et al., 2015), and joint decoding across multiple formalisms using cross-task factors that score combinations of substructures from each (Peng et al., 2017). Parameter sharing can be used in a wide range of multitask scenarios, when there is no data overlap or even any similarity between the tasks (Collobert and Weston, 2008; Søgaard and Goldberg, 2016). But techniques involving joint decoding have so far only been shown to work for parallel annotations of dependency-based formalisms, which are structurally very similar to each other (Lluís et al., 2013; Peng et al., 2017). Of particular interest is the approach of Peng et al., where three kinds of semantic graphs are jointly learned on the same input, using parallel annotations. However, as new annotation efforts cannot be expected to use the same original texts as earlier efforts, the utility of this approach is limited.

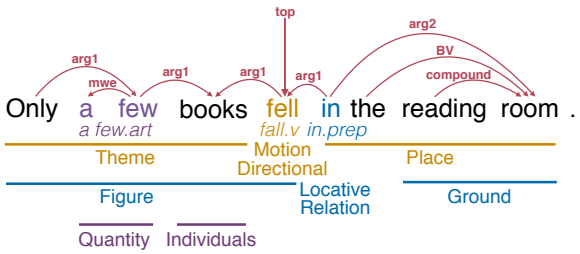

Figure 1: An example sentence from the FrameNet 1.5 corpus, shown with an author-annotated DM semantic dependency graph (above) and frame-semantic annotation (below). Two more gold frames (and their arguments) have been omitted for space.

We propose an extension to Peng et al.'s formulation which addresses this limitation by considering **disjoint resources**, each containing only a single kind of annotation. Moreover, we consider **structurally divergent** formalisms, one dealing with semantic spans and the other with semantic

Proceedings of NAACL-HLT 2018, pages 1492–1502
New Orleans, Louisiana, June 1 - 6, 2018.

dependencies. We experiment on frame-semantic parsing (Gildea and Jurafsky, 2002; Das et al., 2010), a span-based semantic role labeling (SRL) task (§2.1), and on a dependency-based minimum recursion semantic parsing (DELPH-IN MRS, or DM; Flickinger et al., 2012) task (§2.2). See Figure 1 for an example sentence with gold FrameNet annotations, and author-annotated DM representations.

Our joint inference formulation handles missing annotations by treating the structures that are not present in a given training example as latent variables (§3).[1] Specifically, semantic dependencies are treated as a collection of latent variables when training on FrameNet examples.

Using this latent variable formulation, we present an approach for relating spans and dependencies, by explicitly scoring affinities between pairs of potential spans and dependencies. Because there are a huge number of such pairs, we limit our consideration to only certain pairs—our design is inspired by the head rules of Surdeanu et al. (2008). Further possible span-dependency pairs are pruned using an ℓ_1-penalty technique adapted from sparse structure learning (§5). Neural network architectures are used to score frame-semantic structures, semantic dependencies, as well as cross-task structures (§4).

To summarize, our contributions include:

- using a latent variable formulation to extend cross-task scoring techniques to scenarios where datasets do not overlap;
- learning cross-task parts across structurally divergent formalisms; and
- using an ℓ_1-penalty technique to prune the space of cross task parts.

Our approach results in a new state-of-the-art in frame-semantic parsing, improving prior work by 0.8% absolute F_1 points (§6), and achieves competitive performance on semantic dependency parsing. Our code is available at `https://github.com/Noahs-ARK/NeurboParser`.

2 Tasks and Related Work

We describe the two tasks addressed in this work—frame-semantic parsing (§2.1) and semantic dependency parsing (§2.2)—and discuss how their structures relate to each other (§2.3).

2.1 Frame-Semantic Parsing

Frame-semantic parsing is a span-based task, under which certain words or phrases in a sentence evoke semantic **frames**. A **frame** is a group of events, situations, or relationships that all share the same set of participant and attribute types, called **frame elements** or **roles**. Gold supervision for frame-semantic parses comes from the FrameNet lexicon and corpus (Baker et al., 1998).

Concretely, for a given sentence, $\mathbf{x}$, a frame-semantic parse $\mathbf{y}$ consists of:

- a set of **targets**, each being a short span (usually a single token[2]) that evokes a frame;
- for each target t, the **frame** f that it evokes; and
- for each frame f, a set of non-overlapping **argument** spans in the sentence, each argument $a = (i, j, r)$ having a start token index i, end token index j and role label r.

The lemma and part-of-speech tag of a target comprise a **lexical unit** (or **LU**). The FrameNet ontology provides a mapping from an LU ℓ to the set of possible frames it could evoke, $\mathcal{F}_\ell$. Every frame $f \in \mathcal{F}_\ell$ is also associated with a set of roles, $\mathcal{R}_f$ under this ontology. For example, in Figure 1, the LU *"fall.v"* evokes the frame MOTION_DIRECTIONAL. The roles THEME and PLACE (which are specific to MOTION_DIRECTIONAL), are filled by the spans *"Only a few books"* and *"in the reading room"* respectively. LOCATIVE_RELATION has other roles (PROFILED_REGION, ACCESSIBILITY, DEIXIS, etc.) which are not realized in this sentence.

In this work, we assume gold targets and LUs are given, and parse each target independently, following the literature (Johansson and Nugues, 2007; FitzGerald et al., 2015; Yang and Mitchell, 2017; Swayamdipta et al., 2017, *inter alia*). Moreover, following Yang and Mitchell (2017), we perform frame and argument identification jointly. Most prior work has enforced the constraint that a role may be filled by at most one argument span, but following Swayamdipta et al. (2017) we do not impose this constraint, requiring only that arguments for the same target do not overlap.

[1] Following past work on support vector machines with latent variables (Yu and Joachims, 2009), we use the term "latent variable," even though the model is not probabilistic.

[2] 96.5% of targets in the training data are single tokens.

2.2 Semantic Dependency Parsing

Broad-coverage **semantic dependency parsing** (**SDP**; Oepen et al., 2014, 2015, 2016) represents sentential semantics with labeled bilexical dependencies. The SDP task mainly focuses on three semantic formalisms, which have been converted to dependency graphs from their original annotations. In this work we focus on only the DELPHIN MRS (**DM**) formalism.

Each semantic dependency corresponds to a labeled, directed edge between two words. A single token is also designated as the `top` of the parse, usually indicating the main predicate in the sentence. For example in Figure 1, the left-most arc has head *"Only"*, dependent *"few"*, and label `arg1`. In semantic dependencies, the head of an arc is analogous to the target in frame semantics, the destination corresponds to the argument, and the label corresponds to the role. The same set of labels are available for all arcs, in contrast to the frame-specific roles in FrameNet.

2.3 Spans vs. Dependencies

Early semantic role labeling was span-based (Gildea and Jurafsky, 2002; Toutanova et al., 2008, *inter alia*), with spans corresponding to syntactic constituents. But, as in syntactic parsing, there are sometimes theoretical or practical reasons to prefer dependency graphs. To this end, Surdeanu et al. (2008) devised heuristics based on syntactic head rules (Collins, 2003) to transform PropBank (Palmer et al., 2005) annotations into dependencies. Hence, for PropBank at least, there is a very direct connection (through syntax) between spans and dependencies.

For many other semantic representations, such a direct relationship might not be present. Some semantic representations are designed as graphs from the start (Hajič et al., 2012; Banarescu et al., 2013), and have no gold alignment to spans. Conversely, some span-based formalisms are not annotated with syntax (Baker et al., 1998; He et al., 2015),[3] and so head rules would require using (noisy and potentially expensive) predicted syntax.

Inspired by the head rules of Surdeanu et al. (2008), we design cross-task parts, without relying on gold or predicted syntax (which may be either unavailable or error-prone) or on heuristics.

3 Model

Given an input sentence $\mathbf{x}$, and target t with its LU ℓ, denote the set of valid frame-semantic parses (§2.1) as $\mathcal{Y}(\mathbf{x}, t, \ell)$, and valid semantic dependency parses as $\mathcal{Z}(\mathbf{x})$.[4] We learn a parameterized function S that scores candidate parses. Our goal is to *jointly* predict a frame-semantic parse and a semantic dependency graph by selecting the highest scoring candidates:

$$(\hat{\mathbf{y}}, \hat{\mathbf{z}}) = \underset{(\mathbf{y},\mathbf{z}) \in \mathcal{Y}(\mathbf{x},t,\ell) \times \mathcal{Z}(\mathbf{x})}{\arg\max} S(\mathbf{y}, \mathbf{z}, \mathbf{x}, t, \ell). \quad (1)$$

The overall score S can be decomposed into the sum of frame SRL score S_{f}, semantic dependency score S_{d}, and a cross-task score S_{c}:

$$S(\mathbf{y}, \mathbf{z}, \mathbf{x}, t, \ell) = S_{\text{f}}(\mathbf{y}, \mathbf{x}, t, \ell) + S_{\text{d}}(\mathbf{z}, \mathbf{x}) + S_{\text{c}}(\mathbf{y}, \mathbf{z}, \mathbf{x}, t, \ell). \quad (2)$$

S_{f} and S_{c} require access to the target and LU, in addition to $\mathbf{x}$, but S_{d} does not. For clarity, we omit the dependence on the input sentence, target, and lexical unit, whenever the context is clear. Below we describe how each of the scores is computed based on the individual **parts** that make up the candidate parses.

Frame SRL score. The score of a frame-semantic parse consists of

- the score for a predicate part, $s_f(p)$ where each predicate is defined as a combination of a target t, the associated LU, ℓ, and the frame evoked by the LU, $f \in \mathcal{F}_\ell$;
- the score for argument parts, $s_f(a)$, each associated with a token span and semantic role from $\mathcal{R}_f$.

Together, this results in a set of frame-semantic parts of size $O(n^2 \, |\mathcal{F}_\ell| \, |\mathcal{R}_f|)$.[5] The score for a frame semantic structure $\mathbf{y}$ is the sum of local scores of parts in $\mathbf{y}$:

$$S_{\text{f}}(\mathbf{y}) = \sum_{y_i \in \mathbf{y}} s_{\text{f}}(y_i). \quad (3)$$

The computation of s_{f} is described in §4.2.

[3] In FrameNet, phrase types of arguments and their grammatical function in relation to their target have been annotated. But in order to apply head rules, the *internal* structure of arguments (or at least their semantic heads) would also require syntactic annotations.

[4] For simplicity, we consider only a single target here; handling of multiple targets is discussed in §6.

[5] With pruning (described in §6) we reduce this to a number of parts linear in n. Also, $|\mathcal{F}_\ell|$ is usually small (averaging 1.9), as is $|\mathcal{R}_f|$ (averaging 9.5).

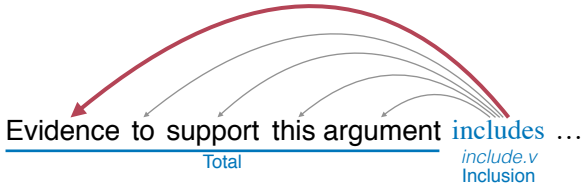

Figure 2: An example of cross-task parts from the FrameNet 1.5 development set. We enumerate all unlabeled semantic dependencies from the first word of the target (*includes*) to any token inside the span. The red bolded arc indicates the prediction of our model.

Semantic dependency score. Following Martins and Almeida (2014), we consider three types of parts in a semantic dependency graph: semantic heads, unlabeled semantic arcs, and labeled semantic arcs. Analogous to Equation 3, the score for a dependency graph $\mathbf{z}$ is the sum of local scores:

$$S_{\mathrm{d}}(\mathbf{z}) = \sum_{z_j \in \mathbf{z}} s_{\mathrm{d}}(z_j), \tag{4}$$

The computation of s_{d} is described in §4.3.

Cross task score. In addition to task-specific parts, we introduce a set $\mathcal{C}$ of cross-task parts. Each cross-task part relates an argument part from $\mathbf{y}$ to an *unlabeled* dependency arc from $\mathbf{z}$. Based on the head-rules described in §2.3, we consider unlabeled arcs from the target to any token inside the span.[6] Intuitively, an argument in FrameNet *would* be converted into a dependency from its target to the semantic head of its span. Since we do not know the semantic head of the span, we consider all tokens in the span as potential modifiers of the target. Figure 2 shows examples of cross-task parts. The cross-task score is given by

$$S_{\mathrm{c}}(\mathbf{y}, \mathbf{z}) = \sum_{(y_i, z_j) \in (\mathbf{y} \times \mathbf{z}) \cap \mathcal{C}} s_{\mathrm{c}}(y_i, z_j). \tag{5}$$

The computation of s_{c} is described in §4.4.

In contrast to previous work (Lluís et al., 2013; Peng et al., 2017), where there are parallel annotations for all formalisms, our input sentences contain only one of the two—either the span-based frame SRL annotations, or semantic dependency graphs from DM. To handle missing annotations, we treat semantic dependencies $\mathbf{z}$ as latent when decoding frame-semantic structures.[7] Because the DM dataset we use does not have target annotations, we do not use latent variables for frame semantic structures when predicting semantic dependency graphs. The parsing problem here reduces to

$$\hat{\mathbf{z}} = \arg\max_{\mathbf{z} \in \mathcal{Z}} S_{\mathrm{d}}(\mathbf{z}), \tag{6}$$

in contrast with Equation 1 .

4 Parameterizations of Scores

This section describes the parametrization of the scoring functions from §3. At a very high level: we learn contextualized token and span vectors using a bidirectional LSTM (biLSTM; Graves, 2012) and multilayer perceptrons (MLPs) (§4.1); we learn lookup embeddings for LUs, frames, roles, and arc labels; and to score a part, we combine the relevant representations into a single scalar score using a (learned) low-rank multilinear mapping. Scoring frames and arguments is detailed in §4.2, that of dependency structures in §4.3, and §4.4 shows how to capture interactions between arguments and dependencies. All parameters are learned jointly, through the optimization of a multitask objective (§5).

Tensor notation. The **order** of a tensor is the number of its dimensions—an order-2 tensor is a matrix and an order-1 tensor is a vector. Let $\otimes$ denote tensor product; the tensor product of two order-2 tensors $\mathcal{A}$ and $\mathcal{B}$ yields an order-4 tensor where $(\mathcal{A} \otimes \mathcal{B})_{i,j,k,l} = \mathcal{A}_{i,j}\mathcal{B}_{k,l}$. We use $\langle \cdot, \cdot \rangle$ to denote inner products.

4.1 Token and Span Representations

The representations of tokens and spans are formed using biLSTMs followed by MLPs.

Contextualized token representations. Each token in the input sentence $\mathbf{x}$ is mapped to an embedding vector. Two LSTMs (Hochreiter and Schmidhuber, 1997) are run in opposite directions over the input vector sequence. We use the concatenation of the two hidden representations at each position i as a contextualized word embedding for each token:

$$\mathbf{h}_i = \left[\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i\right]. \tag{7}$$

[6] Most targets are single-words (§2.1). For multi-token targets, we consider only the first token, which is usually content-bearing.

[7] Semantic dependency parses over a sentence are not constrained to be identical for different frame-semantic targets.

Span representations. Following Lee et al. (2017), span representations are computed based on boundary word representations and discrete length and distance features. Concretely, given a target t and its associated argument $a = (i, j, r)$ with boundary indices i and j, we compute three features $\boldsymbol{\phi}_t(a)$ based on the length of a, and the distances from i and j to the start of t. We concatenate the token representations at a's boundary with the discrete features $\boldsymbol{\phi}_t(a)$. We then use a two-layer $\tanh$-MLP to compute the span representation:

$$\mathbf{g}^{\text{span}}(i, j) = \text{MLP}^{\text{span}}\left([\mathbf{h}_i; \mathbf{h}_j; \boldsymbol{\phi}_t(a)]\right). \quad (8)$$

The target representation $\mathbf{g}^{\text{tgt}}(t)$ is similarly computed using a separate MLP^{tgt}, with a length feature but no distance features.

4.2 Frame and Argument Scoring

As defined in §3, the representation for a predicate part incorporates representations of a target span, the associated LU and the frame evoked by the LU. The score for a predicate part is given by a multilinear mapping:

$$\mathbf{g}^{\text{pred}}(f) = \mathbf{g}^{\text{fr}}(f) \otimes \mathbf{g}^{\text{tgt}}(t) \otimes \mathbf{g}^{\text{lu}}(\ell) \quad (9a)$$

$$s_{\text{f}}(p) = \left\langle \boldsymbol{\mathcal{W}}, \mathbf{g}^{\text{pred}}(f) \right\rangle, \quad (9b)$$

where $\boldsymbol{\mathcal{W}}$ is a low-rank order-3 tensor of learned parameters, and $\mathbf{g}^{\text{fr}}(f)$ and $\mathbf{g}^{\text{lu}}(\ell)$ are learned lookup embeddings for the frame and LU.

A candidate argument consists of a span and its role label, which in turn depends on the frame, target and LU. Hence the score for argument part, $a = (i, j, r)$ is given by extending definitions from Equation 9:

$$\mathbf{g}^{\text{arg}}(a) = \mathbf{g}^{\text{span}}(i, j) \otimes \mathbf{g}^{\text{role}}(r), \quad (10a)$$

$$s_{\text{f}}(a) = \left\langle \boldsymbol{\mathcal{W}} \otimes \boldsymbol{\mathcal{U}}, \mathbf{g}^{\text{pred}}(f) \otimes \mathbf{g}^{\text{arg}}(a) \right\rangle, \quad (10b)$$

where $\boldsymbol{\mathcal{U}}$ is a low-rank order-2 tensor of learned parameters and $\mathbf{g}^{\text{role}}(r)$ is a learned lookup embedding of the role label.

4.3 Dependency Scoring

Local scores for dependencies are implemented with two-layer $\tanh$-MLPs, followed by a final linear layer reducing the represenation to a single scalar score. For example, let $u = i \rightarrow j$ denote an unlabeled arc (ua). Its score is:

$$\mathbf{g}^{\text{ua}}(u) = \text{MLP}^{\text{ua}}\left([\mathbf{h}_i; \mathbf{h}_j]\right) \quad (11a)$$

$$s_{\text{d}}(u) = \mathbf{w}^{\text{ua}} \cdot \mathbf{g}^{\text{ua}}(u), \quad (11b)$$

where $\mathbf{w}^{\text{ua}}$ is a vector of learned weights. The scores for other types of parts are computed similarly, but with separate MLPs and weights.

4.4 Cross-Task Part Scoring

As shown in Figure 2, each cross-task part c consists of two first-order parts: a frame argument part a, and an unlabeled dependency part, u. The score for a cross-task part incorporates both:

$$s_{\text{c}}(c) = \left\langle \boldsymbol{\mathcal{W}} \otimes \boldsymbol{\mathcal{U}} \otimes \boldsymbol{\mathcal{V}}, \mathbf{g}^{\text{pred}}(f) \otimes \mathbf{g}^{\text{arg}}(a) \otimes \mathbf{w}^{\text{ua}} \otimes \mathbf{g}^{\text{ua}}(u) \right\rangle, \quad (12)$$

where $\boldsymbol{\mathcal{V}}$ is a low-rank order-2 tensor of parameters. Following previous work (Lei et al., 2014; Peng et al., 2017), we construct the parameter tensors $\boldsymbol{\mathcal{W}}$, $\boldsymbol{\mathcal{U}}$, and $\boldsymbol{\mathcal{V}}$ so as to upper-bound their ranks.

5 Training and Inference

All parameters from the previous sections are trained using a max-margin training objective (§5.1). For inference, we use a linear programming procedure, and a sparsity-promoting penalty term for speeding it up (§5.2).

5.1 Max-Margin Training

Let $\mathbf{y}^*$ denote the gold frame-semantic parse, and let $\delta(\mathbf{y}, \mathbf{y}^*)$ denote the cost of predicting $\mathbf{y}$ with respect to $\mathbf{y}^*$. We optimize the latent structured hinge loss (Yu and Joachims, 2009), which gives a subdifferentiable upper-bound on δ:

$$\mathcal{L}(\mathbf{y}^*) = \max_{(\mathbf{y}, \mathbf{z}) \in \mathcal{Y} \times \mathcal{Z}} \{S(\mathbf{y}, \mathbf{z}) + \delta(\mathbf{y}, \mathbf{y}^*)\} - \max_{\mathbf{z} \in \mathcal{Z}} \{S(\mathbf{y}^*, \mathbf{z})\}. \quad (13)$$

Following Martins and Almeida (2014), we use a weighted Hamming distance as the cost function, where, to encourage recall, we use costs 0.6 for false negative predictions and 0.4 for false positives. Equation 13 can be evaluated by applying the same max-decoding algorithm twice—once with cost-augmented inference (Crammer et al., 2006), and once more keeping $\mathbf{y}^*$ fixed. Training then aims to minimize the average loss over all training instances.[8]

Another potential approach to training a model on disjoint data would be to marginalize out the

[8] We do not use latent frame structures when decoding semantic dependency graphs (§3). Hence, the loss reduces to structured hinge (Tsochantaridis et al., 2004) when training on semantic dependencies.

latent structures and optimize the conditional log-likelihood (Naradowsky et al., 2012). Although max-decoding and computing marginals are both NP-hard in general graphical models, there are more efficient off-the-shelf implementations for approximate max-decoding, hence, we adopt a max-margin formulation.

5.2 Inference

We formulate the maximizations in Equation 13 as 0–1 integer linear programs and use AD^3 to solve them (Martins et al., 2011). We only enforce a non-overlapping constraint when decoding FrameNet structures, so that the argument identification subproblem can be efficiently solved by a dynamic program (Kong et al., 2016; Swayamdipta et al., 2017). When decoding semantic dependency graphs, we enforce the determinism constraint (Flanigan et al., 2014), where certain labels may appear on at most one arc outgoing from the same token.

Inference speedup by promoting sparsity. As discussed in §3, even after pruning, the number of within-task parts is linear in the length of the input sentence, so the number of cross-task parts is quadratic. This leads to potentially very slow inference. We address this problem by imposing an ℓ_1 penalty on the cross-task part scores:

$$\mathcal{L}(\mathbf{y}^*) + \lambda \sum_{(y_i, z_j) \in \mathcal{C}} \left| s_c(y_i, z_j) \right|, \qquad (14)$$

where λ is a hyperparameter, set to 0.01 as a practical tradeoff between efficiency and development set performance. Whenever the score for a cross-task part is driven to zero, that part's score no longer needs to be considered during inference. It is important to note that by promoting sparsity this way, we do not prune out any candidate solutions. We are instead encouraging fewer terms in the scoring function, which leads to smaller, faster inference problems even though the space of feasible parses is unchanged.

The above technique is closely related to a line of work in estimating the structure of sparse graphical models (Yuan and Lin, 2007; Friedman et al., 2008), where an ℓ_1 penalty is applied to the inverse covariance matrix in order to induce a smaller number of conditional dependencies between variables. To the best of our knowledge, we are the first to apply this technique to the output of neural scoring functions. Here, we are interested in learning sparse graphical models only because they result in faster inference, not because we have any *a priori* belief about sparsity. This results in roughly a $14\times$ speedup in our experiments, without any significant drop in performance.

	Train	Exemplars	Dev.	Test
FN 1.5	17,143	153,952	2,333	4,457
FN 1.7	19,875	192,460	2,308	6,722
DM id	33,961	-	1,692	1,410
DM ood	-	-	-	1,849

Table 1: Number of instances in datasets.

6 Experiments

Datasets. Our model is evaluated on two different releases of FrameNet: FN 1.5 and FN 1.7,[9] using splits from Swayamdipta et al. (2017). Following Swayamdipta et al. (2017) and Yang and Mitchell (2017), each target annotation is treated as a separate training instance. We also include as training data the exemplar sentences, each annotated for a single target, as they have been reported to improve performance (Kshirsagar et al., 2015; Yang and Mitchell, 2017). For semantic dependencies, we use the English DM dataset from the SemEval 2015 Task 18 closed track (Oepen et al., 2015).[10] DM contains instances from the WSJ corpus for training and both in-domain (id) and out-of-domain (ood) test sets, the latter from the Brown corpus.[11] Table 1 summarizes the sizes of the datasets.

Baselines. We compare FN performance of our joint learning model (FULL) to two baselines:

BASIC: A single-task frame SRL model, trained using a structured hinge objective.

NOCTP: A joint model without cross-task parts. It demonstrates the effect of sharing parameters in word embeddings and LSTMs (like in FULL). It does not use latent semantic dependency structures, and aims to minimize the sum of training losses from both tasks.

We also compare semantic dependency parsing performance against the single task model by Peng

[9] https://FN.icsi.berkeley.edu/fndrupal/

[10] http://sdp.delph-in.net/. The closed track does not have access to any syntactic analyses. The impact of syntactic features on SDP performance is extensively studied in Ribeyre et al. (2015).

[11] Our FN training data does not overlap with the DM test set. We remove the 3 training sentences from DM which appear in FN test data.

et al. (2017), denoted as NeurboParser (BASIC). To ensure fair comparison with our FULL model, we made several modifications to their implementation (§6.3). We observed performance improvements from our reimplementation, which can be seen in Table 5.

Pruning strategies. For frame SRL, we discard argument spans longer than 20 tokens (Swayamdipta et al., 2017). We further pretrain an unlabeled model and prune spans with posteriors lower than $1/n^2$, with n being the input sentence length. For semantic dependencies, we generally follow Martins and Almeida (2014), replacing their feature-rich pruner with neural networks. We observe that $O(n)$ spans/arcs remain after pruning, with around 96% FN development recall, and more than 99% for DM.[12]

6.1 Empirical Results

FN parsing results. Table 2 compares our full frame-semantic parsing results to previous systems. Among them, Täckström et al. (2015) and Roth (2016) implement a two-stage pipeline and use the method from Hermann et al. (2014) to predict frames. FitzGerald et al. (2015) uses the same pipeline formulation, but improves the frame identification of Hermann et al. (2014) with better syntactic features. open-SESAME (Swayamdipta et al., 2017) uses predicted frames from FitzGerald et al. (2015), and improves argument identification using a softmax-margin segmental RNN. They observe further improvements from product of experts ensembles (Hinton, 2002).

The best published FN 1.5 results are due to Yang and Mitchell (2017). Their relational model (REL) formulates argument identification as a sequence of local classifications. They additionally introduce an ensemble method (denoted as ALL) to integrate the predictions of a sequential CRF. They use a linear program to jointly predict frames and arguments at test time. As shown in Table 2, our single-model performance outperforms their REL model, and is on par with their ALL model. For a fair comparison, we build an ensemble (FULL, 2×) by separately training two models, differing only in random seeds, and averaging their part scores. Our ensembled model outperforms previous best results by 0.8% absolute.

Model	All	Ambiguous

Table 3: Frame identification accuracy on the FN 1.5 test set. *Ambiguous* evaluates only on lexical units having more than one possible frames. † denotes joint frame and argument identification, and bold font indicates best performance.[13]

Table 3 compares our frame identification results with previous approaches. Hermann et al. (2014) and Hartmann et al. (2017) use distributed word representations and syntax features. We follow the FULL LEXICON setting (Hermann et al., 2014) and extract candidate frames from the offi-

[12]On average, around $0.8n$ argument spans, and $5.7n$ unlabeled dependency arcs remain after pruning.

[13]Our comparison to Hermann et al. (2014) is based on their updated version: http://www.aclweb.org/anthology/P/P14/P14-1136v2.pdf. Ambiguous frame identification results by Yang and Mitchell (2017) and Hartmann et al. (2017) are 75.7 and 73.8. Their ambiguous lexical unit sets are different from the one extracted from the official frame directory, and thus the results are not comparable to those in Table 3.

NeurboParser (BASIC, reimpl.)	90.0	84.6
This work (NOCTP)	89.9	85.2
This work (FULL)	90.5	85.9
This work (FULL, 2×)	**91.2**	**86.6**

Table 5: Labeled parsing performance in F_1 score for DM semantic dependencies. *id* denotes in-domain WSJ test data, and *ood* denotes out-of-domain brown corpus test data. Bold font indicates best performance.

cial directories. The *Ambiguous* setting compares lexical units with more than one possible frames. Our approach improves over all previous models under both settings, demonstrating a clear benefit from joint learning.

We observe similar trends on FN 1.7 for both full structure extraction and for frame identification only (Table 4). FN 1.7 extends FN 1.5 with more consistent annotations. Its test set is different from that of FN 1.5, so the results are not directly comparable to Table 2. We are the first to report frame-semantic parsing results on FN 1.7, and we encourage future efforts to do so as well.

Semantic dependency parsing results. Table 5 compares our semantic dependency parsing performance on DM with the baselines. Our reimplementation of the BASIC model slightly improves performance on in-domain test data. The NOCTP model ties parameters from word embeddings and LSTMs when training on FrameNet and DM, but does not use cross-task parts or joint prediction. NOCTP achieves similar in-domain test performance, and improves over BASIC on out-of-domain data. By jointly predicting FrameNet structures and semantic dependency graphs, the FULL model outperforms the baselines by more than 0.6% absolute F_1 scores under both settings.

Previous state-of-the-art results on DM are due to the joint learning model of Peng et al. (2017), denoted as NeurboParser (FREDA3). They adopted a multitask learning approach, jointly predicting three different parallel semantic dependency annotations. Our FULL model's in-domain test performance is on par with FREDA3, and improves over it by 0.6% absolute F_1 on out-of-domain test data. Our ensemble of two FULL models achieves a new state-of-the-art in both in-domain and out-of-domain test performance.

Operation	**Description**	BASIC	FULL
Frame error	Frame misprediction.	11.3	11.1
Role error	Matching span with incorrect role.	12.6 (5.2)	13.4 (5.9)
Span error	Matching role with incorrect span.	11.4	12.3
Arg. error	Predicted argument does not overlap with any gold span.	18.6	22.4
Missing arg.	Gold argument does not overlap with any predicted span.	43.5	38.0

Table 6: Percentage of errors made by BASIC and FULL models on the FN 1.5 development set. Parenthesized numbers show the percentage of role errors when frame predictions are correct.

6.2 Analysis

Error type breakdown. Similarly to He et al. (2017), we categorize prediction errors made by the BASIC and FULL models in Table 6. Entirely missing an argument accounts for most of the errors for both models, but we observe fewer errors by FULL compared to BASIC in this category. FULL tends to predict more arguments in general, including more incorrect arguments.

Since candidate roles are determined by frames, frame and role errors are highly correlated. Therefore, we also show the role errors when frames are correctly predicted (parenthesized numbers in the second row). When a predicted argument span matches a gold span, predicting the semantic role is less challenging. Role errors account for only around 13% of all errors, and half of them are due to mispredictions of frames.

Performance by argument length. Figure 3 plots dev. precision and recall of both BASIC and FULL against binned argument lengths. We ob-

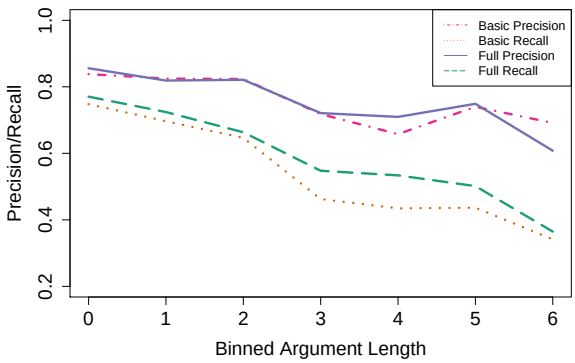

Figure 3: FN 1.5 development precision and recall of BASIC and FULL by different argument lengths. Length ℓ is binned to $\lfloor \log_{1.6} \ell \rfloor$, and precision/recall values are smoothed with `loess`, with a smoothing parameter of 0.1.

serve two trends: (a) FULL tends to predict longer arguments (averaging 3.2) compared to BASIC (averaging 2.9), while keeping similar precision;[14] (b) recall improvement in FULL mainly comes from arguments longer than 4.

6.3 Implementation Details

Our implementation is based on DyNet (Neubig et al., 2017).[15] We use predicted part-of-speech tags and lemmas using NLTK (Bird et al., 2009).[16]

Parameters are optimized with stochastic subgradient descent for up to 30 epochs, with ℓ_2 norms of gradients clipped to 1. We use 0.33 as initial learning rate, and anneal it at a rate of 0.5 every 10 epochs. Early stopping is applied based on FN development F_1. We apply logarithm with base 2 to all discrete features, e.g., $\log_2(d+1)$ for distance feature valuing d. To speed up training, we randomly sample a 35% subset from the FN exemplar instances each epoch.

Hyperparameters. Each input token is represented as the concatenation a word embedding vector, a learned lemma vector, and a learned vector for part-of speech, all updated during training. We use 100-dimensional `GloVe` (Pennington et al., 2014) to initialize word embeddings. We apply word dropout (Iyyer et al., 2015) and randomly replace a word w with a special `UNK` symbol with probability $\frac{\alpha}{1+\#(w)}$, with $\#(w)$ being the count of w in the training set. We follow the default parameters initialization procedure by DyNet, and an ℓ_2 penalty of 10^{-6} is applied to all weights. See Table 7 for other hyperparameters.

Hyperparameter	Value
Word embedding dimension	100 (32)
Lemma embedding dimension	50 (16)
POS tag embedding dimension	50 (16)
MLP dimension	100 (32)
Tensor rank r	100 (32)
BiLSTM layers	2 (1)
BiLSTM dimensions	200 (64)
α for word dropout	1.0 (1.0)

Table 7: Hyperparameters used in the experiments. Parenthesized numbers indicate those used by the pretrained pruners.

Modifications to Peng et al. (2017). To ensure fair comparisons, we note two implementation modifications to Peng et al.'s basic model. We use a more recent version (2.0) of the DyNet toolkit, and we use 50-dimensional lemma embeddings instead of their 25-dimensional randomly-initialized learned word embeddings.

7 Conclusion

We presented a novel multitask approach to learning semantic parsers from disjoint corpora with structurally divergent formalisms. We showed how joint learning and prediction can be done with scoring functions that explicitly relate spans and dependencies, even when they are never observed together in the data. We handled the resulting inference challenges with a novel adaptation of graphical model structure learning to the deep learning setting. We raised the state-of-the-art on DM and FrameNet parsing by learning from both, despite their structural differences and non-overlapping data. While our selection of factors is specific to spans and dependencies, our general techniques could be adapted to work with more combinations of structured prediction tasks. We have released our implementation at `https://github.com/Noahs-ARK/NeurboParser`.

Acknowledgments

We thank Kenton Lee, Luheng He, and Rowan Zellers for their helpful comments, and the anonymous reviewers for their valuable feedback. This work was supported in part by NSF grant IIS-1562364.

[14] Average gold span length is 3.4 after discarding those longer than 20.

Identifying Semantic Divergences in Parallel Text without Annotations

Abstract

Recognizing that even correct translations are not always semantically equivalent, we automatically detect meaning divergences in parallel sentence pairs with a deep neural model of bilingual semantic similarity which can be trained for any parallel corpus without any manual annotation. We show that our semantic model detects divergences more accurately than models based on surface features derived from word alignments, and that these divergences matter for neural machine translation.

1 Introduction

Parallel sentence pairs are sentences that are translations of each other, and are therefore often assumed to convey the same meaning in the source and target language. Occasional mismatches between source and target have been primarily viewed as alignment noise (Goutte et al., 2012) due to imperfect sentence alignment tools in parallel corpora drawn from translated texts (Tiedemann, 2011; Xu and Yvon, 2016), or the noisy process of extracting parallel segments from non-parallel corpora (Fung and Cheung, 2004; Munteanu and Marcu, 2005).

In contrast, we view translation as a process that inherently introduces meaning mismatches, so that even correctly aligned sentence pairs are not necessarily semantically equivalent. This can happen for many reasons: translation lexical choice often involves selecting between near synonyms that introduce language-specific nuances (Hirst, 1995), typological divergences lead to structural mismatches (Dorr, 1994), differences in discourse organization can make it impossible to find one-to-one sentence alignments (Li et al., 2014). Cross-linguistic variations in other discourse phenomena such as coreference, discourse relation and modality (Lapshinova-Koltunski, 2015) compounded with translation effects that distinguish "translationese" from original text (Koppel and Ordan, 2011) might also lead to meaning mismatches between source and target.

In this paper, we aim to provide empirical evidence that semantic divergences exist in parallel corpora and matter for downstream applications. This requires an automatic method to distinguish semantically equivalent sentence pairs from semantically divergent pairs, so that parallel corpora can be used more judiciously in downstream cross-lingual NLP applications. We propose a semantic model to automatically detect whether a sentence pair is semantically divergent (Section 3). While prior work relied on surface cues to detect mis-aligments, our approach focuses on comparing the meaning of words and overlapping text spans using bilingual word embeddings (Luong et al., 2015) and a deep convolutional neural network (He and Lin, 2016). Crucially, training this model requires no manual annotation. Noisy supervision is obtained automatically borrowing techniques developed for parallel sentence extraction (Munteanu and Marcu, 2005). Our model can thus easily be trained to detect semantic divergences in any parallel corpus.

We extensively evaluate our semantically-motivated models on intrinsic and extrinsic tasks: detection of divergent examples in two parallel English-French data sets (Section 5), and data selection for English-French and Vietnamese-English machine translation (MT) (Section 6).The semantic models significantly outperform other methods on the intrinsic task, and help select data to train neural machine translation faster with no loss in translation quality. Taken together, these results provide empirical evidence that sentence-alignment does not necessarily imply semantic equivalence, and that this distinction matters in practice for a downstream NLP application.

2 Background

Translation Divergences We use the term semantic divergences to refer to bilingual sentence pairs, including translations, that do not have the same meaning. These differ from *typological divergences*, which have been defined as structural differences between sentences that convey the same meaning (Dorr, 1994; Habash and Dorr, 2002), and reflect the fact that languages do not encode the same information in the same way.

Non-Parallel Corpora Mismatches in bilingual sentence pairs have previously been studied to extract parallel segments from non-parallel corpora, and augment MT training data (Fung and Cheung, 2004; Munteanu and Marcu, 2005, 2006; Abdul-Rauf and Schwenk, 2009; Smith et al., 2010; Riesa and Marcu, 2012, *inter alia)*. Methods for parallel sentence extraction rely primarily on surface features based on translation lexicons and word alignment patterns (Munteanu and Marcu, 2005, 2006). Similar features have proved to be useful for the related task of translation quality estimation (Specia et al., 2010, 2016), which aims to detect divergences introduced by MT errors, rather than human translation. Recently, sentence embeddings have also been used to detect parallelism (España-Bonet et al., 2017; Schwenk and Douze, 2017). Although embeddings capture semantic generalizations, these models are trained with neural MT objectives, which do not distinguish semantically equivalent segments from divergent parallel segments.

Cross-Lingual Sentence Semantics Cross-lingual semantic textual similarity (Agirre et al., 2016) and cross-lingual textual entailment (Negri and Mehdad, 2010; Negri et al., 2012, 2013) seek to characterize semantic relations between sentences in two different languages beyond translation equivalence, and are therefore directly relevant to our goal. While the human judgments obtained for each task differ, they all take inputs of the same form (two segments in different languages) and output a prediction that can be interpreted as indicating whether they are equivalent in meaning or not. Models share core intuitions, relying either on MT to transfer the cross-lingual task into its monolingual equivalent (Jimenez et al., 2012; Zhao et al., 2013), or on features derived from MT components such as translation dictionaries and word alignments (Turchi and Negri, 2013; Lo et al., 2016). Training requires manually annotated examples, either bilingual, or monolingual when using MT for language transfer.

Impact of mismatched sentence pairs on MT Prior MT work has focused on noise in sentence alignment rather than semantic divergence. Goutte et al. (2012) show that phrase-based systems are remarkably robust to noise in parallel segments. When introducing noise by permuting the target side of parallel pairs, as many as 30% of training examples had to be permuted to degrade BLEU significantly. While such artificial noise does not necessarily capture naturally occurring divergences, there is evidence that data cleaning to remove real noise can benefit MT in low-resource settings (Matthews et al., 2014).

Neural MT quality appears to be more sensitive to the nature of training examples than phrase-based systems. Chen et al. (2016) suggest that neural MT systems are sensitive to sentence pair permutations in domain adaptation settings. Belinkov and Bisk (2018) demonstrate the brittleness of character-level neural MT when exposed to synthetic noise (random permutations of words and characters) as well as natural human errors. Concurrently with our work, Hassan et al. (2018) claim that even small amounts of noise can have adverse effects on neural MT models, as they tend to assign high probabilities to rare events. They filter out noise and select relevant in-domain examples jointly, using similarities between sentence embeddings obtained from the encoder of a bidirectional neural MT system trained on clean in-domain data. In contrast, we detect semantic divergence with dedicated models that require only 5000 parallel examples (see Section 5).

This work builds on our initial study of semantic divergences (Carpuat et al., 2017), where we provide a framework for evaluating the impact of meaning mismatches in parallel segments on MT via data selection: we show that filtering out the most divergent segments in a training corpus improves translation quality. However, we previously detect mismatches using a cross-lingual entailment classifier, which is based on surface features only, and requires manually annotated training examples (Negri et al., 2012, 2013). In this paper, we detect divergences using a semantically-motivated model that can be trained given any existing parallel corpus without manual intervention.

3 Approach

We introduce our approach to detecting divergence in parallel sentences, with the goal of (1) detecting differences ranging from large mismatches to subtle nuances, (2) without manual annotation.

Cross-Lingual Semantic Similarity Model We address the first requirement using a neural model that compares the meaning of sentences using a range of granularities. We repurpose the Very Deep Pairwise Interaction (VDPWI) model, which has been previously been used to detect semantic textual similarity (STS) between English sentence pairs (He and Lin, 2016). It achieved competitive performance on data from the STS 2014 shared task (Agirre et al., 2014), and outperformed previous approaches on sentence classification tasks (He et al., 2015; Tai et al., 2015), with fewer parameters, faster training, and without requiring expensive external resources such as WordNet.

The VDPWI model was designed for comparing the meaning of sentences in the same language, based not only on word-to-word similarity comparisons, but also on comparisons between overlapping spans of the two sentences, as learned by a deep convolutional neural network. We adapt the model to our cross-lingual task by initializing it with bilingual embeddings. To the best of our knowledge, this is the first time this model has been used for cross-lingual tasks in such a way. We give a brief overview of the resulting model here and refer the reader to the original paper for details. Given sentences e and f , VDPWI models the semantic similarity between them using a pipeline consisting of five components:

1. **Bilingual word embeddings**: Each word in e and f is represented as a vector using pretrained, bilingual embeddings.
2. **BiLSTM for contextualizing words**: Contextualized representations for words in e and f are obtained by choosing the output vectors at each time step obtained by running a bidirectional LSTM (Schuster and Paliwal, 1997) on each sentence.
3. **Word similarity cube**: The contextualized representations are used to calculate various similarity scores between each word in *e* with each word in *f*. Each score thus forms a matrix and all such matrices are stacked to form a *similarity cube* tensor.
4. **Similarity focus layer**: The similarity cube is fed to a similarity focus layer that reweights the similarities in the cube to focus on highly similar word pairs, by decreasing the weights of pairs which are less similar. This output is called the *focus cube*.
5. **Deep convolutional network**: The focus cube is treated as an "image" and passed to a deep neural network, the likes of which have been used to detect patterns in images. The network consists of repeating convolution and pooling layers. Each repetition consists of a spatial convolutional layer, a Rectified Linear Unit (Nair and Hinton, 2010), and a max pooling layer, followed by fully connected layers, and a softmax to obtain the final output.

The entire architecture is trained end-to-end to minimize the Kullback-Leibler divergence (Kullback, 1959) between the output similarity score and gold similarity score.

Noisy Synthetic Supervision How can we obtain gold similarity scores as supervision for our task? We automatically construct examples of semantically divergent and equivalent sentences as follows. Since a large number of parallel sentence pairs are semantically equivalent, we use parallel sentences as positive examples. Synthetic negative examples are generated following the protocol introduced by Munteanu and Marcu (2005) to distinguish parallel from non-parallel segments. Specifically, candidate negative examples are generated starting from the positive examples $\{(e_i, f_i)\ \forall i\}$ and taking the Cartesian product of the two sides of the positive examples$\{(e_i, f_j) \forall i, j$ s.t. $i \neq j\}$. This candidate set is filtered to ensure that negative examples are not too easy to identify: we only retain pairs that are close to each other in length (a length ratio of at most 1:2), and have enough words (at least half) which have a translation in the other sentence according to a bilingual dictionary derived from automatic word alignments.

This process yields positive and negative examples that are a noisy source of supervision for our task, as some of the positive examples might not be fully equivalent in meaning. However, experiments will show that, in aggregate, they provide a useful signal for the VDPWI model to learn to detect semantic distinctions (Section 5).

Table 1: Randomly selected sentence pairs (English (en), French (fr) and gloss of French (gl)) annotated as divergent or equivalent, with high and low degrees of agreement between the 5 annotators. Examples are taken either from the OpenSubtitles (subs) or Common Crawl (cc) corpus.

4 Crowdsourcing Divergence Judgments

We crowdsource annotations of English-French sentence pairs to construct test beds for evaluating our models, and also to assess how frequent semantic divergences are in parallel corpora.

Data Selection We draw examples for annotation randomly from two English-French corpora, using a resource-rich and well-studied language pair, and for which bilingual annotators can easily be found. The **OpenSubtitles corpus** contains 33M sentence pairs based on translations of movie subtitles. The sentence pairs are expected to not be completely parallel given the many constraints imposed on translations that should fit on a screen and be synchronized with a movie (Tiedemann, 2007; Lison and Tiedemann, 2016), and the use of more informal registers which might require frequent non-literal translations of figurative language. The **Common Crawl corpus** contains sentence-aligned parallel documents automatically mined from the Internet. Parallel documents are discovered using e.g., URL containing language code patterns, and sentences are automatically aligned after structural cleaning of HTML. The resulting corpus of 3M sentence pairs is noisy, yet extremely useful to improve translation quality for multiple language pairs and domains (Smith et al., 2013).

Annotation Protocol Divergence annotations are obtained via Crowdflower.[1] Since this task requires good command of both French and English, we rely on a combination of strategies to obtain good quality annotations, including Crowdflower's internal worker proficiency ratings, geo-restriction, reference annotations by a bilingual speaker in our lab, and instructions that alternate between the two languages (Agirre et al., 2016).

Annotators are shown an English-French sentence pair, and asked whether they agree or disagree with the statement "the French and English text convey the same information." We do not use the term "divergent", and let the annotators' intuitions about what constitutes the same take precedence. We set up two distinct annotation tasks, one for each corpus, so that workers only see examples sampled from a given corpus in a given job. Each example is shown to five distinct annotators.

Annotation Analysis Forcing an assignment of divergent or equivalent labels by majority vote yields 43.6% divergent examples in OpenSubtitles, and 38.4% in Common Crawl. Fleiss' Kappa indicates moderate agreement between annotators (0.41 for OpenSubtitles and 0.49 for Common Crawl). This suggests that the annotation protocol can be improved, perhaps by using graded judgments as in Semantic Textual Similarity tasks (Agirre et al., 2016), or for sentence alignment

[1] http://crowdflower.com

confidence evaluation (Xu and Yvon, 2016). Current annotations are nevertheless useful, and different degrees of agreement reveal nuances in the nature of divergences (Table 1). Examples labeled as divergent with high confidence (lowest block of the table) are either unrelated or one language misses significant information that is present in the other. Examples labeled divergent with lower confidence contain more subtle differences (e.g., "what does it mean" in English vs. "what are the advantages" in French).

5 Divergence Detection Evaluation

Using the two test sets obtained above, we can evaluate the accuracy of our cross-lingual semantic divergence detector, and compare it against a diverse set of baselines in controlled settings. We test our hypothesis that semantic divergences are more than alignment mismatches by comparing the semantic divergence detector with models that capture mis-alignment (Section 5.2) or translation (Section 5.3). Then, we compare the deep convolutional architecture of the semantic divergence model, with a much simpler model that directly compares bilingual sentence embeddings (Section 5.4). Finally, we compare our model trained on synthetic examples with a supervised classifier used in prior work to predict finer-grained textual entailment categories based on manually created training examples (Section 5.5). Except for the entailment classifier which uses external resources, all models are trained on the exact same parallel corpora (OpenSubtitles or CommonCrawl for evaluating on the corresponding test bed.)

5.1 Neural Semantic Divergence Detection

Model and Training Settings We use the publicly available implementation of the VDPWI model.[2] We initialize with 200 dimensional BiVec French-English word embeddings (Luong et al., 2015), trained on the parallel corpus from which our test set is drawn. We use the default setting for all other VDPWI parameters. The model is trained for 25 epochs and the model that achieves the best Pearson correlation coefficient on the validation set is chosen. At test time, VDPWI outputs a score $\in [0, 1]$, where a higher value indicates less divergence. We tune a threshold on development data to convert the real-valued score to binary predictions.

Synthetic Data Generation The synthetic training data is constructed using a random sample of 5000 sentences from the training parallel corpus as positive examples. We generate negative examples automatically as described in Section 3, and sample a subset to maintain a 1:5 ratio of positive to negative examples.[3]

5.2 Parallel vs. Non-parallel Classifier

Are divergences observed in parallel corpora more than alignment errors? To answer this question, we reimplement the model proposed by Munteanu and Marcu (2005). It discriminates parallel pairs from non-parallel pairs in comparable corpora using a supervised linear classifier with the following features for each sentence pair (e, f):

- Length features: $|f|$, $|e|$, $\frac{|f|}{|e|}$, and $\frac{|e|}{|f|}$
- Alignment features (for each of e and f):[4]
  - Count and ratio of unaligned words
  - Top three largest fertilities
  - Longest contiguous unaligned and aligned sequence lengths
- Dictionary features:[5] fraction of words in e that have a translation in f and vice-versa.

Training uses the exact same synthetic examples as the semantic divergence model (Section 3).

5.3 Neural MT

If divergent examples are nothing more than bad translations, a neural MT system should assign lower scores to divergent segments pairs than to those that are equivalent in meaning. We test this empirically using neural MT systems trained for a single epoch, and use the system to score each of the sentence pairs in the test sets. We tune a threshold on the development set to convert scores to binary predictions. The system architecture and training settings are described in details in the later MT section (Section 6.2). Preliminary experiments showed that training for more than one epoch does not help divergence detection.

[2] https://github.com/castorini/VDPWI-NN-Torch

[3] We experimented with other ratios and found that the results only slightly degraded while using a more balanced ratio (1:1, 1:2), but severely degraded with a skewed ratio (1:9).

[4] Alignments are obtained using IBM Model 2 trained in each direction, combined with `union`, `intersection`, and `grow-diag-final-and` heuristics.

[5] The bilingual dictionary used to extract features is constructed using word alignments from a random sample of a million sentences from the training parallel corpus.

5.4 Bilingual Sentence Embeddings

Our semantic divergence model introduces a large number of parameters to combine the pairwise word comparisons into a single sentence-level prediction. This baseline tests whether a simpler model would suffice. We detect semantic divergence by computing the cosine similarity between sentence embeddings in a bilingual space. The sentence embeddings are bag-of-word representations, build by taking the mean of bilingual word embeddings for each word in the sentence. This approach has been shown to be effective, despite ignoring fundamental linguistic information such as word order and syntax (Mitchell and Lapata, 2010). We use the same 200 dimensional BiVec word embeddings (Luong et al., 2015), trained on OpenSubtitles and CommonCrawl respectively.

5.5 Textual Entailment Classifier

Our final baseline replicates our previous system (Carpuat et al., 2017) where we repurposed annotations and models designed for the task of Cross-Lingual Textual Entailment (CLTE) to detect semantic divergences. This baseline also helps us understand how the synthetic training data compares to training examples generated manually, for a related cross-lingual task. Using CLTE datasets from SemEval (Negri et al., 2012, 2013), we train a supervised linear classifier that can distinguish sentence pairs that entail each other, from pairs where entailment does not hold in at least one direction. The features of the classifier are based on word alignments and sentence lengths.[6]

5.6 Intrinsic Evaluation Results

Table 2 shows that the semantic similarity model is most successful at distinguishing equivalent from divergent examples. The break down per class shows that both equivalent and divergent examples are better detected. The improvement is larger for divergent examples with gains of about 10 points for F-score for the divergent class, when compared to the next-best scores.

Among the baseline methods, the non-entailment model is the weakest. While it uses manually constructed training examples, these examples are drawn from distant domains, and the categories annotated do not exactly match the task at hand. In contrast, the other models benefit from training on examples drawn from the same corpus as each test set.

Next, the machine translation based model and the sentence embedding model, both of which are unsupervised, are significantly weaker than the two supervised models trained on synthetic data, highlighting the benefits of the automatically constructed divergence examples. The strength of the semantic similarity model compared to the sentence embeddings model highlights the benefits of the fine-grained representation of bilingual sentence pairs as a similarity cube, as opposed to the bag-of-words sentence embedding representation.

Finally, despite training on the same noisy synthetic data as the parallel v/s non-parallel system, the semantic similarity model is better able to detect meaning divergences. This highlights the benefits of (1) meaning comparison between words in a shared embedding space, over the discrete translation dictionary used by the baseline, and of (2) the deep convolutional neural network which enables the semantic comparison of overlapping spans in sentence pairs, as opposed to more local word alignment features.

5.7 Analysis

We manually examine the 13-15% of examples in each test set that are correctly detected as divergent by semantic similarity and mis-classified by the non-parallel detector.

On OpenSubtitles, most of these examples are true divergences rather than noisy alignments (i.e. sentences that are not translation of each other.) The non-parallel detector weighs length features highly, and is fooled by sentence pairs of similar length that share little content and therefore have very sparse word alignments. The remaining sentence pairs are plausible translations in some context that still contain inherent divergences, such as details missing or added in one language. The non-parallel detector views these pairs as non-divergent since most words can be aligned. The semantic similarity model can identify subtle meaning differences, and correctly classify them as divergent. As a result, the non-parallel detector has a higher false positive rate (22%) than the semantic similarity classifier (14%), while having similar false negative rates (11% v/s 12%).

On the CommonCrawl test set, the examples with disagreement are more diverse, ranging from

[6] As in the prior work, alignments are trained on 2M sentence pairs from Europarl (Koehn, 2005) using the Berkeley aligner (Liang et al., 2006). The classifier is the linear SVM from Scikit-Learn.

Divergence Detection Approach	OpenSubtitles +P	+R	+F	-P	-R	-F	Overall F	Common Crawl +P	+R	+F	-P	-R	-F	Overall F
Sentence Embeddings	65	60	62	56	61	58	60	78	58	66	52	**74**	61	64
MT Scores (1 epoch)	67	53	59	54	68	60	60	54	65	59	17	11	14	42

Table 2: Intrinsic evaluation on crowdsourced semantic equivalence vs. divergence testsets. We report overall F-score, as well as precision (P), recall (R) and F-score (F) for the equivalent (+) and divergent (-) classes separately. Semantic similarity yields better results across the board, with larger improvements on the divergent class.

noisy segments that should not be aligned to sentences with subtle divergences.

6 Machine Translation Evaluation

Having established the effectiveness of the semantic divergence detector, we now measure the impact of divergences on a downstream task, machine translation. As in our prior work (Carpuat et al., 2017), we take a data selection approach, selecting the least divergent examples in a parallel corpus based on a range of divergence detectors, and comparing the translation quality of the resulting neural MT systems.

6.1 Translation Tasks

English-French We evaluate on 4867 sentences from the Microsoft Spoken Language Translation dataset (Federmann and Lewis, 2016) as well as on 1300 sentences from TED talks (Cettolo et al., 2012), as in past work (Carpuat et al., 2017). Training examples are drawn from OpenSubtitles, which contains ~28M examples after deduplication. We discard 50% examples for data selection.

Vietnamese-English Since the SEMANTIC SIMILARITY model was designed to be easily portable to new language pairs, we also test its impact on the IWSLT Vietnamese-English TED task, which comes with ~120,000 and 1268 in-domain sentences for training and testing respectively (Farajian et al., 2016). This is a more challenging translation task as Vietnamese and English are more distant languages, there is little training data, and the sentence pairs are expected to be cleaner and more parallel than those from OpenSubtitles. In these lower resource settings, we discard 10% of examples for data selection.

6.2 Neural MT System

We use the attentional encoder-decoder model (Bahdanau et al., 2015) implemented in the Sock-Eye toolkit (Hieber et al., 2017). Encoders and decoders are single-layer GRUs (Cho et al., 2014) with 1000 hidden units. Source and target word embeddings have size 512. Using byte-pair encoding (Sennrich et al., 2016), the vocabulary size is 50000. Maximum sequence length is set to 50.

We optimize the standard cross-entropy loss using Adam (Kingma and Ba, 2014), until validation perplexity does not decrease for 8 checkpoints. The learning rate is set to 0.0003 and is halved when the validation perplexity does not decrease for 3 checkpoints. The batch size is set to 80. At decoding time, we construct a new model by averaging the parameters for the 8 checkpoints with best validation perplexity, and decode with a beam of 5. All experiments are run thrice with distinct random seeds.

Note that the baseline in this work is much stronger than in our prior work (>5 BLEU). This is due to multiple factors that have been recommended as best practices for neural MT and have been incorporated in the present baseline – deduplication of the training data, ensemble decoding using multiple random runs, use of Adam as the optimizer instead of AdaDelta (Bahar et al., 2017; Denkowski and Neubig, 2017), and checkpoint averaging (Bahar et al., 2017) – as well as a more recent neural modeling toolkit.

6.3 English-French Results

We train English-French neural MT systems by selecting the least divergent half of the training corpus with the following criteria:

- SEMANTIC SIMILARITY (Section 3)
- PARALLEL: the non-parallel sentence detector (Section 5.2)
- ENTAILMENT: the entailment classifier (Section 5.5), as in Carpuat et al. (2017)
- RANDOM: Randomly downsampling the training corpus

Learning curves (Figure 1) show that data selected using SEMANTIC SIMILARITY yields better

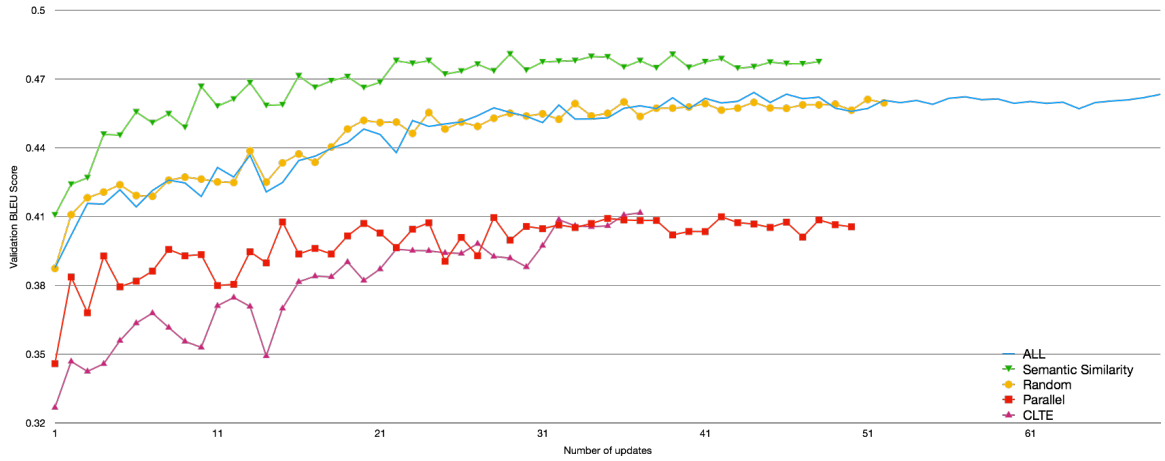

Figure 1: Learning curves on the validation set for English-French models (mean of 3 runs/model). The SEMANTIC SIMILARITY model outperforms other models throughout training, including the one trained on all data.

Model	MSLT BLEU		TED BLEU	
	Avg.	Ensemble	Avg.	Ensemble
RANDOM	43.49	45.64	36.05	38.20
PARALLEL	40.65	42.12	35.99	37.86
ENTAILMENT	39.64	41.86	33.30	35.40
SEMANTIC SIM.	**45.53**	**47.23***	**36.98**	**38.87**
ALL	44.64	46.26	36.98	38.59

Table 3: English-French decoding results. BLEU scores are either averaged across 3 runs ("Avg.") or obtained via ensemble decoding ("Ensemble"). SEMANTIC SIMILARITY reaches BLEU scores on par with ALL with only half of the training data. SEMANTIC SIMILARITY scores marked with * are significanly better ($p < 0.05$) than the corresponding ALL scores.

validation BLEU throughout training compared to all other models. SEMANTIC SIMILARITY selects more useful examples for MT than PARALLEL, even though both selection models are trained on the same synthetic examples. This highlights the benefits of semantic modeling over surface mis-alignment features. Furthermore, SEMANTIC SIMILARITY achieves the final validation BLEU of the model that uses ALL data with only 30% of the updates. This suggests that semantically divergent examples are pervasive in the training corpus, confirming the findings from manual annotation (Section 4), and that the presence of such examples slows down neural MT training.

Decoding results on the blind test sets (Table 3) show that SEMANTIC SIMILARITY outperforms all other data selection criteria (with differences being statistically significant ($p < 0.05$) (Koehn, 2004)), and performs as well or better than the ALL model which has access to twice as many training examples.

Model	Avg. Test Set BLEU
RANDOM (90%)	22.71
SEMANTIC SIM. (90%)	**23.38**
ALL	23.30

Table 4: Vietnamese-English decoding results: dropping 10% of the data based on SEMANTIC SIMILARITY does not hurt BLEU, and performs significantly ($p < 0.05$) better than RANDOM selection.

The SEMANTIC SIMILARITY model also achieves significantly better translation quality than the ENTAILMENT model used in our prior work. Surprisingly, the ENTAILMENT model performs worse than the ALL baseline, unlike in our prior work. We attribute this different behavior to several factors: the strength of the new baseline (Section 6.2), the use of Adam instead of AdaDelta, which results in stronger BLEU scores at the beginning of the learning curves for all models, and finally the deduplication of the training data. In our prior systems, the training corpus was not deduplicated. Data selection had a side-effect of reducing the ratio of duplicated examples. When the ENTAILMENT model was used, longer sentence pairs with more balanced length were selected, yielding longer translations with a better BLEU brevity penalty than the baseline. With the new systems, these advantages vanish. We further analyze output lengths in Section 6.5.

6.4 Vietnamese-English Results

Trends from English-French carry over to Vietnamese English, as the SEMANTIC SIMILARITY model compares favorably to ALL while reducing the number of training updates by 10%. SEMAN-

TIC SIMILARITY also yields better BLEU than RANDOM with the differences being statistically significant. While differences in score here are smaller, these result are encouraging since they demonstrate that our semantic divergence models port to more distant low-resource language pairs.

6.5 Analysis

We break down the results seen in Figure 1 and Table 3, with a focus on the behavior of the ENTAILMENT and ALL models. We start by analyzing the BLEU brevity penalty trends observed on the validation set during training (Figure 2).

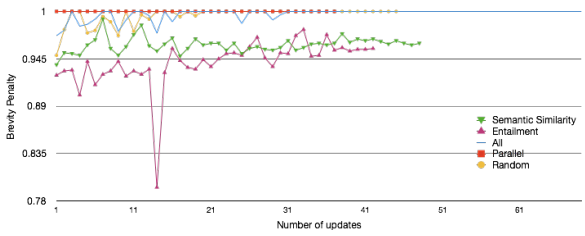

Figure 2: Brevity penalties on the validation set for English-French models (single run).

We observe that both the ENTAILMENT and SEMANTIC SIMILARITY based models have similar brevity penalties despite having performances that are at opposite ends of the spectrum in terms of BLEU. This implies that translations generated by the SEMANTIC SIMILARITY model have better n-gram overlap with the reference, but are much shorter. Manual examination of the translations suggests that the ENTAILMENT model often fails by under-translating sentences, either dropping segments from the beginning or the end of source sentences (Table 5).

The PARALLEL model consistently produces translations that are longer than the reference. [7] This is partially due to the model's propensity to generate a sequence of garbage tokens in the beginning of a sentence, especially while translating shorter sentences. In our test set, almost 12% of the translated sentences were found to begin with the garbage text shown in Table 5. Only a small fraction ($< 0.02\%$) of the French sentences in our training data begin with these tokens, but the tendency of PARALLEL to promote divergent examples above non-divergent ones, seems to exaggerate the generation of this sequence.

[7] The brevity penalty does not penalize translations that are longer than the reference.

ENTAILMENT is inadequate due to under-translation

Table 5: Selected translation examples from the ensemble systems of the various models.

7 Conclusion

We conducted an extensive empirical study of semantic divergences in parallel corpora. Our crowdsourced annotations confirms that correctly aligned sentences are not necessarily meaning equivalent. We introduced an approach based on neural semantic similarity that detects such divergences much more accurately than shallower translation or alignment based models. Importantly, our model does not require manual annotation, and can be trained for any language pair and domain with a parallel corpus. Finally, we show that filtering out divergent examples helps speed up the convergence of neural machine translation training without loss in translation quality, for two language pairs and data conditions. New datasets and models introduced in this work are available at `http://github.com/yogarshi/SemDiverge`.

These findings open several avenues for future work: How can we improve divergence detection further? Can we characterize the nature of the divergences beyond binary predictions? How do divergent examples impact other applications, including cross-lingual NLP applications and semantic models induced from parallel corpora, as well as tools for human translators and second language learners?

Abstract

A core step in statistical data-to-text generation concerns learning correspondences between structured data representations (e.g., facts in a database) and associated texts. In this paper we aim to bootstrap generators from large scale datasets where the data (e.g., DBPedia facts) and related texts (e.g., Wikipedia abstracts) are loosely aligned. We tackle this challenging task by introducing a special-purpose content selection mechanism.[1] We use multi-instance learning to automatically discover correspondences between data and text pairs and show how these can be used to enhance the content signal while training an encoder-decoder architecture. Experimental results demonstrate that models trained with content-specific objectives improve upon a vanilla encoder-decoder which solely relies on soft attention.

1 Introduction

A core step in statistical data-to-text generation concerns learning correspondences between structured data representations (e.g., facts in a database) and paired texts (Barzilay and Lapata, 2005; Kim and Mooney, 2010; Liang et al., 2009). These correspondences describe how data representations are expressed in natural language (*content realisation*) but also indicate which subset of the data is verbalised in the text (*content selection*).

Although content selection is traditionally performed by domain experts, recent advances in generation using neural networks (Bahdanau et al., 2015; Ranzato et al., 2016) have led to the use of large scale datasets containing loosely related data and text pairs. A prime example are online data sources like DBPedia (Auer et al., 2007) and Wikipedia and their associated texts which are often independently edited. Another example are sports databases and related textual resources. Wiseman et al. (2017) recently define a generation task relating statistics of basketball games with commentaries and a blog written by fans.

In this paper, we focus on short text generation from such loosely aligned data-text resources. We work with the biographical subset of the DBPedia and Wikipedia resources where the data corresponds to DBPedia facts and texts are Wikipedia abstracts about people. Figure 1 shows an example for the film-maker *Robert Flaherty*, the Wikipedia infobox, and the corresponding abstract. We wish to bootstrap a data-to-text generator that learns to verbalise properties about an entity from a loosely related example text. Given the set of properties in Figure (1a) and the related text in Figure (1b), we want to learn verbalisations for those properties that are mentioned in the text and produce a short description like the one in Figure (1c).

In common with previous work (Mei et al., 2016; Lebret et al., 2016; Wiseman et al., 2017) our model draws on insights from neural machine translation (Bahdanau et al., 2015; Sutskever et al., 2014) using an encoder-decoder architecture as its backbone. Lebret et al. (2016) introduce the task of generating biographies from Wikipedia data, however they focus on single sentence generation. We generalize the task to multi-sentence text, and highlight the limitations of the standard attention mechanism which is often used as a proxy for content selection. When exposed to sub-sequences that do not correspond to any facts in the input, the soft attention mechanism will still try to justify the sequence and somehow distribute the attention weights over the input representation (Ghader and Monz, 2017). The decoder will still memorise high frequency sub-sequences in spite of these not being supported by any facts in the input.

We propose to alleviate these shortcom-

(a)

Born	Robert Joseph Flaherty February 16, 1884 Iron Mountain, Michigan, U.S.
Died	July 23, 1951 (aged 67) Dummerston, Vermont, U.S.
Cause of death	Cerebral thrombosis
Occupation	Filmmaker
Spouse(s)	Frances Johnson Hubbard

(b) Robert Joseph Flaherty, (February 16, 1884 July 23, 1951) was an American film-maker who directed and produced the first commercially successful feature-length documentary film, Nanook of the North (1922). The film made his reputation and nothing in his later life fully equalled its success, although he continued the development of this new genre of narrative documentary, e.g., with Moana (1926), set in the South Seas, and Man of Aran (1934), filmed in Ireland's Aran Islands. He is considered the "father" of both the documentary and the ethnographic film. Flaherty was married to writer Frances H. Flaherty from 1914 until his death in 1951. Frances worked on several of her husband's films, and received an Academy Award nomination for Best Original Story for Louisiana Story (1948).

(c) *Robert Joseph Flaherty, (February 16, 1884 July 23, 1951) was an American film-maker. Flaherty was married to Frances H. Flaherty until his death in 1951.*

Figure 1: Property-value pairs (a), related biographic abstract (b) for the Wikipedia entity *Robert Flaherty*, and model verbalisation in italics (c).

ings via a specific content selection mechanism based on multi-instance learning (MIL; Keeler and Rumelhart, 1992) which automatically discovers correspondences, namely alignments, between data and text pairs. These alignments are then used to modify the generation function during training. We experiment with two frameworks that allow to incorporate alignment information, namely multi-task learning (MTL; Caruana, 1993) and reinforcement learning (RL; Williams, 1992). In both cases we define novel objective functions using the learnt alignments. Experimental results using automatic and human-based evaluation show that models trained with content-specific objectives improve upon vanilla encoder-decoder architectures which rely solely on soft attention.

The remainder of this paper is organised as follows. We discuss related work in Section 2 and describe the MIL-based content selection approach in Section 3. We explain how the generator is trained in Section 4 and present evaluation experiments in Section 5. Section 7 concludes the paper.

2 Related Work

Previous attempts to exploit loosely aligned data and text corpora have mostly focused on extracting verbalisation spans for data units. Most approaches work in two stages: initially, data units are aligned with sentences from related corpora using some heuristics and subsequently extra content is discarded in order to retain only text spans verbalising the data. Belz and Kow (2010) obtain verbalisation spans using a measure of strength of association between data units and words, Walter et al. (2013) extract textual patterns from paths in dependency trees while Mrabet et al. (2016) rely on crowd-sourcing. Perez-Beltrachini and Gardent (2016) learn shared representations for data units and sentences reduced to subject-predicate-object triples with the aim of extracting verbalisations for knowledge base properties. Our work takes a step further, we not only induce data-to-text alignments but also learn generators that produce short texts verbalising a set of facts.

Our work is closest to recent neural network models which learn generators from independently edited data and text resources. Most previous work (Lebret et al., 2016; Chisholm et al., 2017; Sha et al., 2017; Liu et al., 2017) targets the generation of single sentence biographies from Wikipedia infoboxes, while Wiseman et al. (2017) generate game summary documents from a database of basketball games where the input is always the same set of table fields. In contrast, in our scenario, the input data varies from one entity (e.g., athlete) to another (e.g., scientist) and properties might be present or not due to data incompleteness. Moreover, our generator is enhanced with a content selection mechanism based on multi-instance learning. MIL-based techniques have been previously applied to a variety of problems including image retrieval (Maron and Ratan, 1998; Zhang et al., 2002), object detection (Carbonetto et al., 2008; Cour et al., 2011), text classification (Andrews and Hofmann, 2004), image captioning (Wu et al., 2015; Karpathy and Fei-Fei, 2015), paraphrase detection (Xu et al., 2014), and information extraction (Hoffmann et al., 2011). The application of MIL to content selection is novel to our knowledge.

We show how to incorporate content selection into encoder-decoder architectures following training regimes based on multi-task learning and reinforcement learning. Multi-task learning aims to improve a main task by incorporating joint learning of one or more related auxiliary tasks. It has been applied with success to a variety of sequence-prediction tasks focus-

ing mostly on morphosyntax. Examples include chunking, tagging (Collobert et al., 2011; Søgaard and Goldberg, 2016; Bjerva et al., 2016; Plank, 2016), name error detection (Cheng et al., 2015), and machine translation (Luong et al., 2016). Reinforcement learning (Williams, 1992) has also seen popularity as a means of training neural networks to directly optimize a task-specific metric (Ranzato et al., 2016) or to inject task-specific knowledge (Zhang and Lapata, 2017). We are not aware of any work that compares the two training methods directly. Furthermore, our reinforcement learning-based algorithm differs from previous text generation approaches (Ranzato et al., 2016; Zhang and Lapata, 2017) in that it is applied to documents rather than individual sentences.

3 Bidirectional Content Selection

We consider loosely coupled data and text pairs where the data component is a set $\mathcal{P}$ of property-values $\{p_1 : v_1, \cdots, p_{|\mathcal{P}|} : v_{|\mathcal{P}|}\}$ and the related text $\mathcal{T}$ is a sequence of sentences $(s_1, \cdots, s_{|\mathcal{T}|})$. We define a *mention span* τ as a (possibly discontinuous) subsequence of $\mathcal{T}$ containing one or several words that verbalise one or more property-value from $\mathcal{P}$. For instance, in Figure 1, the mention span *"married to Frances H. Flaherty"* verbalises the property-value $\{Spouse(s) : Frances\ Johnson\ Hubbard\}$.

In traditional supervised data to text generation tasks, data units (e.g., $p_i : v_i$ in our particular setting) are either covered by some mention span τ_j or do not have any mention span at all in $\mathcal{T}$. The latter is a case of content selection where the generator will learn which properties to ignore when generating text from such data. In this work, we consider text components which are independently edited, and will unavoidably contain *unaligned spans*, i.e., text segments which do not correspond to any property-value in $\mathcal{P}$. The phrase *"from 1914"* in the text in Figure (1b) is such an example. Similarly, the last sentence, talks about Frances' awards and nominations and this information is not supported by the properties either.

Our model checks content in both directions; it identifies which properties have a corresponding text span (data selection) and also foregrounds (un)aligned text spans (text selection). This knowledge is then used to discourage the generator from producing text not supported by facts in the property set $\mathcal{P}$. We view a property set $\mathcal{P}$ and its loosely coupled text $\mathcal{T}$ as a coarse level, imperfect alignment. From this alignment signal, we want to discover a set of finer grained alignments indicating which mention spans in $\mathcal{T}$ align to which properties in $\mathcal{P}$. For each pair $(\mathcal{P}, \mathcal{T})$, we learn an alignment set $\mathcal{A}(\mathcal{P}, \mathcal{T})$ which contains property-value word pairs. For example, for the properties *spouse* and *died* in Figure 1, we would like to derive the alignments in Table 1.

married	$spouse : FrancesJohnsonFlaherty$
to	$spouse : FrancesJohnsonFlaherty$
Frances	$spouse : FrancesJohnsonFlaherty$
Flaherty	$spouse : FrancesJohnsonFlaherty$
death	$died : july23, 1951$
in	$died : july23, 1951$
1951	$died : july23, 1951$

Table 1: Example of word-property alignments for the Wikipedia abstract and facts in Figure 1.

We formulate the task of discovering finer-grained word alignments as a multi-instance learning problem (Keeler and Rumelhart, 1992). We assume that words from the text are positive labels for some property-values but we do not know which ones. For each data-text pair $(\mathcal{P}, \mathcal{T})$, we derive $|\mathcal{T}|$ pairs of the form $(\mathcal{P}, s)$ where $|\mathcal{T}|$ is the number of sentences in $\mathcal{T}$. We encode property sets $\mathcal{P}$ and sentences s into a common multimodal h-dimensional embedding space. While doing this, we discover finer grained alignments between words and property-values. The intuition is that by learning a high similarity score for a property set $\mathcal{P}$ and sentence pair s, we will also learn the contribution of individual elements (i.e., words and property-values) to the overall similarity score. We will then use this individual contribution as a measure of word and property-value alignment. More concretely, we assume the pair is aligned (or unaligned) if this individual score is above (or below) a given threshold. Across examples like the one shown in Figure (1a-b), we expect the model to learn an alignment between the text span *"married to Frances H. Flaherty"* and the property-value $\{spouse : Frances\ Johnson\ Hubbard\}$.

In what follows we describe how we encode $(\mathcal{P}, s)$ pairs and define the similarity function.

Property Set Encoder As there is no fixed order among the property-value pairs $p : v$ in $\mathcal{P}$, we individually encode each one of them. Furthermore, both properties p and values v may consist of short phrases. For instance, the property $cause\ of\ death$ and value *cerebral thrombosis* in Figure 1. We

therefore consider property-value pairs as concatenated sequences pv and use a bidirectional Long Short-Term Memory Network (LSTM; Hochreiter and Schmidhuber, 1997) network for their encoding. Note that the same network is used for all pairs. Each property-value pair is encoded into a vector representation:

$$\mathbf{p}_i = \text{biLSTM}_{denc}(pv_i) \quad (1)$$

which is the output of the recurrent network at the final time step. We use addition to combine the forward and backward outputs and generate encoding $\{\mathbf{p}_1, \cdots, \mathbf{p}_{|\mathcal{P}|}\}$ for $\mathcal{P}$.

Sentence Encoder We also use a biLSTM to obtain a representation for the sentence $s = w_1, \cdots, w_{|s|}$. Each word w_t is represented by the output of the forward and backward networks at time step t. A word at position t is represented by the concatenation of the forward and backward outputs of the networks at time step t :

$$\mathbf{w}_t = \text{biLSTM}_{senc}(w_t) \quad (2)$$

and each sentence is encoded as a sequence of vectors $(\mathbf{w}_1, \cdots, \mathbf{w}_{|s|})$.

Alignment Objective Our learning objective seeks to maximise the similarity score between property set $\mathcal{P}$ and a sentence s (Karpathy and Fei-Fei, 2015). This similarity score is in turn defined on top of the similarity scores among property-values in $\mathcal{P}$ and words in s. Equation (3) defines this similarity function using the dot product. The function seeks to align each word to the best scoring property-value:

$$S_{\mathcal{P}s} = \sum_{t=1}^{|s|} max_{i \in \{1,\ldots,|\mathcal{P}|\}} \mathbf{p}_i \cdot \mathbf{w}_t \quad (3)$$

Equation (4) defines our objective which encourages related properties $\mathcal{P}$ and sentences s to have higher similarity than other $\mathcal{P}' \neq \mathcal{P}$ and $s' \neq s$:

$$\begin{aligned} \mathcal{L}_{CA} = & max(0, S_{\mathcal{P}s} - S_{\mathcal{P}s'} + 1) \\ & + max(0, S_{\mathcal{P}s} - S_{\mathcal{P}'s} + 1) \end{aligned} \quad (4)$$

4 Generator Training

In this section we describe the base generation architecture and explain two alternative ways of using the alignments to guide the training of the model. One approach follows multi-task training where the generator learns to output a sequence of words but also to predict alignment labels for each word. The second approach relies on reinforcement learning for adjusting the probability distribution of word sequences learnt by a standard word prediction training algorithm.

4.1 Encoder-Decoder Base Generator

We follow a standard attention based encoder-decoder architecture for our generator (Bahdanau et al., 2015; Luong et al., 2015). Given a set of properties X as input, the model learns to predict an output word sequence Y which is a verbalisation of (part of) the input. More precisely, the generation of sequence Y is conditioned on input X:

$$P(Y|X) = \prod_{t=1}^{|Y|} P(y_t|y_{1:t-1}, X) \quad (5)$$

The encoder module constitutes an intermediate representation of the input. For this, we use the property-set encoder described in Section 3 which outputs vector representations $\{\mathbf{p}_1, \cdots, \mathbf{p}_{|X|}\}$ for a set of property-value pairs. The decoder uses an LSTM and a soft attention mechanism (Luong et al., 2015) to generate one word y_t at a time conditioned on the previous output words and a context vector c_t dynamically created:

$$P(y_{t+1}|y_{1:t}, X) = softmax(g(\mathbf{h}_t, c_t)) \quad (6)$$

where $g(\cdot)$ is a neural network with one hidden layer parametrised by $\mathbf{W}_o \in \mathbb{R}^{|V| \times d}$, $|V|$ is the output vocabulary size and d the hidden unit dimension, over $\mathbf{h}_t$ and c_t composed as follows:

$$g(\mathbf{h}_t, c_t) = \mathbf{W}_o \, tanh(\mathbf{W}_c[c_t; \mathbf{h}_t]) \quad (7)$$

where $\mathbf{W}_c \in \mathbb{R}^{d \times 2d}$. $\mathbf{h}_t$ is the hidden state of the LSTM decoder which summarises $y_{1:t}$:

$$\mathbf{h}_t = \text{LSTM}(y_t, \mathbf{h}_{t-1}) \quad (8)$$

The dynamic context vector c_t is the weighted sum of the hidden states of the input property set (Equation (9)); and the weights α_{ti} are determined by a dot product attention mechanism:

$$c_t = \sum_{i=1}^{|X|} \alpha_{ti} \mathbf{p}_i \quad (9)$$

$$\alpha_{ti} = \frac{\exp(\mathbf{h}_t \cdot \mathbf{p}_i)}{\sum_{i'} \exp(\mathbf{h}_t \cdot \mathbf{p}_{i'})} \quad (10)$$

We initialise the decoder with the averaged sum of the encoded input representations (Vinyals et al., 2016). The model is trained to optimize negative log likelihood:

$$\mathcal{L}_{wNLL} = -\sum_{t=1}^{|Y|} log\, P(y_t|y_{1:t-1}, X) \quad (11)$$

We extend this architecture to multi-sentence texts in a way similar to Wiseman et al. (2017). We view the abstract as a single sequence, i.e., all sentences are concatenated. When training, we cut the abstracts in blocks of equal size and perform forward backward iterations for each block (this includes the back-propagation through the encoder). From one block iteration to the next, we initialise the decoder with the last state of the previous block. The block size is a hyperparameter tuned experimentally on the development set.

4.2 Predicting Alignment Labels

The generation of the output sequence is conditioned on the previous words and the input. However, when certain sequences are very common, the language modelling conditional probability will prevail over the input conditioning. For instance, the phrase *from 1914* in our running example is very common in contexts that talk about periods of marriage or club membership, and as a result, the language model will output this phrase often, even in cases where there are no supporting facts in the input. The intuition behind multi-task training (Caruana, 1993) is that it will smooth the probabilities of frequent sequences when trying to simultaneously predict alignment labels.

Using the set of alignments obtained by our content selection model, we associate each word in the training data with a binary label a_t indicating whether it aligns with some property in the input set. Our auxiliary task is to predict a_t given the sequence of previously predicted words and input X:

$$P(a_{t+1}|y_{1:t},X) = sigmoid(g'(\mathbf{h}_t,c_t)) \quad (12)$$

$$g'(\mathbf{h}_t,c_t) = \mathbf{v}_a \cdot tanh(\mathbf{W}_c[c_t;\mathbf{h}_t]) \quad (13)$$

where $\mathbf{v}_a \in \mathbb{R}^d$ and the other operands are as defined in Equation (7). We optimise the following auxiliary objective function:

$$\mathcal{L}_{aln} = -\sum_{t=1}^{|Y|} log\, P(a_t|y_{1:t-1},X) \quad (14)$$

and the combined multi-task objective is the weighted sum of both word prediction and alignment prediction losses:

$$\mathcal{L}_{MTL} = \lambda\, \mathcal{L}_{wNLL} + (1-\lambda)\, \mathcal{L}_{aln} \quad (15)$$

where λ controls how much model training will focus on each task. As we will explain in Section 5, we can anneal this value during training in favour of one objective or the other.

4.3 Reinforcement Learning Training

Although the multi-task approach aims to smooth the target distribution, the training process is still driven by the imperfect target text. In other words, at each time step t the algorithm feeds the previous word w_{t-1} of the target text and evaluates the prediction against the target w_t.

Alternatively, we propose a training approach based on reinforcement learning (Williams 1992) which allows us to define an objective function that does not fully rely on the target text but rather on a revised version of it. In our case, the set of alignments obtained by our content selection model provides a revision for the target text. The advantages of reinforcement learning are twofold: (a) it allows to exploit additional task-specific knowledge (Zhang and Lapata, 2017) during training, and (b) enables the exploration of other word sequences through sampling. Our setting differs from previous applications of RL (Ranzato et al., 2016; Zhang and Lapata, 2017) in that the reward function is not computed on the target text but rather on its alignments with the input.

The encoder-decoder model is viewed as an agent whose action space is defined by the set of words in the target vocabulary. At each time step, the encoder-decoder takes action $\hat{y}_t$ with policy $P_\pi(\hat{y}_t|\hat{y}_{1:t-1},X)$ defined by the probability in Equation (6). The agent terminates when it emits the End Of Sequence (EOS) token, at which point the sequence of all actions taken yields the output sequence $\hat{Y} = (\hat{y}_1,\cdots,\hat{y}_{|\hat{Y}|})$. This sequence in our task is a short text describing the properties of a given entity. After producing the sequence of actions $\hat{Y}$, the agent receives a reward $r(\hat{Y})$ and the policy is updated according to this reward.

Reward Function We define the reward function $r(\hat{Y})$ on the alignment set $\mathcal{A}(X,Y)$. If the output action sequence $\hat{Y}$ is precise with respect to the set of alignments $\mathcal{A}(X,Y)$, the agent will receive a high reward. Concretely, we define $r(\hat{Y})$ as follows:

$$r(\hat{Y}) = \gamma^{pr}\, r^{pr}(\hat{Y}) \quad (16)$$

where γ^{pr} adjusts the reward value r^{pr} which is the unigram precision of the predicted sequence $\hat{Y}$ and the set of words in $\mathcal{A}(X,Y)$.

Training Algorithm We use the REINFORCE algorithm (Williams, 1992) to learn an agent that maximises the reward function. As this is a gradient descent method, the training loss of a sequence

is defined as the negative expected reward:

$$\mathcal{L}_{RL} = -\mathbb{E}_{(\hat{y}_1,\cdots,\hat{y}_{|\hat{Y}|})} \sim P_\pi(\cdot|X)[r(\hat{y}_1,\cdots,\hat{y}_{|\hat{Y}|})]$$

where P_π is the agent's policy, i.e., the word distribution produced by the encoder-decoder model (Equation (6)) and $r(\cdot)$ is the reward function as defined in Equation (16). The gradient of $\mathcal{L}_{RL}$ is given by:

$$\nabla \mathcal{L}_{RL} \approx \sum_{t=1}^{|\hat{Y}|} \nabla \log P_\pi(\hat{y}_t|\hat{y}_{1:t-1}, X)[r(\hat{y}_{1:|\hat{Y}|}) - b_t]$$

where b_t is a baseline linear regression model used to reduce the variance of the gradients during training. b_t predicts the future reward and is trained by minimizing mean squared error. The input to this predictor is the agent hidden state $\mathbf{h}_t$, however we do not back-propagate the error to $\mathbf{h}_t$. We refer the interested reader to Williams (1992) and Ranzato et al. (2016) for more details.

Document Level Curriculum Learning Rather than starting from a state given by a random policy, we initialise the agent with a policy learnt by pre-training with the negative log-likelihood objective (Ranzato et al., 2016; Zhang and Lapata, 2017). The reinforcement learning objective is applied gradually in combination with the log-likelihood objective on each target block subsequence. Recall from Section 4.1 that our document is segmented into blocks of equal size during training which we denote as MAXBLOCK. When training begins, only the last $\mho$ tokens are predicted by the agent while for the first $(\text{MAXBLOCK} - \mho)$ we still use the negative log-likelihood objective. The number of tokens $\mho$ predicted by the agent is incremented by $\mho$ units every 2 epochs. We set $\mho = 3$ and the training ends when $(\text{MAXBLOCK} - \mho) = 0$. Since we evaluate the model's predictions at the block level, the reward function is also evaluated at the block level.

5 Experimental Setup

Data We evaluated our model on a dataset collated from WIKIBIO (Lebret et al., 2016), a corpus of 728,321 biography articles (their first paragraph) and their infoboxes sampled from the English Wikipedia. We adapted the original dataset in three ways. Firstly, we make use of the entire abstract rather than first sentence. Secondly, we reduced the dataset to examples with a rich set of properties and multi-sentential text. We eliminated examples with less than six property-value pairs and abstracts consisting of one sentence. We also placed a minimum restriction of 23 words in the length of the abstract. We considered abstracts up to a maximum of 12 sentences and property sets with a maximum of 50 property-value pairs. Finally, we associated each abstract with the set of DBPedia properties $p:v$ corresponding to the abstract's main entity. As entity classification is available in DBPedia for most entities, we concatenate class information c (whenever available) with the property value, i.e., $p:vc$. In Figure 1, the property value $spouse:FrancesH.Flaherty$ is extended with class information from the DBPedia ontology to $spouse:FrancesH.FlahertyPerson$.

Pre-processing Numeric date formats were converted to a surface form with month names. Numerical expressions were delexicalised using different tokens created with the property name and position of the delexicalised token on the value sequence. For instance, given the property-value for *birth date* in Figure (1a), the first sentence in the abstract (Figure (1b)) becomes " *Robert Joseph Flaherty, (February DLX_birth_date_2, DLX_birth_date_4 – July ...* ". Years and numbers in the text not found in the values of the property set were replaced with tokens YEAR and NUMERIC.[2] In a second phase, when creating the input and output vocabularies, $\mathcal{V}^I$ and $\mathcal{V}^O$ respectively, we delexicalised words w which were absent from the output vocabulary but were attested in the input vocabulary. Again, we created tokens based on the property name and the position of the word in the value sequence. Words not in $\mathcal{V}^O$ or $\mathcal{V}^I$ were replaced with the symbol UNK. Vocabulary sizes were limited to $|\mathcal{V}^I| = 50k$ and $|\mathcal{V}^O| = 50k$ for the alignment model and $|\mathcal{V}^O| = 20k$ for the generator. We discarded examples where the text contained more than three UNKs (for the content aligner) and five UNKs (for the generator); or more than two UNKs in the property-value (for generation). Finally, we added the empty relation to the property sets.

Table 2 summarises the dataset statistics for the generator. We report the number of abstracts in the dataset (size), the average number of sentences and tokens in the abstracts, and the average number of properties and sentence length in tokens

[2] We exploit these tokens to further adjust the score of the reward function given by Equation (16). Each time the predicted output contains some of these symbols we decrease the reward score by κ which we empirically set to 0.025 .

generation	train	dev	test
size	165,324	25,399	23,162
sentences	3.51±1.99	3.46±1.94	3.22±1.72
tokens	74.13±43.72	72.85±42.54	66.81±38.16
properties	14.97±8.82	14.96±8.85	21.6±9.97
sent.len	21.06±8.87	21.03±8.85	20.77±8.74

Table 2: Dataset statistics.

(sent.len). For the content aligner (cf. Section 3), each sentence constitutes a training instance, and as a result the sizes of the train and development sets are 796,446 and 153,096, respectively.

Training Configuration We adjusted all models' hyperparameters according to their performance on the development set. The encoders for both content selection and generation models were initialised with GloVe (Pennington et al., 2014) pre-trained vectors. The input and hidden unit dimension was set to 200 for content selection and 100 for generation. In all models, we used encoder biLSTMs and decoder LSTM (regularised with a dropout rate of 0.3 (Zaremba et al., 2014)) with one layer. Content selection and generation models (base encoder-decoder and MTL) were trained for 20 epochs with the ADAM optimiser (Kingma and Ba, 2014) using a learning rate of 0.001. The reinforcement learning model was initialised with the base encoder-decoder model and trained for 35 additional epochs with stochastic gradient descent and a fixed learning rate of 0.001. Block sizes were set to 40 (base), 60 (MTL) and 50 (RL). Weights for the MTL objective were also tuned experimentally; we set $\lambda = 0.1$ for the first four epochs (training focuses on alignment prediction) and switched to $\lambda = 0.9$ for the remaining epochs.

Content Alignment We optimized content alignment on the development set against manual alignments. Specifically, two annotators aligned 132 sentences to their infoboxes. We used the Yawat annotation tool (Germann, 2008) and followed the alignment guidelines (and evaluation metrics) used in Cohn et al. (2008). The inter-annotator agreement using macro-averaged f-score was 0.72 (we treated one annotator as the reference and the other one as hypothetical system output).

Alignment sets were extracted from the model's output (cf. Section 3) by optimizing the threshold $avg(sim) + a * std(sim)$ where sim denotes the similarity between the set of property values and words, and a is empirically set to 0.75; avg and std are the mean and standard deviation of sim scores across the development set. Each word was aligned to a property-value if their similarity exceeded a threshold of 0.22. Our best content alignment model (Content-Aligner) obtained an f-score of 0.36 on the development set.

We also compared our Content-Aligner against a baseline based on pre-trained word embeddings (EmbeddingsBL). For each pair $(\mathcal{P}, s)$ we computed the dot product between words in s and properties in $\mathcal{P}$ (properties were represented by the the averaged sum of their words' vectors). Words were aligned to property-values if their similarity exceeded a threshold of 0.4. EmbeddingsBL obtained an f-score of 0.057 against the manual alignments. Finally, we compared the performance of the Content-Aligner at the level of property set $\mathcal{P}$ and sentence s similarity by comparing the average ranking position of correct pairs among 14 distractors, namely rank@15. The Content-Aligner obtained a rank of 1.31, while the EmbeddingsBL model had a rank of 7.99 (lower is better).

6 Results

We compared the performance of an encoder-decoder model trained with the standard negative log-likelihood method (ED), against a model trained with multi-task learning (ED_{MTL}) and reinforcement learning (ED_{RL}). We also included a template baseline system (Templ) in our evaluation experiments.

The template generator used hand-written rules to realise property-value pairs. As an approximation for content selection, we obtained the 50 more frequent property names from the training set and manually defined content ordering rules with the following criteria. We ordered personal life properties (e.g., *birth_date* or *occupation*) based on their most common order of mention in the Wikipedia abstracts. Profession dependent properties (e.g., *position* or *genre*), were assigned an equal ordering but posterior to the personal properties. We manually lexicalised properties into single sentence templates to be concatenated to produce the final text. The template for the property *position* and example verbalisation for the property-value $position : defender$ of the entity *zanetti* are "[NAME] *played as* [POSITION]." and "*Zanetti played as defender.*" respectively.

Automatic Evaluation Table 3 shows the results of automatic evaluation using BLEU-4

Model	Abstract	RevAbs
Templ	5.47	6.43
ED	13.46	35.89
ED_{MTL}	**13.57**	**37.18**
ED_{RL}	12.97	35.74

Table 3: BLEU-4 results using the original Wikipedia abstract (Abstract) as reference and crowd-sourced revised abstracts (RevAbs) for template baseline (Templ), standard encoder-decoder model (ED), and our content-based models trained with multi-task learning (ED_{MTL}) and reinforcement learning (ED_{RL}).

(Papineni et al., 2002) against the noisy Wikipedia abstracts. Considering these as a gold standard is, however, not entirely satisfactory for two reasons. Firstly, our models generate considerably shorter text and will be penalized for not generating text they were not supposed to generate in the first place. Secondly, the model might try to reproduce what is in the imperfect reference but not supported by the input properties and as a result will be rewarded when it should not. To alleviate this, we crowd-sourced using AMT a revised version of 200 randomly selected abstracts from the test set.

Crowdworkers were shown a Wikipedia infobox with the accompanying abstract and were asked to adjust the text to the content present in the infobox. Annotators were instructed to delete spans which did not have supporting facts and rewrite the remaining parts into a well-formed text. We collected three revised versions for each abstract. Inter-annotator agreement was 81.64 measured as the mean pairwise BLEU-4 amongst AMT workers.

Automatic evaluation results against the revised abstracts are also shown in Table 3. As can be seen, all encoder-decoder based models have a significant advantage over Templ when evaluating against both types of abstracts. The model enabled with the multi-task learning content selection mechanism brings an improvement of 1.29 BLEU-4 over a vanilla encoder-decoder model. Performance of the RL trained model is inferior and close to the ED model. We discuss the reasons for this discrepancy shortly.

To provide a rough comparison with the results reported in Lebret et al. (2016), we also computed BLEU-4 on the first sentence of the text generated by our system.[3] Recall that their model generates the first sentence of the abstract, whereas we output multi-sentence text. Using the first sentence in the Wikipedia abstract as reference, we obtained a score of 37.29% (ED), 38.42% (ED_{MTL}) and 38.1% (ED_{RL}) which compare favourably with their best performing model (34.7%±0.36).

[3]We post-processed system output with Stanford CoreNLP (Manning et al., 2014) to extract the first sentence.

System	1^{st}	2^{nd}	3^{rd}	4^{th}	5^{th}	Rank
Templ	12.17	14.33	10.17	15.50	**47.83**	3.72
ED	12.83	24.17	24.67	**25.17**	13.17	3.02
ED_{MTL}	14.83	**26.17**	**26.17**	19.17	13.67	2.90
ED_{RL}	14.67	**25.00**	**25.50**	24.00	10.83	2.91
RevAbs	**47.00**	14.00	12.67	16.17	9.17	2.27

Table 4: Rankings shown as proportions and mean ranks given to systems by human subjects.

Human-Based Evaluation We further examined differences among systems in a human-based evaluation study. Using AMT, we elicited 3 judgements for the same 200 infobox-abstract pairs we used in the abstract revision study. We compared the output of the templates, the three neural generators and also included one of the human edited abstracts as a gold standard (reference). For each test case, we showed crowdworkers the Wikipedia infobox and five short texts in random order. The annotators were asked to rank each of the texts according to the following criteria: (1) Is the text faithful to the content of the table? and (2) Is the text overall comprehensible and fluent? Ties were allowed only when texts were identical strings. Table 5 presents examples of the texts (and properties) crowdworkers saw.

Table 4 shows, proportionally, how often crowdworkers ranked each system, first, second, and so on. Unsurprisingly, the human authored gold text is considered best (and ranked first 47% of the time). ED_{MTL} is mostly ranked second and third best, followed closely by ED_{RL}. The vanilla encoder-decoder system ED is mostly forth and Templ is fifth. As shown in the last column of the table (Rank), the ranking of ED_{MTL} is overall slightly better than ED_{RL}. We further converted the ranks to ratings on a scale of 1 to 5 (assigning ratings 5…1 to rank placements 1…5). This allowed us to perform Analysis of Variance (ANOVA) which revealed a reliable effect of system type. Post-hoc Tukey tests showed that all systems were significantly worse than RevAbs and significantly better than Templ ($p < 0.05$). ED_{MTL} is not significantly better than ED_{RL} but is significantly ($p < 0.05$) different from ED.

Discussion The texts generated by ED_{RL} are shorter compared to the other two neural systems

Table 5: Examples of system output.

which might affect BLEU-4 scores and also the ratings provided by the annotators. As shown in Table 5 (entity *dorsey burnette*), ED_{RL} drops information pertaining to dates or chooses to just verbalise birth place information. In some cases, this is preferable to hallucinating incorrect facts; however, in other cases outputs with more information are rated more favourably. Overall, ED_{MTL} seems to be more detail oriented and faithful to the facts included in the infobox (see *dorsey burnette*, *aaron moores*, or *kirill moryganov*). The template system manages in some specific configurations to verbalise appropriate facts (*indrani bose*), however, it often fails to verbalise infrequent properties (*aaron moores*) or focuses on properties which are very frequent in the knowledge base but are rarely found in the abstracts (*kirill moryganov*).

7 Conclusions

In this paper we focused on the task of bootstrapping generators from large-scale datasets consisting of DBPedia facts and related Wikipedia biography abstracts. We proposed to equip standard encoder-decoder models with an additional content selection mechanism based on multi-instance learning and developed two training regimes, one based on multi-task learning and the other on reinforcement learning. Overall, we find that the proposed content selection mechanism improves the accuracy and fluency of the generated texts. In the future, it would be interesting to investigate a more sophisticated representation of the input (Vinyals et al., 2016). It would also make sense for the model to decode hierarchically, taking sequences of words *and* sentences into account (Zhang and Lapata, 2014; Lebret et al., 2015).

Acknowledgments

We thank the NAACL reviewers for their constructive feedback. We also thank Xingxing Zhang, Li Dong and Stefanos Angelidis for useful discussions about implementation details. We gratefully acknowledge the financial support of the European Research Council (award number 681760).

Abstract

Supervised training of abstractive language generation models results in learning conditional probabilities over language sequences based on the supervised training signal. When the training signal contains a variety of writing styles, such models may end up learning an 'average' style that is directly influenced by the training data make-up and cannot be controlled by the needs of an application. We describe a family of model architectures capable of capturing both generic language characteristics via shared model parameters, as well as particular style characteristics via private model parameters. Such models are able to generate language according to a specific learned style, while still taking advantage of their power to model generic language phenomena. Furthermore, we describe an extension that uses a mixture of output distributions from all learned styles to perform on-the-fly style adaptation based on the textual input alone. Experimentally, we find that the proposed models consistently outperform models that encapsulate single-style or average-style language generation capabilities.

1 Introduction

Encoder-decoder models have recently pushed forward the state-of-the-art performance on a variety of language generation tasks, including machine translation (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017), text summarization (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017), dialog systems (Li et al., 2016; Asghar et al., 2017), and image captioning (Xu et al., 2015; Ranzato et al., 2015; Liu et al., 2017). This framework consists of an encoder that reads the input data and encodes it as a sequence of vectors, which is in turn used by a decoder to generate another sequence of vectors used to produce output symbols step by step.

The prevalent approach to training such a model is to update all the model parameters using all the examples in the training data (over multiple epochs). This is a reasonable approach, under the assumption that we are modeling a single underlying distribution in the data. However, in many applications and for many natural language datasets, there exist multiple underlying distributions, characterizing a variety of language styles. For instance, the widely-used Gigaword dataset (Graff and Cieri, 2003) consists of a collection of articles written by various publishers (The New York Times, Agence France Presse, Xinhua News, etc.), each with its own style characteristics. Training a model's parameters on all the training examples results in an averaging effect across style characteristics, which may lower the quality of the outputs; additionally, this averaging effect may be completely undesirable for applications that require a level of control over the output style. At the opposite end of the spectrum, one can choose to train one independent model per each underlying distribution (assuming we have the appropriate signals for identifying them at training time). This approach misses the opportunity to exploit common properties shared by these distributions (e.g., generic characteristics of a language, such as noun-adjective position), and leads to models that are under-trained due to limited data availability per distribution.

In order to address these issues, we propose a novel neural architecture called SHAPED (shared-private encoder-decoder). This architecture has both shared encoder/decoder parameters that are updated based on all the training examples, as well as private encoder/decoder parameters that are updated using only examples from their corresponding underlying training distributions. In addition

to learning different parametrization between the shared model and the private models, we jointly learn a classifier to estimate the probability of each example belonging to each of the underlying training distributions. In such a setting, the shared parameters ('shared model') are expected to learn characteristics shared by the entire set of training examples (i.e., language generic), whereas each private parameter set ('private model') learns particular characteristics (i.e., style specific) of their corresponding training distribution. At the same time, the classifier is expected to learn a probability distribution over the labels used to identify the underlying distributions present in the input data. At test time, there are two possible scenarios. In the first one, the input signal explicitly contains information about the underlying distribution (e.g., the publisher's identity). In this case, we feed the data into the shared model and also the corresponding private model, and perform sequence generation based on a concatenation of their vector outputs; we refer to this model as the SHAPED model. In a second scenario, the information about the underlying distribution is either not available, or it refers to a distribution that was not seen during training. In this case, we feed the data into the shared model and all the private models; the output distribution of the symbols of the decoding sequence is estimated using a mixture of distributions from all the decoders, weighted according to the classifier's estimates for that particular example; we refer to this model as the Mix-SHAPED model.

We test our models on the headline-generation task based on the aforementioned Gigaword dataset. When the publisher's identity is presented as part of the input, we show that the SHAPED model significantly surpasses the performance of the shared encoder-decoder baseline, as well as the performance of private models (where one individual, per-publisher model is trained for each in-domain style). When the publisher's identity is not presented as part of the input (i.e., not presented at run-time but revealed at evaluation-time for measurement purposes), we show that the Mix-SHAPED model exhibits a high level of classification accuracy based on textual inputs alone (accuracy percentage in the 80s overall, varying by individual publisher), while its generation accuracy still surpasses the performance of the baseline models. Finally, when the publisher's identity is unknown to the model (i.e., a publisher that was not part of the training dataset), we show that the Mix-SHAPED model performance far surpasses the shared model performance, due to the ability of the Mix-SHAPED model to perform on-the-fly adaptation of output style. This feat comes from our model's ability to perform two distinct tasks: match the incoming, previously-unseen input style to existing styles learned at training time, and use the correlations learned at training time between input and output style characteristics to generate style-appropriate token sequences.

2 Related Work

Encoder-Decoder Models for Structured Output Prediction

Encoder-decoder architectures have been successfully applied to a variety of structure prediction tasks recently. Tasks for which such architectures have achieved state-of-the-art results include machine translation (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017), automatic text summarization (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Paulus et al., 2017; Nema et al., 2017), sentence simplification (Filippova et al., 2015; Zhang and Lapata, 2017), dialog systems (Li et al., 2016, 2017; Asghar et al., 2017), image captioning (Vinyals et al., 2015; Xu et al., 2015; Ranzato et al., 2015; Liu et al., 2017), etc. By far the most used implementation of such architectures is based on the original sequence-to-sequence model (Sutskever et al., 2014), augmented with its attention-based extension (Bahdanau et al., 2015). Although our SHAPED and Mix-SHAPED model formulations do not depend on a particular architecture implementation, we do make use of the (Bahdanau et al., 2015) model to instantiate our models.

Domain Adaptation for Neural Network Models

One general approach to domain adaptation for natural language tasks is to perform data/feature augmentation that represents inputs as both general and domain-dependent data, as originally proposed in (Daumé III, 2009), and ported to neural models in (Kim et al., 2016). For computer vision tasks, a line of work related to our approach has been proposed by Bousmalis et al. (2016) using what they call domain separation networks. As a tool for studying unsupervised domain adaptation

for image recognition tasks, their proposal uses CNNs for encoding an image into a feature representation, and also for reconstructing the input sample. It also makes use of a private encoder for each domain, and a shared encoder for both the source and the target domain. The approach we take in this paper shares this idea of model parametrization according to the domain/style, but goes further with the Mix-SHAPED model, performing on-the-fly adaptation of the model outputs. Other CNN-based domain adaptation methods for object recognition tasks are presented in (Long et al., 2016; Chopra et al., 2013; Tzeng et al., 2015; Sener et al., 2016).

For NLP tasks, Peng and Dredze (2017) take a multi-task approach to domain adaptation and sequence tagging. They use a shared encoder to represent instances from all of the domains, and use a domain projection layer to project the shared layer into a domain-specific space. They only consider the supervised domain-adaptation case, in which labeled training data exists for the target domain. Glorot et al. (2011) use auto-encoders for learning a high-level feature extraction across domains for sentiment analysis, while Zhou et al. (2016) employ auto-encoders to directly transfer the examples across different domains also for the same sentiment analysis task. Hua and Wang (2017) perform an experimental analysis on domain adaptation for neural abstractive summarization.

An important requirement of all the methods in the related work described above is that they require access to the (unlabeled) target domain data, in order to learn a domain-invariant representation across source and target domains. In contrast, our Mix-SHAPED model does not need access to a target domain or style at training time, and instead performs the adaptation on-the-fly, according to the specifics of the input data and the correlations learned at training time between available input and output style characteristics. As such, it is a more general approach, which allows adaptation for a much larger set of target styles, under the weaker assumption that there exists one or more styles present in the training data that can act as representative underlying distributions.

3 Model Architecture

Generally speaking, a standard encoder-decoder model has two components: an encoder that takes as input a sequence of symbols $\mathbf{x} = (x_1, x_2, ..., x_{T_x})$ and encodes them into a set of vectors $\mathbf{H} = (h_1, h_2, ..., h_{T_x})$,

$$\mathbf{H} = f_{\text{enc}}(\mathbf{x}), \tag{1}$$

where f_{enc} is the computation unit in the encoder; and, a decoder that generates output symbols at each time stamp t, conditioned on $\mathbf{H}$ as well as the decoder inputs $\mathbf{y}_{1:t-1}$,

$$s_t = f_{\text{dec}}(\mathbf{y}_{1:t-1}, \mathbf{H}), \tag{2}$$

where f_{dec} is the computation unit in the decoder. Instantiations of this framework include the widely-used attention-based sequence-to-sequence model (Bahdanau et al., 2015), in which f_{enc} and f_{dec} are implemented by an RNN architecture using LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Chung et al., 2014) units. A more recent instantiation of this architecture is the Transformer model (Vaswani et al., 2017), built using self-attention layers.

3.1 SHAPED: Shared-private encoder-decoder

The abstract encoder-decoder model described above is usually trained over all examples in the training data. We call such a model a *shared* encoder-decoder model, because the model parameters are shared across all training and test instances. Formally, the shared encoder-decoder consists of the computation units f^s_{enc} and f^s_{dec}. Given an instance $\mathbf{x}$, it generates a sequence of vectors $\mathbf{S}^s = (s^s_1, ...s^s_T)$ by:

$$\mathbf{H}^s = f^s_{\text{enc}}(\mathbf{x}), s^s_t = f^s_{\text{dec}}(\mathbf{y}_{1:t-1}, \mathbf{H}^s). \tag{3}$$

The drawback of the shared encoder-decoder is that it fails to account for particular properties of each style that may be present in the data. In order to capture such particular style characteristics, a straightforward solution is to train a *private* model for each style. Assuming a style set $\mathbb{D} = \{D_1, D_2..., D_{|\mathbb{D}|}\}$, such a solution implies that each style has its own private encoder computation unit and decoder computation unit. At both training and testing time, each private encoder and decoder only process instances that belong to their own style. Given an instance along with its style $(\mathbf{x}, z)$ where $z \in \{1, \ldots, |\mathbb{D}|\}$, the private encoder-decoder generates a sequence of vectors $\mathbf{S}^z = (s^z_1, ...s^z_T)$ by:

$$\mathbf{H}^z = f^z_{\text{enc}}(\mathbf{x}), s^z_t = f^z_{\text{dec}}(\mathbf{y}_{1:t-1}, \mathbf{H}^z). \tag{4}$$

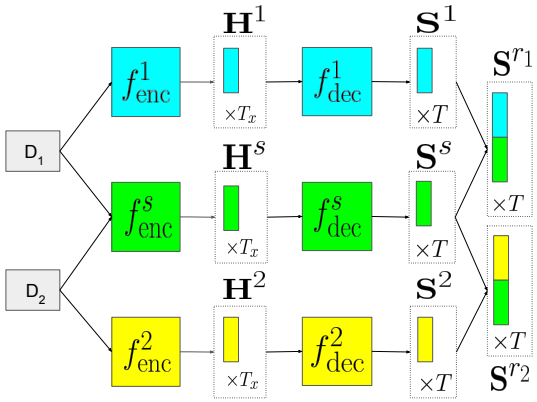

Figure 1: Illustration of the SHAPED model using two styles D_1 and D_2. D_1 articles pass through the private encoder f^1_{enc} and decoder f^1_{dec}. D_2 articles pass through the private encoder f^2_{enc} and decoder f^2_{dec}. Both of them also go through the shared encoder f^s_{dec} and decoder f^s_{dec}.

Although the private encoder/decoder models do preserve style characteristics, they fail to take into account the common language features shared across styles. Furthermore, since each style is represented by a subset of the entire training set, such private models may end up as under-trained, due to limited number of available data examples.

In order to efficiently capture both common and unique features of data with different styles, we propose the SHAPED model. In the SHAPED model, each data-point goes through both the shared encoder-decoder and its corresponding private encoder-decoder. At each step of the decoder, the output from private and shared ones are concatenated to form a new vector:

$$s^{r_z}_t = [s^z_t, s^s_t], \tag{5}$$

that contains both private features for style z and shared features induced from other styles, as illustrated in Fig 1. The output symbol distribution over tokens $o_t \in V$ (where V is the output vocabulary) at step t is given by:

$$p(o_t|\mathbf{x}, y_{1:t-1}, z) = \text{Softmax}(g(s^{r_z}_t)), \tag{6}$$

where g is a multi-layer feed-forward network that maps $s^{r_z}_t$ to a vector of size $|V|$. Given N training examples $(\mathbf{x}^{(1)}, \mathbf{y}^{(1)}, z^{(1)}), \ldots, (\mathbf{x}^{(N)}, \mathbf{y}^{(N)}, z^{(N)})$, the conditional probability of the output $\mathbf{y}^{(i)}$ given article $\mathbf{x}^{(i)}$ and its style $z^{(i)} \in \{1, \ldots, |\mathbb{D}|\}$ is:

$$p(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}, z^{(i)}) = \prod_t p(o_t = y^{(i)}_t|\mathbf{x}^{(i)}, \mathbf{y}^{(i)}_{1:t-1}, z^{(i)}). \tag{7}$$

At inference time, given an article $\mathbf{x}$ with style z, we feed $\mathbf{x}$ into $f^s_{\text{enc}}, f^s_{\text{dec}}, f^z_{\text{enc}}, f^z_{\text{dec}}$ (Eq. 3-4) and obtain symbol distributions at each step t using Eq. 6. We sample from the distribution and obtain a symbol o_t which will be used as the estimated y_t and fed to the next steps.

3.2 The Mix-SHAPED Model

One limitation of the above model is that it can only handle test data containing an explicit style label from $\mathbb{D} = \{D_1, D_2..., D_{|\mathbb{D}|}\}$. However, there is frequently the case that, at test time, the style label is not present as part of the input, or that the input style is not part of the modeled set $\mathbb{D}$.

We treat both of these cases similarly, as a case of modeling an unknown style. We first describe our treatment of such a case at run-time. We use a latent random variable $z \in \{1, \ldots, |\mathbb{D}|\}$ to denote the underlying style of a given input. When generating a token at step t, the output token distribution takes the form of a mixture of SHAPED (Mix-SHAPED) model outputs:

$$p(o_t|\mathbf{x}, \mathbf{y}_{1:t-1}) = \sum_{d=1}^{|\mathbb{D}|} p(o_t|\mathbf{x}, \mathbf{y}_{1:t-1}, z = d)p(z = d|\mathbf{x}), \tag{8}$$

where $p(o_t|\mathbf{x}, \mathbf{y}_{1:t-1}, z = d)$ is the output symbol distribution of SHAPED decoder d, evaluated as in Eq. 6. Fig. 2 contains an illustration of such a model. In this formulation, $p(z|\mathbf{x})$ denotes the style conditional probability distribution from a trainable style classifier.

The joint data likelihood of target sequence $\mathbf{y}$ and target domain label z for input sequence $\mathbf{x}$ is:

$$p(\mathbf{y}, z|\mathbf{x}) = p(\mathbf{y}|z, \mathbf{x}) \cdot p(z|\mathbf{x}) \tag{9}$$

Training the Mix-SHAPED model involves minimizing a loss function that combines the negative log-likelihood of the style labels and the negative log-likelihood of the symbol sequences (see the model in Fig 3):

$$\begin{aligned}\text{Loss}_{\text{Mix-SHAPED}} = &-\sum_{i=1}^{N} \log p(z^{(i)}|\mathbf{x}^{(i)}) \\ &-\sum_{i=1}^{N} \log p(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}, z^{(i)}).\end{aligned} \tag{10}$$

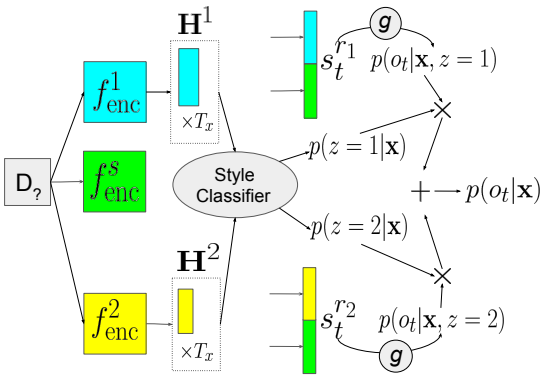

Figure 2: Decoding data with unknown style using a Mix-SHAPED model. The data is run through all encoders and decoders. The output of private encoders is fed into a classifier that estimates style distribution. The output symbol distribution is a mixture over all decoder outputs.

At run-time, if the style d of the input is available and $d \in \mathbb{D}$, we decode the sequence using Eq. 6. This also corresponds to the case $p(z = d|\mathbf{x}) = 1$ and 0 for all other styles, and reduces Eq. 8 to Eq. 6. If the style of the input is unknown (or known, but with $d' \notin \mathbb{D}$), we decode the sequence using Eq. 8, in which case the mixture over SHAPED models given by $p(z|\mathbf{x})$ is approximating the desired output style.

4 Model Instantiation

As an implementation of the encoder-decoder model, we use the attention-based sequence-to-sequence model from (Bahdanau et al., 2015), with an RNN architecture using GRU units (Chung et al., 2014). The input token sequences are first projected into an embedding space via an embedding matrix $\mathbf{E}$, resulting in a sequence of vectors as input representations.

The private and shared RNN cells generate a sequence of hidden state vectors $\mathbf{H}^z = \{h^z_j\}$, $z \in \{1, ..., |\mathbb{D}|\}$ and $\mathbf{H}^s = \{h^s_j\}$, for $j \in \{1, ..., T_x\}$. At each step in the encoder, h^z_j and h^s_j are concatenated to form a new output vector $h^{r_z}_j = [h^z_j, h^s_j]$. The final state of each encoder is used as the initial state of the corresponding decoder. At time step t in the decoder, the private and shared RNN cell first generate hidden state vectors $\{s^z_t\}, z \in \{1, ..., |\mathbb{D}|\}$ and s^s_t, then s^s_t is concatenated with each s^z_t to form new vectors $\{s^{r_z}_t\}$ ($z \in \{1, ..., |\mathbb{D}|\}$).

We apply the attention mechanism on $s^{r_z}_t$, using

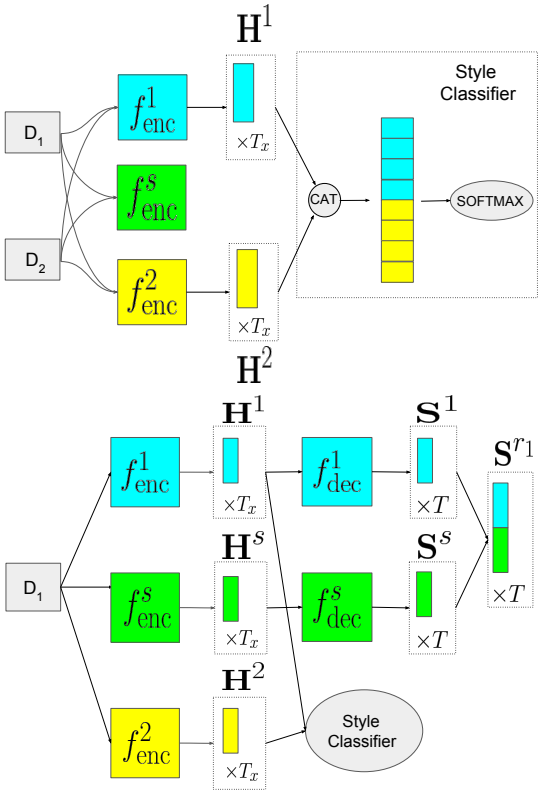

Figure 3: Training a Mix-SHAPED model. (a) Each example is fed to all private encoders f^1_{enc}, f^2_{enc}, whose outputs are concatenated and fed to a style classifier. (b) The D_1 examples only use $f^1_{enc}, f^1_{dec}, f^s_{enc}, f^s_{dec}$ to decode texts. Private encoder-decoders of other styles are not used.

attention weights calculated as:

$$q^{r_z}_{tj} = v_a \tanh(W_a h^{r_z}_j + U_a s^{r_z}_t), \quad (11)$$

which are normalized to a probability distribution:

$$\alpha^{r_z}_{tj} = \frac{\exp(q^{r_z}_{tj})}{\sum_{i=1}^{T_x} \exp(q^{r_z}_{ti})} \quad (12)$$

Context vectors are computed using normalized attention weights:

$$c^{r_z}_t = \sum_{j=1}^{T_x} \alpha^{r_z}_{tj} h^{r_z}_j \quad (13)$$

Given the context vector and the hidden state vectors, the symbol distribution at step t is:

$$p(o_t|\mathbf{x}, \mathbf{y}_{1:t}, z) = \text{softmax}(g([c^{r_z}_t, s^{r_z}_t])) \quad (14)$$

The attention weights in W_a, U_a, and v_a, as well as the embedding matrix $\mathbf{E}$ and vocabulary V are shared by all encoders and decoders. We use Eq. 14 to calculate the symbol loss in Eq. 10.

5 Quantitative Experiments

We perform a battery of quantitative experiments, designed to answer several main questions: 1) Do the proposed model improve generation performance over alternative approaches? 2) Can a style classifier built using an auxiliary loss provide a reliable estimate on text style? 3) In the case of unknown style, does the Mix-SHAPED model improve generation performance over alternative approaches? 4) To what extent do our models capture style characteristics as opposed to, say, content characteristics?

We perform our experiments using text summarization as the main task. More precisely, we train and evaluate headline generation models using the publicly-available Gigaword dataset (Graff and Cieri, 2003; Napoles et al., 2012).

5.1 Headline-generation Setup

The Gigaword dataset contains news articles from seven publishers: Agence France-Presse (AFP), Associated Press Worldstream (APW), Central News Agency of Taiwan (CNA), Los Angeles Times/Washington Post Newswire Service (LTW), New York Times (NYT), Xinhua News Agency (XIN), and Washington Post/Bloomberg Newswire Service (WPB). We pre-process this dataset in the same way as in (Rush et al., 2015), which results in articles with average length 31.4 words, and headlines with average length 8.5 words.

We consider the publisher identity as a proxy for style, and choose to model as in-domain styles the set $\mathbb{D} = \{\text{AFP, APW, NYT, XIN}\}$, while holding out CNA and LTW for out-of-domain style testing. This results in a training set containing the following number of (article, headline) instances: 993,584 AFP, 1,493,758 APW, 578,259 NYT, and 946,322 XIN. For the test set, we sample a total number of 10,000 in-domain examples from the original Gigawords test dataset, which include 2,886 AFP, 2,832 APW, 1,610 NYT, and 2,012 XIN. For out-of-domain testing, we randomly sample 10,000 LTW and 10,000 CNA test data examples. We remove the WPB articles due to their small number of instances.

5.1.1 Experimental Setup

We compare the following models:

- A Shared encoder-decoder model (S) trained on all styles in $\mathbb{D}$;
- A suite of Private encoder-decoder models (P), each one trained on a particular style from $\mathbb{D} = \{\text{AFP, APW, NYT, XIN}\}$;[1]
- A SHAPED model (SP) trained on all styles in $\mathbb{D}$; at test time, the style of test data is provided to the model; the article is only run through its style-specific private network and shared network (style classifier is not needed);
- A Mix-SHAPED model (M-SP) trained on all styles in $\mathbb{D}$; at test time, the style of article is not provided to the model; the output is computed using the mixture model, with the estimated style probabilities from the style classifier used as weights.

When testing on the out-of-domain styles CNA/LTW, we only compare the Shared (S) model with the Mix-SHAPED (M-SP) model, as the others cannot properly handle this scenario.

As hyper-parameters for the model instantiation, we used 500-dimension word embeddings, and a three-layer, 500-dimension GRU-cell RNN architecture; the encoder was instantiated as a bi-directional RNN. The lengths of the input and output sequences were truncated to 40 and 20 tokens, respectively. All the models were optimized using Adagrad (Duchi et al., 2011), with an initial learning rate of 0.01. The training procedure was done over mini-batches of size 128, and the updates were done asynchronously across 40 workers for 5M steps. The encoder/decoder word embedding and the output projection matrices were tied to minimize the number of parameters. To avoid the slowness from the softmax operator over large vocabulary sizes, and also mitigate the impact of out-of-vocabulary tokens, we applied a subtokenization method (Wu et al., 2016), which invertibly transforms a native token into a sequence of subtokens from a limited vocabulary (here set to 32K).

Comparison with Previous Work In the next section, we report our main results using the in-domain and out-of-domain (w.r.t. the selected publisher styles) test sets described above, since these test sets have a balanced publisher style frequency that allows us to measure the impact of our style-adaptation models. However, we also report

[1] We also tried to warm-start a private model using the best checkpoint of the shared model, but found that it cannot improve over the shared model.

	AFP/APW/XIN/NYT Test		
	Rouge-1	Rouge-2	Rouge-L
P	39.14±0.47	19.74±0.48	36.42±0.46
S	39.32±0.26	19.63±0.24	36.51±0.26
SP	**40.34**±0.26	**20.38**±0.25	**37.52**±0.25
M-SP	40.10±0.25	20.21±0.26	37.30±0.26

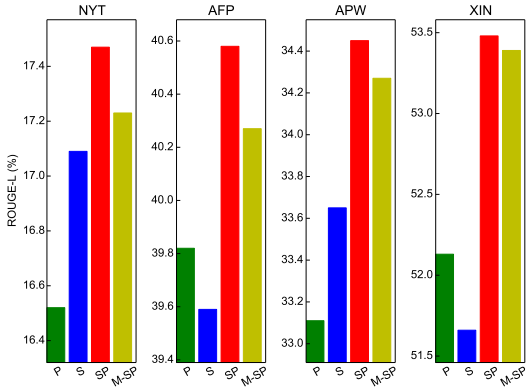
here the performance of our Shared (S) baseline model (with the above hyper-parameters) on the original 2K test set used in (Rush et al., 2015). On that test set, our S model obtains 30.13 F1 ROUGE-L score, compared to 28.34 ROUGE-L obtained by the ABS+ model (Rush et al., 2015), and 30.64 ROUGE-L obtained by the words-lvt2k-1sent model (Nallapati et al., 2016). This comparison indicates that our S model is a competitive baseline, making the comparisons against the SP and M-SP models meaningful when using our in-domain and out-of-domain test sets.

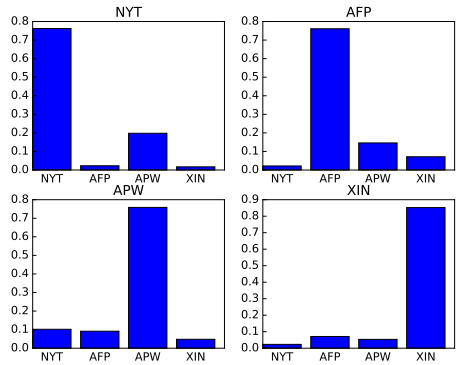
5.1.2 Main Results

The Rouge scores for the in-domain testing data are reported in Table 1 (over the combined AFP/APW/XIN/NYT testset) and Fig. 4a (over individual-style test sets). The numbers indicate that the SP and M-SP models consistently outperform the S and P model, supporting the conclusion that the S model loses important characteristics due to averaging effects, while the P models miss the opportunity to efficiently exploit the training data. Additionally, the performance of SP is consistently better than M-SP in this setting, which indicates that the style label is helpful. As shown in Fig. 4b, the style classifier achieves around 80% accuracy overall in predicting the style under the M-SP model, with some styles (e.g., XIN) being easier to predict than others. The performance of the classifier is directly reflected in the quantitative difference between the SP and M-SP models on individual-style test sets (see Fig. 4a, where the XIN style has the smallest difference between the two models).

The evaluation results for the out-of-domain scenario are reported in Table 2. The numbers indicate that the M-SP model significantly outperforms the S model, supporting the conclusion that the M-SP model is capable of performing on-the-fly adaptation of output style. This conclusion is further strengthened by the style probability distributions shown in Fig 5: they indicate that, for



(a) Rouge-L scores on headline generation, shown separately on four in-domain styles.



(b) Average estimated probability distribution by the M-SP model over the four styles, for each in-domain target style in the test set.

Figure 4: Experimental results on the headline generation task, for in-domain styles.

the out-of-domain CNA style, the output mixture is heavily weighted towards the XIN style (0.6 of the probability mass), while for the LTW style, the output mixture weights heavily the NYT style (0.72 of the probability mass). This result is likely to reflect true style characteristics shared by these publishers, since both CNA and XIN are produced by Chinese news agencies (from Taiwan and mainland China, respectively), while both LTW and NYT are U.S. news agencies owned by the same media corporation.

5.1.3 Experiment Variants

Model capacity In order to remove the possibility that the improved performance of the SP model is due simply to an increased model size compared to the S model, we perform an experiment in which we triple the size of the GRU cell dimensions for the S model. However, we find no significant performance difference compared to the

	CNA Test			LTW Test

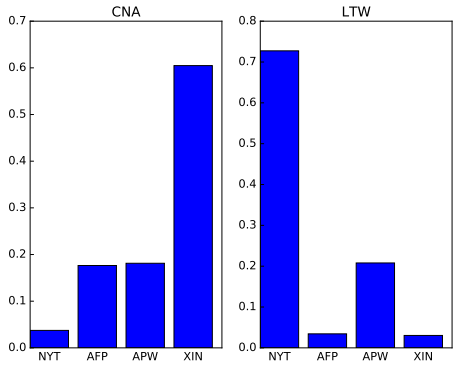

Figure 5: Estimated style probabilities over the four in-domain styles AFP/APW/XIN/NYT, for out-of-domain styles CNA and LTW.

original dimensions (the ROUGE-L score of the triple-size S model is 36.61, compared to 36.51 obtained of the original S model).

Style embedding A competitive approach to modeling different styles is to directly encode the style information into the embedding space. In (Johnson et al., 2016), the style label is converted into a one-hot vector and is concatenated with the word embedding at each time step in the S model. The outputs of this model are at 36.68 ROUGE-L, slightly higher than the baseline S model, but significantly lower than the SP model performance (37.52 ROUGE-L).

Another style embedding approach is to augment the S model with continuous trainable style embeddings for each predefined style label, similar to (Ammar et al., 2016). The resulting outputs achieve 37.2 ROUGE-L, which is better than the S model with one-hot style embedding, but still worse than the SP method (statistically significant at p-value=0.025 using paired t-test). However, neither of these approaches apply to the cases when the style is out-of-domain or unknown during testing. In contrast, such cases are handled naturally by the proposed M-SP model.

Ensemble model Another question is whether the SP model simply benefits from ensembling multiple models rather than style adaptation. To answer this question, we apply a uniform mixture over the private model output along with the shared model output, rather than using the learnt probability distribution from the style classifier. The ROUGE-1/2/L scores are 39.9/19.7/37.0. They are higher than the S model but significantly lower than the SP model and the M-SP model (p-value 0.016). This result confirms that the information that the style classifier encodes is beneficiary, and leads to improved performance.

Style vs. Content Previous experiments indicate that the SP and M-SP models have superior generation accuracy, but it is unclear to what extent the difference comes from improved modeling of style versus modeling of content. To clarify this issue, we performed an experiment in which we replace the named entities appearing in both article and headline with corresponding entity tags, in effect suppressing almost completely any content signal. For instance, given an input such as "China called Thursday on the parties involved in talks on North Korea's nuclear program to show flexibility as a deadline for implementing the first steps of a breakthrough deal approached.", paired with goldtruth output "China urges flexibility as NKorea deadline approaches", we replaced the named entities with their types, and obtained: "LOC_0 called Thursday on the ORG_0 involved in NON_2 on LOC_1 's NON_3 to show NON_0 as a NON_1 for implementing the first NON_4 of a NON_5 approached .", paired with "LOC_0 urges NON_0 as LOC_1 NON_1 approaches."

Under this experimental conditions, both the SP and M-SP models still achieve significantly better performance compared to the S baseline. On the combined AFP/APW/XIN/NYT in-domain test set, the SP model achieves 61.70 ROUGE-L and M-SP achieves 61.52 ROUGE-L, compared to 60.20 ROUGE-L obtained by the S model. On the CNA/LTW out-of-domain test set, M-SP achieves 60.75 ROUGE-L, compared to 59.47 ROUGE-L by the S model.

In Table 3, we show an example which indi-

article	the org_2 is to forge non_1 with the org_3 located in loc_2 , loc_1 , the per_0 of the loc_0 org_4 said tuesday .
title	loc_0 org_0 to forge non_0 with loc_1 org_1
output by S	org_0 to org_1 in non_0
output by M-SP	loc_0 org_0 to forge non_0 with loc_1 org_1
article	loc_0 - born per_0 per_0 will pay non_1 here next month to per_1 , the org_2 (org_1) per_1 who per_1 perished in an non_2 in february , the org_3 said thursday .
title	per_0 to pay non_0 to late org_1 org_0
output by S	per_0 to visit org_0 in non_0
output by M-SP	per_0 to pay non_0 to org_1 org_0

Table 3: Examples of input article (and groundtruth title) and output generated by S and M-SP. Named entities in the training instances (both article and title) are replaced the entity type.

cates the ability of style adaptation benifiting summarization. For instance, we find that both CNA and XIN make more frequent use of the style pattern "xxx will/to [verb] yyy ..., zzz said ???day" (about 15% of CNA articles contain this pattern, while only 2% of LTW articles have it). From Table 3, we can see that the S model sometimes misses or misuses the verb in its output, while the M-SP model does a much better job at capturing both the verb/action as well as other relations (via prepositions, etc.)

Fig. 6 shows the estimated style probabilities over the four styles AFP/APW/XIN/NYT for CNA and LTW, under this experiment condition. We observe that, in this version as well, CNA is closely matching the style of XIN, while LTW is matching that of NYT. The distribution is similar to the one in Fig. 5, albeit a bit flatter as a result of content removal. As such, it supports the conclusion that the classifier indeed learns style (in addition to content) characteristics.

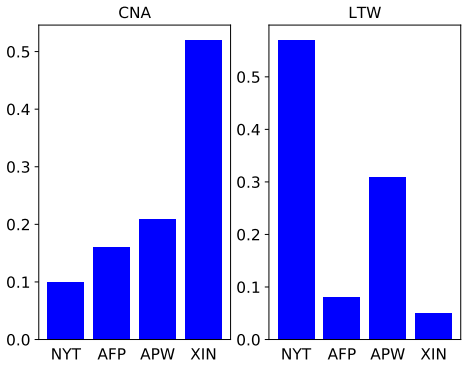

Figure 6: Estimated style probabilities over the four in-domain styles AFP/APW/XIN/NYT, for out-of-domain styles CNA and LTW, after named entities in the article and summary are replaced with entity tags.

6 Conclusion

In this paper, we describe two new style-adaptation model architectures for text sequence generation tasks, SHAPED and Mix-SHAPED. Both versions are shown to significantly outperform models that are either trained in a manner that ignores style characteristics (and hence exhibit a style-averaging effect in their outputs), or models that are trained single-style.

The latter is a particularly interesting result, as a model that is trained (with enough data) on a single-style and evaluated on the same style would be expected to exhibit the highest performance. Our results show that, even for single-style models trained on over 1M examples, their performance is inferior to the performance of SHAPED models on that particular style.

Our conclusion is that the proposed architectures are both efficient and effective in modeling both generic language phenomena, as well as particular style characteristics, and are capable of producing higher-quality abstractive outputs that take into account style characteristics.

Abstract

In this work, we focus on the task of generating natural language descriptions from a structured table of facts containing *fields* (such as nationality, occupation, *etc*) and *values* (such as Indian, {actor, director}, *etc*). One simple choice is to treat the table as a sequence of *fields* and *values* and then use a standard seq2seq model for this task. However, such a model is too generic and does not exploit task-specific characteristics. For example, while generating descriptions from a table, a human would attend to information at two levels: (i) the fields (macro level) and (ii) the values within the field (micro level). Further, a human would continue attending to a field for a few timesteps till all the information from that field has been rendered and then never return back to this field (because there is nothing left to say about it). To capture this behavior we use (i) a fused bifocal attention mechanism which exploits and combines this micro and macro level information and (ii) a gated orthogonalization mechanism which tries to ensure that a field is remembered for a few time steps and then forgotten. We experiment with a recently released dataset which contains fact tables about people and their corresponding one line biographical descriptions in English. In addition, we also introduce two similar datasets for French and German. Our experiments show that the proposed model gives 21% relative improvement over a recently proposed state of the art method and 10% relative improvement over basic seq2seq models. The code and the datasets developed as a part of this work are publicly available. [1]

1 Introduction

Rendering natural language descriptions from structured data is required in a wide variety of commercial applications such as generating descriptions of products, hotels, furniture, *etc*., from a corresponding table of facts about the entity. Such a table typically contains {*field, value*} pairs where the field is a property of the entity (*e.g.*, *color*) and the value is a set of possible assignments to this property (*e.g.*, *color* = *red*). Another example of this is the recently introduced task of generating one line biography descriptions from a given Wikipedia infobox (Lebret et al., 2016). The Wikipedia infobox serves as a table of facts about a person and the first sentence from the corresponding article serves as a one line description of the person. Figure 1 illustrates an example input infobox which contains fields such as Born, Residence, Nationality, Fields, Institutions and Alma Mater. Each field further contains some words (*e.g.*, particle physics, many-body theory, *etc*.). The corresponding description is coherent with the information contained in the infobox.

Note that the number of fields in the infobox and the ordering of the fields within the infobox varies from person to person. Given the large size (700K examples) and heterogeneous nature of the dataset which contains biographies of people from different backgrounds (sports, politics, arts, *etc*.), it is hard to come up with simple rule-based templates for generating natural language descriptions from infoboxes, thereby making a case for data-driven models. Based on the recent success of data-driven neural models for various other NLG tasks (Bahdanau et al., 2014; Rush et al., 2015; Yao et al., 2015; Chopra et al., 2016; Nema et al., 2017), one simple choice is to treat the infobox as

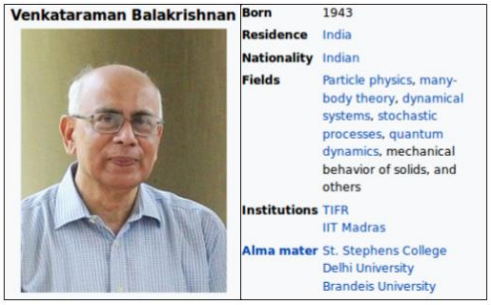

Figure 1: Sample Infobox with description : *V. Balakrishnan (born 1943 as Venkataraman Balakrishnan) is an Indian theoretical physicist who has worked in a number of fields of areas, including particle physics, many-body theory, the mechanical behavior of solids, dynamical systems, stochastic processes, and quantum dynamics.*

a sequence of {field, value} pairs and use a standard seq2seq model for this task. However, such a model is too generic and does not exploit the specific characteristics of this task as explained below.

First, note that while generating such descriptions from structured data, a human keeps track of information at two levels. Specifically, at a macro level, she would first decide which field to mention next and then at a micro level decide which of the values in the field needs to be mentioned next. For example, she first decides that at the current step, the field *occupation* needs attention and then decides which is the next appropriate occupation to attend to from the set of occupations (*actor, director, producer, etc.*). To enable this, we use a bifocal attention mechanism which computes an attention over *fields* at a macro level and over *values* at a micro level. We then fuse these attention weights such that the attention weight for a field also influences the attention over the values within it. Finally, we feed a fused context vector to the decoder which contains both field level and word level information. Note that such two-level attention mechanisms (Nallapati et al., 2016; Yang et al., 2016; Serban et al., 2016) have been used in the context of unstructured data (as opposed to structured data in our case), where at a macro level one needs to pay attention to sentences and at a micro level to words in the sentences.

Next, we observe that while rendering the output, once the model pays attention to a field (say, occupation) it needs to stay on this field for a few timesteps (till all the occupations are produced in the output). We refer to this as the *stay on* behavior. Further, we note that once the tokens of a field are referred to, they are usually not referred to later. For example, once all the occupations have been listed in the output we will never visit the occupation field again because there is nothing left to say about it. We refer to this as the *never look back* behavior. To model the *stay on* behaviour, we introduce a forget (or remember) gate which acts as a signal to decide when to forget the current field (or equivalently to decide till when to remember the current field). To model the *never look back* behaviour we introduce a gated orthogonalization mechanism which ensures that once a field is forgotten, subsequent field context vectors fed to the decoder are orthogonal to (or different from) the previous field context vectors.

We experiment with the WIKIBIO dataset (Lebret et al., 2016) which contains around 700K {infobox, description} pairs and has a vocabulary of around 400K words. We show that the proposed model gives a relative improvement of 21% and 20% as compared to current state of the art models (Lebret et al., 2016; Mei et al., 2016) on this dataset. The proposed model also gives a relative improvement of 10% as compared to the basic seq2seq model. Further, we introduce new datasets for French and German on the same lines as the English WIKIBIO dataset. Even on these two datasets, our model outperforms the state of the art methods mentioned above.

2 Related work

Natural Language Generation has always been of interest to the research community and has received a lot of attention in the past. The approaches for NLG range from (i) rule based approaches (*e.g.*, (Dale et al., 2003; Reiter et al., 2005; Green, 2006; Galanis and Androutsopoulos, 2007; Turner et al., 2010)) (ii) modular statistical approaches which divide the process into three phases (planning, selection and surface realization) and use data driven approaches for one or more of these phases (Barzilay and Lapata, 2005; Belz, 2008; Angeli et al., 2010; Kim and Mooney, 2010; Konstas and Lapata, 2013) (iii) hybrid approaches which rely on a combination of handcrafted rules and corpus statistics (Langkilde and Knight, 1998; Soricut and Marcu, 2006; Mairesse and Walker, 2011) and (iv) the more recent neural network based models (Bahdanau et al., 2014).

Neural models for NLG have been proposed in the context of various tasks such as machine translation (Bahdanau et al., 2014), document summarization (Rush et al., 2015; Chopra et al., 2016), paraphrase generation (Prakash et al., 2016), image captioning (Xu et al., 2015), video summarization (Venugopalan et al., 2014), query based document summarization (Nema et al., 2017) and so on. Most of these models are data hungry and are trained on large amounts of data. On the other hand, NLG from structured data has largely been studied in the context of small datasets such as WEATHERGOV (Liang et al., 2009), ROBOCUP (Chen and Mooney, 2008), NFL RECAPS (Barzilay and Lapata, 2005), PRODIGY-METEO (Belz and Kow, 2009) and TUNA Challenge (Gatt and Belz, 2010). Recently Mei et al. (2016) proposed RNN/LSTM based neural encoder-decoder models with attention for WEATHERGOV and ROBOCUP datasets.

Unlike the datasets mentioned above, the biography dataset introduced by Lebret et al. (2016) is larger (700K {table, descriptions} pairs) and has a much larger vocabulary (400K words as opposed to around 350 or fewer words in the above datasets). Further, unlike the feed-forward neural network based model proposed by (Lebret et al., 2016) we use a sequence to sequence model and introduce components to address the peculiar characteristics of the task. Specifically, we introduce neural components to address the need for attention at two levels and to address the *stay on* and *never look back* behaviour required by the decoder. Kiddon et al. (2016) have explored the use of checklists to track previously visited ingredients while generating recipes from ingredients. Note that two-level attention mechanisms have also been used in the context of summarization (Nallapati et al., 2016), document classification (Yang et al., 2016), dialog systems (Serban et al., 2016), *etc*. However, these works deal with unstructured data (sentences at the higher level and words at a lower level) as opposed to structured data in our case.

3 Proposed model

As input we are given an infobox $\mathcal{I} = \{(g_i, k_i)\}_{i=1}^{M}$, which is a set of pairs (g_i, k_i) where g_i corresponds to *field* names and k_i is the sequence of corresponding *values* and M is the total number of fields in $\mathcal{I}$. For example, (g = *occupation*, k = *actor, writer, director*) could be one such pair in this set. Given such an input, the task is to generate a description $y = y_1, y_2, \ldots, y_m$ containing m words. A simple solution is to treat the infobox as a sequence of *fields* followed by the *values* corresponding to the field in the order of their appearance in the infobox. For example, the infobox could be flattened to produce the following input sequence (the words in bold are field names which act as delimiters)

[Name] *John Doe* ***[Birth_Date]*** *19 March 1981* ***[Nationality]*** *Indian .....*

The problem can then be cast as a seq2seq generation problem and can be modeled using a standard neural architecture comprising of three components (i) an input encoder (using GRU/LSTM cells), (ii) an attention mechanism to attend to important values in the input sequence at each time step and (iii) a decoder to decode the output one word at a time (again, using GRU/LSTM cells). However, this standard model is too generic and does not exploit the specific characteristics of this task. We propose additional components, *viz.*, (i) a fused bifocal attention mechanism which operates on fields (macro) and values (micro) and (ii) a gated orthogonalization mechanism to model *stay on* and *never look back* behavior.

3.1 Fused Bifocal Attention Mechanism

Intuitively, when a human writes a description from a table she keeps track of information at two levels. At the macro level, it is important to decide which is the appropriate field to attend to next and at a micro level (*i.e.*, within a field) it is important to know which values to attend to next. To capture this behavior, we use a bifocal attention mechanism as described below.

Macro Attention: Consider the i-th field g_i which has values $k_i = (w_1, w_2, ..., w_p)$. Let h_i^g be the representation of this field in the infobox. This representation can either be (i) the word embedding of the field name or (ii) some function f of the values in the field or (iii) a concatenation of (i) and (ii). The function f could simply be the sum or average of the embeddings of the values in the field. Alternately, this function could be a GRU (or LSTM) which treats these values within a field as a sequence and computes the field representation as the final representation of this sequence (*i.e.*, the representation of the last timestep). We found that bidirectional GRU is a bet-

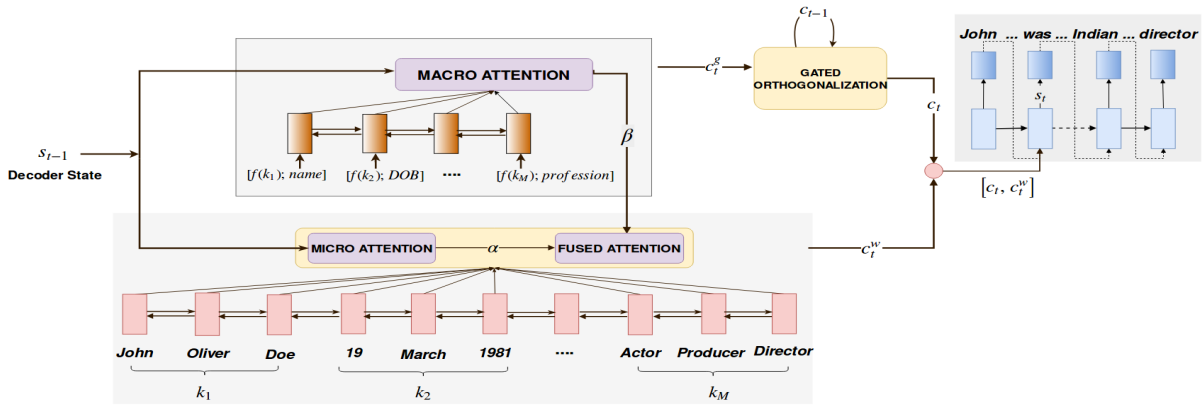

Figure 2: Proposed model

ter choice for f and concatenating the embedding of the field name with this GRU representation works best. Further, using a bidirectional GRU cell to take contextual information from neighboring fields also helps (these are the orange colored cells in the top-left block in Figure 2 with macro attention). Given these representations $\{h_i^g\}_{i=1}^M$ for all the M fields we compute an attention over the fields (macro level).

$$b_{t,i}^g = v_g^T \tanh(U_g s_{t-1} + V_g h_i^g)$$
$$\beta_{t,i} = \frac{\exp(b_{t,i}^g)}{\sum_{l=1}^M \exp(b_{t,l}^g)}$$
$$c_t^g = \sum_{i=1}^M \beta_{t,i} h_i^g \quad (1)$$

where s_{t-1} is the state of the decoder at time step $t-1$. U_g, V_g and v_g are parameters, M is the total number of fields in the input, c_t^g is the macro (field level) context vector at the t-th time step of the decoder.

Micro Attention: Let h_j^w be the representation of the j-th value in a given field. This representation could again either be (i) simply the embedding of this value (ii) or a contextual representation computed using a function f which also considers the other values in the field. For example, if $(w_1, w_2, ..., w_p)$ are the values in a field then these values can be treated as a sequence and the representation of the j-th value can be computed using a bidirectional GRU over this sequence. Once again, we found that using a bi-GRU works better then simply using the embedding of the value. Once we have such a representation computed for all values across all the fields, we compute the attention over these values (micro level) as shown below :

$$a_{t,j}^w = v_w^T \tanh(U_w s_{t-1} + V_w h_j^w) \quad (2)$$
$$\alpha_{t,j}^w = \frac{\exp(a_{t,j}^w)}{\sum_{l=1}^W \exp(a_{t,l}^w)} \quad (3)$$

where s_{t-1} is the state of the decoder at time step $t-1$. U_w, V_w and v_w are parameters, W is the total number of values across all the fields.

Fused Attention: Intuitively, the attention weights assigned to a field should have an influence on all the values belonging to the particular field. To ensure this, we reweigh the micro level attention weights based on the corresponding macro level attention weights. In other words, we fuse the attention weights at the two levels as:

$$\alpha'_{t,j} = \frac{\alpha_{t,j}\beta_{t,F(j)}}{\sum_{l=1}^W \alpha_{t,l}\beta_{t,F(l)}} \quad (4)$$
$$c_t^w = \sum_{j=1}^W \alpha'_{t,j} h_j^w \quad (5)$$

where $F(j)$ is the field corresponding to the j-th value, c_t^w is the macro level context vector.

3.2 Gated Orthogonalization for Modeling Stay-On and Never Look Back behaviour

We now describe a series of choices made to model *stay-on* and *never look back* behavior. We first begin with the *stay-on* property which essentially implies that if we have paid attention to the field i at timestep t then we are likely to pay attention to the same field for a few more time steps. For example, if we are focusing on the *occupation* field at this timestep then we are likely to focus on

it for the next few timesteps till all relevant values in this field have been included in the generated description. In other words, we want to remember the field context vector c_t^g for a few timesteps. One way of ensuring this is to use a remember (or forget) gate as given below which remembers the previous context vector when required and forgets it when it is time to move on from that field.

$$f_t = \sigma(W_t^f c_{t-1}^g + W_g^f c_{t-1} + b_f) \quad (6)$$

$$c_t = (1 - f_t) \odot c_t^g + f_t \odot c_{t-1} \quad (7)$$

where ${W_t}^f, {W_g}^f, b_f$ are parameters to be learned. The job of the forget gate is to ensure that c_t is similar to c_{t-1} when required (i.e., by learning $f_t \rightarrow 1$ when we want to continue focusing on the same field) and different when it is time to move on (by learning that $f_t \rightarrow 0$).

Next, the *never look back* property implies that once we have moved away from a field we are unlikely to pay attention to it again. For example, once we have rendered all the occupations in the generated description there is no need to return back to the occupation field. In other words, once we have moved on ($f_t \rightarrow 0$), we want the successive field context vectors c_t^g to be very different from the previous field vectors c_{t-1}. One way of ensuring this is to orthogonalize successive field vectors using

$$c_t^g = c_t^g - \gamma_t \odot \frac{< c_{t-1}, c_t^g >}{< c_{t-1}, c_{t-1} >} c_{t-1} \quad (8)$$

where $< a, b >$ is the dot product between vectors a and b. The above equation essentially subtracts the component of c_t^g along c_{t-1}. γ_t is a learned parameter which controls the degree of orthogonalization thereby allowing a soft orthogonalization (*i.e.,* the entire component along c_{t-1} is not subtracted but only a fraction of it). The above equation only ensures that c_t^g is soft-orthogonal to c_{t-1}. Alternately, we could pass the sequence of context vectors, $c_1, c_2, ..., c_t$ generated so far through a GRU cell. The state of this GRU cell at each time step would thus be aware of the history of the field vectors till that timestep. Now instead of orthogonalizing c_t^g to c_{t-1} we could orthogonalize c_t^g to the hidden state of this GRU at time-step $t-1$. In practice, we found this to work better as it accounts for all the field vectors in the history instead of only the previous field vector.

In summary, Equation 7 provides a mechanism for remembering the current field vector when appropriate (thus capturing *stay-on* behavior) using a remember gate. On the other hand, Equation 8 explicitly ensures that the field vector is very different (soft-orthogonal) from the previous field vectors once it is time to move on (thus capturing *never look back* behavior). The value of c_t^g computed in Equation 8 is then used in Equation 7. The c_t (macro) thus obtained is then concatenated with c_t^w (micro) and fed to the decoder (see Fig. 2)

4 Experimental setup

We now describe our experimental setup:

4.1 Datasets

We use the WIKIBIO dataset introduced by Lebret et al. (2016). It consists of $728,321$ biography articles from English Wikipedia. A biography article corresponds to a person (sportsman, politician, historical figure, actor, *etc.*). Each Wikipedia article has an accompanying infobox which serves as the structured input and the task is to generate the first sentence of the article (which typically is a one-line description of the person). We used the same train, valid and test sets which were made publicly available by Lebret et al. (2016).

We also introduce two new biography datasets, one in French and one in German. These datasets were created and pre-processed using the same procedure as outlined in Lebret et al. (2016). Specifically, we extracted the infoboxes and the first sentence from the corresponding Wikipedia article. As with the English dataset, we split the French and German datasets randomly into train (80%), test (10%) and valid (10%). The French and German datasets extracted by us has been made publicly available.[2] The number of examples was 170K and 50K and the vocabulary size was 297K and 143K for French and German respectively. Although in this work we focus only on generating descriptions in one language, we hope that this dataset will also be useful for developing models which jointly learn to generate descriptions from structured data in multiple languages.

4.2 Models compared

We compare with the following models:

1. (Lebret et al., 2016): This is a conditional language model which uses a feed-forward neural network to predict the next word in the description conditioned on *local characteristics* (*i.e.,*

[2] https://github.com/PrekshaNema25/StructuredData_To_Descriptions

Model	BLEU-4	NIST-4	ROUGE-4
(Lebret et al., 2016)	34.70	7.98	25.80
(Mei et al., 2016)	35.10	7.27	30.90
Basic Seq2Seq	38.20	8.47	34.28
+Fused bifocal attention	41.22	8.96	38.71
+Gated orthogonalization	**42.03**	**9.17**	**39.11**

Table 1: Comparison of different models on the English WIKIBIO dataset

words within a field) and *global characteristics* (*i.e.,* overall structure of the infobox).

2. (Mei et al., 2016): This model was proposed in the context of the WEATHERGOV and ROBOCUP datasets which have a much smaller vocabulary. They use an improved attention model with additional regularizer terms which influence the weights assigned to the fields.

3. Basic Seq2Seq: This is the vanilla encode-attend-decode model (Bahdanau et al., 2014). Further, to deal with the large vocabulary ($\sim$400K words) we use a copying mechanism as a post-processing step. Specifically, we identify the time steps at which the decoder produces unknown words (denoted by the special symbol UNK). For each such time step, we look at the attention weights on the input words and replace the UNK word by that input word which has received maximum attention at this timestep. This process is similar to the one described in (Luong et al., 2015). Even Lebret et al. (2016) have a copying mechanism tightly integrated with their model.

4.3 Hyperparameter tuning

We tuned the hyperparameters of all the models using a validation set. As mentioned earlier, we used a bidirectional GRU cell as the function f for computing the representation of the fields and the values (see Section 3.1). For all the models, we experimented with GRU state sizes of 128, 256 and 512. The total number of unique words in the corpus is around 400K (this includes the words in the infobox and the descriptions). Of these, we retained only the top 20K words in our vocabulary (same as (Lebret et al., 2016)). We initialized the embeddings of these words with 300 dimensional Glove embeddings (Pennington et al., 2014). We used Adam (Kingma and Ba, 2014) with a learning rate of 0.0004, $\beta_1 = 0.9$ and $\beta_2 = 0.999$. We trained the model for a maximum of 20 epochs and used early stopping with the patience set to 5 epochs.

5 Results and Discussions

We now discuss the results of our experiments.

5.1 Comparison of different models

Following Lebret et al. (2016), we used BLEU-4, NIST-4 and ROUGE-4 as the evaluation metrics. We first make a few observations based on the results on the English dataset (Table 1). The basic seq2seq model, as well as the model proposed by Mei et al. (2016), perform better than the model proposed by Lebret et al. (2016). Our final model with bifocal attention and gated orthogonalization gives the best performance and does 10% (relative) better than the closest baseline (basic seq2seq) and 21% (relative) better than the current state of the art method (Lebret et al., 2016). In Table 2, we show some qualitative examples of the output generated by different models.

5.2 Human Evaluations

To make a qualitative assessment of the generated sentences, we conducted a human study on a sample of 500 Infoboxes which were sampled from English dataset. The annotators for this task were undergraduate and graduate students. For each of these infoboxes, we generated summaries using the basic seq2seq model and our final model with bifocal attention and gated orthogonalization. For each description and for each model, we asked three annotators to rank the output of the systems based on i) adequacy (*i.e.* does it capture relevant information from the infobox), (ii) fluency (*i.e.* grammar) and (iii) relative preference (*i.e.*, which of the two outputs would be preferred). Overall the average fluency/adequacy (on a scale of 5) for basic seq2seq model was $4.04/3.6$ and $4.19/3.9$ for our model respectively.

The results from Table 3 suggest that in general gated orthogonalization model performs better than the basic seq2seq model. Additionally, annotators were asked to verify if the generated summaries look natural (*i.e*, as if they were generated by humans). In 423 out of 500 cases, the annotators said "Yes" suggesting that gated orthogonalization model indeed produces good descriptions.

5.3 Performance on different languages

The results on the French and German datasets are summarized in Tables 4 and 5 respectively. Note that the code of (Lebret et al., 2016) is not publicly available, hence we could not report numbers

Reference: Samuel Smiles (23 December 1812 - 16 April 1904), was a Scottish author and government reformer who campaigned on a Chartist platform. **Basic Seq2Seq:** samuel smiles (23 december 1812 – 16 april 1904) was an english books and author. **+Bifocal attention:** samuel smiles (23 december 1812 - 16 april 1904) was a british books and books. **+Gated Orthogonalization:** samuel smiles (23 december 1812 - 16 april 1904) was a british biographies and author.

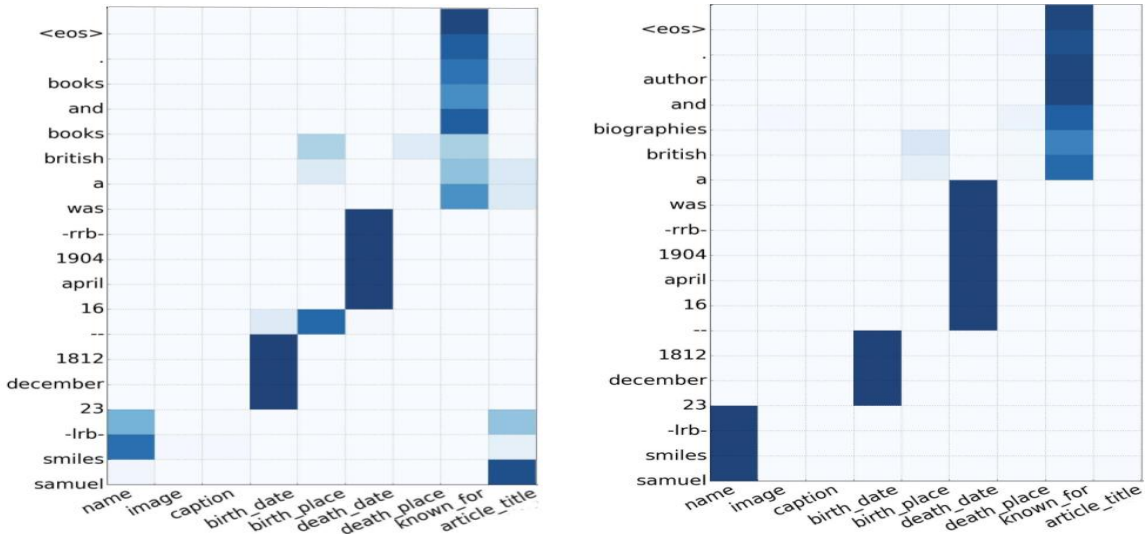
+Gated orthogonalization	**23.33**	**4.24**	**16.40**

Table 5: Comparison of different models on the German WIKIBIO dataset

for French and German using their model. We observe that our final model gives the best performance - though the bifocal attention model performs poorly as compared to the basic seq2seq model on French. However, the overall performance for French and German are much smaller than those for English. There could be multiple reasons for this. First, the amount of training data in these two languages is smaller than that in English. Specifically, the amount of training data available in French (German) is only 24.2 (7.5)% of that available for English. Second, on average the descriptions in French and German are longer than that in English (EN: 26.0 words, FR: 36.5 words and DE: 32.3 words). Finally, a manual inspection across the three languages suggests that the English descriptions have a more consistent structure than the French descriptions. For example, most English descriptions start with *name* followed by *date of birth* but this is not the case in French. However, this is only a qualitative observation and it is hard to quantify this characteristic of the French and German datasets.

5.4 Visualizing Attention Weights

If the proposed model indeed works well then we should see attention weights that are consistent with the *stay on* and *never look back* behavior. To verify this, we plotted the attention weights in cases where the model with gated orthogonalization does better than the model with only bifocal attention. Figure 3 shows the attention weights corresponding to infobox in Figure 4. Notice that the model without gated orthogonalization has attention on both name field and article title while rendering the name. The model with gated orthogonalization, on the other hand, stays on the name



(a) Fused Bifocal Attention

(b) Fused Bifocal Attention + Gated Orthogonalization

Figure 3: Comparison of the attention weights and descriptions produced for Infobox in Figure 4

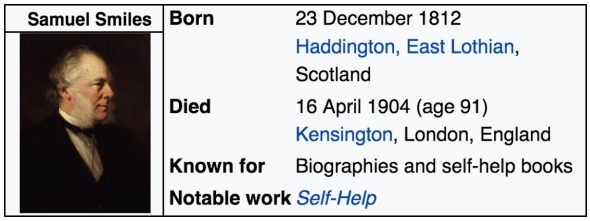


Figure 4: Wikipedia Infobox for Samuel Smiles

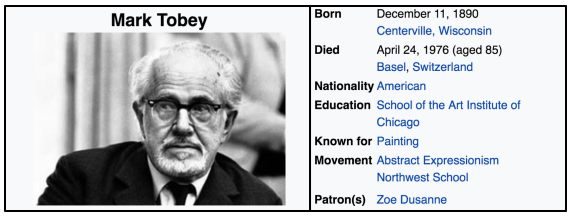

Figure 5: Wikipedia Infobox for Mark Tobey

field for as long as it is required but then moves and never returns to it (as expected).

Due to lack of space, we do not show similar plots for French and German but we would like to mention that, in general, the differences between the attention weights learned by the model with and without gated orthogonalization were more pronounced for the French/German dataset than the English dataset. This is in agreement with the results reported in Table 4 and 5 where the improvements given by gated orthogonalization are more for French/German than for English.

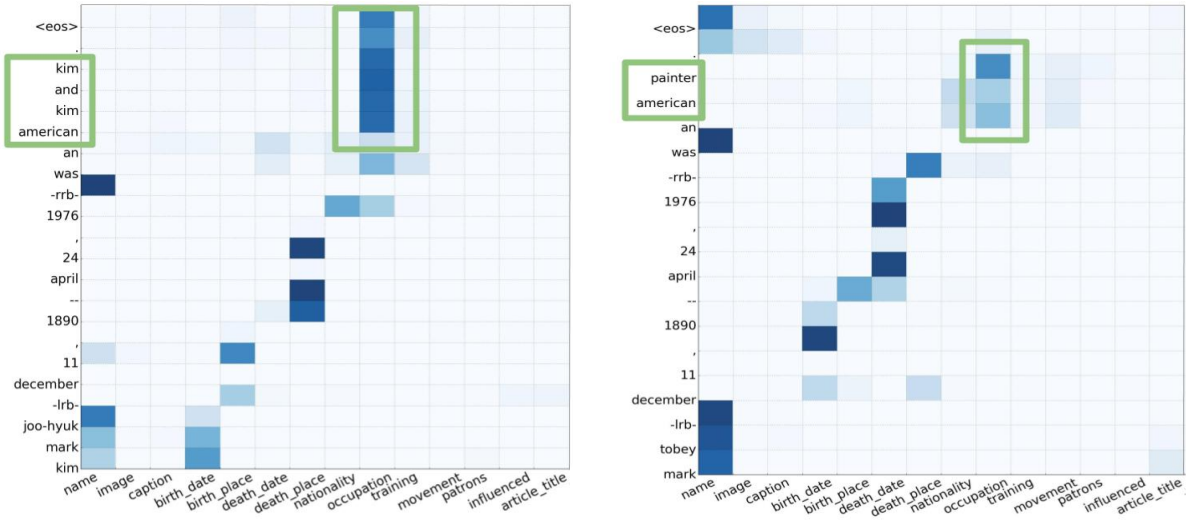
Training data	Target (test) data	
	Arts	Sports
Entire dataset	33.6	52.4
Without target domain data	24.5	29.3
+5k target domain data	31.2	41.8
+10k target domain data	32.2	43.3

Table 6: Out of domain results(BLEU-4)

5.5 Out of domain results

What if the model sees a different *type* of person at test time? For example, what if the training data does not contain any sportspersons but at test time we encounter the infobox of a sportsperson. This is the same as seeing out-of-domain data at test time. Such a situation is quite expected in the products domain where new products with new features (fields) get frequently added to the catalog. We were interested in three questions here. First, we wanted to see if testing the model on out-of-domain data indeed leads to a drop in the performance. For this, we compared the performance of our best model in two scenarios (i) trained on data from all domains (including the target domain) and tested on the target domain (sports, arts) and (ii) trained on data from all domains except the target domain and tested on the target domain. Comparing rows 1 and 2 of Table 6 we observed a significant drop in the performance. Note that the numbers for sports domain in row 1 are much better than the Arts domain because roughly 40% of the WIKIBIO training data contains sportspersons.

Next, we wanted to see if we can use a small



(a) Without fine tuning.

(b) With fine tuning with 5K in-domain data.

Figure 6: Comparison of the attention weights and descriptions (see highlighted boxes) produced by an out-of-domain model with and without fine tuning for the Infobox in Figure 5

amount of data from the target domain to fine tune a model trained on the out of domain data. We observe that even with very small amounts of target domain data the performance starts improving significantly (see rows 3 and 4 of Table 6). Note that if we train a model from scratch with only limited data from the target domain instead of fine-tuning a model trained on a different source domain then the performance is very poor. In particular, training a model from scratch with 10K training instances we get a BLEU score of 16.2 and 28.4 for arts and sports respectively. Finally, even though the actual words used for describing a sportsperson (footballer, cricketer, *etc.*) would be very different from the words used to describe an artist (actor, musician, *etc.*) they might share many fields (for example, date of birth, occupation, *etc.*). As seen in Figure 6 (attention weights corresponding to the infobox in Figure 5), the model predicts the attention weights correctly for common fields (such as occupation) but it is unable to use the right vocabulary to describe the occupation (since it has not seen such words frequently in the training data). However, once we fine tune the model with limited data from the target domain we see that it picks up the new vocabulary and produces a correct description of the occupation.

6 Conclusion

We present a model for generating natural language descriptions from structured data. To address specific characteristics of the problem we propose neural components for fused bifocal attention and gated orthogonalization to address *stay on* and *never look back* behavior while decoding. Our final model outperforms an existing state of the art model on a large scale WIKIBIO dataset by 21%. We also introduce datasets for French and German and demonstrate that our model gives state of the art results on these datasets. Finally, we perform experiments with an out-of-domain model and show that if such a model is fine-tuned with small amounts of in domain data then it can give an improved performance on the target domain.

Given the multilingual nature of the new datasets, as future work, we would like to build models which can jointly learn to generate natural language descriptions from structured data in multiple languages. One idea is to replace the concepts in the input infobox by Wikidata concept ids which are language agnostic. A large amount of input vocabulary could thus be shared across languages thereby facilitating joint learning.

Abstract

We present a new dataset for machine comprehension in the medical domain. Our dataset uses clinical case reports with around 100,000 gap-filling queries about these cases. We apply several baselines and state-of-the-art neural readers to the dataset, and observe a considerable gap in performance (20% F1) between the best human and machine readers. We analyze the skills required for successful answering and show how reader performance varies depending on the applicable skills. We find that inferences using domain knowledge and object tracking are the most frequently required skills, and that recognizing omitted information and spatio-temporal reasoning are the most difficult for the machines.

1 Introduction

Machine comprehension is a task in which a system reads a text passage and then answers questions about it. The progress in machine comprehension heavily depends on the introduction of new datasets (Burges, 2013), which encourages the development of new algorithms and deepens our understanding of the (linguistic) challenges that can or can not be tackled well by these algorithms. Recently, a number of reading comprehension datasets have been proposed (§ 2), differing in various aspects such as mode of construction, answer-query formulation and required understanding skills. Most are open-domain datasets built from news, fiction and Wikipedia texts. For specialized domains, however, large machine comprehension datasets are extremely scarce (Welbl et al., 2017a), and the required comprehension skills poorly understood. With our work we hope to narrow this gap by proposing a new resource for reading comprehension in the clinical domain, and by analyzing the different types of comprehension skills that are triggered while answering (Sugawara et al., 2017; Lai et al., 2017).

passage:
[...] A gradual improvement in clinical and laboratory status was achieved within 20 days of antituberculous treatment . The patient was then subjected to a thoracic CT scan that also showed significant radiological improvement . *Thereafter , tapering of corticosteroids was initiated with no clinical relapse* . The patient was discharged after being treated for a total of 30 days and continued receiving antituberculous therapy with no reported problems for a total of 6 months under the supervision of his hometown physicians . [...]
query:
If steroids are used , great caution should be exercised on their gradual tapering to avoid _____ .
answer:
relapse (sem_type=problem, cui=C0035020)

Figure 1: An example from the dataset, with the passage sentence relevant for answering italicized. The passage has been shortened for clarity.

Machine comprehension for healthcare and medicine has received little attention so far, although it offers great potential for practical use. A typical application would be clinical decision support, where given a massive amount of text, a clinician asks questions about either external, medical knowledge (reading literature) or about particular patients (reading electronic health records). Currently, patient-specific questions are tackled by manually browsing or searching those records. This task can be facilitated by summarization and QA systems (Demner-Fushman and Lin, 2007; Demner-Fushman et al., 2009), and we believe, by fine-grained machine reading. Reading comprehension systems that perform on a finer level could play an important role especially when combined with

*We provide the information about accessing the dataset, as well as the code for the experiments, at http://github.com/clips/clicr.

New Orleans, Louisiana, June 1 - 6, 2018.

document retrieval to perform machine reading at scale, such as in the models of Chen et al. (2017) and Watanabe et al. (2017) for the general domain.

For our dataset, we construct queries, answers and supporting passages from BMJ Case Reports, the largest online repository of such documents. A case report is a detailed description of a clinical case that focuses on rare diseases, unusual presentation of common conditions and novel treatment methods. Each report contains a *Learning points* section, summarizing the key pieces of information from that report. The learning points are typically paraphrased portions of passage text and do not match passage sentences exactly. We use these learning points to create queries by blanking out a medical entity. To counteract potential errors and inconsistencies due to automated dataset creation, we perform several checks to improve the quality of the dataset (§ 3). Our dataset contains around 100,000 queries on 12,000 case reports, has long support passages (around 1,500 tokens on average) and includes answers which are single- or multi-word medical entities. We show an example from the dataset in Figure 1.

We examine the performance on the dataset in two ways. First, we report machine performance for several baselines and neural readers. To enable a more flexible answer evaluation, we expand the answers with their respective synonyms from a medical knowledge base, and additionally supplement the standard evaluation metrics with BLEU and embedding-based methods. We investigate different ways of representing medical entities in the text and how this affects the neural readers. We obtain the best results with a recurrent neural network (RNN) with gated attention (Dhingra et al., 2017a), but a simple approach based on embedding similarity proves to be a strong baseline as well. Second, we look at how well humans perform on this task, by asking both a medical expert and a novice to answer a portion of the validation set. When categorizing the skills necessary to find the right answer, we observe that a large number of comprehension skills get activated and that prior knowledge in the form of the ability to perform lexico-grammatical inferences matters the most. This suggests that for our dataset and possibly for domain-specific datasets more generally, more background knowledge should be incorporated in machine comprehension models. The current gap between the best machine and the best human performance is nearly 20% F1, which leaves ample space for further study of machine readers on our dataset. In brief, the contributions of our paper are:

- We propose a large dataset for reading comprehension in the medical domain, using clinical case descriptions.
- We carry out an empirical analysis of *a*) system and human performance on reading comprehension, and *b*) comprehension skills that are required for answering the queries correctly and that allow us to position the dataset according to its difficulty on each of the skills.

Dataset	Question origin	Domain	Size
CliCR (this work)	Learning points	Medical	105K
Quasar-S (Dhingra et al., 2017b)	Definitions	Software	37K
SciQ (Welbl et al., 2017a)	Crowdsourced	Science	14K
MedHop (Welbl et al., 2017b)	KB	Drugs	2.5K

Table 1: Survey of closed-domain reading comprehension datasets. Size: number of questions. We did not include remotely related datasets which concern a different task (e.g. information retrieval) (Roberts et al., 2015; Voorhees and Tice, 2000).

2 Related datasets

Numerous **general-domain datasets** have been recently created to allow machine comprehension using data-intensive methods. These datasets were collected from Wikipedia (Hewlett et al., 2016; Joshi et al., 2017; Rajpurkar et al., 2016), web search queries (Nguyen et al., 2016), news articles (Hermann et al., 2015; Onishi et al., 2016; Trischler et al., 2017), books (Bajgar et al., 2016; Hill et al., 2016; Paperno et al., 2016) and English exams (Lai et al., 2017). In Table 1, we compare our dataset to several **domain-specific datasets** for machine comprehension. In Quasar-S, the queries are constructed from definitions of software entity tags in a community QA website, while in our case the queries are more varied and explicitly relate to the supporting passages. SciQ is a dataset of science exam questions, in which question-answer pairs are used to retrieve the text passages. For each question, four candidate answers are available. In our dataset, the number of candidate answer is much

higher as the candidate answers come from the relatively long passages. Other datasets mentioned in the table are smaller, so they could not be used as training sets for statistical NLP models.

Cloze datasets require the reader to fill in gaps by relying on accompanying text. Representative datasets are Children's Book Test (Hill et al., 2016) and Book Test (Bajgar et al., 2016), in which queries are created by removing a word or a named entity from the running text in a book; and Hermann et al. (2015), who similarly to us blank out entities in abstractive CNN and Daily Mail summaries, but who are only concerned with short proper nouns and short passages. Who-did-what (Onishi et al., 2016) requires the reader to select the person name from a short candidate list that best answers the query about a news event. They do not use summaries for query formation but remove a named entity from the initial sentence in a news article, and then perform information retrieval to find independent passages relevant to the query. Another cloze dataset for language understanding is ROCStories (Mostafazadeh et al., 2016), but it is targeted more towards script knowledge evaluation, and only contains five-sentence stories. Another related task is predicting rare entities only, with a focus on improving a reading comprehension system with external knowledge sources (Long et al., 2017).

Another popular way of creating datasets for reading comprehension is **crowdsourcing** (Rajpurkar et al., 2016; Richardson et al., 2013; Nguyen et al., 2016; Trischler et al., 2017). These datasets exist primarily for the general domain; for specialized domains where background knowledge is crucial, crowdsourcing is intuitively less suitable (Welbl et al., 2017b), although some positive precedent exists for example in crowdsourcing annotations of radiology reports (Cocos et al., 2015). Compared to automated dataset construction, crowdsourcing is more likely to provide high-quality queries and answers. On the other hand, human question generation may also lead to less varied datasets as questions would tend to be of *wh-* type; for cloze datasets, the questions may be more varied and might require readers to possess a different set of skills.[1]

[1]Support for this is given in Sugawara et al. (2017), who show that Who-did-what dataset, for example, requires on average a larger number of reading skills than SQuAD (Rajpurkar et al., 2016) and MCTest (Richardson et al., 2013).

3 Dataset design

We collected the articles from BMJ Case Reports[2]. The data span the years 2005–2016 and amount to almost 12 thousand reports. We removed the HTML boilerplate from the crawled reports using jusText[3], segmented and tokenized the texts with cTakes (Savova et al., 2010), and annotated the medical entities using Clamp (Soysal et al., 2017). We apply two simple heuristics to refine the recognized entities and to decrease their sparsity. Namely, we move the function words (determiners and pronouns) from the beginning of the entity outside of it, and we adjust the entity boundary so that it does not include a parenthetical at the end of the entity. Clamp assigns entities following the i2b2-2010 shared task specifications (Uzuner et al., 2011). For each entity, a concept unique identifier (CUI) is also available, which links it to the UMLS® Metathesaurus® (Lindberg et al., 1993). To check the quality of the recognized entities, we carried out a small manual analysis on 250 entities. We found that in 89% of cases, the boundaries were correct and defined a true entity. Wrongly recognized cases occurred mostly when two entities were coordinated and recognized as one; when a verb was wrongly included in the entity; or when a pre-modifier was left out.

3.1 Query construction

We create a query by replacing a medical entity in one learning point with a blank. For example, in a report describing comorbid disorders of ADHD, we could obtain the following query:

(1) "Patients with ADHD have higher incidence of ___."

The missing entity "enuresis" is taken as the correct answer. Even though one query corresponds to at most one learning point, there can be more than one query built from a learning point. Occasionally, a learning point contains an exact repetition from the passage. These instances would be trivial to answer, so we remove them. We count as an exact match every instance whose longer side to left/right of the query blank coincides with a part in the passage text. This curation step reduces the dataset size by 5%. More commonly, the learning points are paraphrases of crucial parts of the passage. Sometimes, the entity answering the query is expressed

[2]http://casereports.bmj.com/
[3]https://pypi.python.org/pypi/jusText

differently in the passage. For example, in place of "enuresis", the passage might include its synonym "bedwetting". We manage these cases in two ways, by extending the set of answers for a certain query (§ 3.2), and adding a semantic relatedness metric to the standard evaluation (§ 6).

3.2 Answer set

We account for lexical variation of the ground-truth answers (compared to mentions in the passages) by extending each original ground-truth answer a to a set of ground-truth answers A using a knowledge base. Since our entity recognizer already provides the CUI labels, we can use them to obtain the list of alternative word and phrase forms (synonyms, abbreviations and acronyms) from UMLS®.

Similarly to previous work (Choi et al., 2016; Hewlett et al., 2016), for certain queries none of the answers in A occurs verbatim in the passage. We have found upon manual inspection that this is mostly due to lexical variation that is not captured by answer extension, and to a lesser degree, due to the introduction of entirely new information in the learning point and the entity recognition errors. In the empirical part, we use for training only the instances for which at least one answer occurs in the passage, but we evaluate on all instances in the validation and test sets, including those for which $A \cap E = \emptyset$, where E is the set of all entities in the passage. This mimics a likely real-life scenario where the set of ground-truth answers is a priori unknown.

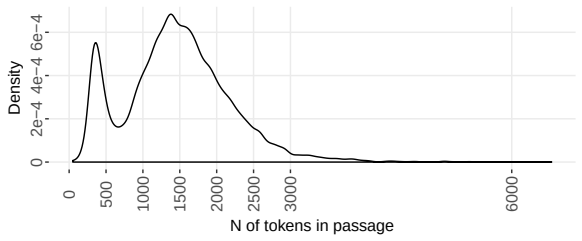
3.3 Task formulation

The reading comprehension problem in our case can be represented as a tuple (q, p, A), where q is the query, built from a learning point; the passage p is the entire report excluding the Learning points section; and A is the set of ground-truth entities answering q. In defining the task, it is important to consider how to take into account entity annotation and how to define the answer output space. We look at these more closely in the rest of this section.

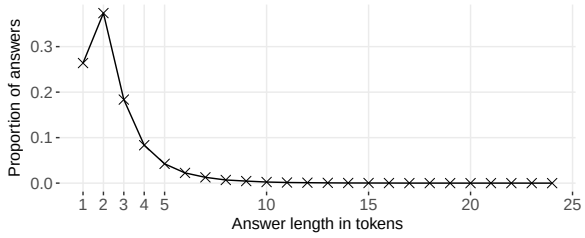
Whenever the entities are marked in the passage, the system can learn to exploit this cue to find the answers more easily (Wang et al., 2017). Although this simplifies the task, it also makes it less realistic as the entities may not be recognized at test time. Realizing that the presence of entities makes the task easier for the machines, Hermann et al. (2015) anonymize the entities, also with a goal of discouraging language model solutions to the queries. In our case, it is not clear how relevant the anonymization is since we deal with medical entities, which have different properties than proper name entities (Kim et al., 2003; Niu et al., 2003). We explore different entity-annotation choices in the empirical part, where we refer to them as **Ent** (entities marked) and **Anonym** (entities marked but anonymized). We further examine a more challenging setup in which the reader can not rely on entity markers as they are not present in the passage (**NoEnt**). In all cases, the reader chooses an answer among the candidates E collected from all entities in the passage.[4] Multi-word entities, which are common in our dataset, are treated as a single token by Ent and Anonym.

N of cases	11,846
N of queries in train/dev/test	91,344/6,391/7,184
N of tokens in passages	16,544,217
N of word types in passages	112,673
N of entity types in passages	591,960
N of distinct answers	56,093
N of distinct answers (incl. extended)	288,211
% answers verbatim in passage	59

Table 2: Data statistics based on the lowercased dataset. For *N of tokens in passages*, we count each passage exactly once, although several queries are normally associated with a passage.



(a)



(b)

Figure 2: Distribution of (a) passage and (b) answer length. Curve (a) is bimodal due to shorter lengths of articles published prior to 2008.

[4] The candidate answers could in principle be obtained also in some other way, so we do not list them in our dataset.

Type	%	Example
problem	67	tuberculosis, abdominal pain, acute myocardial infarction
treatment	22	chemotherapy, surgical intervention, vitamin D suppl.
test	11	MRI, histopathological exam.

Table 3: Answer type statistics.

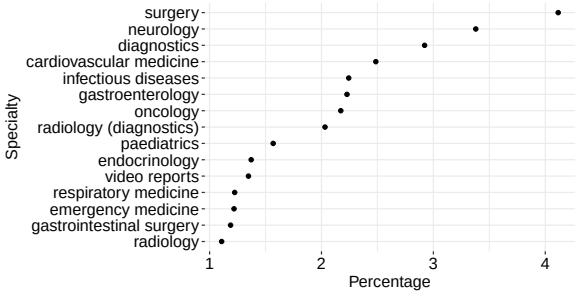


Figure 3: The 15 most common medical specialties represented in the dataset.

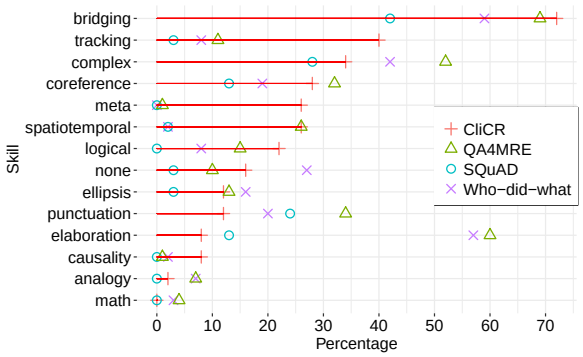

Figure 4: Percentage of times a skill is required in a given dataset. The percentages for the datasets other than ours are from Sugawara et al. (2017).

4 Dataset analysis

We now describe the dataset in more detail, starting with the general statistics summarized in Table 2. It is worth pointing out that the support passages are rather long, which stems from the data origin (journal articles). We show the passage length distribution in Figure 2a, which has the average length of 1,466 tokens. Furthermore, passages are rich with medical entities. There is little repetition of answers—the total of around 100,000 queries are answered by 50,000 distinct entities. Upon extending the answer set with UMLS® we introduce on average four alternative answers for each original one. In 59% of instances, the answer entity is found verbatim in the relevant passage. The answers can belong to any of the problem, treatment or test categories (Table 3), and usually consist of multiple words (Figure 2b). The diversity of medical specialties represented in the articles is shown in Figure 3.

4.1 Analysis of comprehension skills

We estimate the types of skills required in answering by following the categorization of Sugawara et al. (2017). We include the skill definitions with examples from our dataset in Appendix B. We annotated 100 instances in the validation set (with ground-truth answers provided), which yielded on average 2.85 skills per query. The distribution of the required skills is shown in Figure 4. In comparison to the general-domain datasets (SQuAD, Who-did-what), our dataset and QA4MRE (which is also a domain-specific dataset, but with human-generated questions) require more bridging inferences (inferences using background knowledge about the domain), spatio-temporal reasoning and coreference resolution. In our dataset, meta knowledge and object tracking are required more often than in any other dataset. This can be explained by the data origin and the nature of queries. In the case reports, a prominent topic can be discussed which the author refers to in the query, but the query itself is never answered in the passage (meta knowledge). Furthermore, the authors often enumerate medical entities in the query, which leads to the frequent use of object tracking. The queries which were unanswerable are marked as "none". The fraction of these cases was around 16%.

In our experience, the annotation of skills proved quite challenging due to certain confusables. For example, object tracking and coreference both need to maintain the link between objects; object tracking, which includes establishing set relations and membership, may be overlaid with the schematic clause relation skill (subordination); and bridging inference can overlap with coreference resolution. Nevertheless, we adhered to this classification of skills to increase comparability to other datasets included in Figure 4.

5 Methods

5.1 Baselines

Our simplest baselines that we apply on the test set include choosing a random entity (**rand-entity**)

and selecting the most frequent passage entity (**maxfreq-entity**) as the answer. We also include a distance-based method that uses word embeddings (**sim-entity**). Here, we vectorize the passage and the query, and then choose that entity from the passage whose representation has the highest cosine similarity to the query representation:

$$\textit{sim-entity} = \underset{i \in E}{\operatorname{argmax}} \cos\Big(\sum_{j \in C_i} c_j, \sum_{k \in Q} q_k \Big), \quad (1)$$

where $c, q \in \mathbb{R}^d$. The multiset C_i contains the words $\{x_{i-n}, \ldots, x_{i-1}, x_{i+1}, \ldots, x_{i+n}\}$ surrounding the passage entity $i \in E$. We define Q, the context words of the query, likewise. To find out how well the queries can be answered without reading the passage, we also predict the most likely continuation with a language model (**lang-model**). We trained a 4-gram Kneser-Ney model on CliCR training data (with multi-word entities represented as a single token) using SRILM (Stolcke, 2002).

5.2 Neural readers

We apply two types of bidirectional RNNs to our data. Following Wang et al. (2017), we distinguish between *aggregation* readers and *explicit reference* readers, which differ in their formulation of the attention mechanism and how it is being used for answer prediction.

Stanford Attentive (SA) Reader The model proposed by Chen et al. (2016) is an aggregation reader based on the Attentive Reader (Hermann et al., 2015). It predicts the answer using:

$$\hat{a} = \underset{i \in E}{\operatorname{argmax}}\, e_o(i)^T o, \quad (2)$$

where $e_o(i)$ is the answer's output embedding and o is the passage representation obtained by weighting every token representation in the passage with attention: $o = \sum_t \alpha_t h_t$. The attention mechanism is used here to measure the compatibility between token (h_t) and query (q) representations with a bilinear form, $\alpha_t = \text{softmax}_t h_t^T W_\alpha q$. At prediction time, attention should highlight that position t in the passage where the answer occurs. Note that the prediction relies on the aggregate representation o, hence the name of the reader category. As we see in (2), the prediction score does not allow accounting for multi-word entities, unless they are treated as a single token. Returning to our different set-ups based on entity annotation (§ 3.3), this means that we can apply SA reader with Ent and Anonym set-ups, but not with NoEnt, where multi-word answers should be allowed.

Gated-Attention (GA) Reader Dhingra et al. (2017a) investigate neural readers with a fine-grained attention mechanism that learns token representations for the passage that are also conditional on the query, but are in addition refined through multiple hops of the network. The model predicts the answer using attention weights with *explicit reference* to answer positions in the passage:

$$\hat{a} = \underset{i \in E}{\operatorname{argmax}} \sum_{t \in R(i,p)} \alpha_t, \quad (3)$$

where R is the set of indices in passage p at which a token from the candidate i occurs. This operation is also called the pointer sum attention (Kadlec et al., 2016). Since the model marks the references for each token in the answer separately, it allows us to investigate also the NoEnt set-up.[5]

We train each reader with the best hyper-parameters found on the validation set using random search (Bergstra and Bengio, 2012), and evaluate it on the test part of the dataset. We provide more details about parameter optimization in Appendix A. The models use word embeddings pre-trained on biomedical texts.

5.3 Embedding data and pre-training

We induce the word embeddings on a combination of the CliCR training corpus and PubMed abstracts with open-access PMC articles available until 2015 (segmented and tokenized), amounting to over 9 billion tokens (Hakala et al., 2016). Considering the large effect of hyper-parameter selection on the quality of word embeddings (Levy et al., 2015), we optimize the embedding hyper-parameters also using random search.

6 Evaluation

A model f takes as input a passage–query pair and outputs an answer $\hat{a}$.[6] We carry out the evaluation

[5] We assume the candidate entities are known in advance.

[6] In our case, the answer is a word or a word phrase representing a medical entity. Alternatively, one could also take the UMLS® CUI identifier as the answering unit. However, in that case, it would mean that sometimes the original word phrase is lost. This is because entity linking with CUIs can be noisy, and only a part of a word phrase may be linked to the ontology. In the current setup, we are able to keep both the original word phrase as well as the extended answers. The CUI information is still an integral part of the answer field in our dataset, so it can be used by other researchers if preferred.

with different metrics described below. The final score m for a metric v is obtained by averaging over the test set:

$$m_v(f) = \frac{1}{|D_{\text{test}}|} \sum_{(p,q,A) \in D_{\text{test}}} \max_{a \in A} v(f(p,q), a). \quad (4)$$

Since there are multiple correct answers A, we take the highest scoring answer $\hat{a}$ at each instance, as done in Rajpurkar et al. (2016). Note that in the dataset we do not supply the candidate answers; in the experiments, we constrain the candidates to the set of entities in the passage.

The two standardly used metrics for machine comprehension evaluation are the **exact match** (EM) and the **F1** score. For EM, the predicted and the ground truth answers must match precisely, safe for articles, punctuation and case distinction (same for other metrics). F1 metric is applied per instance and measures the overlap between the prediction $\hat{a}$ and the ground truth a, which are treated as bags of words.[7] While these two metrics are arguably sufficient in news-style machine comprehension where the entities are proper nouns which allow for little variation and synonymy, in our case the medical entities are often mostly common nouns modified by specifiers and qualifiers. To take into account potentially large lexical and word-order variation, we use two additional metrics. First, we measure **BLEU** (Papineni et al., 2002) for n-grams of length 2 (shortly, B2) and 4 (B4) using the package by Chen et al. (2015), with which we aim to capture contiguity of tokens in longer answers. Second, it may occur that answers contain no word overlap yet still be good candidates because of their semantical relatedness, as in "renal failure"–"kidney breakdown". We take this into account by using an **embedding metric** (Emb), in which we construct mean vectors for both ground-truth and system answer sequences, and then compare them with the cosine similarity. This and other embedding metrics for evaluation were previously studied in dialog-system research (Liu et al., 2016).

7 Results and analysis

We show the results in Table 4. We see that answer prediction based on contextual representation of queries and passages (sim-entity) achieves a strong base performance that is only outperformed by GA reader. The language model performs poorly on EM and F1, but the embedding-metric score is higher, likely reflecting the fact that the predicted answers—though mostly incorrect—are related to the ground-truth answers. The poor performance means that based on queries alone (without reading the passage), it is difficult to provide accurate answers. The GA reader performs well across all entity set-ups, even when the entities are not marked in the passage. Interestingly, the exact match and BLEU scores in this case are much lower compared to other entity set-ups. Upon inspecting the predicted answers more closely, we have observed that GA-NoEnt tends to predict longer answers than GA-Ent/Anonym. For example, the average predicted answer length for GA-NoEnt was as high as 3.7 tokens, whereas for the other two set-ups and the ground-truth answers the numbers range between 2.3 and 2.5. A plausible explanation for this lies in how GA reaches its prediction (3), which is by accumulating the attention weights without normalizing. This would then drive the model to prefer longer answers. For example, for the ground-truth entity "chest CT", GA-NoEnt predicts "interval CT scans of the chest". Although all neural models use pre-trained word embeddings, for Ent and Anonym the multi-word entities do not have pre-trained embeddings since our embeddings are induced on the word level. This may partly explain the competitive performance of NoEnt compared to Ent. We leave the integration of entity embeddings for the future work.

The results for SA reader are far below the per-

Method	EM	F1	B2	B4	Emb
rand-entity	1.4	5.1	.03	.01	.23
maxfreq-ent.	8.5	12.6	.10	.05	.31
sim-entity	20.8	29.4	.22	.15	.45
lang-model	2.1	3.5	.00	.00	.30
SA-Anonym	19.6	27.2	.22	.16	.43
SA-Ent	6.1	11.4	.07	.05	.31
GA-Anonym	24.5	33.2	.28	.20	.48
GA-Ent	22.2	30.2	.25	.18	.46
GA-NoEnt	14.9	33.9	.21	.11	.51
human-expert	*35*	*53.7*	*.46*	*.23*	*.67*
human-novice	*31*	*45.1*	*.43*	*.24*	*.62*

Table 4: Answering results on the test set. EM and F1 scores are percentages. The human scores (in italics) are based on the validation set.

[7] In precision, the number of correct words is divided by the number of all predicted words. In recall, the former is divided by the number of words in the ground-truth answer.

formance of GA reader. We also see that it performs much better on anonymized entities than on non-anonymized ones. This is in line with Wang et al. (2017) who find that SA reader suffers a drop of 19 points in exact match on Who-did-what dataset when anonymization is not done. A possible explanation is that anonymization reduces the output space to only several hundred entity candidates for which the output embedding needs to be trained. When we do not use anonymization, the set of output entities increases to the set of all entity types found in all passages, which is several orders of magnitude more. While this effect also occurs for GA reader, it is less pronounced because GA reader scores words in the passage and does not need to learn separate answer word embeddings.

7.1 Human performance

To measure the accuracy of human answering, we have used the same sample of data instances as used for the analysis of skills.[8] The queries were answered separately by a novice reader (linguistics background, little-to-none medical knowledge) and by an expert reader (both linguistics and medical background). The annotators needed around 15 minutes on average to read the passage and answer the query. The results are shown at the bottom of Table 4. The expert scores higher across all evaluation metrics, with as much as a 7-point advantage in % F1. This advantage is largely coming from the better performance on those instances where bridging inferences are required (the average F1 score was 10 points higher on these queries), which suggests that domain knowledge is beneficial in the comprehension task. For a novice in a specialized domain, it is harder to build a good situation model that would lead to successful comprehension since it requires more effort—active, strategic processing and establishing ontological relationships in that specific domain. For an expert reader this process is more automatized (Kintsch and Rawson, 2008).

We can see from the table that the best human performance is well below its theoretical upper bound of 100% F1. An important part of explanation for this lies in the automated dataset construction, which leaves certain queries unanswerable, especially when the authors do not refer to a part in the article but introduce completely new information. Another reason is the problem of "answer openness": Typically more than one correct answer is possible and the answers can be correct to various degrees, which we aimed to capture with the use of the embedding metric in the evaluation. Nevertheless, the gap between the best human and machine F1 score is large (around 20 points), leaving considerable space for future applications of machine readers on our dataset.[9]

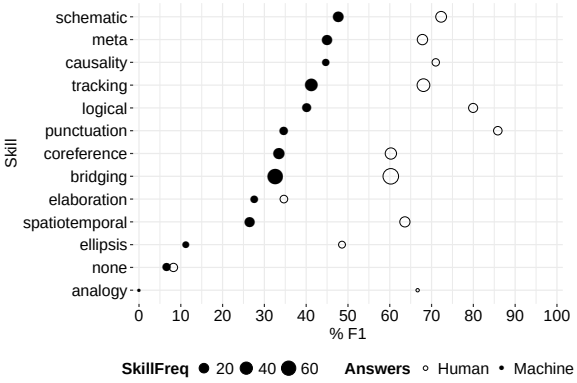

Figure 5: Performance per required skill for the human expert and GA-NoEnt reader.

7.2 Breakdown of results by skill

To see how the answering performance relates to the skill requirements, we have analyzed the part of the validation set annotated with the skills by averaging F1 values for all instances with a particular skill. In this way, we are able to break down both human and machine performance skill-wise, as shown in Figure 5. Because of the small sample size, the results should only be taken as a general indication. The most difficult cases for the GA reader are those annotated with "none" (unanswerable) and "ellipsis" (recognizing implicit and omitted information), ignoring "analogy" for which we only have a single annotated case. Furthermore, spatio-temporal reasoning, elaboration (inferences using general knowledge) and bridging—which is also the most commonly required skill—are the next most difficult ones. The human scores are mostly much higher, which is especially apparent for spatio-temporal reasoning, logical skills and the skill involving punctuation. Our findings align with those of Chu et al. (2017) on the Lambada dataset (Paperno et al., 2016): Although they used a different categorization of comprehension skills, they also find that GA reader has most difficulties with elaboration (which they refer to as "external

[8] Human answers were collected before the skill analysis.

[9] For comparison, the gap for SQuAD was 12.2 and for NewsQA 19.8 (Trischler et al., 2017).

knowledge"), followed by coreference resolution.

8 Conclusion and future work

We have introduced a new dataset for domain-specific reading comprehension in which we have constructed around 100,000 cloze queries from clinical case reports. We analyzed the dataset in terms of the skills required for successful comprehension, and applied various baseline methods and state-of-the-art neural readers. We showed that a large gap still exists between the best machine reader and the expert human reader. One direction for future research is improving the reading models on the queries that are currently the most challenging, i.e. those requiring world and background domain knowledge. Better representing background knowledge by inducing embeddings for entities or otherwise integrating ontological knowledge is in our opinion a promising avenue for future research.

Acknowledgments

We would like to thank Madhumita Sushil and the anonymous reviewers for useful comments. We are also grateful to BMJ Case Reports for allowing the collection of case reports. This work was carried out in the framework of the Accumulate IWT SBO project (nr. 150056), funded by the government agency for Innovation by Science and Technology. We also acknowledge the support of the Nvidia GPU Grant Program.

A Training details and hyper-parameter optimization

We train the word embeddings using word2vec (Mikolov et al., 2013), and optimize the window size, the model type (CBOW, skip-gram), the dimensionality and the number of negative samples using random search. For the embedding baseline sim-entity, the evaluation was carried out 20 times on the validation part of our dataset, and we chose the parameter configuration that led to the highest-performing embedding model as measured by F1. We find that higher embedding dimensionality works better, that CBOW obtains somewhat better scores than Skipgram, and that medium-sized word windows work best. The best configuration: 'win_size': 5, 'min_freq': 200, 'model': 'cbow', 'dimension': 750, 'neg_samples': 5. The difference between the lowest and the highest scoring model was 3.4 F1. At prediction time (equation (1)) we set the window size to 3, which worked best on the validation set.

For inclusion in the neural readers, it would be impractical to use the high embedding dimensionality found in the hyper-parameter search from the previous paragraph, so we fix the input embedding dimensionality to 200, as done in Chen et al. (2016) to keep the training time practical. We optimize the remaining embedding hyper-parameters just like above. The best parameters were: 'win_size': 4, 'min_freq': 200, 'model': 'cbow', 'dimension': 200, 'neg_samples': 9.

For SA reader, we optimized the hidden state size and the dropout rate using 20 different random configurations. The best values were 70 and 0.57, respectively. We explore the same parameters for the GA reader, but add to the search space the feature that indicates the presence of a passage token in the query, which was found useful in the NoEnt set-up. The best hidden state number and dropout rate were 64 and 0.5, respectively. We used the default values for all the remaining hyper-parameters.

B List of skills with selected examples

In annotating the skills, we followed the categorization by Sugawara et al. (2017):

1. Object tracking: tracking or grasping multiple objects; it is a version of list/enumeration skill used in previous skill classifications
2. Mathematical reasoning: whenever a mathematical operation is involved in finding the answer
3. Coreference resolution: direct reference to an object, includes anaphoras. These include inferential processes based on background knowledge or context.
4. Logical reasoning: conditionals, quantifiers, negation, transitivity
5. Analogy: metaphors, metonymy
6. Causal relation: explicit expression such as "why", "the reason of"
7. Spatio-temporal relations
8. Ellipsis: recognizing implicit or omitted information
9. Bridging: inference through grammatical and lexical knowledge (synonymy, idioms etc). This link however is not automatic or stereotypical, as in the category of elaboration.
10. Elaboration: inference through commonsense reasoning. Note that unlike in the previous category, there is no direct way in which grammatical, lexical or ontological knowledge could help.
11. Meta-knowledge: knowing about the text genre and the main topic being discussed assists in comprehending. In our dataset, knowing the way the queries are constructed (Learning points) is sometimes beneficial.
12. Schematic clause relation: complex sentences that include coordination or subordination
13. Punctuation: understanding parentheses, dashes, quotations, colons etc.

In the following examples, we mark the medical entities in blue, and italicize the parts in the passage that are crucial for answering. Whenever we shorten a part of the passage, we use [...].

B.1 Bridging inference

passage

We report a case of a 72 - year - old Caucasian woman with pl-7 positive antisynthetase syndrome . Clinical presentation included interstitial lung disease , myositis , mechanic 's hands and dysphagia

. As lung injury was the main concern , treatment consisted of *prednisolone and cyclophosphamide* . Complete remission with reversal of pulmonary damage was achieved , as reported by CT scan , pulmonary function tests and functional status . [...]
query
Therefore , in severe cases an aggressive treatment , combining _____ and glucocorticoids as used in systemic vasculitis , is suggested .
answer
cyclophoshamide
explanation The reader needs to have the background knowledge that prednisolone is a glucocorticoid, then it becomes obvious that the answer is cyclophoshamide.

B.2 Object tracking

passage
[...] The patient was managed with supportive measures and the National Poisons Information Service was contacted . A toxicology consultant was involved in view of the unusual mode of administration . Although there was no precedent on how to treat a significant rectal overdose of amitriptyline , *it was advised that the patient be administered a phosphate enema and if failed to adequately remove the tablets then the patient should be given whole bowel irrigation* with 2 litre of Klean - Prep via a nasogastric tube . It was also advised that we admit the patient to a high dependency unit and manage him according to the usual protocol for a tricyclic overdose if complications arose . [...]
query
It seems reasonable to attempt careful removal of the drug from the rectum and if that fails to consider _____ and whole bowel irrigation .
answer
phosphate enemas
explanation The query mentions removal (A), then _____ (B) and whole bowel irrigation (C). In the passage, one needs to track those elements and choose the right one. This skill should be considered whenever the gap is part of an enumeration or is mentioned as a part of another entity.

B.3 Meta knowledge

query
bedaquiline , a new agent with bactericidal and sterilising activity against mycobacterium tuberculosis , is effective against _____ when given together with a background regimen , and is well tolerated and safe if there is awareness of drug interactions and precautions are taken to avoid potential qt prolongation .
answer
tuberculosis
explanation The right answer can be inferred from several parts in the passage (not shown), or even from the title or the query. The query, though, is nowhere in the document explicitly answered.

Abstract

Question answering (QA) and question generation (QG) are closely related tasks that could improve each other; however, the connection of these two tasks is not well explored in literature. In this paper, we give a systematic study that seeks to leverage the connection to improve both QA and QG. We present a training algorithm that generalizes both Generative Adversarial Network (GAN) and Generative Domain-Adaptive Nets (GDAN) under the question answering scenario. The two key ideas are improving the QG model with QA through incorporating additional QA-specific signal as the loss function, and improving the QA model with QG through adding artificially generated training instances. We conduct experiments on both document based and knowledge based question answering tasks. We have two main findings. Firstly, the performance of a QG model (e.g in terms of BLEU score) could be easily improved by a QA model via a policy gradient. Secondly, directly applying GAN that regards all the generated questions as negative instances could not improve the accuracy of the QA model. Learning when to regard generated questions as positive instances could bring performance boost.

1 Introduction

In this work, we consider the task of joint learning of question answering and question generation. Question answering (QA) and question generation (QG) are closely related natural language processing tasks. The goal of QA is to obtain an answer given a question. The goal of QG is almost reverse which is to generate a question from the answer. In this work, we consider answer selection (Yang et al., 2015; Balakrishnan et al., 2015) as the QA task, which assigns a numeric score to each candidate answer, and selects the top ranked one as the answer. We consider QG as a generation problem and exploit sequence-to-sequence learning (Seq2Seq) (Du et al., 2017; Zhou et al., 2017) as the backbone of the QG model.

The key idea of this work is that QA and QG are two closely tasks and we seek to leverage the connection between these two tasks to improve both QA and QG. Our primary motivations are twofolds. **On one hand**, the Seq2Seq based QG model is trained by maximizing the literal similarity between the generated sentence and the ground truth sentence with maximum-likelihood estimation objective function (Du et al., 2017). However, there is no signal indicating whether or not the generated sentence could be correctly answered by the input. This problem could be precisely mitigated through incorporating QA-specific signal into the QG loss function. **On the other hand**, the capacity of a statistical model depends on the quality and the amount of the training data (Sun et al., 2017). In our scenario, the capacity of the QA model depends on the difference between the positive and negative patterns embodied in the training examples. A desirable training dataset should contain the question-answer pairs that are literally similar yet have different category labels, i.e. some question-answer pairs are correct and some are wrong. However, this kind of dataset is hard to obtain in most situations because of the lack of manual annotation efforts. From this perspective, the QA model could exactly benefit from the QG model through incorporating additional question-answer pairs whose questions are automatically generated by the QG model[1].

To achieve this goal, we present a training algorithm that improves the QA model and the

[1]An alternative way is to automatically generate answers for each question. Solving the problem in this condition requires an answer generation model (He et al., 2017), which is out of the focus of this work. Our algorithm could also be adapted to this scenario.

Proceedings of NAACL-HLT 2018, pages 1564–1574
New Orleans, Louisiana, June 1 - 6, 2018.

QG model in a loop. The QA model improves QG through introducing an additional QA-specific loss function, the objective of which is to maximize the expectation of the QA scores of the generated question-answer pairs. Policy gradient method (Williams, 1992; Yu et al., 2017) is used to update the QG model. In turn, the QG model improves QA through incorporating additional training instances. Here the key problem is how to label the generated question-answer pair. The application of Generative Adversarial Network (GAN) (Goodfellow et al., 2014; Wang et al., 2017) in this scenario regards every generated question-answer pair as a negative instance. On the contrary, Generative Domain-Adaptive Nets (GDAN) (Yang et al., 2017) regards every generated question-answer pair appended with special domain tag as a positive instance. However, it is non-trivial to label the generated question-answer pairs because some of which are good paraphrases of the ground truth yet some might be negative instances with similar utterances. To address this, we bring in a collaboration detector, which takes two question-answer pairs as the input and determines their relation as collaborative or competitive. The output of the collaboration detector is regarded as the label of the generated question-answer pair.

We conduct experiments on both document based (Yang et al., 2015) and knowledge (e.g. web table) based question answering tasks (Balakrishnan et al., 2015). Results show that the performance of a QG model (e.g in terms of BLEU score) could be consistently improved by a QA model via policy gradient. However, regarding all the generated questions as negative instances (*competitive*) could not improve the accuracy of the QA model. Learning when to regard generated questions as positive instances (*collaborative*) could improve the accuracy of the QA model.

2 Related Work

Our work connects to existing works on question answering (QA), question generation (QG), and the use of generative adversarial nets in question answering and text generation.

We consider two kinds of answer selection tasks in this work, one is table as the answer (Balakrishnan et al., 2015) and another is sentence as the answer (Yang et al., 2015). In natural language processing community, there are also other types of QA tasks including knowledge based QA (Berant et al., 2013), community based QA (Qiu and Huang, 2015) and reading comprehension (Rajpurkar et al., 2016). We believe that our algorithm is generic and could also be applied to these tasks with dedicated QA and QG model architectures. Despite the use of sophisticated features could learn a more accurate QA model, in this work we implement a simple yet effective neural network based QA model, which could be conventionally jointly learned with the QG model through back propagation.

Question generation draws a lot of attentions recently, which is partly influenced by the remarkable success of neural networks in natural language generation. There are several works on generating questions from different resources, including a sentence(Heilman, 2011), a topic (Chali and Hasan, 2015), a fact from knowledge base (Serban et al., 2016), etc. In computer vision community, there are also recent studies on generating questions from an image (Mostafazadeh et al., 2016). Our QG model belongs to sentence-based question generation.

GAN has been successfully applied in computer vision tasks (Goodfellow et al., 2014). There are also some recent trials that adapt GAN to text generation (Yu et al., 2017), question answering (Wang et al., 2017), dialogue generation (Li et al., 2016), etc. The relationship of the discriminator and the generator in GAN are competitive. The key finding of this work is that, directly applying the idea of "competitive" in GAN does not improve the accuracy of a QA model. We contribute a generative collaborative network that learns when to collaborate and yields empirical improvements on two QA tasks.

This work relates to recent studies which attempt to improve the performance of a discriminative QA model with generative models (Wang et al., 2017; Yang et al., 2017; Dong et al., 2017; Duan et al., 2017). These works regard QA as the primary task and use auxiliary task, such as question generation and question paraphrasing, to improve the primary task. This is one part of our goal and our another goal is to improve the QG model with the QA system and further to increasingly improve both tasks in a loop.

In terms of assigning category label to the generated question, Generative Adversarial Network (GAN) (Goodfellow et al., 2014; Wang et al.,

2017) and Generative Domain-Adaptive Nets (GDAN) (Yang et al., 2017) could be viewed as special cases of our algorithm. Our algorithm learns when to assign positive or negative labels, while GAN always assigns negative labels and GDAN always assigns positive labels. Besides, our work differs from (Wang et al., 2017) in that our question generation model is a generative model while theirs is actually a discriminative matching model. The approach of (Dong et al., 2017) learns to generate question from question via paraphrasing, and use the generated questions in the inference process. In this work, the QA model and the QG model are applied separately in the inference process. This inspires us to jointly conduct QA and QG in the inference process, which we leave as a future work.

3 Generative Collaborative Network

In this section, we first formulate the task of QA and QG, and then present our algorithm that jointly trains the QA and QG models.

3.1 Task Formulation

This work involves two tasks: question answering (QA) and question generation (QG).

There are different kinds of QA tasks in the natural language processing area. To verify the scalability of our algorithm, we consider two types of answer selection tasks, both of which are fundamental QA tasks in research community and of great importance in industrial applications including web search and chatbot. Both tasks take a question q and a list of candidate answers $A = \{a_1, a_2, ..., a_n\}$ as input, and outputs an answer a_i which has the largest probability to correctly answer the question. The only difference is that the answer in the task of answer sentence selection (Yang et al., 2015) is a natural language sentence, while the answer in table search (Balakrishnan et al., 2015) is a structured table consisting of caption, attributes and cells. Our QA model is abbreviated as $P_{qa}(a, q; \theta_{qa})$, whose output is the probability that q and a being a correct question-answer pair, and the parameter is denoted as θ_{qa}.

The task of QG takes an answer a which is a natural language sentence or a structured table, and outputs a natural language question q which could be answered by a. Inspired by the remarkable progress of sequence-to-sequence (Seq2Seq) learning in natural language generation, we deal with QG in an end-to-end fashion and develop a generative model based on Seq2Seq learning. Our QG model is abbreviated as $P_{qg}(q|a; \theta_{qg})$, whose output is the probability of generating q from a and the parameter is denoted as θ_{qg}.

3.2 Algorithm Description

We describe the joint learning algorithm in this part. The end goal is to leverage the connection of QA and QG to improve the performances on both QA and QG tasks. A brief illustration of the training progress is given in Figure 1 , which includes a QA model, a QG model and a collaboration detector (CD). A formal description of the algorithm is given in Algorithm 1. We can see that the QA model and the QG model both have two training objectives. One part is the standard supervised learning objective based on task-specific supervisions. Another part of the objective is obtained by leveraging auxiliary tasks.

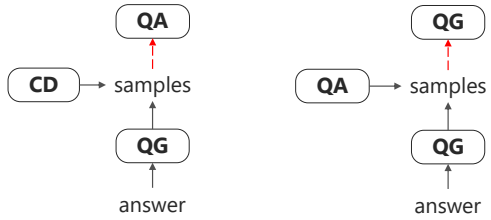

Figure 1: An brief illustrating of the joint training process. The red dashed line stands for the model being updated. QA, QG and CD stand for question answering, question generation and collaboration detection, respectively.

The supervised objective of the QA model is to maximize the probability of the correct category label, and the supervised objective of the QG model is to maximize the probability of the correct question sequence. Since the goal of QA is to predict whether a question-answer pair is correct or not, training the QA model requires negative QA pairs whose labels are zero. But these negative QA pairs are not used for training the QG model as the goal of QG is to generate the correct question.

The main contribution of this work is to explore effective learning objectives that leverage auxiliary tasks. In order to improve the QA model, we generate additional training instances, each of which is composed of a question, an answer and a category label. In this work, we clamp the answer part and feed the answer to the QG model to

Algorithm 1 Generative Collaborative Network for QA and QG

Input: training data D; the batch size for QG training m; the beam size for QG inference k; hyper parameters λ_{qg} and λ_{qg}; hyper parameters b_{qa} and b_{qg}; pretrained collaboration detector $P_{cd}(q, q')$
Output: QA model $P_{qa}(a, q)$ parameterized by θ_{qa}; QG model $P_{qg}(q|a)$ parameterized by θ_{qg}

pretrain $P_{qa}(a, q)$ and $P_{qg}(q|a)$ separately on D
repeat
  get a minibatch of positive QA pairs $PD = \{q_i^p, a_i^p\} \in D, 1 \leq i \leq m$, in which a_i^p is the answer of q_i^p
  get a minibatch of negative QA pairs $ND = \{q_i^n, a_i^n\} \in D, 1 \leq i \leq m$, in which a_i^n is not the answer of q_i^n
  apply $P_{qg}(q|a)$ on PD to generate in a list of question-answer beams $GD = \{q_{ij}^g, a_i^g\}, 1 \leq i \leq m, 1 \leq j \leq k$
  apply $P_{qa}(a, q)$ on GD to assign a QA-specific score to each generated instance
  choose the top ranked result from each beam in GD, and then apply $P_{cd}(q, q')$ on the selected instance
  update θ_{qa} by maximizing the following objective

$$\sum_{i=1}^{m} \Big(logP_{qa}(a_i^p, q_i^p) + log\big(1 - P_{qa}(a_i^n, q_i^n)\big) \Big) + \lambda_{qa} \sum_{i=1}^{m} \Big(\mathbb{I}_{b_{qa}}[P_{cd}(q_i^p, q_{i0}^g)] logP_{qa}(a_i^p, q_{i0}^g) \Big) + \lambda_{qa} \sum_{i=1}^{m} \Big(\big(1 - \mathbb{I}_{b_{qa}}[P_{cd}(q_i^p, q_{i0}^g)]\big) log\big(1 - P_{qa}(a_i^p, q_{i0}^g)\big) \Big) \quad (1)$$

  update θ_{qg} by maximizing the following objective

$$\sum_{i=1}^{m} logP_{qa}(q_i^p|a_i^p) + \lambda_{qg} \sum_{i=1}^{m} \sum_{j=1}^{k} P_{qa}(a_i^p, q_{ij}^g) logP_{qg}(q_{ij}^g|a_i^p) \quad (2)$$

until models converge

generate the question. We use beam search and select the top ranked result as the question.[2] Here the issue is how to infer the label of the generated instance. We believe that heuristically assigning the label as 0 or 1 is problematic. For instance, let us suppose the answer sentence is *"Microsoft was founded by Paul Allen and Bill Gates on April 4, 1975."*, and the ground truth question is *"who founded Microsoft"*. In this case, the generated question *"who is the founder of Microsoft"* is a good one yet *"who is the founder of Google"* and *"how old is Bill Gates"* are both bad cases. To address this, we introduce an additional collaboration detector (CD) to infer the label of the generated instance. Intuitively, the CD acts as a discriminative paraphrase model, which measures the semantic similarity between the ground truth question and generated question. In equation (1), the $\mathbb{I}_{b_{qa}}(x)$ is an indicator function whose value is 1 if the value of x is larger than a threshold b_{qa}, such as 0.5 or 0.3. The hyper parameter λ_{qa} controls the weight of the auxiliary objective to the QA model.

In turn, the QA model is used to assign a QA-specific score $P_{qa}(a, q')$ to each generated question q'. We follow the recent reinforcement learning based approach for dialogue prediction (Li et al., 2016), and define simple heuristic rewards that characterize good questions. The goodness of the generated question is measured by the prediction of the QA model. Similar to the strategy adopted by (Zaremba and Sutskever, 2015), we use a baseline strategy b_{qg} (e.g. 0.5) to decrease the learning variance. The expected reward (Williams, 1992; Yu et al., 2017) for a generated question is given in Equation (2). In this way, the parameters of the QG model could be conventionally updated with stochastic gradient descent.

We pretrain the QA model and the QG model before the joint learning process. The main reason is that a randomized QA model will provide unreliable rewards to the QG model, and a randomized QG model will generate bad questions.

4 The Neural Architecture of Each Module

Our algorithm includes a question answer (QA) model, a question generation (QG) model and a collaboration detector (CD) model. We implement these models with dedicated neural networks.

As we have mentioned before, our training algorithm is applied to both document-based and web table based question answer tasks. In this section, we take table based QA and QG tasks to describe the neural architecture of each module. A question/query q is a natural language expression consisting of a list of words. A table t has fixed

[2] We also implemented using all the beam search results or sampling one result from the beam. However, these tricks do not bring performance boost.

schema including one or more $headers$, one or more $cells$, and a $caption$. A header indicates the property of a column, and a cell is a unit where a row and a column intersects. The caption is typically an explanatory text about the table.

4.1 The Question Answer (QA) Model

We develop a neural network to match a natural language question/query to a structured table. Since a table has multiple aspects including headers, cells and the caption, the model is developed to capture the semantic relevance between a query and a table at different levels.

As the meaning of a query is sensitive to the word order, i.e. the intentions of "*list of flights london to berlin*" and "*list of flights berlin to london*" are totally different, we represent a query with a sequential model. In this work, recurrent neural network (RNN) is used to map a query of variable length to a fixed-length vector. We use gated recurrent unit (GRU) (Cho et al., 2014) as the basic computation unit, which adaptively forgets the history and remembers the input.

$$z_i = \sigma(W_z e_i^q + U_z h_{i-1}) \quad (3)$$

$$r_i = \sigma(W_r e_i^q + U_r h_{i-1}) \quad (4)$$

$$\widetilde{h}_i = \tanh(W_h e_i^q + U_h(r_i \odot h_{i-1})) \quad (5)$$

$$h_i = z_i \odot \widetilde{h}_i + (1 - z_i) \odot h_{i-1} \quad (6)$$

where z_i and r_i are update and reset gates of GRU. We use bi-directional RNN to get the meaning of a query from forward and backward directions, and concatenate two last hidden states as the query vector.

An important property of a table is that exchanging two rows or two columns does not change its meaning. To satisfy this condition, we develop an attention based approach, in which the header and cells are regarded as the external memory. Each header/cell is represented as a vector. Given a query vector, the model calculates the weight of each memory unit and then output a query-specific header/cell representation through weighted average (Bahdanau et al., 2015; Sukhbaatar et al., 2015). This process could be repeated executed for several times, so that more abstractive evidences could be retrieved and composed to support the final decision. Similar techniques have been successfully applied in table-based question answering (Yin et al., 2015b; Neelakantan et al., 2015).

We represent the table caption with RNN, the same strategy we have adopted to represent the query. Element-wised multiplication is used to compose the query vector and the caption vector. Furthermore, since the number of co-occurred words directly reflect the relatedness between the question and the answer, we incorporate the embedding of co-occurred word count as additional features. Finally, we feed the concatenation of all the vectors to a $softmax$ layer whose output length is 2. We have implemented a ranking based loss function $l_{qa} = max(0, 1 - P_{qa}(a, q) + P_{qa}(a', q))$ and a negative log-likelihood (NLL) base loss function $l_{qa} = -\log(P_{qa}(a, q))$. We find that NLL works better and use it in the following experiments.

4.2 The Question Generation (QG) Model

Inspired by the notable progress that sequence-to-sequence learning (Seq2Seq) (Sutskever et al., 2014) has made in natural language generation, we implement a table-to-sequence (Table2Seq) approach that generates natural language question from a structured table.

Table2Seq is composed of an encoder and a decoder. The encoder maps the caption, headers, and cells into continuous vectors, which will be fed to the decoder to generate a question in a sequential way. Similar with the way we have adopted in the QA model, we represent the caption with bidirectional GRU based RNN. The vector of each word in the caption is the concatenation of hidden states from both directions. The vectors of headers and cells are regarded as additional hidden states of the encoder. The representation of each cell is also mixed with the corresponding header representation. The initial vector of the decoder is the average of the caption vector, header vector, and the cell vector.

The backbone of the decoder is an attention based GRU RNN, which generates a word at each time step and repeats the process until generating the end-of-sentence symbol. We made two modifications to adapt the decoder to the table structure. The first modification is that the attention model is calculated over the headers, cells and the caption of a table. Ideally, the decoder should learn to focus on a region of the table when generating a word. The second modification is a table based copying mechanism. It has been proven that the copying mechanism (Gulcehre et al., 2016; Gu

et al., 2016) is an effective way to replicate low-frequent words from the source to the target sequence in sequence-to-sequence learning. In the decoding process, a word is generated either from the target vocabulary via standard $softmax$ or from a table via the copy mechanism. A neural gate g_t is used to trade-off between generating from the target vocabulary and copying from the table. The probability of generating a word y calculated as follows, where $\alpha_t(y)$ is the attention probability of the word y from the table at time step t and $\beta_t(y)$ is the probability of predicting the word y from the $softmax$ at time step t.

$$p_t(y) = g_t \odot \alpha_t(y) + (1 - g_t) \odot \beta_t(y) \quad (7)$$

Since every component of the Table2Seq is differentiable, the parameters could be optimized in an end-to-end fashion with back-propagation. Given a question-answer pair (x, y), the supervised training objective is to maximize the probability of question word at each time step. In the inference process, beam search is used to generate top-k confident results, where k is the beam size.

4.3 The Collaboration Detector (CD)

The goal of a collaboration detector is to determine the label of the instance generated by the QG model. The positive prediction, namely the predicted value is equals to 1, stands for the collaborative relationship between the generated instance and the ground truth, while the negative prediction stands for the competitive relationship.

We consider this task as predicting the category of the given two question-answer pairs, one of which is the ground truth, and another is the generated question-answer pair. Since the answer part is the same, we simplify the problem as classifying two questions as related or not, which is a binary classification problem.

The neural architecture of the collaboration detector (CD) is exactly the same as the caption component in the QA model. We represent two questions with bidirectional RNN, and use element-wise multiplication to do the composition. The result is further concatenated with a co-occurred word count embedding, followed by a $softmax$ layer. The model is trained by minimizing the negative log-likelihood label, which is provided in the training data.

The training data of the CD model includes two parts. The first part is from Quora dataset[3], which is built for detecting if pairs of question text are semantically equivalent. The Quora dataset has 345,989 positive question pairs and 255,027 negative pairs. We further obtain the second part of the training data from the web queries, which are more similar to the web queries in our two QA task. We obtain the query dataset from query logs through clustering the web queries that click the same web page. In this way, we obtain 6,118,023 positive query pairs. We use a heuristic rule to generate the negative instances for the query dataset. For each pair of query text, we clamp the first query and retrieve a query that is mostly similar to the second query. To improve the efficiency of this process, we randomly sample 10,000 queries and define the "similarity" as the number of co-occurred words in two questions. In this way we collect another 6,118,023 negative pairs of query text. We initialize the values of word embeddings with $300d$ Glove vectors[4], which is learned on Wikipedia texts. We use a held-out data consisting of 20K query pairs to check the performance of the CD model. The accuracy of the CD model on the held-out dataset is 83%. In the joint training process, we clamp the parameters of the CD model and use its outputs to facilitate the learning of the QA model.

5 Experiment

We conduct experiments on table-based QA and document-based QA tasks. We will describe experimental settings and report results on these two tasks in this section.

5.1 Table based QA and QG

Setting We take table retrieval (Balakrishnan et al., 2015) as the table-based QA task. Given a query and a collection of candidate table answers, the task aims to return a table that is most relevant to the query. Figure 2 gives an example of this task, in which a query matches to different aspects of a table. We regard document-based QA tasks as a special case of the table-based QA task, in which the cells and the headers are both empty.

We conduct experiments on the web data. The queries come from real-world user queries which we obtain from the search log of a commercial

[3] https://data.quora.com/First-Quora-Dataset-Release-Question-Pairs

[4] https://nlp.stanford.edu/projects/glove/

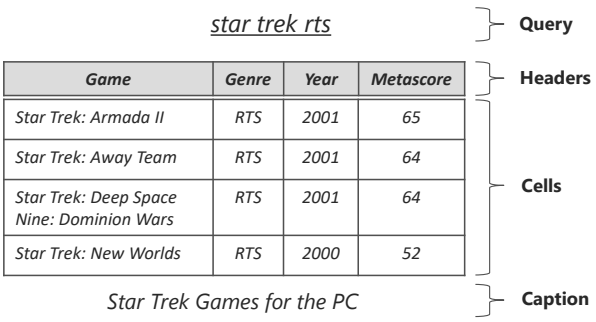

Figure 2: An example illustrating the table-based QA task.

search engine. We filter them down to only those that are directly answered by a table. In this way, we collect 1.49M query-table pairs. An example of the data is given in Figure 2. We randomly select 1.29M as the training set, 0.1M as the dev set and 0.1M as the test set.

We evaluate the performance on table-based QA with *Mean Average Precision (MAP)* and *Precision@1 (P@1)* (Manning et al., 2008). We use the same candidate retrieval adopted in (Yan et al., 2017), namely representing a table as bag-of-words, to guarantee the efficiency of the approach. Each query has 50 candidate tables on average. It is still an open problem to automatically evaluate the performance of a natural language generation system (Lowe et al., 2017). In this work, we use BLEU-4 (Papineni et al., 2002) score as the evaluation metric, which measures the overlap between the generated question and the referenced question. The hyper parameters are tuned on the validation set and the performance is reported on the test set.

Results and Analysis We report the results and our analysis on table-based QA and QG respectively in this part.

We first report the results of single systems on table-based QA. We compare to four single systems implemented by (Yan et al., 2017). In **BM25**, each table is represented as a flattened vector, and the similarity between a query and a table is calculated with the BM25 algorithm. **WordCnt** uses the number of co-occurred words in query-caption pair, query-header pair, and query-cell pair, respectively. **MT based PP** is a phrase-level feature. The features come from a phrase table which is extracted from bilingual corpus via statistical machine translation approach (Koehn et al., 2003). LambdaMART (Burges, 2010) is used to train the ranker. **CNN** uses convolutional neural network to measure the similarity between the query and table caption, table headers, and table cells, respectively. **TQNN** is the table-based QA model implemented in this work, which is regard as the baseline for the joint learning algorithm. Results of single systems are given in Table 1. We can see that BM25 is a simple yet very effective baseline method. Our basic model performs better than all the single models in terms of MAP.

Method	MAP	Acc@1
BM25	0.429	0.294
WordCnt	0.318	0.190
MT based PP	0.327	0.213
CNN	0.359	0.238
TQNN (baseline)	0.439	0.285
Seq2SeqPara	0.437	0.283
GCN (competitive)	0.436	0.282
GCN (collaborative)	0.446	0.292
GCN (final)	**0.456**	**0.301**

Table 1: The performances of single systems on table-based question answering (p-value < 0.01 with t-test between TQNN and GCN).

We also implement four different joint learning settings. In these settings, the QA model and the QG model are all pretrained, and the same way (policy gradient) is used to improve the QG model via the QA predictions. The only difference is how the QA model benefits from the QG model. As we use external resources to train a CD model, we also implement **Seq2SeqPara** for comparison. We train a question generator with a Seq2Seq model on the CD training data, and regard the generated questions as positive instances. Our generative collaborative network is abbreviated as **GCN**. **GCN (competitive)** is analogous to (Goodfellow et al., 2014), where all the generated questions are regarded as negative instances (with label as zero). On the contrary, **GCN (collaborative)** is analogous to (Yang et al., 2017), where the generated questions are regard as positive instances. Our main observation from Table 1 is that simply regarding all the generated questions as negative instances ("competitive") could not bring performance boost. On the contrary, regarding the generated questions as positive ones ("collaborative") improves the QA model. Our algorithm (GCN) significantly improves the TQNN model. Based on these results, we believe that the relationship

between the QA model and the QG model should not be always competitive. Learning when to collaborate through leveraging a CD model is a practical way to improve the performance on question answering.

As described in Equation (1), the influence of the CD model on the QA model also depends on the value of the hyper parameter b_{qa}. A small value of b_{qa} stands for a preference of "collaborative", while a large value of b_{qa} represents a preference of "competitive". Results are given in Figure 3. The GCN model performs better when b_{qa} is in the range $[0.3, 0.5]$, in which the model prefers "collaborative".

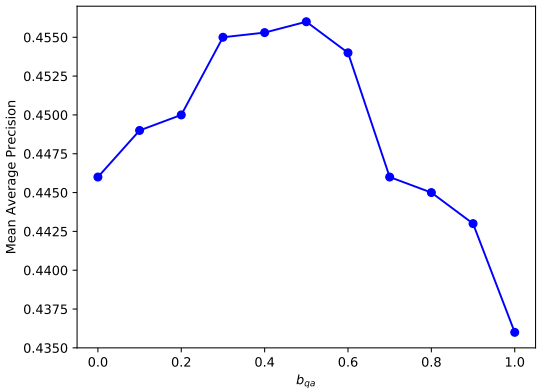

Figure 3: The performances of GCN on table-based QA with different values of b_{qa}. GCN falls back to "competitive" when b_{qa} equals to one. GCN is totally collaborative when b_{qa} equals to zero.

We conduct an additional experiment to test whether our algorithm could improve an existing system. We take BM25 as the baseline, and incorporate one of the five joint models as an additional feature. LambdaMART is used to train the combined ranker. Results are given in Table 2. We can see that the baseline system could be dramatically improved by our system, despite the improvements of different approaches are on par.

Method	MAP	Acc@1
BM25	0.429	0.294
BM25 + TQNN (baseline)	0.650	0.513
BM25 + GAN	0.654	0.519
BM25 + Seq2SeqPara	0.650	0.513
BM25 + GDAN	0.658	0.523
BM25 + GCN (this work)	**0.660**	**0.526**

Table 2: The performances of combined systems on table-based question answering..

We have reported the results on table-based QA. Here we show the performances of different approaches on table-based QG. Results in terms of BLEU-4 are given in Table 3. Different from the trends on QA, "competitive" performs better than "collaborative" on QG. This is reasonable because as the joint training progresses, the QA model in "collaborative" keeps telling the QG model that the generated instances are good enough. On the contrary, the "competitive" model is more critical, which tells the QG model how wrong the generated questions are. In this way, the QG model could be increasingly improved by the QA signal. The QG model is easier to be improved compared to the QA model. Our GCN approach obtains a significant improvement over the baseline model on this task.

Method	Dev	Test
Table2Seq (baseline)	15.71	15.54
Seq2SeqPara	17.01	16.95
GCN (competitive)	17.28	17.34
GCN (collaborative)	16.77	16.66
GCN (final)	**17.59**	**17.61**

Table 3: The performances on table-based question generation. Evaluation metric is BLEU-4 score.

We also report the learning curve of the GCN model as the joint training progresses. The performance on the dev set is given in Figure 4.

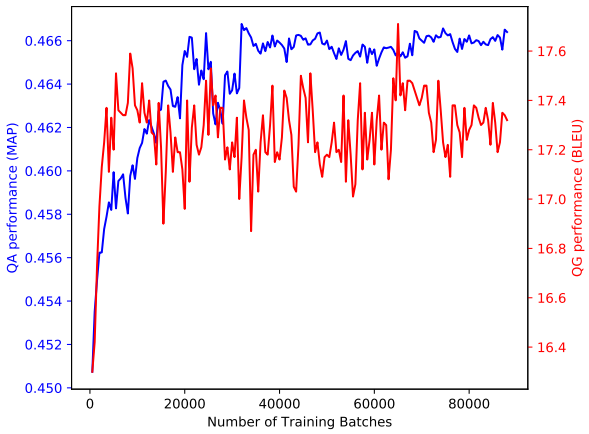

Figure 4: The learning curve of GCN on the dev data. The evaluation metrics are MAP (for QA) and BLEU (for QG).

5.2 Document based QA and QG

To test the scalability of the algorithm, we also apply it to document based QA and QG tasks. The QA task is answer sentence selection (Yang et al.,

Method	MAP	P@1
WordCnt	0.395	0.179
CDSSM (Shen et al., 2014)	0.442	0.228
ABCNN (Yin et al., 2015a)	0.469	0.263
DSL (Tang et al., 2017)	0.484	0.275
DQNN (baseline)	0.471	0.263
Seq2SeqPara	0.470	0.260
GCN (competitive)	0.468	0.257
GCN (collaborative)	0.476	0.272
GCN (final)	**0.492**	**0.282**

Table 4: The performance on document-based QA task (p-value < 0.05 with t-test between DQNN and GCN).

2015). Given a question and a list of candidate answer sentences from a document, the goal is to find a most relevant answer sentence as the answer. Since the WikiQA dataset (Yang et al., 2015) is too small to learn a powerful question generator, we use the MARCO dataset (Nguyen et al., 2016), which is originally designed for reading comprehension yet also has manually annotated labels for sentence/passage selection. A characteristic of MARCO dataset is that the ground truth of the test is invisible to the public. Therefore, we follow (Tang et al., 2017) and split the original validation set into the dev set and the test set. The results on QA and QG are given in Table 4 and Table 5. We can see that the results are almost consistent with the results on table-based QA and QG tasks. Our GCN algorithms achieves promising performances compared to strong baseline methods.

Method	BLEU-4
Seq2Seq (baseline)	8.87
DSL (Tang et al., 2017)	9.31
Seq2SeqPara	9.16
GCN (competitive)	9.22
GCN (collaborative)	9.04
GCN (final)	**9.89**

Table 5: The performance on document-based QG task.

6 Conclusion

We present an algorithm dubbed generative collaborative network for jointly training the question answering (QA) model and the question generation (QG) model. Different from standard GAN, the relationship between QA model (discriminator) and the QG model (generator) in our algorithm is not always competitive. We show that "collaborative" performs better than "competitive" in terms of QA accuracy, and our algorithm that learns when to collaborate obtains further improvement on both QA and QG tasks.

This work could be further improved from several directions. Our current algorithm focuses on the joint training of QA and QG models, while the inferences of these two models are independent. How to conduct joint inference is an interesting future work. Besides, the samples are currently generated from the QG model via beam search. Improving the diversity of the samples requires different sampling mechanisms. Another potential direction is to jointly learn the collaboration detector together with the QA and QG models.

Seoul National University, Seoul, Korea
{mysmilesh,jbshin,kjung}@snu.ac.kr

Abstract

In this paper, we propose a novel end-to-end neural architecture for ranking candidate answers, that adapts a hierarchical recurrent neural network and a latent topic clustering module. With our proposed model, a text is encoded to a vector representation from an word-level to a *chunk-level* to effectively capture the entire meaning. In particular, by adapting the hierarchical structure, our model shows very small performance degradations in longer text comprehension while other state-of-the-art recurrent neural network models suffer from it. Additionally, the latent topic clustering module extracts semantic information from target samples. This clustering module is useful for any text related tasks by allowing each data sample to find its nearest topic cluster, thus helping the neural network model analyze the entire data. We evaluate our models on the Ubuntu Dialogue Corpus and consumer electronic domain question answering dataset, which is related to Samsung products. The proposed model shows state-of-the-art results for ranking question-answer pairs.

1 Introduction

Recently neural network architectures have shown great success in many machine learning fields such as image classification, speech recognition, machine translation, chat-bot, question answering, and other task-oriented areas. Among these, the automatic question answering (QA) task has long been considered a primary objective of artificial intelligence.

In the commercial sphere, the QA task is usually tackled by using pre-organized knowledge bases and/or by using information retrieval (IR) based methods, which are applied in popular intelligent voice agents such as *Siri*, *Alexa*, and *Google Assistant* (from Apple, Amazon, and Google, respectively). Another type of advanced QA systems is IBM's Watson who builds knowledge bases from unstructured data. These raw data are also indexed in search clusters to support user queries (Fan et al., 2012; Chu-Carroll et al., 2012).

In academic literature, researchers have intensely studied sentence pair ranking task which is core technique in QA system. The ranking task selects the best answer among candidates retrieved from knowledge bases or IR based modules. Many neural network architectures with end-to-end learning methods are proposed to address this task (Yin et al., 2016; Wang and Jiang, 2016; Wang et al., 2017). These works focus on matching sentence-level text pair (Wang et al., 2007; Yang et al., 2015; Bowman et al., 2015). Therefore, they have limitations in understanding longer text such as multi-turn dialogue and explanatory document, resulting in performance degradation on ranking as the length of the text become longer.

With the advent of the huge multi-turn dialogue corpus (Lowe et al., 2015), researchers have proposed neural network models to rank longer text pair (Kadlec et al., 2015; Baudiš et al., 2016). These techniques are essential for capturing context information in multi-turn conversation or understanding multiple sentences in explanatory text.

In this paper, we focus on investigating a novel neural network architecture with additional data clustering module to improve the performance in ranking answer candidates which are longer than a single sentence. This work can be used not only for the QA ranking task, but also to evaluate the relevance of next utterance with given dialogue generated from the dialogue model. The key contributions of our work are as follows:

First, we introduce a Hierarchical Recurrent Dual Encoder (HRDE) model to effectively calculate the affinity among question-answer pairs to determine the ranking. By encoding texts from an word-level to a chunk-level with hierarchi-

Proceedings of NAACL-HLT 2018, pages 1575–1584
New Orleans, Louisiana, June 1 - 6, 2018.

cal architecture, the HRDE prevents performance degradations in understanding longer texts while other state-of-the-art neural network models suffer.

Second, we propose a Latent Topic Clustering (LTC) module to extract latent information from the target dataset, and apply these additional information in end-to-end training. This module allows each data sample to find its nearest topic cluster, thus helping the neural network model analyze the entire data. The LTC module can be combined to any neural network as a source of additional information. This is a novel approach using latent topic cluster information for the QA task, especially by applying the combined model of HRDE and LTC to the QA pair ranking task.

Extensive experiments are conducted to investigate efficacy and properties of the proposed model. Our proposed model outperforms previous state-of-the-art methods in the Ubuntu Dialogue Corpus, which is one of the largest text pair scoring datasets. We also evaluate the model on real world QA data crawled from crowd-QA web pages and from Samsung's official web pages. Our model also shows the best results for the QA data when compared to previous neural network based models.

2 Related Work

Researchers have released question and answer datasets for research purposes and have proposed various models to solve these datasets. (Wang et al., 2007; Yang et al., 2015; Tan et al., 2015) introduced small dataset to rank sentences that have higher probabilities of answering questions such as WikiQA and insuranceQA. To alleviate the difficulty in aggregating datasets, that are large and have no license restrictions, some researchers introduced new datasets for sentence similarity rankings (Baudiš et al., 2016; Lowe et al., 2015). As of now, the Ubuntu Dialogue dataset is one of the largest corpus openly available for text ranking.

To tackle the Ubuntu dataset, (Lowe et al., 2015) adopted the "term frequency-inverse document frequency" approach to capture important words among context and next utterances (Ramos et al., 2003). (Bordes et al., 2014; Yu et al., 2014) proposed deep neural network architecture for embedding sentences and measuring similarities to select answer sentence for a given question. (Kadlec et al., 2015) used convolution neural network (CNN) architecture to embed the sentence while a final output vector was compared to the target text to calculate the matching score. They also tried using long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), bidirectional LSTM and ensemble method with all of those neural network architectures and achieved the best results on the Ubuntu Dialogues Corpus dataset. Another type of neural architecture is the RNN-CNN model, which encodes each token with a recurrent neural network (RNN) and then feeds them to the CNN (Baudiš et al., 2016). Researchers also introduced an attention based model to improve the performance (Tan et al., 2015; Wang and Jiang, 2016; Wang et al., 2017).

Recently, the hierarchical recurrent encoder-decoder model was proposed to embed contextual information in user query prediction and dialogue generation tasks (Sordoni et al., 2015; Serban et al., 2016). This shows improvement in the dialogue generation model where the context for the utterance is important. As another type of neural network architecture, memory network was proposed by (Sukhbaatar et al., 2015). Several researchers adopted this architecture for the reading comprehension (RC) style QA tasks, because it can extract contextual information from each sentence and use it in finding the answer (Xiong et al., 2016; Kumar et al., 2016). However, none of this research is applied to the QA pair ranking task directly.

3 Model

In this section, we depict a previously released neural text ranking model, and then introduce our proposed neural network model.

3.1 Recurrent Dual Encoder (RDE)

A subset of sequential data is fed into the recurrent neural network (RNN) which leads to the formation of the network's internal hidden state h_t to model the time series patterns. This internal hidden state is updated at each time step with the input data w_t and the hidden state of the previous time step h_{t-1} as follows:

$$h_t = f_\theta(h_{t-1}, w_t), \tag{1}$$

where f_θ is the RNN function with weight parameter θ, h_t is hidden state at t-th word input, w_t is t-th word in a target question $\boldsymbol{w}^Q = \{w^Q_{1:t_q}\}$ or an answer text $\boldsymbol{w}^A = \{w^A_{1:t_a}\}$.

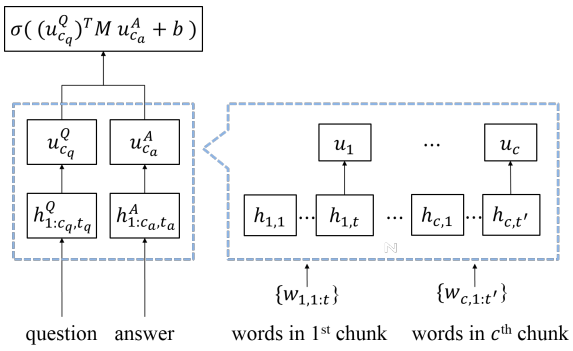

Figure 1: Diagram of the HRDE model. The word-lever RNN encodes words sequences of each chunk. The the final hidden status of the word-level RNN is fed into chunk-level RNN.

The previous RDE model uses two RNNs for encoding question text and answer text to calculate affinity among texts (Lowe et al., 2015). After encoding each part of the data, the affinity among the text pairs is calculated by using the final hidden state value of each question and answer RNNs. The matching probability between question text $\boldsymbol{w}^Q$ and answer text $\boldsymbol{w}^A$ with the training objective are as follows:

$$
\begin{aligned}
p(\text{label}) &= \sigma((h_{t_q}^Q)^T M\ h_{t_a}^A + b), \\
\mathcal{L} &= -\log \prod_{n=1}^{N} p(\text{label}_n | h_{n,t_q}^Q, h_{n,t_a}^A),
\end{aligned}
\tag{2}
$$

where $h_{t_q}^Q$ and $h_{t_a}^A$ are last hidden state of each question and answer RNN with the dimensionality $h_t \in \mathbb{R}^d$. The $M \in \mathbb{R}^{d \times d}$ and bias b are learned model parameters. The N is total number of samples used in training and σ is the sigmoid function.

3.2 Hierarchical Recurrent Dual Encoder (HRDE)

From now we explain our proposed model. The previous RDE model tries to encode the text in question or in answer with RNN architecture. It would be less effective as the length of the word sequences in the text increases because RNN's natural characteristic of forgetting information from long ranging data. To address this RNN's forgetting phenomenon, (Bahdanau et al., 2014) proposed an attention mechanism, however, we found that it still showed a limitation when we consider very large sequential length data such as 162 steps average in the Ubuntu Dialogue Corpus dataset (see Table 1). To overcome this limitation, we designed the HRDE architecture. The HRDE model divides long sequential text data into small chunk such as sentences, and encodes the whole text from word-level to chunk-level by using two hierarchical level of RNN architecture.

Figure 1 shows a diagram of the HRDE model. The word-level RNN part is responsible for encoding the words sequence $\boldsymbol{w}_c = \{w_{c,1:t}\}$ in each chunk. The chunk can be sentences in paragraph, paragraphs in essay, turns in dialogue or any kinds of smaller meaningful sub-set from the text. Then the final hidden states of each chunk will be fed into chunk-level RNN with its original sequence order kept. Therefore the chunk-level RNN can deal with pre-encoded chunk data with less sequential steps. The hidden states of the hierarchical RNNs are as follows:

$$
\begin{aligned}
h_{c,t} &= f_\theta(h_{c,t-1}, w_{c,t}), \\
u_c &= g_\theta(u_{c-1}, h_c),
\end{aligned}
\tag{3}
$$

where f_θ and g_θ are the RNN function in hierarchical architecture with weight parameters θ, $h_{c,t}$ is word-level RNN's hidden status at t-th word in c-th chunk. The $w_{c,t}$ is t-th word in c-th chunk of target question or answer text. The u_c is chunk-level RNN's hidden state at c-th chunk sequence, and h_c is word-level RNN's last hidden state of each chunk $h_c \in \{h_{1:c,t}\}$.

We use the same training objective as the RDE model, and the final matching probability between question and answer text is calculated using chunk-level RNN as follows:

$$
p(\text{label}) = \sigma((u_{c_q}^Q)^T M\ u_{c_a}^A + b), \tag{4}
$$

where $u_{c_q}^Q$ and $u_{c_a}^A$ are chunk-level RNN's last hidden state of each question and answer text with the dimensionality $u_c \in \mathbb{R}^{d^u}$, which involves the $M \in \mathbb{R}^{d^u \times d^u}$.

3.3 Latent Topic Clustering (LTC)

To learn how to rank QA pairs, a neural network should be trained to find the proper feature that represents the information within the data and fits the model parameter that can approximate the true-hypothesis. For this type of problem, we propose the LTC module for grouping the target data to help the neural network find the true-hypothesis with more information from the topic cluster in end-to-end training.

The blue-dotted box on the right-side of Figure 2 shows LTC structure diagram. To assign topic information, we build internal latent topic memory

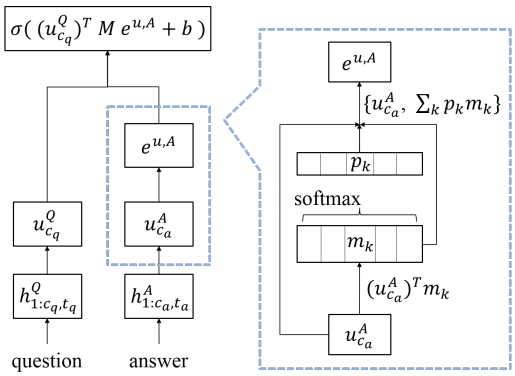

Figure 2: Diagram of the HRDE-LTC. Input vector is compared to each latent topic memory m_k to calculate cluster-info contained vector. This vector will be concatenated to original input vector.

$m \in \mathbb{R}^{d^m \times K}$, which is only model parameter to be learned, where d^m is vector dimension of each latent topic and K is number of latent topic cluster. For a given input sequence $\boldsymbol{x} = \{x_{1:t}\}$with these K vectors, we construct LTC process as follows:

$$
\begin{aligned}
p_k &= \text{softmax}((\boldsymbol{x})^T m_k), \\
\boldsymbol{x}_K &= \sum_{k=1}^{K} p_k m_k, \\
\boldsymbol{e} &= \text{concat}\{\boldsymbol{x}, \boldsymbol{x}_K\}.
\end{aligned}
\tag{5}
$$

First, the similarity between the $\boldsymbol{x}$ and each latent topic vector is calculated by dot-product. Then the resulting K values are normalized by the softmax function $\text{softmax}(z_k) = e^{z_k} / \sum_i e^{z_i}$ to produce a similarity probability p_k. After calculating the latent topic probability p_k, x_K is retrieved from summing over m_k weighted by the p_k. Then we concatenate this result with the original encoding vector to generate the final encoding vector $\boldsymbol{e}$ with the LTC information added.

Note that the input sequence of the LTC could be any type of neural network based encoding function $\boldsymbol{x} = f^{\text{enc}}_\theta(\boldsymbol{w})$ such as RNN, CNN and multilayer perceptron model (MLP). In addition, if the dimension size of $\boldsymbol{x}$ is different from that of memory vector, additional output projection layer should be placed after $\boldsymbol{x}$ before applying dot-product to the memory.

3.4 Combined Model of (H)RDE and LTC

As the LTC module extracts additional topic cluster information from the input data, we can combine this module with any neural network in their end-to-end training flow. In our experiments, we combine the LTC module with the RDE and HRDE models.

3.4.1 RDE with LTC

The RDE model encodes question and answer texts to $h^Q_{t_q}$ and $h^A_{t_a}$, respectively. Hence, the LTC module could take these vectors as the input to generate latent topic cluster information added vector $\boldsymbol{e}$. With this vector, we calculate the affinity among question and answer texts as well as additional cluster information. The following equation shows our RDE-LTC process:

$$
p(\text{label}) = \sigma((h^Q_{t_q})^T M\, e^A + b). \tag{6}
$$

In this case, we applied the LTC module only for the answer side, assuming that the answer text is longer than the question. Thus, it needs to be clustered. To train the network, we use the same training objective, to minimize cross-entropy loss, as in equation (2).

3.4.2 HRDE with LTC

The LTC can be combined with the HRDE model, in the same way it is applied to the RDE-LTC model by modifying equation (6 as follows:

$$
p(\text{label}) = \sigma((u^Q_{c_q})^T M\, e^{u,A} + b), \tag{7}
$$

where $u^Q_{c_q}$ is the final network hidden state vector of the chunk-level RNN for a question input sequence. The $e^{u,A}$ is the LTC information added vector from equation (5), where the LTC module takes the input $\boldsymbol{x} = \boldsymbol{u}^A$ from the HRDE model equation (3). The HRDE-LTC model also use the same training objective, minimizing cross-entropy loss, as in equation (2). Figure 2 shows a diagram of the combined model with the HRDE and the LTC.

4 Experimental Setup and Dataset

4.1 The Ubuntu Dialogue Corpus

The Ubuntu Dialogue Corpus has been developed by expanding and preprocessing the Ubuntu Chat Logs[1], which refer to a collection of logs from the Ubuntu-related chat room for solving problem in using the Ubuntu system by (Lowe et al., 2015).

Among the utterances in the dialogues, they consider each utterance, starting from the third one, as a potential {response} while the previous utterance is considered as a {context}. The data

[1]These logs are available from http://irclogs.ubuntu.com

Dataset	# Samples			Message (Avg.)			Response (Avg.)		
	Train	Val.	Test	# tokens	# groups	# tokens /group	# tokens	# groups	# tokens /group
Ubuntu-v1	1M	35,609	35,517	162.47 ±132.47	8.43 ±6.32	20.14 ±18.41	14.44 ±13.93	1	-
Ubuntu-v2	1M	19,560	18,920	85.92 ±74.71	4.95 ±2.98	20.73 ±20.19	17.01 ±16.41	1	-
Samsung QA	163,616	10,000	10,000	12.84 ±6.42	1	-	173.48 ±192.12	6.09 ±5.58	29.28 ±31.91

Table 1: Properties of the Ubuntu and Samsung QA dataset. The message and response are {context}, {response} in Ubuntu and {question}, {answer} in the Samsung QA dataset.

was processed extracting ({context}, {response}, flag) tuples from the dialogues.

We called this original Ubuntu dataset as Ubuntu-v1 dataset. After releasing the Ubuntu-v1 dataset, researchers published v2 version of this dataset. Main updates are separating train/valid/test dataset by time so that mimics real life implementation, where we are training a model on past data to predict future data, changing sampling procedure to increase average turns in the {context}. We consider this Ubuntu dataset is one of the best dataset in terms of its quality, quantity and availability for evaluating the performance of the text ranking model.

To encode the text with the HRDE and HRDE-LTC model, a text needs to be divided into several chunk sequences with predefined criteria. For the Ubuntu-v1 dataset case, we divide the {context} part by splitting with end-of-sentence delimiter "_eos_", and we do not split the {response} part since it is normally short and does not contain "_eos_" information. For the Ubuntu-v2 dataset case, we split the {context} part in the same way as we do in the Ubuntu-v1 dataset while only using end-of-turn delimiter "_eot_". Table 1 shows properties of the Ubuntu dataset.

Question
how do i set a timer of clock in applications and development for samsung galaxy s4 mini?

Answer
1 from within the clock application, tap timer tab. 2 tap the hours, minutes, or seconds field and use the on-screen keypad to enter the hour, minute, or seconds. the timer plays an alarm at the end of the countdown. 3 tap start to start the timer. 4 tap stop to stop the timer or reset to reset the timer and start over. 5 tap restart to resume the timer counter.

Table 2: Example of the Samsung QA dataset.

4.2 Consumer Product QA Corpus

To test the robustness of the proposed model, we introduce an additional question and answer pair dataset related to an actual user's interaction with the consumer electronic product domain. We crawled data from various sources like the Samsung Electronics' official web site[2] and crowd QA web sites[3][4] in a similar way that (Yoon et al., 2016) did in building QA system for consumer products. On the official web page, we can retrieve data consisting of user questions and matched answers like frequently asked questions and troubleshooting. From the crowd QA sites, there are many answers from various users for each question. Among these answers, we choose answers from company certificated users to keep the reliability of the answers high. If there are no such answers, we skip that question answer pair. Table 2 shows an example of question-answer pair crawled from the web page. In addition, we crawl hierarchical product category information related to QA pairs. In particular, *mobile*, *office*, *photo*, *tv/video*, *accessories*, and *home appliance* as top-level categories, and specific categories like *galaxy s7*, *tablet*, *led tv*, and *others* are used. We collected these meta-information for further use. The total size of the Samsung QA data is over 100,000 pairs and we split the data into approximately 80,000/10,000/10,000 samples to create train/valid/test sets, respectively. To create the train set, we use a QA pair sample as a ground-truth and perform negative sampling for answers among training sets to create *false*-label datasets. In this way, we generated ({question}, {answer}, flag) triples (see Table 1). We do the same procedure to create valid and test sets by only differentiating more negative sampling within each dataset to generate 9 *false*-label samples with one

[2]http://www.samsung.com/us
[3]http://answers.yahoo.com
[4]http://answers.us.samsung.com

ground-truth sample. We apply the same method in such a way that the Ubuntu dataset is generated from the Ubuntu Dialogue Corpus to maintain the consistency. The Samsung QA dataset is available via web repository. We refer the readers to Appendix A for more examples of each dataset.

4.3 Implementation Details

4.3.1 Ubuntu dataset case

To implement the RDE model, we use two single layer Gated Recurrent Unit (GRU) (Chung et al., 2014) with 300 hidden units . Each GRU is used to encode {context} and {response}, respectively. The weight for the two GRU are shared. The hidden units weight matrix of the GRU are initialized using orthogonal weights (Saxe et al., 2013), while input embedding weight matrix is initialized using a pre-trained embedding vector, the Glove (Pennington et al., 2014), with 300 dimension. The vocabulary size is 144,953 and 183,045 for the Ubuntu-v1/v2 case, respectively. We use the Adam optimizer (Kingma and Ba, 2014), with gradients clipped with norm value 1. The maximum time step for calculating gradient of the RNN is determined according to the input data statistics in Table 1.

For the HRDE model, we use two single layer GRU with 300 hidden units for word-level RNN part, and another two single layer GRU with 300 hidden units for chunk-level RNN part. The weight of the GRU is shared within the same hierarchical part, word-level and chunk-level. The other settings are the same with the RDE model case. As for the combined model with the (H)RDE and the LTC, we choose the latent topic memory dimensions as 256 in both ubuntu-v1 and ubuntu-v2. The number of the cluster in LTC module is decided to 3 for both the RDE-LTC and the HRDE-LTC cases. In HRDE-LTC case, we applied LTC module to the {context} part because we think it is longer having enough information to be clustered with. All of these hyper-parameters are selected from additional parameter searching experiments.

The dropout (Srivastava et al., 2014) is applied for the purpose of regularization with the ratio of: 0.2 for the RNN in the RDE and the RDE-LTC, 0.3 for the word-level RNN part in the HRDE and the HRDE-LTC, 0.8 for the latent topic memory in the RDE-LTC and the HRDE-LTC.

We need to mention that our implementation of the RDE module has the same architecture as the LSTM model (Kadlec et al., 2015) in ubuntu-v1/v2 experiments case. It is also the same architecture with the RNN model (Baudiš et al., 2016) in ubuntu-v2 experiment case. We implement the same model ourselves, because we need a baseline model to compare with other proposed models such as the RDE-LTC, HRDE and HRDE-LTC.

4.3.2 Samsung QA dataset case

To test the Samsung QA dataset, we use the same implementation of the model (RDE, RDE-LTC, HRDE and HRDE-LTC) used in testing the Ubuntu dataset. Only the differences are, we use 100 hidden units for the RDE and the RDE-LTC, 300 hidden units for the HRDE and 200 hidden units for the HRDE-LTC, and the vocabulary size of 28,848. As for the combined model with the (H)RDE and LTC, the dimensions of the latent topic memory is 64 and the number of latent cluster is 4. We chose best performing hyper-parameter of each model by additional extensive hyper-parameter search experiments.

All of the code developed for the empirical results are available via web repository [5].

5 Empirical Results

5.1 Evaluation Metrics

We regards all the tasks as selecting the best answer among text candidates for the given question. Following the previous work (Lowe et al., 2015), we report model performance as recall at k (R@k) relevant texts among given 2 or 10 candidates (e.g., 1 in 2 R@1). Though this metric is useful for ranking task, R@1 metric is also meaningful for classifying the best relevant text.

Each model we implement is trained multiple times (10 and 15 times for Ubuntu and the Samsung QA datasets in our experiments, respectively) with random weight initialization, which largely influences performance of neural network model. Hence we report model performance as mean and standard derivation values (Mean±Std).

5.2 Performance Evaluation

5.2.1 Comparison with other methods

As Table 3 shows, our proposed HRDE and HRDE-LTC models achieve the best performance for the Ubuntu-v1 dataset. We also find that the RDE-LTC model shows improvements from the baseline model, RDE.

[5] http://github.com/david-yoon/QA_HRDE_LTC

Model	Ubuntu-v1			
	1 in 2 R@1	1 in 10 R@1	1 in 10 R@2	1 in 10 R@5

RDE-LTC	0.899 ±0.002	0.625 ±0.004	0.788 ±0.004	0.951 ±0.001
HRDE	0.914 ±0.001	0.649 ±0.001	0.813 ±0.001	0.964 ±0.001
HRDE-LTC	**0.915** ±0.002	0.652 ±0.003	**0.815** ±0.001	**0.966** ±0.001

Table 4: Model performance results for the Ubuntu-v2 dataset. Models [1,3-6] are from (Lowe et al., 2015; Wang and Jiang, 2016; Wang et al., 2017; Baudiš et al., 2016; Tan et al., 2015), respectively.

For the ubuntu-v2 dataset case, Table 4 reveals that the HRDE-LTC model is best for three cases (1 in 2 R@1, 1 in 10 R@2 and 1 in 10 R@5). Comparing the same model with our implementation (RDE) and (Baudiš et al., 2016)'s implementation (RNN), there is a large gap in the accuracy (0.610 and 0.664 of 1 in 10 R@1 for RDE and RNN, receptively). We think this is largely influenced by the data preprocessing method, because the only differences between these models is the data preprocessing, which is (Baudiš et al., 2016)'s contribution to the research. We are certain that our model performs better with the exquisite datasets which adapts extensive preprocessing method, because we see improvements from the RDE model to the HRDE model and additional improvements with the LTC module in all test cases (the Ubuntu-v1/v2 and the Samsung QA).

Model	Samsung QA			
	1 in 2 R@1	1 in 10 R@1	1 in 10 R@2	1 in 10 R@5
TF-IDF	0.939	0.834	0.897	0.953
RDE	0.978 ±0.002	0.869 ±0.009	0.966 ±0.003	0.997 ±0.001
RDE-LTC	0.981 ±0.002	0.880 ±0.009	0.970 ±0.003	0.997 ±0.001
HRDE	0.981 ±0.002	0.885 ±0.011	0.971 ±0.004	0.997 ±0.001
HRDE-LTC	**0.983** ±0.002	**0.890** ±0.010	**0.972** ±0.003	**0.998** ±0.001

Table 5: Model performance results for the Samsung QA dataset.

# clusters	Accuracy (1 in 10 R@1)		
	Ubuntu-v1	Ubuntu-v2	Samsung QA
1	0.643 ±0.009	0.610 ±0.008	0.869 ±0.009
2	0.655 ±0.005	0.616 ±0.006	0.876 ±0.011
3	**0.656** ±0.003	**0.625** ±0.004	0.877 ±0.010
4	0.651 ±0.005	0.622 ±0.005	**0.880** ±0.009

Table 6: The RDE-LTC model results with different numbers of latent clusters. "Cluster 1" is the baseline model, RDE.

In the Samsung QA case, Table 5 indicates that the proposed RDE-LTC, HRDE, and the HRDE-LTC model show performance improvements when compared to the baseline model, TF-IDF and RDE. The average accuracy statistics are higher in the Samsung QA case when compared to the Ubuntu case. We think this is due to in the smaller vocabulary size and context variety. The Samsung QA dataset deals with narrower topics than in the Ubuntu dataset case. We are certain that our proposed model shows robustness in several datasets and different vocabulary size environments.

5.2.2 Degradation Comparison for Longer Texts

To verify the HRDE model's ability compared to the baseline model RDE, we split the testset of the Ubuntu-v1/v2 datasets based on the "number of chunks" in the {context}. Then, we measured the top-1 recall (same case as 1 in 10 R@1 in Table 3, and 4) for each group. Figure 3 demonstrates that the HRDE models, in darker blue and red colors, shows better performance than the RDE models, in lighter colors, for every "number of chunks" evaluations. In particular, the HRDE models are consistent when the "number-of-chunks" increased, while the RDE models degrade as the "number-of-chunks" increased.

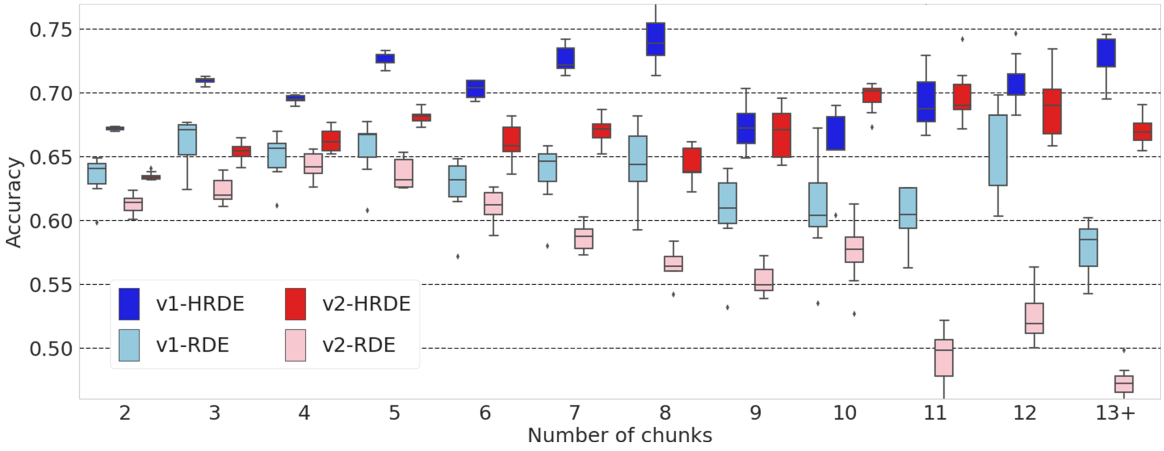

Figure 3: The HRDE and RDE model performance comparisons for the number-of-chunk in the Ubuntu dataset. Each boxplot shows average accuracy with standard deviation. The HRDE models, in darker blue and red colors, show consistent performances as the number-of-chunks increased. Meanwhile, the RDE models in lighter colors show performance degradation as the number-of-chunks increased. Furthermore, 13+ indicates all data over 13-chunks.

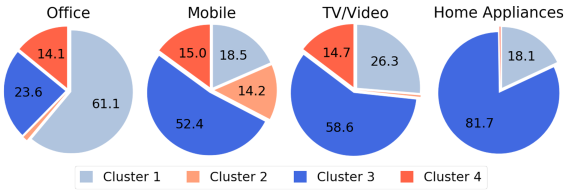

Figure 4: Examples of the cluster proportions for four real *categories* from $20k$ evaluated samples. Each color corresponds to each cluster.

Cluster	Example
1	How to adjust the brightness on the s**d300 series monitors
2	How do I reject an incoming call on my Samsung Galaxy Note 3?
3	How should I clean and maintain the microwave?
4	How do I connnect my surround sound to this TV and what type of cables do I need

Table 7: Example sentences for each cluster.

5.2.3 Effects of the LTC Numbers

We analyze the RDE-LTC model for different numbers of latent clusters. Table 6 indicates that the model performances increase as the number of latent clusters increase (until 3 for the Ubuntu and 4 for the Samsung QA case). This is probably a major reason for the different number of subjects in each dataset. The Samsung QA dataset has an internal *category* related to the type of consumer electronic products (6 top-level *categories*; *mobile*, *office*, *photo*, *tv/video*, *accessories*, and *home appliance*), so that the LTC module makes clusters these *categories*. The Ubuntu dataset, however, has diverse contents related to issues in using the Ubuntu system. Thus, the LTC module has fewer clusters with the sparse topic compared to the Samsung QA dataset.

5.2.4 Comprehensive Analysis of LTC

We conduct quantitative and qualitative analysis on the HRDE-LTC model for four latent topic clusters. The Samsung QA dataset has *category* information; hence, latent topic clustering results can be compared with real *categories*. We randomly choose $20k$ samples containing real *category* information and evaluate each sample with the HRDE-LTC model. The cluster with the highest similarity among the latent topic clusters is considered a representative cluster of each sample.

Figure 4 shows proportion of four latent clusters among these samples according to real *category* information. Even though the HRDE-LTC model is trained without any ground-truth *category* labels, we observed that the latent cluster is formed accordingly. For instance, cluster 2 is shown mostly in "Mobile" *category* samples while "clusters 2 and 4" are rarely shown in "Home Appliance" *category* samples.

Additionally, we explore sentences with higher similarity score from the HRDE-LTC module for each four cluster. As can be seen in Table 7, "cluster 1" contains "screen" related sentences (e.g., brightness, pixel, display type) while "cluster 2" contains sentences with exclusive information re-

lated to the "Mobile" *category* (e.g., call rejection, voice level). This qualitative analysis explains why "cluster 2" is shown mostly in the "Mobile" *category* in Figure 4. We also discover that "cluster 3" has the largest portion of samples. As "cluster 3" contains "security" and "maintenance" related sentences (e.g., password, security, log-on, maintain), we assume that this is one of the frequently asked issues across all *categories* in the Samsung QA dataset. Table 7 shows example sentences with high scores from each cluster.

6 Conclusion

In this paper, we proposed the HRDE model and LTC module. HRDE showed higher performances in ranking answer candidates and less performance degradations when dealing with longer texts compared to conventional models. The LTC module provided additional performance improvements when combined with both RDE and HRDE models, as it added latent topic cluster information according to dataset properties. With this proposed model, we achieved state-of-the-art performances in Ubuntu datasets. We also evaluated our model in real world question answering dataset, Samsung QA. This demonstrated the robustness of the proposed model with the best results.

Abstract

Although transfer learning has been shown to be successful for tasks like object and speech recognition, its applicability to question answering (QA) has yet to be well-studied. In this paper, we conduct extensive experiments to investigate the transferability of knowledge learned from a source QA dataset to a target dataset using two QA models. The performance of both models on a TOEFL listening comprehension test (Tseng et al., 2016) and MCTest (Richardson et al., 2013) is significantly improved via a simple transfer learning technique from MovieQA (Tapaswi et al., 2016). In particular, one of the models achieves the state-of-the-art on all target datasets; for the TOEFL listening comprehension test, it outperforms the previous best model by 7%. Finally, we show that transfer learning is helpful even in unsupervised scenarios when correct answers for target QA dataset examples are not available.

1 Introduction

1.1 Question Answering

One of the most important characteristics of an intelligent system is to understand stories like humans do. A story is a sequence of sentences, and can be in the form of plain text (Trischler et al., 2017; Rajpurkar et al., 2016; Weston et al., 2016; Yang et al., 2015) or spoken content (Tseng et al., 2016), where the latter usually requires the spoken content to be first transcribed into text by automatic speech recognition (ASR), and the model will subsequently process the ASR output. To evaluate the extent of the model's understanding of the story, it is asked to answer questions about the story. Such a task is referred to as question answering (QA), and has been a long-standing yet challenging problem in natural language processing (NLP).

Several QA scenarios and datasets have been introduced over the past few years. These scenarios differ from each other in various ways, including the length of the story, the format of the answer, and the size of the training set. In this work, we focus on context-aware multi-choice QA, where the answer to each question can be obtained by referring to its accompanying story, and each question comes with a set of answer choices with only one correct answer. The answer choices are in the form of open, natural language sentences. To correctly answer the question, the model is required to understand and reason about the relationship between the sentences in the story.

1.2 Transfer Learning

Transfer learning (Pan and Yang, 2010) is a vital machine learning technique that aims to use the knowledge learned from one task and apply it to a different, but related, task in order to either reduce the necessary fine-tuning data size or improve performance. Transfer learning, also known as domain adaptation[1], has achieved success in numerous domains such as computer vision (Sharif Razavian et al., 2014), ASR (Doulaty et al., 2015; Huang et al., 2013), and NLP (Zhang et al., 2017; Mou et al., 2016). In computer vision, deep neural networks trained on a large-scale image classification dataset such as ImageNet (Russakovsky et al., 2015) have proven to be excellent feature extractors for a broad range of visual tasks such as image captioning (Lu et al., 2017; Karpathy and Fei-Fei, 2015; Fang et al., 2015) and visual

[1]In this paper, we do not distinguish conceptually between transfer learning and domain adaptation. A 'domain' in the sense we use throughout this paper is defined by datasets.

Proceedings of NAACL-HLT 2018, pages 1585–1594
New Orleans, Louisiana, June 1 - 6, 2018.

question answering (Xu and Saenko, 2016; Fukui et al., 2016; Yang et al., 2016; Antol et al., 2015), among others. In NLP, transfer learning has also been successfully applied to tasks like sequence tagging (Yang et al., 2017), syntactic parsing (McClosky et al., 2010) and named entity recognition (Chiticariu et al., 2010), among others.

1.3 Transfer Learning for QA

Although transfer learning has been successfully applied to various applications, its applicability to QA has yet to be well-studied. In this paper, we tackle the TOEFL listening comprehension test (Tseng et al., 2016) and MCTest (Richardson et al., 2013) with transfer learning from MovieQA (Tapaswi et al., 2016) using two existing QA models. Both models are pre-trained on MovieQA and then fine-tuned on each target dataset, so that their performance on the two target datasets are significantly improved. In particular, one of the models achieves the state-of-the-art on all target datasets; for the TOEFL listening comprehension test, it outperforms the previous best model by 7%.

Transfer learning without any labeled data from the target domain is referred to as unsupervised transfer learning. Motivated by the success of unsupervised transfer learning for speaker adaptation (Chen et al., 2011; Wallace et al., 2009) and spoken document summarization (Lee et al., 2013), we further investigate whether unsupervised transfer learning is feasible for QA.

Although not well studied in general, transfer Learning for QA has been explored recently. To the best of our knowledge, Kadlec et al. (2016) is the first work that attempted to apply transfer learning for machine comprehension. The authors showed only limited transfer between two QA tasks, but the transferred system was still significantly better than a random baseline. Wiese et al. (2017) tackled a more specific task of biomedical QA with transfer learning from a large-scale dataset. The work most similar to ours is by Min et al. (2017), where the authors used a simple transfer learning technique and achieved significantly better performance. However, none of these works study unsupervised transfer learning, which is especially crucial when the target dataset is small. Golub et al. (2017) proposed a two-stage synthesis network that can generate synthetic questions and answers to augment insufficient training data without annotations. In this work, we aim to handle the case that the questions from the target domain are available.

2 Task Descriptions and Approaches

Among several existing QA settings, in this work we focus on multi-choice QA (MCQA). We are particularly interested in understanding whether a QA model can perform better on one MCQA dataset with knowledge transferred from another MCQA dataset. In Section 2.1, we first formalize the task of MCQA. We then describe the procedures for transfer learning from one dataset to another in Section 2.2. We consider two kinds of settings for transfer learning in this paper, one is supervised and the other is unsupervised.

2.1 Multi-Choices QA

In MCQA, the inputs to the model are a story, a question, and several answer choices. The story, denoted by $\mathbf{S}$, is a list of sentences, where each of the sentences is a sequence of words from a vocabulary set V. The question and each of the answer choices, denoted by $\mathbf{Q}$ and $\mathbf{C}$, are both single sentences also composed of words from V. The QA model aims to choose one correct answer from multiple answer choices based on the information provided in $\mathbf{S}$ and $\mathbf{Q}$.

2.2 Transfer Learning

The procedure of transfer learning in this work is straightforward and includes two steps. The first step is to pre-train the model on one MCQA dataset referred to as the **source** task, which usually contains abundant training data. The second step is to fine-tune the same model on the other MCQA dataset, which is referred to as the **target** task, that we actually care about, but that usually contains much less training data. The effectiveness of transfer learning is evaluated by the model's performance on the target task.

Supervised Transfer Learning

In supervised transfer learning, both the source and target datasets provide the correct answer to each question during pre-training and fine-tuning, and the QA model is guided by the correct answer to optimize its objective function in a supervised manner in both stages.

Unsupervised Transfer Learning

We also consider unsupervised transfer learning where the correct answer to each question in the target dataset is not available. In other words, the entire process is supervised during pre-training, but unsupervised during fine-tuning. A self-labeling technique inspired by Lee et al. (2013); Chen et al. (2011); Wallace et al. (2009) is used during fine-tuning on the target dataset. We present the proposed algorithm for unsupervised transfer learning in Algorithm 1.

Algorithm 1 Unsupervised QA Transfer Learning

Input: Source dataset with correct answer to each question; Target dataset without any answer; Number of training epochs.

Output: Optimal QA model M^*

1: Pre-train QA model M on the source dataset.
2: **repeat**
3: For each question in the target dataset, use M to predict its answer.
4: For each question, assign the predicted answer to the question as the correct one.
5: Fine-tune M on the target dataset as usual.
6: **until** Reach the number of training epochs.

3 Datasets

We used MovieQA (Tapaswi et al., 2016) as the source MCQA dataset, and TOEFL listening comprehension test (Tseng et al., 2016) and MCTest (Richardson et al., 2013) as two separate target datasets. Examples of the three datasets are shown in Table 1.

MovieQA is a dataset that aims to evaluate automatic story comprehension from both video and text. The dataset provides multiple sources of information such as plot synopses, scripts, subtitles, and video clips that can be used to infer answers. We only used the plot synopses of the dataset, so our setting is the same as pure textual MCQA. The dataset contains 9,848/1,958 train/dev examples; each question comes with a set of five possible answer choices with only one correct answer.

TOEFL listening comprehension test is a recently published, very challenging MCQA dataset that contains 717/124/122 train/dev/test examples. It aims to test knowledge and skills of academic English for global English learners whose native languages are not English. There are only four answer choices for each question. The stories in this dataset are in audio form. Each story comes with two transcripts: manual and ASR transcriptions, where the latter is obtained by running the CMU Sphinx recognizer (Walker et al., 2004) on the original audio files. We use TOEFL-manual and TOEFL-ASR to denote the two versions, respectively. We highlight that the questions in this dataset are not easy because most of the answers cannot be found by simply matching the question and the choices without understanding the story. For example, there are questions regarding the gist of the story or the conclusion for the conversation.

MCTest is a collection of 660 elementary-level children's stories. Each question comes with a set of four answer choices. There are two variants in this dataset: MC160 and MC500. The former contains 280/120/240 train/dev/test examples, while the latter contains 1,200/200/600 train/dev/test examples and is considered more difficult.

The two chosen target datasets are challenging because the stories and questions are complicated, and only small training sets are available. Therefore, it is difficult to train statistical models on only their training sets because the small size limits the number of parameters in the models, and prevents learning any complex language concepts simultaneously with the capacity to answer questions. We demonstrate that we can effectively overcome these difficulties via transfer learning in Section 5.

4 QA Neural Network Models

Among numerous models proposed for multiple-choice QA (Trischler et al., 2016; Fang et al., 2016; Tseng et al., 2016), we adopt the End-to-End Memory Network (MemN2N)[2] (Sukhbaatar et al., 2015) and Query-Based Attention CNN (QACNN)[3] (Liu et al., 2017), both open-sourced, to conduct the experiments. Below we briefly introduce the two models in Section 4.1 and Section 4.2, respectively. For the details of the models, please refer to the original papers.

4.1 End-to-End Memory Networks

An End-to-End Memory Network (MemN2N) first transforms **Q** into a vector representation with

[2]MemN2N was originally designed to output a single word within a fixed vocabulary set. To apply it to MCQA, some modification is needed. We describe the modifications in Section 4.1.

[3]https://github.com/chun5212021202/ACM-Net

	Source Dataset	Target Dataset	
	MovieQA	TOEFL	MCTest
$\mathbf{S}$	After entering the boathouse, the trio witness Voldemort telling Snape that the elder Wand cannot serve Voldemort until Snape dies ... Before dying, Snape tells Harry to take his memories to the Pensieve ...	I just wanted to take a few minutes to meet with everyone to make sure your class presentations for next week are all in order and coming along well. And as you know, you're supposed to report on some areas of recent research on genetics ...	James the Turtle was always getting in trouble. Sometimes he'd reach into the freezer and empty out all the food ... Then he walked to the fast food restaurant and ordered 15 bags of fries. He didn't pay, and instead headed home ...
$\mathbf{Q}$	What does Snape tell Harry before he dies?	Why does the professor meet with the student?	What did James do after he ordered the fries?
$\mathbf{C}_1$	To bury him in the forest	To find out if the student is interested in taking part in a genetics project	went to the grocery store
$\mathbf{C}_2$	That he always respected him	To discuss the student's experiment on the taste perception	**went home without paying**
$\mathbf{C}_3$	To remember to him for the good deeds	**To determine if the student has selected an appropriate topic for his class project**	ate them
$\mathbf{C}_4$	**To take his memories to the Pensieve**	To explain what the student should focus on for his class presentation	made up his mind to be a better turtle
$\mathbf{C}_5$	To write down his memories in a book		

Table 1: Example of the story-question-choices triplet from MovieQA, TOEFL listening comprehension test, and MCTest datasets. $\mathbf{S}, \mathbf{Q}$, and $\mathbf{C}_i$ denote the story, question, and one of the answer choices, respectively. For MovieQA, each question comes with five answer choices; and for TOEFL and MCTest, each question comes with only four answer choices. The correct answer is marked in bold.

an embedding layer B. At the same time, all sentences in $\mathbf{S}$ are also transformed into two different sentence representations with two additional embedding layers A and C. The first sentence representation is used in conjunction with the question representation to produce an attention-like mechanism that outputs the similarity between each sentence in $\mathbf{S}$ and $\mathbf{Q}$. The similarity is then used to weight the second sentence representation. We then obtain the sum of the question representation and the weighted sentence representations over $\mathbf{S}$ as $\mathbf{Q}'$. In the original MemN2N, $\mathbf{Q}'$ is decoded to provide the estimation of the probability of being an answer for each word within a fixed set. The word with the highest probability is then selected as the answer. However, in multiple-choice QA, $\mathbf{C}$ is in the form of open, natural language sentences instead of a single word. Hence we modify MemN2N by adding an embedding layer F to encode $\mathbf{C}$ as a vector representation $\mathbf{C}'$ by averaging the embeddings of words in $\mathbf{C}$. We then compute the similarity between each choice representation $\mathbf{C}'$ and $\mathbf{Q}'$. The choice $\mathbf{C}$ with the highest probability is then selected as the answer.

4.2 Query-Based Attention CNN

A Query-Based Attention CNN (QACNN) first uses an embedding layer E to transform $\mathbf{S}, \mathbf{Q}$, and $\mathbf{C}$ into a word embedding. Then a compare layer generates a story-question similarity map $\mathbf{SQ}$ and a story-choice similarity map $\mathbf{SC}$. The two similarity maps are then passed into a two-stage CNN architecture, where a question-based attention mechanism on the basis of $\mathbf{SQ}$ is applied to each of the two stages. The first stage CNN generates a word-level attention map for each sentence in $\mathbf{S}$, which is then fed into the second stage CNN to generate a sentence-level attention map, and yield choice-answer features for each of the choices. Finally, a classifier that consists of two fully-connected layers collects the information from every choice answer feature and outputs the most likely answer. The trainable parameters are the embedding layer E that transforms $\mathbf{S}, \mathbf{Q}$, and $\mathbf{C}$ into word embeddings, the two-stage CNN $W_{CNN}^{(1)}$ and $W_{CNN}^{(2)}$ that integrate information from the word to the sentence level, and from the sentence to the story level, and the two fully-connected layers $W_{FC}^{(1)}$ and $W_{FC}^{(2)}$ that make the final prediction. We mention the trainable parameters here because in Section 5 we will conduct experiments to analyze the transferability of the QACNN by fine-tuning some parameters while keeping others fixed. Since QACNN is a newly proposed QA model has a relatively complex structure, we illustrate its architecture in Figure 1, which is enough for understanding the rest of the paper. Please refer to the original paper (Liu et al., 2017) for more details.

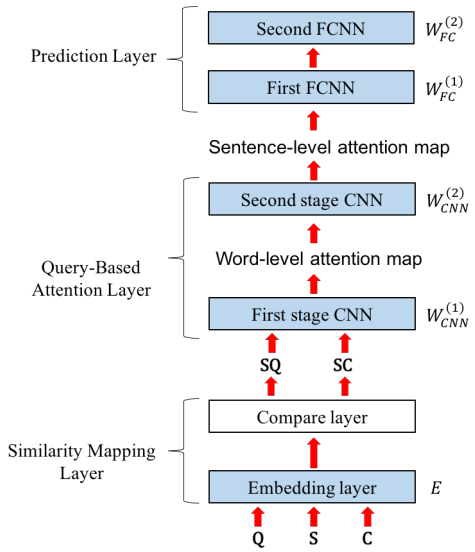

Figure 1: QACNN architecture overview. QACNN consists of a similarity mapping layer, a query-based attention layer, and a prediction layer. The two-stage attention mechanism takes place in the query-based attention layer, yielding word-level and sentence-level attention map, respectively. The trainable parameters, including $E, W_{CNN}^{(1)}, W_{CNN}^{(2)}, W_{FC}^{(1)}$, and $W_{FC}^{(2)}$, are colored in light blue.

5 Question Answering Experiments

5.1 Training Details

For pre-training MemN2N and QACNN on MovieQA, we followed the exact same procedure as in Tapaswi et al. (2016) and Liu et al. (2017), respectively. Each model was trained on the training set of the MovieQA task and tuned on the dev set, and the best performing models on the dev set were later fine-tuned on the target dataset. During fine-tuning, the model was also trained on the training set of target datasets and tuned on the dev set, and the performance on the testing set of the target datasets was reported as the final result. We use accuracy as the performance measurement.

5.2 Supervised Transfer Learning

Experimental Results

Table 2 reports the results of our transfer learning on TOEFL-manual, TOEFL-ASR, MC160, and MC500, as well as the performance of the previous best models and several ablations that did not use pre-training or fine-tuning. From Table 2, we have the following observations.

Model	Training	TOEFL		MCTest	
		manual	ASR	MC160	MC500
QACNN	(a) Target Only	48.9	47.5	57.5	56.4
	(b) Source Only	51.2	49.2	68.1	61.5
	(c) Source + Target	52.5	49.7	72.1	64.6
	(d) Fine-tuned (1)	53.4 (4.5)	51.5 (4.0)	**76.4** (18.9)	68.7 (12.3)
	(e) Fine-tuned (2)	**56.1** (7.2)	**55.3** (7.8)	73.8 (16.3)	**72.3** (15.9)
	(f) Fine-tuned (all)	56.0 (7.1)	55.1 (7.6)	69.3 (11.8)	67.7 (11.3)
MemN2N	(g) Target Only	45.2	44.4	57.2	53.6
	(h) Source Only	43.7	41.9	56.8	52.3
	(i) Source + Target	46.8	45.7	60.4	56.9
	(j) Fine-tuned	48.6 (3.4)	46.6 (2.2)	66.7 (9.5)	62.8 (9.2)
Fang et al. (2016)		49.1	48.8	-	-
Trischler et al. (2016)		-	-	74.6	71.0
Wang et al. (2015)		-	-	75.3	69.9

Table 2: Results of transfer learning on the target datasets. The number in the parenthesis indicates the accuracy increased via transfer learning (compared to rows (a) and (g)). The best performance for each target dataset is marked in bold. We also include the results of the previous best performing models on the target datasets in the last three rows.

Transfer learning helps. Rows (a) and (g) show the respective results when the QACNN and MemN2N are trained directly on the target datasets without pre-training on MovieQA. Rows (b) and (h) show results when the models are trained only on the MovieQA data. Rows (c) and (i) show results when the models are trained on both MovieQA and each of the four target datasets, and tested on the respective target dataset. We observe that the results achieved in (a), (b), (c), (g), (h), and (i) are worse than their fine-tuned counterparts (d), (e), (f), and (j). Through transfer learning, both QACNN and MemN2N perform better on all the target datasets. For example, QACNN only achieves 57.5% accuracy on MC160 without pre-training on MovieQA, but the accuracy increases by 18.9% with pre-training (rows (d) vs. (a)). In addition, with transfer learning, QACNN outperforms the previous best models on TOEFL-manual by 7%, TOEFL-ASR (Fang et al., 2016) by 6.5%, MC160 (Wang et al., 2015) by 1.1%, and MC500 (Trischler et al., 2016) by 1.3%, and becomes the state-of-the-art on all target datasets.

Which QACNN parameters to transfer? For the QACNN, the training parameters are $E, W_{CNN}^{(1)}, W_{CNN}^{(2)}, W_{FC}^{(1)}$, and $W_{FC}^{(2)}$ (Section 4.2). To better understand how transfer learning affects the performance of QACNN, we

also report the results of keeping some parameters fixed and only fine-tuning other parameters. We choose to fine-tune either only the last fully-connected layer $W_{FC}^{(2)}$ while keeping other parameters fixed (row (d) in Table 2), the last two fully-connected layers $W_{FC}^{(1)}$ and $W_{FC}^{(2)}$ (row (e)), and the entire QACNN (row (f)). For TOEFL-manual, TOEFL-ASR, and MC500, QACNN performs the best when only the last two fully-connected layers were fine-tuned; for MC160, it performs the best when only the last fully-connected layer was fine-tuned. Note that for training the QACNN, we followed the same procedure as in Liu et al. (2017), whereby pre-trained GloVe word vectors (Pennington et al., 2014) were used to initialize the embedding layer, which were not updated during training. Thus, the embedding layer does not depend on the training set, and the effective vocabularies are the same.

Fine-tuning the entire model is not always best. It is interesting to see that fine-tuning the entire QACNN doesn't necessarily produce the best result. For MC500, the accuracy of QACNN drops by 4.6% compared to just fine-tuning the last two fully-connected layers (rows (f) vs. (e)). We conjecture that this is due to the amount of training data of the target datasets - when the training set of the target dataset is too small, fine-tuning all the parameters of a complex model like QACNN may result in overfitting. This discovery aligns with other domains where transfer learning is well-studied such as object recognition (Yosinski et al., 2014).

A large quantity of mismatched training examples is better than a small training set. We expected to see that a MemN2N, when trained directly on the target dataset without pre-training on MovieQA, would outperform a MemN2N pre-trained on MovieQA without fine-tuning on the target dataset (rows (g) vs. (h)), since the model is evaluated on the target dataset. However, for the QACNN this is surprisingly not the case - QACNN pre-trained on MovieQA without fine-tuning on the target dataset outperforms QACNN trained directly on the target dataset without pre-training on MovieQA (rows (b) vs. (a)). We attribute this to the limited size of the target dataset and the complex structure of the QACNN.

Percentage of the target dataset used for fine-tuning	TOEFL		MCTest	
	manual	ASR	MC160	MC500
0	51.2	49.2	68.1	61.5
25%	53.9 (2.7)	52.3 (3.1)	70.3 (2.2)	65.6 (4.1)
50%	54.8 (0.9)	54.4 (2.1)	71.9 (1.6)	68.0 (2.4)
75%	55.3 (0.5)	54.8 (0.4)	72.5 (0.6)	71.1 (3.1)
100%	56.0 (0.7)	55.1 (0.3)	73.8 (1.3)	72.3 (1.2)

Table 3: Results of varying sizes of the target datasets used for fine-tuning QACNN. The number in the parenthesis indicates the accuracy increases from using the previous percentage for fine-tuning to the current percentage.

Varying the fine-tuning data size

We conducted experiments to study the relationship between the amount of training data from the target dataset for fine-tuning the model and the performance. We first pre-train the models on MovieQA, then vary the training data size of the target dataset used to fine-tune them. Note that for QACNN, we only fine-tune the last two fully-connected layers instead of the entire model, since doing so usually produces the best performance according to Table 2. The results are shown in Table 3[4]. As expected, the more training data is used for fine-tuning, the better the model's performance is. We also observe that the extent of improvement from using 0% to 25% of target training data is consistently larger than using from 25% to 50%, 50% to 75%, and 75% to 100%. Using the QACNN fine-tuned on TOEFL-manual as an example, the accuracy of the QACNN improves by 2.7% when varying the training size from 0% to 25%, but only improves by 0.9%, 0.5%, and 0.7% when varying the training size from 25% to 50%, 50% to 75%, and 75% to 100%, respectively.

Varying the pre-training data size

We also vary the size of MovieQA for pre-training to study how large the source dataset should be to make transfer learning feasible. The results are shown in Table 4. We find that even a small amount of source data can help. For example, by using only 25% of MovieQA for pre-training, the accuracy increases 6.3% on MC160. This is because 25% of MovieQA training set (2,462 examples) is still much larger than the MC160 training set (280 examples). As the size of the source dataset increases, the performance of QACNN continues to improve.

[4]We only include the results of QACNN in Table 3, but the results of MemN2N are very similar to QACNN.

Percentage of MovieQA used for pre-training	TOEFL		MCTest	
	manual	ASR	MC160	MC500
0	48.9	47.6	57.5	56.4
25%	51.7 (2.8)	50.7 (3.1)	63.8 (6.3)	62.4 (6.0)
50%	53.5 (1.8)	52.3 (1.6)	67.3 (3.5)	66.7 (4.3)
75%	54.8 (1.3)	54.6 (2.3)	71.2 (3.9)	70.2 (3.5)
100%	56.0 (1.2)	55.1 (0.5)	73.8 (2.6)	72.3 (2.1)

Table 4: Results of varying sizes of the MovieQA used for pre-training QACNN. The number in the parenthesis indicates the accuracy increases from using the previous percentage for pre-training to the current percentage.

Analysis of the Questions Types

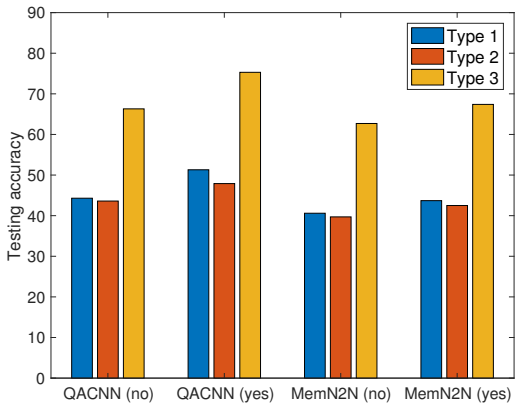

Figure 2: The performance of QACNN and MemN2N on different types of questions in TOEFL-manual with and without pre-training on MovieQA. 'No' in the parenthesis indicates the models are not pre-trained, while 'Yes' indicates the models are pre-trained on MovieQA.

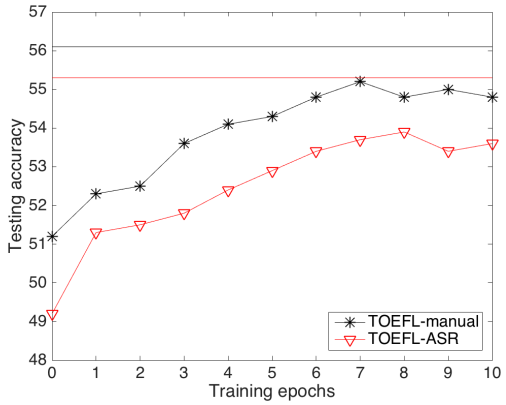
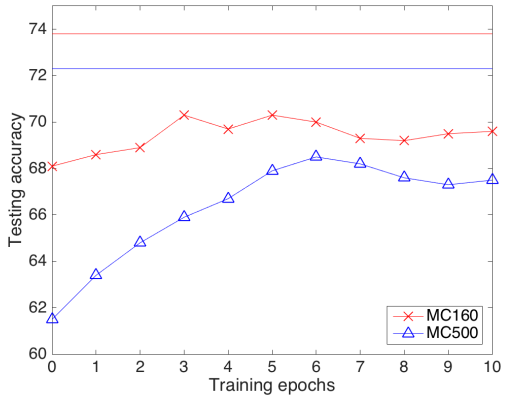
We are interested in understanding what types of questions benefit the most from transfer learning. According to the official guide to the TOEFL test, the questions in TOEFL can be divided into 3 types. Type 1 questions are for basic comprehension of the story. Type 2 questions go beyond basic comprehension, but test the understanding of the functions of utterances or the attitude the speaker expresses. Type 3 questions further require the ability of making connections between different parts of the story, making inferences, drawing conclusions, or forming generalizations. We used the split provided by Fang et al. (2016), which contains 70/18/34 Type 1/2/3 questions. We compare the performance of the QACNN and MemN2N on different types of questions in TOEFL-manual with and without pre-training on MovieQA, and show the results in Figure 2. From Figure 2 we can observe that for both the QACNN and MemN2N, their performance on all three types of questions improves after pre-training, showing that the effectiveness of transfer learning is not limited to specific types of questions.

5.3 Unsupervised Transfer Learning



(a) Results of TOEFL-manual and TOEFL-ASR



(b) Results of MC160 and MC500

Figure 3: The figures show the results of unsupervised transfer learning. The x-axis is the number of training epochs, and the y-axis is the corresponding testing accuracy on the target dataset. When training epoch = 0, the performance of QACNN is equivalent to row (b) in Table 2. The horizontal lines, where each line has the same color to its unsupervised counterpart, are the performances of QACNN with supervised transfer learning (row (e) in Table 2), and are the upperbounds for unsupervised transfer learning.

So far, we have studied the property of supervised transfer learning for QA, which means

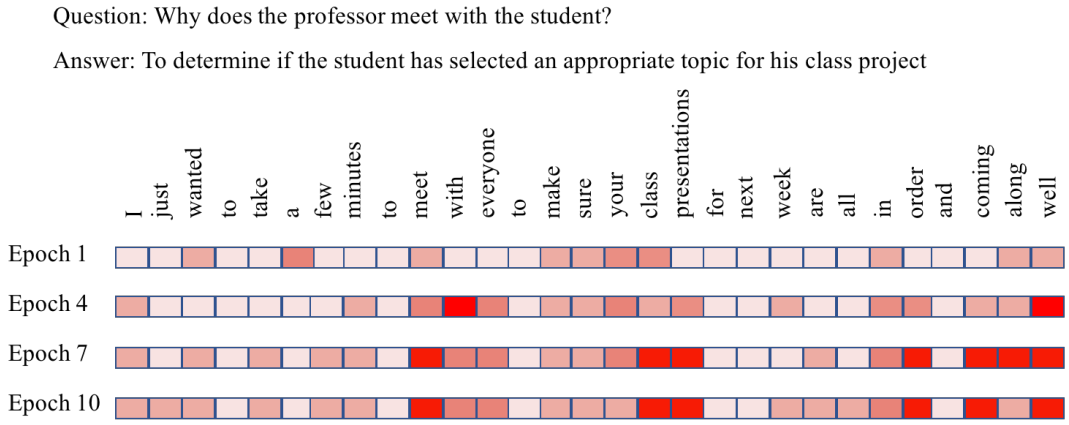


Figure 4: Visualization of the changes of the word-level attention map in the first stage CNN of QACNN in different training epochs. The more red, the more the QACNN views the word as a key feature. The input story-question-choices triplet is same as the one in Table 1.

that during pre-training and fine-tuning, both the source and target datasets provide the correct answer for each question. We now conduct unsupervised transfer learning experiments described in Section 2.2 (Algorithm 1), where the answers to the questions in the target dataset are not available. We used QACNN as the QA model and all the parameters ($E, W^{(1)}_{CNN}, W^{(2)}_{CNN}, W^{(1)}_{FC}$, and $W^{(2)}_{FC}$) were updated during fine-tuning in this experiment. Since the range of the testing accuracy of the TOEFL-series (TOEFL-manual and TOEFL-ASR) is different from that of MCTest (MC160 and MC500), their results are displayed separately in Figure 3(a) and Figure 3(b), respectively.

Experimental Results

From Figure 3(a) and Figure 3(b) we can observe that without ground truth in the target dataset for supervised fine-tuning, transfer learning from a source dataset can still improve the performance through a simple iterative self-labeling mechanism. For TOEFL-manual and TOEFL-ASR, QACNN achieves the highest testing accuracy at Epoch 7 and 8, outperforming its counterpart without fine-tuning by approximately 4% and 5%, respectively. For MC160 and MC500, the QACNN achieves the peak at Epoch 3 and 6, outperforming its counterpart without fine-tuning by about 2% and 6%, respectively. The results also show that the performance of unsupervised transfer learning is still worse than supervised transfer learning, which is not surprising, but the effectiveness of unsupervised transfer learning when no ground truth labels are provided is validated.

Attention Maps Visualization

To better understand the unsupervised transfer learning process of QACNN, we visualize the changes of the word-level attention map during training Epoch 1, 4, 7, and 10 in Figure 4. We use the same question from TOEFL-manual as shown in Table 1 as an example. From Figure 4 we can observe that as the training epochs increase, the QACNN focuses more on the context in the story that is related to the question and the correct answer choice. For example, the correct answer is related to "class project". In Epoch 1 and 4, the model does not focus on the phrase "class representation", but the model attends on the phrase in Epoch 7 and 10. This demonstrates that even without ground truth, the iterative process in Algorithm 1 is still able to lead the QA model to gradually focus more on the important part of the story for answering the question.

6 Conclusion and Future Work

In this paper we demonstrate that a simple transfer learning technique can be very useful for the task of multi-choice question answering. We use a QACNN and a MemN2N as QA models, with MovieQA as the source task and a TOEFL listening comprehension test and MCTest as the target tasks. By pre-training on MovieQA, the performance of both models on the target datasets improves significantly. The models also require much less training data from the target dataset to achieve similar performance to those without pre-training. We also conduct experiments to study the influence of transfer learning on different types

of questions, and show that the effectiveness of transfer learning is not limited to specific types of questions. Finally, we show that by a simple iterative self-labeling technique, transfer learning is still useful, even when the correct answers for target QA dataset examples are not available, through quantitative results and visual analysis.

One area of future research will be generalizing the transfer learning results presented in this paper to other QA models and datasets. In addition, since the original data format of the TOEFL listening comprehension test is audio instead of text, it is worth trying to initialize the embedding layer of the QACNN with semantic or acoustic word embeddings learned directly from speech (Chung and Glass, 2018, 2017; Chung et al., 2016) instead of those learned from text (Mikolov et al., 2013; Pennington et al., 2014).

Abstract

We present a new dataset and models for comprehending paragraphs about processes (e.g., photosynthesis), an important genre of text describing a dynamic world. The new dataset, ProPara, is the first to contain natural (rather than machine-generated) text about a changing world along with a full annotation of entity states (location and existence) during those changes (81k datapoints). The end-task, tracking the location and existence of entities through the text, is challenging because the causal effects of actions are often implicit and need to be inferred. We find that previous models that have worked well on synthetic data achieve only mediocre performance on ProPara, and introduce two new neural models that exploit alternative mechanisms for state prediction, in particular using LSTM input encoding and span prediction. The new models improve accuracy by up to 19%. The dataset and models are available to the community at http://data.allenai.org/propara.

1 Introduction

Building a reading comprehension (RC) system that is able to read a text document and to answer questions accordingly has been a long-standing goal in NLP and AI research. Impressive progress has been made in factoid-style reading comprehension, e.g., (Seo et al., 2017a; Clark and Gardner, 2017), enabled by well-designed datasets and modern neural network models. However, these models still struggle with questions that require *inference* (Jia and Liang, 2017).

Consider the paragraph in Figure 1 about photosynthesis. While top systems on SQuAD (Rajpurkar et al., 2016) can reliably answer lookup questions such as:
Q1: What do the roots absorb? (A: water, minerals)
they struggle when answers are not explicit, e.g.,
Q2: Where is sugar produced? (A: in the leaf)[1]

Chloroplasts in the leaf of the plant trap light from the sun. The roots absorb water and minerals from the soil. This combination of water and minerals flows from the stem into the leaf. Carbon dioxide enters the **leaf**. Light, water and minerals, and the carbon dioxide all combine into a mixture. This mixture forms **sugar** (glucose) which is what the plant eats.

Q: Where is sugar produced?
A: in the leaf

Figure 1: A paragraph from *ProPara* about photosynthesis (bold added, to highlight question and answer elements). Processes are challenging because questions (e.g., the one shown here) often require inference about the process states.

To answer Q2, it appears that a system needs knowledge of the world and the ability to reason with state transitions in multiple sentences: If carbon dioxide *enters* the leaf (stated), then it will be *at* the leaf (unstated), and as it is then used to produce sugar, the sugar production will be at the leaf too.

This challenge of modeling and reasoning with a changing world is particularly pertinent in text about *processes*, demonstrated by the paragraph in Figure 1. Understanding what is happening in such texts is important for many tasks, e.g., procedure execution and validation, effect prediction. However, it is also difficult because the world state is changing, and the causal effects of actions on that state are often implicit.

To address this challenging style of reading comprehension problem, researchers have created several datasets. The bAbI dataset (Weston et al., 2015) includes questions about objects moved throughout a paragraph, using machine-generated language over a deterministic domain with a small lexicon. The SCoNE dataset (Long et al., 2016) contains paragraphs describing a changing world state in three synthetic, deterministic domains, and

[*]Bhavana Dalvi Mishra and Lifu Huang contributed equally to this work.
[1]For example, the RC system BiDAF (Seo et al., 2017a) answers "glucose" to this question.

Proceedings of NAACL-HLT 2018, pages 1595–1604
New Orleans, Louisiana, June 1 - 6, 2018.

Paragraph (seq. of steps):		Participants: water	light	CO2	mixture	sugar
	state0	soil	sun	?	-	-
Roots absorb water from soil						
	state1	roots	sun	?	-	-
The water flows to the leaf.						
	state2	leaf	sun	?	-	-
Light from the sun and CO2 enter the leaf.						
	state3	leaf	leaf	leaf	-	-
The light, water, and CO2 combine into a mixture.						
	state4	-	-	-	leaf	-
Mixture forms sugar.						
	state5	-	-	-	-	leaf

Time

Figure 2: A (simplified) annotated paragraph from ProPara. Each filled row shows the existence and location of participants between each step ("?" denotes "unknown", "-" denotes "does not exist"). For example in state0, water is located at the soil.

assumes that a complete and correct model of the initial state is given for each task. However, approaches developed using synthetic data often fail to handle the inherent complexity in language when applied to organic, real-world data (Hermann et al., 2015; Winograd, 1972).

In this work, we create a new dataset, *ProPara* (Process Paragraphs), containing 488 human-authored paragraphs of procedural text, along with 81k annotations about the changing states (existence and location) of entities in those paragraphs, with an end-task of predicting location and existence changes that occur. This is the first dataset containing annotated, natural text for real-world processes, along with a simple representation of entity states during those processes. A simplified example is shown in Figure 2.

When applying existing state-of-the-art systems, such as Recurrent Entity Networks (Henaff et al., 2016) and Query-reduction Networks (Seo et al., 2017b), we find that they do not perform well on *ProPara* and the results are only slightly better than the majority baselines. As a step forward, we propose two new neural models that use alternative mechanisms for state prediction and propagation, in particular using LSTM input encoding and span prediction. The new models improve accuracy by up to 19%.

Our contributions in this work are twofold: (1) we create *ProPara*, a new dataset for process paragraph comprehension, containing annotated, natural language paragraphs about real-world processes, and (2) we propose two new models that learn to infer and propagate entity states in novel ways, and outperform existing methods on this dataset.

2 Related Work

Datasets: Large-scale reading comprehension datasets, e.g., SQuAD (Rajpurkar et al., 2016), TriviaQA (Joshi et al., 2017), have successfully driven progress in question answering, but largely targeting explicitly stated facts. Often, the resulting systems can be fooled (Jia and Liang, 2017), prompting efforts to create harder datasets where a deeper understanding of the text appears necessary (Welbl et al., 2017; Araki et al., 2016).

Procedural text is a genre that is particularly challenging, because the worlds they describe are largely implicit and changing. While there are few large datasets in this genre, two exceptions are bAbI (Weston et al., 2015) and SCoNE (Long et al., 2016), described earlier[2]. bAbI has helped advance methods for reasoning over text, such as memory network architectures (Weston et al., 2014), but has also been criticized for using machine-generated text over a simulated domain. SCoNE is closer to our goal, but has a different task (*given* a perfect world model of the initial state, predict the end state) and different motivation (handling ellipsis and coreference in context). It also used a deterministic, simulated world to generate data.

Models: For answering questions about procedural text, early systems attempted to extract a process structure (events, arguments, relations) from the paragraph, e.g., ProRead (Berant et al., 2014) and for newswire (Caselli et al., 2017). This allowed questions about event ordering to be answered, but not about state changes, unmodelled by these approaches.

More recently, several neural systems have been developed to answer questions about the world state after a process, inspired in part by the bAbI dataset. Building on the general Memory Network architecture (Weston et al., 2014) and gated recurrent models such as GRU (Cho et al., 2014), Recurrent Entity Networks (EntNet) (Henaff et al., 2016) is a state-of-the-art method for bAbI. EntNet uses a dynamic memory of hidden states (memory blocks) to maintain a representation of the world state, with a gated update at each step. Memory keys can be preset ("tied") to particular entities in the text, to encourage the memories to record information about those entities. Similarly, Query Reduction Networks (QRN) (Seo et al., 2017b) tracks state in

[2]The ProcessBank (Berant et al., 2014) dataset is smaller and does not address state change, instead containing 585 questions about event ordering and event arguments.

a paragraph, represented as a hidden vector h. QRN performs gated propagation of h across each time-step (corresponding to a state update), and uses h to modify ("reduce") the query to keep pointing to the answer at each step (e.g., "Where is the apple?" at step_1 might be modified to "Where is Joe?" at step_2 if Joe picks up the apple). A recent proposal, Neural Process Networks (NPN) (Bosselut et al., 2018), also models each entity's state as a vector (analogous to EntNet's tied memories). NPN computes the state change at each step from the step's predicted action and affected entity(s), then updates the entity(s) vectors accordingly, but does not model different effects on different entities by the same action.

Both EntNet and QRN find a final answer by decoding the final vector(s) into a vocabulary entry via softmax classification. In contrast, many of the best performing factoid QA systems, e.g., (Seo et al., 2017a; Clark and Gardner, 2017), return an answer by finding a *span* of the original paragraph using attention-based span prediction, a method suitable when there is a large vocabulary. We combine this span prediction approach with state propagation in our new models.

3 The ProPara Dataset

Task: Our dataset, *ProPara*, focuses on a particular genre of procedural text, namely simple scientific processes (e.g., photosynthesis, erosion). A system that understands a process paragraph should be able to answer questions such as: "*What are the inputs to the process?*", "*What is converted into what?*", and "*Where does the conversion take place?*"[3] Many of these questions reduce to understanding the basic dynamics of entities in the process, and we use this as our task: Given a process paragraph and an entity e mentioned in it, identify: (1) **Is** e created (destroyed, moved) in the process? (2) **When** (step #) is e created (destroyed, moved)? (3) **Where** is e created (destroyed, moved from/to)? If we can track the entities' *states* through the process and answer such questions, many of the higher-level questions can be answered too. To do this, we now describe how these states are representated in ProPara, and how the dataset was built.

Process State Representation: The states of the world throughout the whole process are represented as a grid. Each column denotes a *participant* entity (a span in the paragraph, typically a noun phrase) that undergoes some creation, destruction, or movement in the process. Each row denotes the *states* of all the participants after a *step*. Each sentence is a step that may change the state of one or more participants. Therefore, a process paragraph with m sentences and n participants will result in an $(m + 1) \times n$ grid representation. Each cell l_{ij} in this grid records the *location* of the j-th participant after the i-th step, and l_{0j} stores the location of j-th participant before the process.[4] Figure 2 shows one example of this representation.

Paragraph Authoring: To collect paragraphs, we first generated a list of 200 process-evoking prompts, such as "*What happens during photosynthesis?*", by instantiating five patterns[5], with nouns of the corresponding type from a science vocabulary, followed by manual rewording. Then, crowdsourcing (MTurk) workers were shown one of the prompts and asked to write a sequence of event sentences describing the process. Each prompt was given to five annotators to produce five (independent) paragraphs. Short paragraphs (4 or less sentences) were then removed for a final total of 488 paragraphs describing 183 processes. An example paragraph is the one shown earlier in Figure 1.

Grid and Existence: Once the process paragraphs were authored, we asked expert annotators[6] to create the initial grids. First, for each paragraph, they listed the participant entities that underwent a state change during the process, thus creating the column headers. They then marked the steps where a participant was created or destroyed. All state cells before a Create or after a Destroy marker were labeled as "not exists". Each initial grid annotation was checked by a second expert annotator.

Locations: Finally, MTurk workers were asked to fill in all the location cells. A location can be "unknown" if it is not specified in the text, or a span of the original paragraph. Five grids for the same paragraph were completed by five different Turkers, with average pairwise inter-annotator agreement of 0.67. The end result was 81,345 annotations over 488 paragraphs about 183 processes. The dataset

[3] For example, science exams pose such questions to test student's understanding of the text in various ways.

[4] We only trace locations in this work, but the representation can be easily extended to store other properties (e.g., temperature) of the participants.

[5] The five patterns are: How are ***structure*** formed? How does ***system*** work? How does ***phenomenon*** occur? How do you use ***device***? What happens during ***process***?

[6] Expert annotators were from our organization, with a college or higher degree.

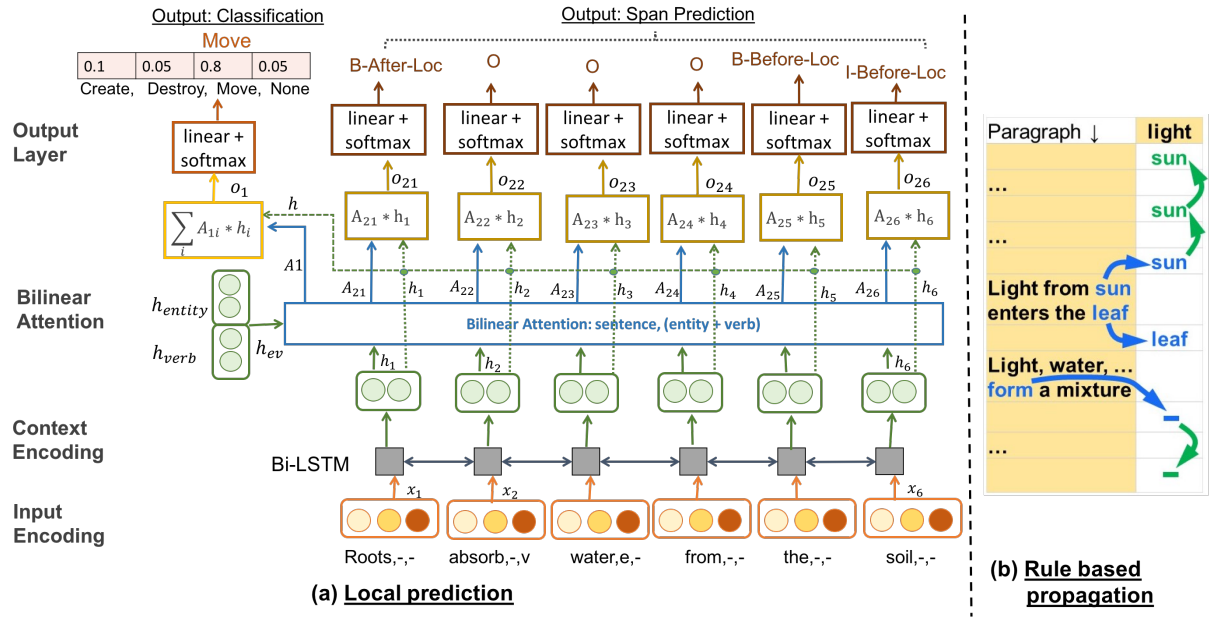

Figure 3: (a) ProLocal uses bidirectional attention to make local predictions about state change type and location (left), and then (b) propagates those changes globally using a persistence rule (right, shown for a single participant (the Light), local predictions shown in blue, propagations via persistence in green).

	bAbI	SCoNE	ProPara
Sentences	Synthetic	Natural	Natural
Questions	templated	templated	templated
# domains	20	3	183
Vocab #words	119	1314	2501
# sentences	131.1k	72.9k	3.3k
# unique sents	3.2k	37.4k	3.2k
Avg words/sent	6.5	10.2	9.0

Table 1: ProPara vs. other procedural datasets.

was then split 80/10/10 into train/dev/test by *process prompt*, ensuring that the test paragraphs were all about processes unseen in train and dev. Table 1 compares our dataset with bAbI and SCoNE.

4 Models

We present two new models for this task. The first, ProLocal, makes local state predictions and then algorithmically propagates them through the process. The second, ProGlobal, is an end-to-end neural model that makes all state predictions using global information.

4.1 ProLocal: A Local Prediction Model

The design of ProLocal consists of two main components: *local prediction* and *commonsense persistence*. The former infers all direct effects of individual sentences and the latter algorithmically propagates known values forwards and backwards to fill in any remaining unknown states.

4.1.1 Local Prediction

The intuition for local prediction is to treat it as a surface-level QA task. BiLSTMs with span prediction have been effective at answering surface-level questions, e.g., Given "Roots absorb water." and "Where is the water?", they can be reliably trained to answer "Roots" (Seo et al., 2017a). We incorporate a similar mechanism here.

Given a sentence (step) and a participant e in it, the local prediction model makes two types of predictions: the change type of e (one of: *no change*, *created*, *destroyed*, *moved*) and the locations of e before and after this step. The change type prediction is a multi-class classification problem, while the location prediction is viewed as a SQuAD-style surface-level QA task with the goal to find a location span in the input sentence. The design of this model is depicted in Figure 3(a), which adapts a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) recurrent neural network architecture (biLSTM) with attention for input encoding. The prediction tasks are handled by two different output layers. We give the detail of these layers below.

Input Encoding: Each word w_i in the input sentence is encoded with a vector $x_i = [v_w : v_e : v_v]$, the concatenation of a pre-trained GloVe (Pennington et al., 2014) word embedding v_w, indicator variables v_e on whether w_i is the specified participant and v_v on whether w_i is a verb (via a POS tagger).

Context Encoding: A biLSTM is used to contextualize the word representations in a given sentence. h_i denotes the concatenated output of the bidirectional LSTM for the embedded word x_i, and encodes the word's meaning in context.

Bilinear Attention: Given the participant and verb, the role of this layer is to identify which contextual word embeddings to attend to for generating the output. We first create h_{ev} by concatenating the contextual embedding of the participant and verb.[7] We then use a bilinear similarity function $sim(h_i, h_{ev}) = (h_i^T * B * h_{ev}) + b$, similar to (Chen et al., 2016), to compute attention weights A_i over each word w_i in the sentence.

For state change type prediction, the words between the verb and participant may be important, while for the location tagging, contextual cues such as "from" and "to" could be more predictive. Hence, we train two sets of attention parameters resulting in weights A_1 and A_2 which are combined with the contextual vectors h_i as described below to produce hidden states o_1 and o_2 that are fed to the output layers. Here, $|step|$ refers to number of words in the given step or sentence.

$$o_1 = \sum_i A_{1i} * h_i$$

$$o_2 = [(A_{21} * h_1) : (A_{22} * h_2) : \ldots : (A_{2|step|} * h_{|step|})]$$

Output 1: State Change Type: We apply a feed-forward network on hidden state o_1 to derive the probabilities of the four state change type categories: Create, Destroy, Move and None.

Output 2: Location Spans: The second output is computed by predicting BIO tags (one of five tags: B-Before-LOC, I-Before-LOC, B-After-LOC, I-After-LOC, O) for each word in the sentence. We apply a feed-forward network on hidden state o_{2i} for $word_i$ to derive the probabilities of these location tags. Notice that if the change type is predicted as "Create" (or "Destroy") then only the "after" (or "before") location prediction is used.

Training: We train the state change type prediction and location tag prediction models jointly, where the loss is the sum of their negative log likelihood losses. We use Adadelta (Zeiler, 2012) with learning rate 0.2 to minimize the total loss.

4.1.2 Commonsense Persistence

The local prediction model will partially fill in the state change grid, showing the direct locational effects of actions (including "not exists" and "unknown location"). To complete the grid, we then algorithmically apply a commonsense rule of persistence that propagates locations forwards and backwards in time where locations are otherwise missing. Figure 3(b) shows an example when applying this rule, where '?' indicates "unknown location". This corresponds to a rule of inertia: things are by default unchanged unless told otherwise. If there is a clash, then the location is predicted as unknown.

4.2 ProGlobal: A Global Prediction Model

Unlike ProLocal, the design principle behind ProGlobal is to model the persistence of state information *within* the neural model itself, rather than as a post-processing step. ProGlobal infers the states of *all* participants at each step, even if they are not mentioned in the current sentence, using: (1) the global context (i.e., previous sentences), and (2) the participant's state from the previous step.

Given a sentence (step) with its context (paragraph) and a participant e, ProGlobal predicts the existence and location of e after this step in two stages. It first determines the state of e as one of the classes ("not exist", "unknown location", "known location"). A follow-up location span prediction is made if the state is classified as "known location".

Figure 4 shows ProGlobal's neural architecture, where the left side is the part for state prediction at each step, and the right side depicts the propagation of hidden states from one step to the next. We discuss the detail of this model below.

Input Encoding: Given a participant e, for each step_i, we take the entire paragraph as input. Each word w in the paragraph is represented with three types of embeddings: the general word embedding v_w, a position embedding v_d which indicates the relative distance to the participant in the paragraph, and a sentence indicator embedding v_s which shows the relative position (*previous, current, following*) of each sentence in terms of the current step i. Both the position embedding and the sentence indicator embedding are of size 50 and are randomly initialized and automatically trained by the model. We concatenate these three types of embeddings to represent each word $x = [v_w : v_d : v_s]$.

Context Encoding: Similar to ProLocal, we use a biLSTM to encode the whole paragraph and use $\tilde{h}$ to denote the biLSTM output for each word.

State Prediction: As discussed earlier, we first predict the location state of a participant e. Let

[7] Multi-word entities/verbs or multiple verbs are represented by the average word vectors.

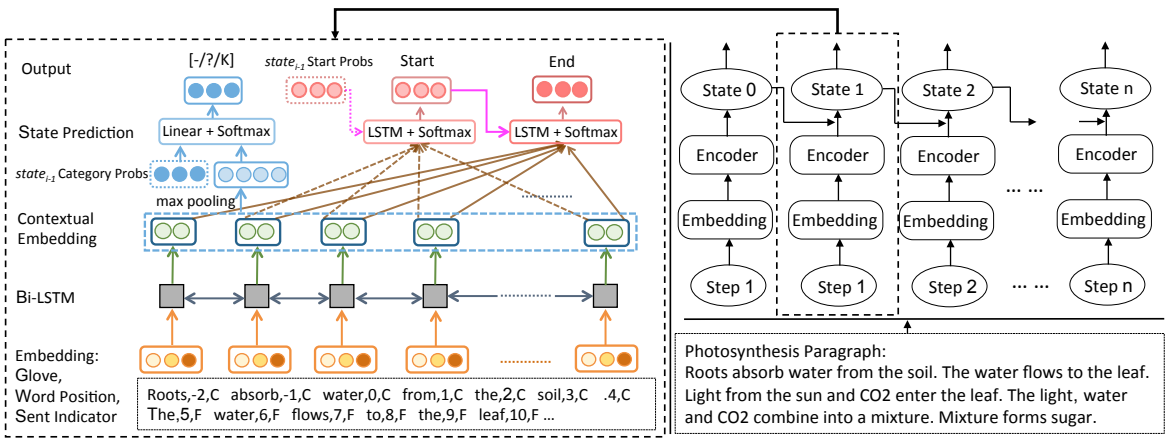

Figure 4: ProGlobal predicts a participant's state (type and location) after a given step using bilinear attention over the entire paragraph, combined with its predictions from the previous step.

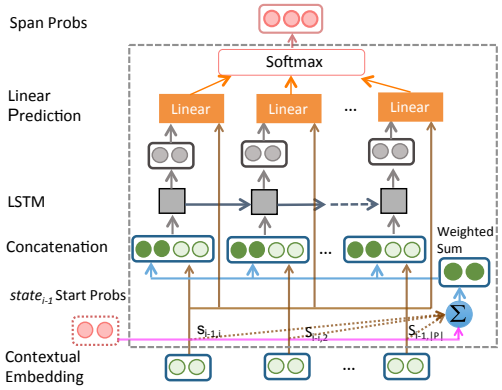

Figure 5: Details of the LSTM+Softmax unit, used for predicting the start/end words of a location.

$\tilde{H}_i^P = [\tilde{h}_i^1, \tilde{h}_i^2, ..., \tilde{h}_i^{|P|}]$ denote the hidden vectors (contextual embeddings) for words in step$_i$ with respect to participant e, where h_i^t denotes the t-th word representation output by the biLSTM layer and P is the whole paragraph. We then apply max pooling to derive a paragraph representation: $\mu_i^P = \max(\tilde{H}_i^P)$. To incorporate the category prediction of the previous step, step$_{i-1}$, we concatenate its probability vector $c_{i-1}^P \in \mathbb{R}^3$ with μ_i^P, and apply a feed-forward network to derive the probabilities of the three categories:

$$c_i^P = \text{softmax}(W_c \cdot [\mu_i^P : c_{i-1}^P] + b_c)$$

Location Span Prediction: (Figure 5). To predict the location span, we predict the start word of the span (by generating a probability distribution over words) and the end word. To predict the location start, we take two types of information as input: the start probability distribution $s_{i-1}^P \in \mathbb{R}^{|P|}$ predicted from step$_{i-1}$, and the contextual embeddings $\tilde{H}_i^P$ of words in the current step$_i$:

$$\tilde{H}_i^* = \sum_{t=1}^{|P|} s_{i-1}^t \cdot \tilde{H}_i^t$$

$$\varphi_i^t = \text{LSTM}([\tilde{H}_i^t : \tilde{H}_i^*])$$

where $\tilde{H}_i^*$ is a sum of word vectors in the paragraph, weighted by the start probabilities from the previous step step$_{i-1}$. φ_i^t is the encoded vector representation for the t-th word in the paragraph. We then concatenate $\tilde{H}_i^P$ and φ_i^P, and apply a feed-forward network to obtain the start probability distribution for step$_i$: $s_i^P = \text{softmax}(W_s \cdot [\tilde{H}_i^P : \varphi_i^P] + b_s)$. Similarly, to predict the end word of the span, we use the start probability distribution s_i^P of $step_i$ and $\tilde{H}_i^P$, and apply another LSTM and feed-forward networks to obtain the probabilities. For state$_0$ (the initial location before any steps), we directly feed the sequence of the vectors from the encoding layer to a linear transformation to predict the location start, and apply the same architecture to predict the location end.

Training: For each participant e of paragraph P, the objective is to optimize the sum of the negative log likelihood of the category classification and location span prediction[8]. We use Adadelta to optimize the models with learning rate 0.5.

5 Experiments and Analysis

5.1 Tasks & Evaluation Metrics

As described in Section 3, the quality of a model is evaluated based on its ability to answer three categories of questions, with respect to a given participant e:

[8]We compute the loss for location span prediction only when the category is annotated as "known location".

	Sentence Encoding	Intermediate State Representn.	Propagation through time	Answer Decoding
EntNet	positional encoding	Dynamic memory blocks	Gated propagation	Softmax classification
QRN	positional encoding	Single latent vector *h*	Gated propagation of *h*	Softmax classification
ProLocal	LSTM	Explicit symbolic	Algorithmic	Span prediction
ProGlobal	LSTM	Distribution over spans	LSTM	Span prediction

Table 2: Design decisions in the four neural models.

(Cat-1) **Is** *e* created (destroyed, moved) in the process?
(Cat-2) **When** (step#) is *e* created (destroyed, moved)?
(Cat-3) **Where** is *e* created (destroyed, moved from/to)?
These questions are answered by simple scans over the state predictions for the whole process. (Cat-1) is asked over all participants, while (Cat-2) and (Cat-3) are asked over just those participants that were created (destroyed, moved). The accuracy of the answers is used as the evaluation metric, except for questions that may have multiple answers (e.g., "*When is e moved?*"). In this case, we compare the predicted and gold answers and use the F_1 score as the "accuracy" of the answer set prediction.[9]

For questions in category (3), an answer is considered correct if the predicted location is identical to, or a sub-phrase of, the labeled location (typically just one or two words), after stop-word removal and lemmatizing.

5.2 Baseline Methods

We compare our models with two top methods inspired by the bAbI dataset, Recurrent Entity Networks (EntNet) and Query Reduction Networks (QRN), described earlier in Section 2. Both models make different use of gated hidden states to propagate state information through time, and generate answers using softmax. The detailed comparisons in their design are shown in Table 2.

We use the released implementations[10] (with default hyper-parameter values), and retrained them on our dataset, adapted to the standard bAbI QA format. Specifically, we create three separate variations of data by adding three bAbI-style questions after each step in a paragraph, respectively:

Q1. "Does *e* exist?" (yes/no)
Q2. "Is the location of *e* known?" (yes/no)
Q3. "Where is *e*?" (span)

The template Q1 is applied to all participants. Q2 will only be present in the training data if Q1 is "yes", and similarly Q3 is only present if Q2 is "yes". These three variations of data are used to train three different models from the same method.

At test time, we cascade the questions (e.g., ask Q2 only if the answer to the Q1 model is "yes"), and combine the model outputs accordingly to answer the questions in our target tasks (Section 5.1).

We also compare against a rule-based baseline and a feature-based baseline. The rule-based method, called ProComp, uses a set of rules that map (a SRL analysis of) each sentence to its effects on the world state, e.g., IF X moves to Y THEN after: at(X,Y). The rules were extracted from VerbNet (Schuler, 2005) and expanded. A full description of ProComp is available at (Clark et al., 2018). The feature-based method uses a Logistic Regression (LR) classifier to predict the state change type (Move, Create, etc.) for each participant + sentence pair, then a NER-style CRF model to predict the from/to locations as spans of the sentence. The LR model uses bag-of-word features from the sentence, along with a discrete feature indicating whether the participant occurs before or after the verb in the given sentence. The CRF model uses standard NER features including capitalization, a verb indicator, the previous 3 words, and the POS-tag of the current and previous word. Similar to our ProLocal model, we apply commonsense persistence rules (Section 4.1.2) to complete the partial state-change grids predicted by both these baselines.

5.3 Results

Parameter settings: Both our models use GloVe embeddings of size 100 pretrained on Wikipedia 2014 and Gigaword 5 corpora[11]. The number of hidden dimensions for the biLSTM are set to 50(ProLocal) and 100(ProGlobal). Dropout rates (Srivastava et al., 2014) for the contextual encoding layer are 0.3(ProLocal) and 0.2(ProGlobal). ProGlobal uses word position and sentence indicator embeddings each of size 50, and span prediction LSTMs with a hidden dimension of 10. The learning rates for Adadelta optimizer were

[9] This approach has been adopted previously for questions with multiple answers (e.g., (Berant et al., 2013)). For questions with only one answer, F_1 is equivalent to accuracy.

Table 3: Model accuracy on the end task (test partition of *ProPara*). Questions are (Section 5.1): (Cat-1) **Is** e_i created (destroyed, moved)? (Cat-2) **When** is e_i created (...)? (Cat-3) **Where** is e_i created (...)?

0.2(ProLocal) and 0.5(ProGlobal). Our models are trained on the train partition and the parameters tuned on the dev partition.

Table 3 compares the performance of various models on the *ProPara* test partition. For the first category of questions, we also include a simple majority baseline. We aggregate results over the questions in each category, and report both macro and micro averaged accuracy scores.

From Table 3, we can see that EntNet and QRN perform comparably when applied to *ProPara*. However, despite being the top-performing systems for the bAbI task, when predicting whether a participant entity is created, destroyed or moved, their predictions are only slightly better than the majority baseline. Compared to our local model ProLocal, EntNet and QRN are worse in predicting the exact step where a participant is created, destroyed or moved, but better in predicting the location. The weak performance of EntNet and QRN on *ProPara* is understandable: both systems were designed with a different environment in mind, namely a large number of examples from a few conceptual domains (e.g., moving objects around a house), covering a limited vocabulary. As a result, they might not scale well when applied to real procedural text, which justifies the importance of having a real challenge dataset like *ProPara*.

Although the rule-based baseline (Clark et al., 2018) uses rules mapping SRL patterns to state changes, its performance appears limited by the incompleteness and approximations in the rulebase, and by errors by the SRL parser. The feature-based baseline performs slightly better, but its performance is still poor compared to our neural models. This suggests that it has not generalized as well to unseen vocabulary (25% of the test vocabulary is not present in the train/dev partitions of *ProPara*).

When comparing our two models, it is interesting that ProGlobal performs substantially better than ProLocal. One possible cause of this is cascading errors in ProLocal: if a local state prediction is wrong, it may still be propagated to later time steps without any potential for correction, thus amplifying the error. In contrast, ProGlobal makes a state decision for every participant entity at every time-step, taking the global context into account, and thus appears more robust to cascading errors. Furthermore, ProGlobal's gains are mainly in Cat-2 and Cat-3 predictions, which rely more heavily on out-of-sentence cues. For example, 30% of the time the end-location is not explicitly stated in the state-change sentence, meaning ProLocal cannot predict the end-location in these cases (as no sentence span contains the end location). ProGlobal, however, uses the entire paragraph and may identify a likely end-location from earlier sentences.

Finally, we computed a human upper bound for this task (last column of Table 3). During dataset creation, each grid was fully annotated by 5 different Turkers (Section 3). Here, for each grid, we identify the Turker whose annotations result in the best score for the end task with respect to the other Turkers' annotations. The observed upper bound of ~80% suggests that the task is both feasible and well-defined, and that there is still substantial room for creating better models.

5.4 Analysis

To further understand the strengths and weaknesses of our systems, we ran the simplified paragraph in Figure 2 verbatim through the models learned by ProLocal and ProGlobal. The results are shown in Figure 6, with errors highlighted in red.

ProLocal correctly interprets "*Light from the sun and CO2 enters the leaf.*" to imply that the light was at the sun before the event. In addition, as there were no earlier mentions of light, it propagates this location backwards in time, (correctly) concluding the light was initially at the sun. However, it fails to predict that "*combine*" (after state 3) destroys the inputs, resulting in continued prediction of the existence and locations for those inputs. One contributing factor is that ProLocal's predic-

Paragraph (seq. of steps):		ProLocal Predictions: water	light	CO2	mixture	sugar
	state0	soil	sun	?	-	-
Roots absorb water from soil						
	state1	roots	sun	?	-	-
The water flows to the leaf.						
	state2	leaf	sun	?	-	-
Light from the sun and CO2 enter the leaf.						
	state3	leaf	?	?	-	-
The light, water, and CO2 combine into a mixture.						
	state4	leaf	?	?	?	-
Mixture forms sugar.						
	state5	leaf	?	?	-	?

	state0	soil	-	-	-	-
Roots absorb water from soil						
	state1	soil	-	-	-	-
The water flows to the leaf.						
	state2	leaf	-	-	-	-
Light from the sun and CO2 enter the leaf.						
	state3	leaf	leaf	leaf	-	-
The light, water, and CO2 combine into a mixture.						
	state4	-	-	-	leaf	-
Mixture forms sugar.						
	state5	-	-	-	-	leaf

Figure 6: ProLocal (top) and ProGlobal (bottom) predictions on a simple paragraph (errors in red).

tions ignore surrounding sentences (context), potentially making it harder to distinguish destructive vs. non-destructive uses of "*combine*".

ProGlobal also makes some errors on this text, most notably not realizing the light and CO2 exist from the start (rather, they magically appear at the leaf). Adding global consistency constraints may help avoid such errors. It is able to predict the sugar is formed at the leaf, illustating its ability to persist and transfer location information from earlier sentences to draw correct conclusions.

We additionally randomly selected 100 prediction errors from the dev set for ProGlobal, and identified four phenomena contributing to errors:

(1) Implicit Creation/Destruction: In 37% of the errors, the information about the creation or destruction of a participant is implicit or missing, which resulted in existence classification errors. For example, in the sentences "*A fuel goes into the generator. The generator converts mechanical energy into electrical energy.*", "*fuel*" is implicitly consumed as the generator converts mechanical energy into electrical energy.

(2) Location Errors: In 27% of the examples, the location spans were not perfectly identified as follows: absolute wrong location span prediction (17%), longer span prediction (6%), and location prediction from different granularity (4%).

(3) Complex Syntax: In 13% of the examples, a moving participant and its target location are separated with a wide context within a sentence, making it harder for the model to locate the location span.

(4) Propagation: ProGlobal tends to propagate the previous location state to next step, which may override locally detected location changes or propagate the error from previous step to next steps. 9% of the errors are caused by poor propagation.

5.5 Future Directions

This analysis suggests several future directions:
Enforcing global consistency constraints: e.g., it does not make sense to create an already-existing entity, or destroy a non-existent entity. Global constraints were found useful in the earlier ProRead system (Berant et al., 2014).
Data augmentation through weak supervision: additional training data can be generated by applying existing models of state change, e.g., from VerbNet (Kipper et al., 2008), to new sentences to create additional sentence+state pairs.
Propagating state information backwards in time: if e_j is at l_{ij} after $step_i$, it is likely to also be there at $step_{i-1}$ given no information to the contrary. ProGlobal, EntNet, and QRNs are inherently unable to learn such a bias, given their forward-propagating architectures.

6 Conclusion

New datasets and models are required to take reading comprehension to a deeper level of machine understanding. As a step in this direction, we have created the ProPara dataset, the first to contain natural text about a changing world along with an annotation of entity states during those changes. We have also shown that this dataset presents new challenges for previous models, and presented new models that exploit ideas from surface-level QA, in particular LSTM input encoding and span prediction, producing performance gains. The dataset and models are available at `http://data.allenai.org/propara`.

Abstract

With the rise of e-commerce, people are accustomed to writing their reviews after receiving the goods. These comments are so important that a bad review can have a direct impact on others buying. Besides, the abundant information within user reviews is very useful for extracting user preferences and item properties. In this paper, we investigate the approach to effectively utilize review information for recommender systems. The proposed model is named LSTM-Topic matrix factorization (LTMF) which integrates both LSTM and Topic Modeling for review understanding. In the experiments on popular review dataset Amazon , our LTMF model outperforms previous proposed HFT model and ConvMF model in rating prediction. Furthermore, LTMF shows the better ability on making topic clustering than traditional topic model based method, which implies integrating the information from deep learning and topic modeling is a meaningful approach to make a better understanding of reviews.

1 Introduction

Recommender systems (RSs) are widely used in the field of electronic commerce to provide personalized recommendation services for customers. Most popular RSs are based on *Collaborative Filtering* (CF), which makes use of users' explicit ratings or implicit behaviour for recommendations (Koren, 2008). But CF models suffer from data sparsity, which is also called "*cold-start*" problem. Models perform poorly when there is few available data. To alleviate this problem, utilizing user reviews can be a good approach because user reviews can directly reflect users' preferences and items' properties and exactly correspond to the user latent factors and item latent factors in CF models.

*corresponding author

To understand user reviews, previous approaches are mainly based on *topic modeling*, a suite of algorithms that aim to discover the thematic information among documents (Blei, 2012). The simplest and commonly used topic model is *latent dirichlet allocation*(LDA). Recently, as deep learning shows great performance in computer vision (Krizhevsky et al., 2017) and NLP (Kim, 2014), some approaches combining deep learning with CF are proposed to capture latent context features from reviews.

However, we find there are some limitations in existing models. First, the LDA algorithm used in previous models like Hidden Factors as Topics (HFT) (McAuley and Leskovec, 2013) ignores contextual information. If a user writes "***I prefer apple than banana when choosing fruits***" in a review, we can clearly know the user's preference and recommend items including apple. But LDA ignores the structural information and considers the two words as the same since they both appear once in the sentence.

Compared with topic modeling, deep learning methods such as *Convolutional Neural Network* (CNN) and *Recurrent Neural Network* (RNN) are able to retain more context information. CNN uses sliding windows to capture local context and word order. RNN considers a sentence as a word sequence, and the former word information will be reserved and passed back, which gives RNN the ability to retain the whole sentence information.

But these still exist some problems. For CNN, the sizes of sliding windows are often small, which causes CNN model fails to link words in the sentence begin and end. Given the review ***"I prefer apple than google when choosing jobs"***, CNN can not notice the two words *'apple'* and *'jobs'* simultaneously if the windows size is small, so it will meet the ambiguity problem that the word *'apple'* means fruit or company. For RNN, al-

Proceedings of NAACL-HLT 2018, pages 1605–1614
New Orleans, Louisiana, June 1 - 6, 2018.

though it performs better than CNN on persisting former information, the information will still decreases with the length of sentences increasing. So when a review is long, the effect of RNN is limited.

Faced with these problems, we propose to integrate deep learning and topic modeling to extract more global context information and get a deeper understanding of user reviews. Deep learning methods can reserve context information, while topic modeling can provide word co-occurrence relation to make a supplement for information loss.

We use *Long Short-Term Memory* (LSTM) network for the deep learning part, because it is a special type of RNN which has better performance on gradient vanishing and long term dependence problems than vanilla RNN structure. We use LDA for the topic modeling part. Then the two parts are integrated into a matrix factorization framework. The final model is named **LSTM-Topic matrix factorization** (**LTMF**).

Furthermore, as the topic modeling part and deep learning part are connected in our model, the topic clustering results will be influenced by the deep learning information. In experiments, LTMF shows a better topic clustering ability than traditional LDA based HFT model. This gives us some inspiration on using the integrating methods into other tasks like sentiment classification.

In the remainder of the paper, we first review previous work related to our work. Then we address preliminaries and present our models in detail. After that we evaluate our approach by comparing our approach with state-of-the-art algorithms. Finally we conclude the paper with future work.

2 Related Work

There has been some earlier approaches to extract review information for RSs. Wang and Blei (2011) proposed *collaborative topic regression* (CTR) that combined topic modeling and collaborative filtering in a probabilistic model. McAuley and Leskovec (2013) developed a statistical model HFT using a transfer function to combine rating and review tightly. Ling et al. (2014) and Bao et al. (2014) proposed models similar to CTR and HFT with some structural differences.

Recently, several researchers begin to utilize deep learning in RSs. Wang et al. (2015) presented a Bayesian model *collaborative deep learning* (CDL) leveraging SDAE neural networks as a text feature learning component. Bansal et al. (2016) trained a *gated recurrent units* (GRUs) network to encode text sequences into latent vectors. Zhao et al. (2016) trained a deep CNN to discover the abstract representation of movie posters and still frames, and incorporated it into a neighborhood CF model. Kim et al. (2016) utilized CNN to retain contextual information in review, and developed a document context-aware recommendation model (ConvMF). The ConvMF model is a recently proposed model and is shown to outperform PMF and CDL, and we choose it as a baseline in our experiments. Zheng et al. (2017) proposed the *Deep Cooperative Neural Networks* (DeepCoNN) model which constructed two concurrent CNN to simultaneously model user and item reviews and then combined the features into Factorization Machine. Attention in neural networks has been popular in nearly years, Seo et al. (2017) proposed a model using CNN with dual attention for rating prediction. There are some similarity between the D-attn model with our LTMF model for we both want to extract more global information, where they use attention CNN model and we utilize the information from both topic modeling and deep learning. The D-attn model fail to work if there is not enough reviews, while our LTMF model use review information as a supplementary of rating. So it can still work effectively even there are few reviews.

Besides, Diao et al. (2014) proposed a method jointly modeling aspects, sentiments and ratings for movie recommendation. Hu et al. (2015) proposed MR3 model to combine ratings, social relations and reviews together for rating prediction. These hybrid models boost the performance than individual components, which also give us some inspiration on proposing the LTMF framework.

3 Preliminary

3.1 Notations

We use explicit ratings as the training and test data. Suppose there are M users

$$\mathcal{U} = \{u_1, u_2, ..., u_i, ..., u_M\}$$

and N items

$$\mathcal{V} = \{v_1, v_2, ..., v_j, ..., v_N\},$$

where each user and item is represented by a K-dimension latent vector, $u_i \in \mathbb{R}^K$ and $v_j \in \mathbb{R}^K$. The rating sparse matrix is denoted as $R \in \mathbb{R}^{M \times N}$, where r_{ij} is the rating of user u_i on item v_j. D is the review (document) corpus where d_{ij} is the review of user u_i on item v_j.

3.2 PMF: a standard matrix factorization model

Probabilistic Matrix Factorization (PMF) (Mnih and Salakhutdinov, 2008) is an effective recommendation model that uses matrix factorization (MF) technique to find the latent features of users and items from a probabilistic perspective. In PMF, the predicted rating $\hat{R}_{ij}$ is expressed as the inner product of user latent vector u_i and item latent vector v_j : $\hat{R}_{ij} = u_i^T v_j$. To get latent vectors, PMF minimises the following loss function:

$$\mathcal{L} = \sum_i^M \sum_j^N I_{ij}(R_{ij} - u_i^T v_j)^2 + \lambda_u \sum_i^M \| u_i \|_F^2 + \lambda_v \sum_j^N \| v_j \|_F^2, \quad (1)$$

where R_{ij} is the observed rating. The first part of Eq.(1) is the sum-of-squared-error between predicted and observed ratings and the second part is quadratic regularization terms to avoid overfitting. λ_u and λ_v are corresponding regularization parameters. I_{ij} is the indicator function which equals 1 if i-th user rated j-th item, and equals 0 otherwise.

3.3 HFT: understand reviews through topic modeling

Hidden Factors as Topics (HFT) (McAuley and Leskovec, 2013) provides an effective approach to integrates topic modeling into traditional CF models. It utilizes LDA, the simplest topic model which assumes there are k topics $\mathcal{T} = \{t_1, t_2, ..., t_k\}$ in document corpus D. Each document $d \in D$ has a topic distribution θ_d over $\mathcal{T}$ and each topic has a word distribution ϕ over a fixed vocabulary. To connect the document-topic distribution θ and item factors v, HFT proposes a transformation function:

$$\theta_{j,k} = \frac{\exp(\kappa v_{j,k})}{\sum_k \exp(\kappa v_{j,k})}, \quad (2)$$

where $v_{j,k}$ is the k-th latent factor in item vector v_j and $\theta_{j,k}$ is the k-th topic probability in item document-topic distribution θ_j, κ is the parameter controlling the "peakiness" of the transformation. Besides, HFT introduces an additional variable ψ to ensure the word distribution ϕ_k is a stochastic vector which satisfies $\sum_w \phi_{k,w} = 1$, the relation is denoted as follows:

$$\phi_{k,w} = \frac{\exp(\psi_{k,w})}{\sum_w \exp(\psi_{k,w})} \quad s.t. \quad \sum_w \phi_{k,w} = 1. \quad (3)$$

The final loss function is :

$$\mathcal{L} = \sum_i^M \sum_j^N I_{ij}(R_{ij} - \hat{R}_{ij})^2 - \lambda_t \sum_d^N \sum_{n \in N_d} \log \theta_{d,z_{d,n}} \phi_{z_{d,n},w_{d,n}}, \quad (4)$$

where $\hat{R}_{ij}$ is predicted ratings, θ and ϕ are the topic and word distribution respectively, $w_{d,n}$ is the n-th word in document d and $z_{d,n}$ is the word's corresponding topic, λ_t is a regularization parameters.

4 The LTMF Model

We propose the LSTM-Topic matrix factorization (LTMF) model, which integrates LSTM and topic modeling for recommendation. The model utilizes both rating and review information. For the rating part, we use probabilistic matrix factorization to extract rating latent vectors. For the review part, we use LDA (following the way of HFT) to extract topic latent vectors and adopt an LSTM architecture to generate document latent vectors . Then we combine the three vectors into a unified model. The overview of LTMF model is shown in Figure 1.

4.1 Parameter Relation

The left of Figure 1 is the parameters relations in LTMF model, which can be divided into three parts: $\Theta = \{\mathcal{U}, \mathcal{V}\}$ is the parameters associated with rating MF, $\Phi = \{\theta, \phi\}$ is the parameters associated with topic model, $\Omega = \{W, l\}$ is the parameters associated with LSTM. The shaded nodes are data (R:rating, D: reviews) where the others are parameters. Single connection lines represent there are constraint relationship between the two nodes. Double connections (e.g. $\mathcal{V}$ and θ) mean the relationship is bidirectional so they can affect each other's results.

4.2 LSTM Architecture

The right of Figure 1 is the LSTM architecture used in our models. For the j-th item, we concatenate all of its reviews as one document se-

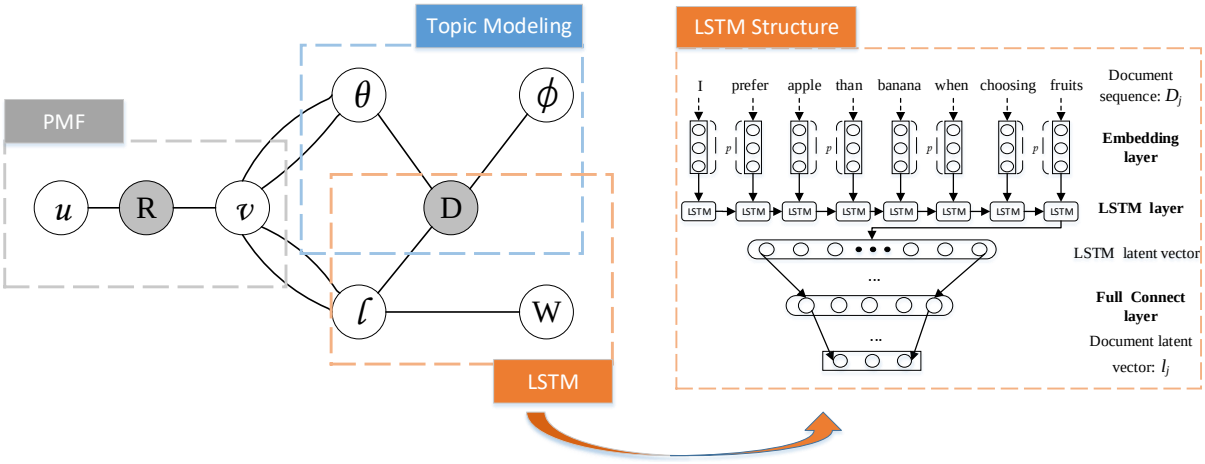

Figure 1: The overview of LTMF model. Left:Parameters relations of LTMF. Right:the detailed LSTM architecture.

quence D_j. Every word in the document sequence $D_j = (w_1, w_2, ..., w_{nj})$ will firstly be embedded into a p dimension vector. Next, word vectors are sent into LSTM network according to the word order in D_j and produces a latent vector. Finally, the latent vector is sent to a full connect layer whose output is the document latent vector l_j. The above process can be written as:

$$l_j = LSTM(D_j, W), \tag{5}$$

where D_j is the input document sequence, W represents weights and bias variables in LSTM network.

4.3 Probabilistic Prior

Gaussian distribution is the basic prior hypothesis in our model. We place zero-mean spherical Gaussian priors on user latent features u, LSTM weights W and observed ratings R. For item vector v, we place the Gaussian prior on its difference with LSTM output l_j :

$$p(v|l_j, \sigma_v^2) = \prod_{j=1}^{N} \mathcal{N}(v_j - l_j|0, \sigma_v^2 I)$$
$$= \prod_{j=1}^{N} \mathcal{N}(v_j|l_j, \sigma_v^2 I).$$

The function is important for connecting ratings and reviews. Although document vector l_j is closed to item feature vector v_j for they both reflect item's properties. There still exists some discrepancies. For example, when writing reviews, users usually write more about appearance and only briefly mention price. So in review based document vector l_j, the weight of "appearance" will be larger than rating based latent vector v_j. To preserve the discrepancy between v_j and l_j , we import the Gaussian noise vector σ_v as the offset.

4.4 Objective Function

Finally, we maximize the log-posterior of the three parts and get the objective function as follows:

$$\begin{aligned}\mathcal{L} = &\sum_{i}^{M}\sum_{j}^{N} I_{ij}(R_{ij} - u_i^T v_j)^2 \\ &- \lambda_t \sum_{d}^{N}\sum_{n\in N_d} \log \theta_{z_{d,n}} \phi_{z_{d,n},w_{d,n}} \\ &+ \lambda_u \sum_{i}^{M} \| u_i \|_F^2 + \lambda_v \sum_{j}^{N} \| v_j - l_j \|_F^2 \\ &+ \lambda_W \sum_{k}^{N_k} \| W_k \|_F^2,\end{aligned} \tag{6}$$

where N_k is the number of weighs in LSTM network, $\lambda_u, \lambda_v, \lambda_W$ are regularization parameters. z is the topic assignment for each word, λ_t is the regularization parameters to control the proportion of topic part.

The objective function of LTMF can be considered as an extended PMF model where the information from topic modeling and LSTM is included as regular terms. In the next section, we will explain how LTMF leverages the information from topic modeling and LSTM, and why LTMF can combine the information of the two parts.

4.5 The Effectiveness of LTMF

As shown in Figure 1, item vectors $\mathcal{V}$ connect with both topic part and LSTM part, which means the information from the two part will both affect the

result of item vectors. If we take partial derivative of Eq.(6) with respect to v_j, the constraint relationship can be clearer:

$$\frac{\partial \mathcal{L}}{\partial v_j} = \sum_{i=1}^{M} 2I_{ij}(R_{ij} - u_i^T v_j)u_i + 2\lambda_v(v_j - l_j) - \lambda_t \kappa \sum_{k=1}^{K}(n_{j,k} - N_j \frac{\exp(\kappa v_{j,k})}{\sum \exp(\kappa v_{j,k})}), \quad (7)$$

In Eq.(7), the optimization direction of v_j is subject to two regular terms. The former one is controlled by LSTM vector l_j. The latter one is controlled by topic parameters (κ, $n_{j,k}$, N_j). Hence, we can leverages the information from both LSTM and topic modeling for recommendation.

Besides, note the double connections between item vector $\mathcal{V}$ and topic distribution θ in Figure 1. They mean the information from topic modeling can affect the result of $\mathcal{V}$, while the change in $\mathcal{V}$ can also be passed to topic part and affect the review understanding result of topic modeling by Eq.2. For $\mathcal{V}$ and LSTM vector l, the analysis is the same. Indeed, item vectors $\mathcal{V}$ plays the role of transporter to connect LSTM part and topic modeling part. This is why LTMF can combine the information of topic modeling and LSTM to make a deeper understanding of user reviews.

Furthermore, LTMF provides an effective framework to integrate topic model with deep learning networks for recommendation. In experiments, we replace the LSTM part with CNN to make a comparison model. Experiments show both models boost the rating prediction accuracy.

4.6 Optimization

Our objective is to search:

$$\arg\min_{\Theta,\Phi,z,\kappa,\Omega} \mathcal{L}(\Theta, \Phi, z, \kappa, \Omega). \quad (8)$$

Recall that Θ is the parameters associated with ratings MF, Φ is the parameters associated with topic modeling, z is the topic assignment for each word, κ is the peakiness parameter to control the transformation between item vector v and topic distribution θ, Ω is the parameters associated with LSTM.

For v_j is coupled with the parameters of topic modeling and LSTM vector, we cannot optimize these parameters independently. We adopt a procedure that alternates between two steps. In each step we fix some parameters and optimize the others. The optimization process is shown below:

1. solve the objective by fixing z^t and Ω^t:
$$\arg\min_{\Theta,\Phi,\kappa} \mathcal{L}(\Theta, \Phi, z^t, \kappa, \Omega^t)$$
to update Θ^{t+1}, Φ^{t+1}, κ^{t+1}.

2. (a) update Ω^{t+1} with fixing ${v_j}^{t+1}$ and document sequence D_j.

   (b) sample $z_{d,j}^{t+1}$ with probability
$$p(z_{d,j}^{t+1} = k) = \phi_{k,w_{d,j}}^{t+1}.$$

In the step 1, we fix z and Ω to update remaining terms Θ, Φ, κ by L-BFGS algorithm. In the step 2, we fix Θ, Φ and κ to update LSTM parameters Ω and topic model parameters z. Since LSTM part and topic part are independent when item vectors $\mathcal{V}$ are certain, we can update the two term respectively. In step 2(a), we update Ω by back propagation algorithm. With fixing the other parameters, the objective function of W can be seen as a weighted squared error function ($\| v_j - l_j \|_F^2$) with L_2 regularized terms ($\| W \|_F^2$), which means we can use D_j as the input and v_j is the label to run the back propagation process. In step 2(b), we iterates through all documents and each word within to update $z_{d,j}$ via Gibbs Sampling. The reason why we do not divide the process into three steps is that the step 2(a) and 2(b) are independent with step 1 finished, which means we can parallelize the two steps.

Finally, we repeat these two steps until convergence. In practice, we run the step 1 with 5 gradient iterations using LBFGS, then we iterate the LSTM part 5 times. At the same time, we update the topic model part once. The whole process is called a cycle, and it usually takes 30 cycles to reach a local optimum.

In addition to the gradient of v_j, the gradients of other parameters used in step 1 are listed as follows:

$$\frac{\partial \mathcal{L}}{\partial u_i} = \sum_{j=1}^{N} 2I_{ij}(R_{ij} - u_i^T v_j)v_j + 2\lambda_u u_i. \quad (9)$$

$$\frac{\partial \mathcal{L}}{\partial \psi} = -\lambda_t \sum_{w=1}^{N_w} \sum_{k=1}^{K} \left(n_{k,w} - N_k \frac{\exp(\psi_{k,w})}{z_w} \right) \quad (10)$$

$$\frac{\partial \mathcal{L}}{\partial \kappa} = -\lambda_t \sum_{j=1}^{N} \sum_{k=1}^{K} v_{j,k} \left(n_{jk} - N_j \frac{\exp(\kappa v_{j,k})}{z_j} \right). \quad (11)$$

where ψ is used to determine word distribution ϕ by Eq.(3); $n_{k,w}$ is the number of times that word

w occurs in topic k; N_w is the word vocabulary size of the document corpus; N_k is the number of words in topic k; $n_{j,k}$ is the number of times when topic k occurs in the document of item j; N_j is the total number of words in document j; z_w and z_j are the corresponding normalizers:

$$z_w = \sum_{k=1}^{K} \exp(\psi_{k,w}), \quad z_j = \sum_{k=1}^{K} \exp(\kappa v_{j,k}).$$

5 Experiment

5.1 Datasets

We use the real-world Amazon dataset[1] (collected by McAuley et al. (2015)) for our experiments. For the original dataset is too large, we choose 10 sub datasets in experiments. To increase data density, we remove users which have less than 3 ratings. For raw review texts, we adopt the same preprocessing methods as ConvMF[2]: set the maximum length of a item document to 300; remove common stop words and document specific words which have document frequency higher than 0.5; choose top 8000 distinct words as the vocabulary; remove all non-vocabulary words to construct input document sequences. After preprocessing, the statistics of datasets are listed in Table 1, where the abbreviations of datasets are shown in parentheses.

5.2 Evaluation Procedure

5.2.1 Baseline

The baselines used in our experiments are listed as follows:

- PMF: Probabilistic Matrix Factorization (PMF) (Mnih and Salakhutdinov, 2008) is a standard matrix factorization model for RSs. It only uses rating information.

- HFT: This is a state-of-art method that combines reviews with ratings (McAuley and Leskovec, 2013). It utilizes LDA to capture unstructured textual information in reviews.

- ConvMF: Convolutional Matrix Factorization (ConvMF) (Kim et al., 2016) is a recently proposed recommendation model. It utilizes CNN to capture contextual information of item reviews.

- LMF: LSTM Matrix Factorization (LMF) is a submodel of LTMF without the topic part. We can compare it with ConvMF to show the effectiveness of LSTM than CNN on review understanding.

- CTMF: We modify the LTMF model by replacing the LSTM part with CNN (following the structure of ConvMF) and construct the comparison model CNN-Topic Matrix Factorization (CTMF). CTMF can be used to evaluate the effectiveness of combining deep learning and topic modeling.

In experiments, we randomly split one dataset into training set, test set, validation set under proportions of 80%, 10%, 10%, where each user and item appears at least once in the training set. We use Mean Square Error (MSE) as metric to evaluate various models.

Table 2: MSE results of various models (K=5). The best results are highlighted in bold. The standard deviations of MSE results are shown in parenthesis.

5.2.2 Implementation Details

For all models, we set the dimension of user and item latent vectors $K = 5$, and initialize the vectors randomly between 0 and 1. Topic number and the dimension of document latent vector l are also set to 5. For methods using deep learning, we initialized word latent vectors randomly with the embedding dimension $p = 200$. The optimization algorithm used in back propagation is *rmsprop* and the activation function used in fully connected layer is *tanh* . In LSTM network, we set the output dimension to 128 and dropout rate 0.2. For CTMF, we adopt the same setting as ConvMF where the sliding window sizes is $\{3, 4, 5\}$ and the shared weights per window size is 100.

Hyper parameters are set as follows. For PMF, $\lambda_u = \lambda_v = 0.1$. For HFT, we select $\lambda_t \in \{1, 5\}$ which gives better result in each experiment. For LMF and ConvMF, we set $\lambda_u = 0.1$ and $\lambda_v = 5$. For LTMF and CTMF, we select $\lambda_t \in \{0.05, 0.1, 0.5\}$ which gives the lowest validation set error.

5.3 Quantitative analysis of rating prediction

We evaluate these models and report the lowest test set error on each dataset. The MSE results are shown in Table 2 where the best result of each dataset is highlighted in bold and the standard deviations of corresponding MSE are recorded in parenthesis.

We can see that the **LTMF model consistently outperform these baselines on all datasets** . This clearly confirms the effectiveness of our proposed method. To make a more intuitive comparison, the improvement histograms of these models are shown in Figure 2.

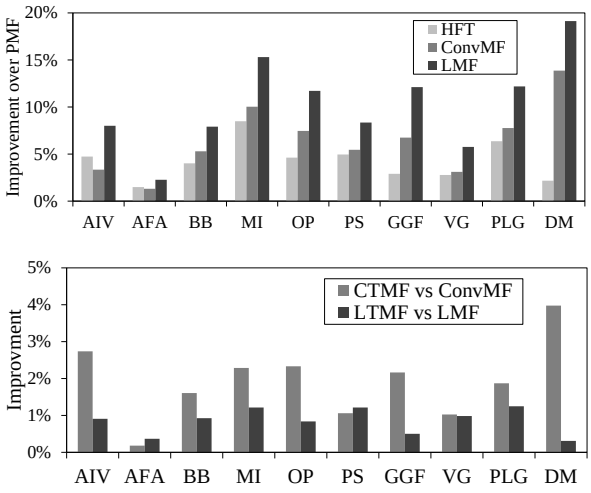

Figure 2: Above: Improvements of HFT, ConvMF and LMF, compared with PMF on different datasets. Below: Improvements of CTMF and LTMF, compared with ConvMF and LMF respectively.

The figure above are the improvements of HFT, ConvMF and LMF compared with PMF on different datasets, where PMF only uses rating information and the other three use both rating and review information with different approaches. We observe that all three methods make significant improvements over PMF, which indicates review information is helpful to model user and item features as well as improve recommendation results. Compared with HFT, LMF makes over 3% improvement on 9 out of the 10 datasets. ConvMF performs better than HFT while LMF still obtains over 3% improvement than ConvMF on 7 datasets. The differences between HFT, ConvMF and LMF can be attributed to their individual methods for re-

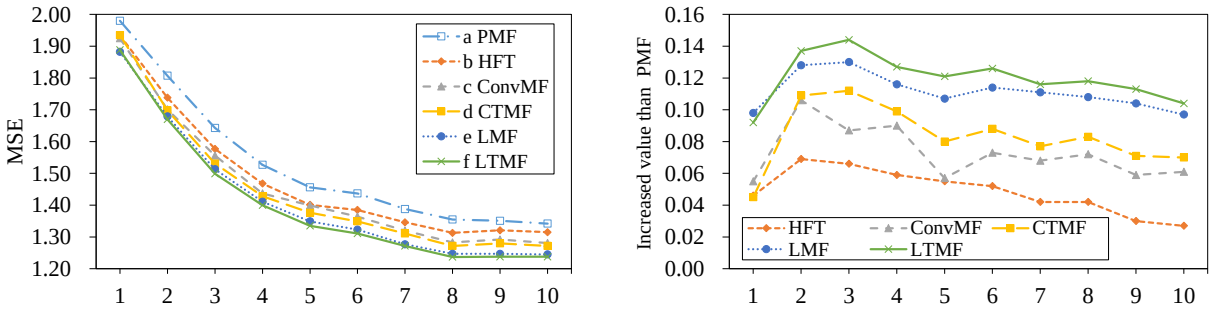

Figure 3: Results for recommendation within limited ratings and reviews. Left: the MSE values of all models. Right: the incerase compared with PMF.

views understanding. As mentioned in Section 1, Topic Modeling based HFT only considers the co-existence of words in texts and ignores structural context information. CNN based ConvMF lacks the ability to capture global context information due to the size limitation of sliding windows. This is exactly what LSTM possesses and why LSTM based LMF model outperforms ConvMF.

The figure below is the comparison of two integrated models (LTMF and CTMF) that import topic information with two original models that only use deep learning (LMF and ConvMF). We can see that both integrated models outperform the original models, which confirms our conjecture that **recommendation results can be improved by combining structural and unstructured information**. For CTMF model, it makes over 2% improvement on 5 out of 10 datasets compared with ConvMF. As to LTMF model, it achieves nearly 1% improvements that LMF on 7 out of 10 datasets.

The reason why LTMF gains less promotion can be explained from two sides. Numerically, for the comparison model LMF is already a strong baseline proposed by ourselves, it's more difficult to make a significant improvement. Theoretically, since LSTM can persist enough global information when the input sentence is relatively short, the supplements of topic information in LTMF are not so remarkable. As an illustration, we can compare the results on datasets "DM" and "VG". For the dataset "DM", as shown in Table 1, it has the fewest words per item (38.79) and the improvement of LTMF is minimum. But for the dataset "VG", it has the most words per item (92.55). The global context information obtained by LSTM will still decrease with such long sentences, and the topic information can make an effective supplement. So the improvement of LTMF on "VG" is greater and comparable with CTMF.

5.4 Recommendation with different data sparsity

Rating data and review data are always sparse in RSs. To compare these models on making recommendation in different data sparsity, especially for new users who only have limited ratings, we choose the dataset "Baby" and refilter it to make sure every user has at least N ratings (N varies from 1 to 10). A greater N means the user has rated more items, so the data sparsity problem is weaker. We test all models on the 10 subsets of "Baby" with the same dataset split ratio and text preprocessing. The final results are shown in Figure 3, where the left one is the MSE values of all models, and the right one is the increase of the other models compared with PMF.

We can observe that all models gain better recommendation accuracy with the increment of user rating number N. In other words, user and item latent features can be better extracted with more useful information. When N is small, especially when $N = \{2, 3\}$, the models which utilize both review and rating information achieve biggest improvements over PMF. It suggests that **review information can provide effective supplement when rating data is scarce**. With the increase of N, the improvements of all review used models become smaller. This is because models can extract more features from gradually dense ratings data, and the effectiveness of review data begins to decrease. Same as the previous experiment, our LTMF model achieve the best results in the comparison with other models.

5.5 Qualitative Analysis

In HFT, the result of topic words only depends on the information from Topic Modeling. But in our

proposed LTMF framework, the information extracted by LSTM and Topic Modeling will both affect the final word clustering results. So, we can compare the topic words discovered by HFT and LTMF to evaluate whether combing LSTM and Topic Modeling is able to make a better understanding of user reviews.

We choose the dataset "Office Product" (OP) and show the top topic words of HFT and LTMF in Table 3 and Table 4. As we can see, there are many words existed in both tables (e.g. "wallet", "notebooks", "document"). These words are closely related to the category of dataset "Office Product", which implies both models can get a good interpretation of user reviews.

However, when we carefully compare the two tables, there exists some differences. In Table 3, there are some adjectives and verbs which have little help for topic clustering (e.g. "nice", "huge", "attach"), but they still get large weights and appear in the front of topic words list. Obviously, HFT misinterprets these words for they usually appear together with the real topic words. In Table 4, we are not able to find them in top words list, because extra information from LSTM makes a timely supplement. Besides, similar situations also occur on words "document" and "compatible". The word "document" is an apparent topic word, so LTMF gives it a larger weight in topic words list. For the word "compatible", as an adjectives, it can provide less topic information than nouns, so LTMF decreases its weight and put "camera" in the second place. From the above analysis we can see LTMF shows the better topic clustering ability than HFT.

6 Conclusion and Future Work

In this paper, we investigate the approach to effectively utilize review information for RSs. We propose the LTMF model which integrates both LSTM and Topic modeling in context aware recommendation. In the experiments, our LTMF model outperforms HFT and ConvMF in rating prediction especially when the data is sparse. Furthermore, LTMF shows better ability on making topic clustering than traditional topic model based method HFT, which implies integrating the information from deep learning and topic modeling is a meaningful approach to make a better understanding of reviews. In the future, we plan to evaluate more complex networks for recommendation tasks under the framework proposed by LTMF. Besides, we are interested to apply the method of combing topic model and deep learning into some traditional NLP tasks.

Abstract

NLP algorithms are increasingly used in computational social science to take linguistic observations and predict outcomes like human preferences or actions. Making these social models transparent and interpretable often requires identifying features in the input that predict outcomes while also controlling for potential confounds. We formalize this need as a new task: inducing a lexicon that is predictive of a set of target variables yet uncorrelated to a set of confounding variables. We introduce two deep learning algorithms for the task. The first uses a bifurcated architecture to separate the explanatory power of the text and confounds. The second uses an adversarial discriminator to force confound-invariant text encodings. Both elicit lexicons from learned weights and attentional scores. We use them to induce lexicons that are predictive of timely responses to consumer complaints (controlling for product), enrollment from course descriptions (controlling for subject), and sales from product descriptions (controlling for seller). In each domain our algorithms pick words that are associated with *narrative persuasion*; more predictive and less confound-related than those of standard feature weighting and lexicon induction techniques like regression and log odds.

1 Introduction

Applications of NLP to computational social science and data science increasingly use *lexical features* (words, prefixes, etc) to help predict non-linguistic outcomes like sales, stock prices, hospital readmissions, and other human actions or preferences. Lexical features are useful beyond predictive performance. They enhance interpretability in machine learning because practitioners know why their system works. Lexical features can also be used to understand the subjective properties of a text.

For social models, we need to be able to select lexical features that predict the desired outcome(s) while also controlling for potential confounders. For example, we might want to know which words in a product description lead to greater sales, regardless of the item's price. Words in a description like "luxury" or "bargain" might increase sales but also interact with our confound (price). Such words don't reflect the *unique* part of text's effect on sales and should not be selected. Similarly, we might want to know which words in a consumer complaint lead to speedy administrative action, regardless of the product being complained about; which words in a course description lead to higher student enrollment, regardless of the course topic. These instances are associated with *narrative persuasion*: language that is responsible for altering cognitive responses or attitudes (Spence, 1983; Van Laer et al., 2013).

In general, we want words which are predictive of their targets yet decorrelated from confounding information. The lexicons constituted by these words are useful in their own right (to develop causal domain theories or for linguistic analysis) but also as interpretable features for down-stream modeling. Such work could help widely in applications of NLP to tasks like linking text to sales figures (Ho and Wu, 1999), to voter preference (Luntz, 2007; Ansolabehere and Iyengar, 1995), to moral belief (Giles et al., 2008; Keele et al., 2009), to police respect (Voigt et al., 2017), to financial outlooks (Grinblatt and Keloharju, 2001; Chatelain and Ralf, 2012), to stock prices (Lee et al., 2014), and even to restaurant health inspections (Kang et al., 2013).

Identifying linguistic features that are indicative of such outcomes and decorrelated with confounds is a common activity among social scientists, data scientists, and other machine learning practitioners. Indeed, it is essential for developing transpar-

Proceedings of NAACL-HLT 2018, pages 1615–1625
New Orleans, Louisiana, June 1 - 6, 2018.

ent and interpretable machine learning NLP models. Yet there is no generally accepted and rigorously evaluated procedure for the activity. Practitioners have conducted it on a largely ad-hoc basis, applying various forms of logistic and linear regression, confound-matching, or association quantifiers like mutual information or log-odds to achieve their aims, all of which have known drawbacks (Imai and Kim, 2016; Gelman and Loken, 2014; Wurm and Fisicaro, 2014; Estévez et al., 2009; Szumilas, 2010).

We propose to overcome these drawbacks via two new algorithms that consider the causal structure of the problem. The first uses its architecture to learn the part of the text's effect which the confounds cannot explain. The second uses an adversarial objective function to match text encoding distributions regardless of confound treatment. Both elicit lexicons by considering learned weights or attentional scores. In summary, we

1. Formalize the problem into a new task.
2. Propose a pair of well-performing neural network based algorithms.
3. Conduct the first systematic comparison of algorithms in the space, spanning three domains: consumer complaints, course enrollments, and e-commerce product descriptions.

The techniques presented in this paper will help scientists (1) better interpret the relationship between words and real-world phenomena, and (2) render their NLP models more interpretable[1].

2 Deconfounded Lexicon Induction

We begin by formalizing this language processing activity into a task. We have access to text(s) T, target variable(s) Y, and confounding variable(s) C. The goal is to pick a lexicon L such that when words in T belonging to L are selected, the resulting set $L(T)$ is related to Y but not C. There are two types of signal at play: the part of Y that T can explain, and that explainable by C. These signals often overlap because language reflects circumstance, but we are interested in the part of T's explanatory power which is *unique* to T, and hope to choose L accordingly.

So if $\text{Var}\left[\mathbb{E}\left[Y|L(T), C\right]\right]$ is the information in Y explainable by both $L(T)$ and C, then our goal is to choose L such that this variance is maximized *after* C has been fixed. With this in mind, **we formalize the task of deconfounded lexicon induction as finding a lexicon L that maximizes an *informativeness coefficient***,

$$\mathcal{I}(L) = \mathbb{E}\left[\text{Var}\left[\mathbb{E}\left[Y\middle|L(T),\, C\right]\middle|C\right]\right], \quad (1)$$

which measures the explanatory power of the lexicon beyond the information already contained in the confounders C. Thus, highly informative lexicons cannot simply collect words that reflect the confounds. Importantly, this coefficient is only valid for comparing different lexicons of the same size, because in terms of maximizing this criterion, using the entire text will trivially make for the best possible lexicon.

Our coefficient $\mathcal{I}(L)$ can also be motivated via connections to the causal inference literature: in Section 7, we show that—under assumptions often used to analyze causal effects in observational studies—the coefficient $\mathcal{I}(L)$ can correspond exactly to the strength of T's causal effects on Y.

Finally, note that by expanding out an ANOVA decomposition for Y, we can re-write this criterion as

$$\begin{aligned}\mathcal{I}(L) = \mathbb{E}\left[\left(Y - \mathbb{E}\left[Y\middle|C,\, L(T)\right]\right)^2\right] \\ - \mathbb{E}\left[\left(Y - \mathbb{E}\left[Y\middle|C\right]\right)^2\right],\end{aligned} \quad (2)$$

i.e., $\mathcal{I}(L)$ measures the performance improvement $L(T)$ affords to optimal predictive models that already have access to C. We use this fact for evaluation in Section 4.

3 Proposed Algorithms

We continue by describing the pair of novel algorithms we are proposing for deconfounded lexicon induction problems.

3.1 Deep Residualization (DR)

Motivation. Our first method is directly motivated by the setup from Section 2. Recall that $\mathcal{I}(L)$ measures the amount by which $L(T)$ can improve predictions of Y made from the confounders C. We accordingly build a neural network architecture that first predicts Y directly from C as well as possible, and then seeks to fine-tune those predictions using T.

Description. First we pass the confounds through a feed-forward neural network (FFNN) to obtain

[1]Code, hyperparameters, and instructions for practitioners are online at https://nlp.stanford.edu/projects/deconfounded-lexicon-induction/

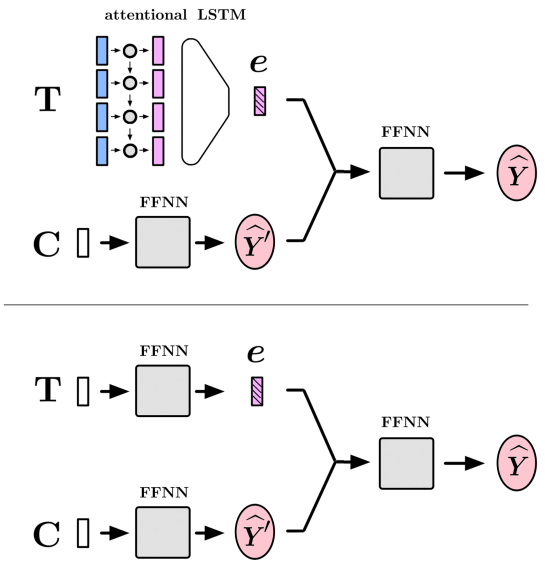

Figure 1: The Deep Residualization (DR) selector. Values which are used to calculate losses are enclosed in red ovals. *Top*: DR+ATTN, which represents text as a sequence of word embeddings. *Bottom*: DR+BOW, which represents text as a vector of word frequencies.

preliminary predictions $\hat{Y}'$. We also encode the text into a continuous vector $\boldsymbol{e} \in \mathcal{R}^d$ via two alternative mechanisms:

1. DR+ATTN: the text is converted into a sequence of embeddings and fed into Long Short-Term Memory (LSTM) cell(s) (Hochreiter and Schmidhuber, 1997) followed by an attention mechanism inspired by Bahdanau et al. (2015). If the words of a text have been embedded as vectors $\boldsymbol{x}_1$, $\boldsymbol{x}_2$, ..., $\boldsymbol{x}_n$ then $\boldsymbol{e}$ is calculated as a weighted average of hidden states, where the weights are decided by a FFNN whose parameters are shared across timesteps:

$$\begin{aligned}
\boldsymbol{h}_0 &= \vec{0} \\
\boldsymbol{h}_t &= LSTM(\boldsymbol{x}_t, \boldsymbol{h}_{t-1}) \\
l_t &= ReLU(\boldsymbol{W}^{attn}\boldsymbol{h}_t) \cdot \boldsymbol{v}^{attn} \\
p_t &= \frac{exp(l_t)}{\sum exp(l_i)} \\
\boldsymbol{e} &= \sum p_i \boldsymbol{h}_i
\end{aligned}$$

2. DR+BOW: the text is converted into a vector of word frequencies, which is compressed with a two-layer feedforward neural network (FFNN):

$$\begin{aligned}
\boldsymbol{t} &= [freq_1, freq_2, ..., freq_k] \\
\boldsymbol{h} &= ReLU(\boldsymbol{W}^{hidden}\boldsymbol{t}) \\
\boldsymbol{e} &= ReLU(\boldsymbol{W}^{output}\boldsymbol{t})
\end{aligned}$$

We then concatenate $\boldsymbol{e}$ with $\hat{Y}'$ and feed the result through another neural network to generate final predictions $\hat{Y}$. If Y is continuous we compute loss with

$$\mathcal{L}_{continuous} = ||\hat{Y} - Y||_2$$

If Y is categorical we compute loss with

$$\mathcal{L}_{categorical} = -p^* \log \widehat{p^*}$$

Where $\widehat{p^*}$ corresponds to the predicted probability of the correct class. The errors from $\hat{Y}$ are propagated through the whole model, but the errors from $\hat{Y}'$ are only used to train its progenitor (Figure 1).

Note the similarities between this model and the popular residualizing regression (RR) technique (Jaeger et al., 2009; Baayen et al., 2010, inter alia). Both use the text to improve an estimate generated from the confounds. RR treats this as two separate regression tasks, by regressing the confounds against the variables of interest, and then using the residuals as features, while our model introduces the capacity for nonlinear interactions by backpropagating between RR's steps.

Lexicon Induction. We elicit lexicons from +ATTN style models by (1) running inference on a test set, but rather than saving those predictions, saving the attentional distribution over each source text, and (2) mapping each word to its average attentional score and selecting the k highest-scoring words.

For +BOW style models, we take the matrix that compresses the text's word frequency vector, then score each word by computing the l_1 norm of the column that multiplies it, with the intuition that important words are dotted with big vectors in order to be a large component of $\boldsymbol{e}$.

3.2 Adversarial Selector (A)

Motivation. We begin by observing that a desirable L can explain Y, but is unrelated to C, which implies it should should struggle to predict C. The Adversarial Selector draws inspiration from this.

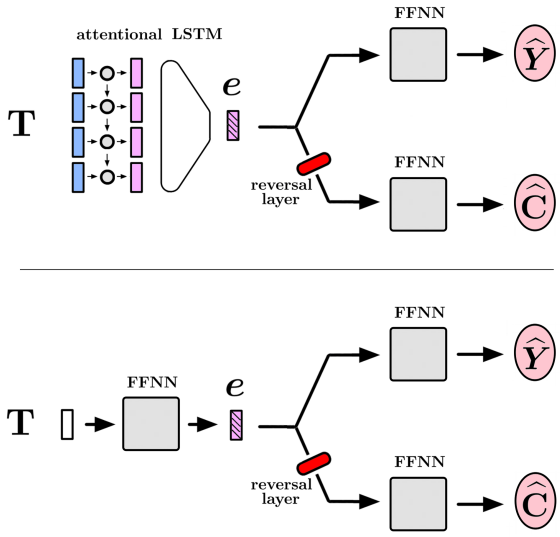

Figure 2: The Adversarial (A) selector. Values which are used to calculate losses are enclosed in red ovals. *Top*: A+ATTN, which represents text as a sequence of word embeddings. *Bottom*: A+BOW, which represents text as a vector of word frequencies.

It learns adversarial encodings of T which are useful for predicting Y, but *not* useful for predicting C. It is depicted in Figure 2.

Description. First, we encode T into $\boldsymbol{e} \in \mathcal{R}^d$ via the same mechanisms as the Deep Residualizer of Section 3.1. $\boldsymbol{e}$ is then passed to a series of FFNNs ("prediction heads") which are trained to predict each target and confound with the same loss functions as that of Section 3.1. As gradients backpropagate from the confound prediction heads to the encoder, we pass them through a *gradient reversal layer* in the style of Ganin et al. (2016) and Britz et al. (2017), which multiplies gradients by -1. If the cumulative loss of the target variables is $\mathcal{L}_t$ and that of the confounds is $\mathcal{L}_c$, then the loss which is implicitly used to train the encoder is $\mathcal{L}_e = \mathcal{L}_t - \mathcal{L}_c$, thereby encouraging the encoder to learn representations of the text which are not useful for predicting the confounds.

Lexicons are elicited from this model via the same mechanism as the Deep Residualizer of Section 3.1.

4 Experiments

We evaluate the approaches described in Sections 3 and 5 by generating and evaluating deconfounded lexicons in three domains: financial complaints, e-commerce product descriptions, and course descriptions. In each case the goal is to find words which can *always* help someone net a positive outcome (fulfillment, sales, enrollment), regardless of their situation. This involves finding words associated with *narrative persuasion*: predictive of human decisions or preferences but decorrelated from non-linguistic information which could also explain things. We analyze the resulting lexicons, especially with respect to the classic Aristotelian modes of persuasion: logos, pathos, and ethos.

We compare the following algorithms: **R**egression (R), **R**egression with **C**onfound features (RC), **M**ixed effects Regression (M), **R**esidualizing **R**egressions (RR), Log-**O**dds **R**atio (OR), **M**utual **I**nformation (MI), and MI/OR with regresssion (R+MI and R+OR). See Section 5 for a discussion of these baselines, and the online supplementary information for implementation details. We also compare the proposed algorithms: **D**eep **R**esidualization using word frequencies (DR+BOW) and embeddings (DR+ATTN), and **A**dversarial Selection using word frequencies (A+BOW) and embeddings (A+ATTN).

In Section 2 we observed that $\mathcal{I}(L)$ measures the improvement in predictive power that $L(T)$ affords a model already having access to C. Thus, we evaluate each algorithm by (1) regressing C on Y, (2) drawing a lexicon L, (3) regressing $C + L(T)$ on Y, and (4) measuring the size of gap in test prediction error between the models of step (1) and (3). For classification problems, we measured error with cross-entropy (XE):

$$XE = -\sum_i p_i \log \hat{p}_i$$

$$\text{performance} = XE_C - XE_{L(T),C}$$

And for regression, we computed the mean squared error (MSE):

$$MSE = \frac{1}{n}\sum_i (\hat{Y}_i - Y_i)^2$$

$$\text{performance} = MSE_C - MSE_{L(T),C}$$

Because we fix lexicon size but vary lexicon content, lexicons with good words will score highly under this metric, yielding the large performance improvements when combined with C.

We also report the average strength of association between words in L and C. For categorical confounds, we measure Cramer's V (V) (Cramér, 2016), and for continuous confounds, we use the

point-biserial correlation coefficient (r_{pb}) (Glass and Hopkins, 1970). Note that r_{pb} is mathematically equivalent to Pearson correlation in bivariate settings. Here the best lexicons will score the lowest.

We implemented neural models with the Tensorflow framework (Abadi et al., 2016) and optimized using Adam (Kingma and Ba, 2014). We implemented linear models with the scikit learn package (Pedregosa et al., 2011). We implemented mixed models with the lme4 R package (Bates et al., 2014). We refer to the online supplementary materials for per-experiment hyperparameters.

For each dataset, we constructed vocabularies from the 10,000 most frequently occurring tokens, and randomly selected 2,000 examples for evaluation. We then conducted a wide hyperparameter search and used lexicon performance on the evaluation set to select final model parameters. We then used these parameters to induce lexicons from 500 random train/test splits. Significance is estimated with a bootstrap procedure: we counted the number of trials each algorithm "won" (i.e. had the largest $error_C - error_{L(T),C}$). We also report the average performance and correlation of all the lexicons generated from each split. We ran these experiments using lexicon sizes of k = 50, 150, 250, and 500 and observed similar behavior. The results reported in the following sections are for $k = 150$, and the words in Tables 1, and 2, 3 are from randomly selected lexicons (other lexicons had similar characteristics).

4.1 Consumer Financial Protection Bureau (CFPB) Complaints

Setup. We consider 189,486 financial complaints publicly filed with the Consumer Financial Protection Bureau (CFPB)[2]. The CFPB is a product of Dodd-Frank legislation which solicits and addresses complaints from consumers regarding a variety of financial products: mortgages, credit reports, etc. Some submissions are handled on a timely basis (< 15 days) while others languish.

We are interested in identifying salient words which help push submissions through the bureaucracy and obtain timely responses, regardless of the specific nature of the complaint. Thus, our target variable is a binary indicator of whether the complaint obtained a timely response. Our confounds are twofold, (1) a categorical variable tracking the type of issue (131 categories), and (2) a categorical variable tracking the financial product (18 categories). For the proposed DR+BOW, DR+ATTN, A+BOW, and A+ATTN models, we set $|\boldsymbol{e}|$ to 1, 64, 1, and 256, respectively.

Results. In general, this seems to be a tractable classification problem, and the confounds alone are moderately predictive of timely response (XE_C = 1.06). The proposed methods appear to perform the best, and DR+BOW achieved the largest performance/correlation ratio (Figure 3).

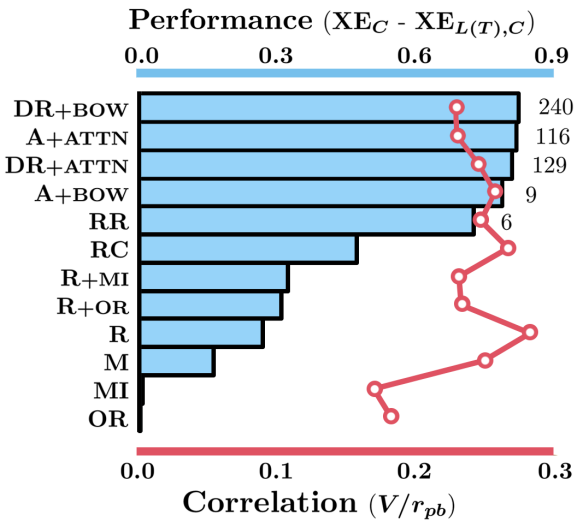

Figure 3: Predictive performance ($XE_C - XE_{L(T),C}$) and average confound correlation (V/r_{pb}) of lexicons generated via our proposed algorithms and a variety of methods in current use. The numbers to the right of each bar indicate the number of winning bootstrap trials.

Table 1: The ten highest-scoring words in lexicons generated by Deep Residualization + BOW (DR+BOW), Mutual Information (MI), Residialized Regression (RR), and regression (R).

[2]These data can be obtained from https://www.consumerfinance.gov/data-research/consumer-complaints/

We obtain further evidence upon examining the lexicons selected by four representative algorithms: proposed (DR+BOW), a well-performing baseline (RR), and two naive baselines (R, MI) (Table 1). MI's words appear unrelated to the confounds, but don't seem very persuasive, and our results corroborate this: these words failed to add predictive power over the confounds (Figure 3). On the opposite end of the spectrum, R's words appear somewhat predictive of the timely response, but are confound-related: they include the FDCPA (Fair Debt Collection Practices Act) and HIPAA (Health Insurance Portability and Accountability Act), which are directly related to the confound of financial product.

The top-scoring words in RR's lexicon include numbers ("6", "150.00") and words that suggest that the issue is ongoing ("being", "starting"). On the other hand, the words of DR+BOW draw on the rhetorical devices of ethos by respecting the reader's authority ("ma'am", "honor"), and logos by suggesting that the writer has been proactive about solving the issue ("multiple", "submitted", "xx/xx/xxx", "ago"). These are narrative qualities that align with two of the persuasion literature's "weapons of influence": reciprocation and commitment (Kenrick et al., 2005). Several algorithms implicitly favored longer (presumably more detailed) complaints by selecting common punctuation.

4.2 University Course Descriptions

Setup. We consider 141,753 undergraduate and graduate course offerings over a 6-year period (2010 - 2016) at Stanford University. We are interested in how the writing style of a description convinces students to enroll. We therefore choose log(enrollment) as our target variable and control for non-linguistic information which students also use when making enrollment decisions: course subject (227 categories), course level (26), number of requirements satisfied (7), whether there is a final (3), the start time, and the combination of days the class meets (26). All except start time are modeled as categorical variables. For the proposed DR+BOW, DR+ATTN, A+BOW, and A+ATTN models, we set $|e|$ to 1, 100, 16, and 64, respectively.

Results. This appears to be a tractable regression problem; the confounds alone are highly predictive of course enrollment (MSE_C = 3.67). (Figure 4). A+ATTN performed the best, and in general, the proposed techniques produced the most-predictive and least-correlated lexicons. Interestingly, Residualization (RR) and Regression with Confounds (RC) appear to outperform the Deep Residualization selector.

A+ATTN	R	OR
future	programming	summer
instructor	required	interpretation
eating	prerequisites	stability
or	computer	attitude
doing	management	optimization
guest	introduction	completion
sexual	chemical	during
culture	applications	labor
research	you	production
project	clinical	background

Table 2: The ten highest-scoring words in lexicons generated by Adversarial + ATTN (A+ATTN), Regression (R), and Log-Odds Ratio (OR).

In Table 2 we observe stark differences between the highest-scoring words of a proposed technique (A+ATTN) and two baselines with opposing characteristics (R, OR) (Table 2). Words chosen via Regression (R) appear predictive of enrollment, but also related to the confounds of subject ("programming", "computer", "management", "chemical", "clinical") and level ("required", "prerequisites", "introduction").

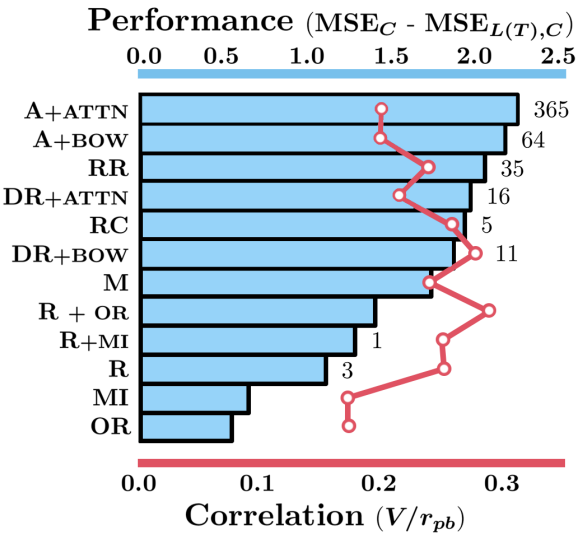

Figure 4: Course description comparative performance.

Log-Odds Ratio (OR) selected words which

大豆	*daizu*	soy	ミニ	*mini*	mini

Table 3: The ten highest-scoring words in lexicons generated by Adversarial Selection + BOW (A+BOW) and Residualization (RR).

appear unrelated to both the confounds and enrollment. The Adversarial Selector (A+ATTN) selected words which are both confound-decorrelated and predictive of enrollment. Its words appeal to the concept of variety ("or", "guest"), and to pathos, in the form of universal student interests ("future", "eating", "sexual"). Notably, the A+ATTN words are also shorter (mean length of 6.2) than those of R (9.3) and OR (9.0), which coincides with intuition (students often skim descriptions) and prior research (short words are known to be more persuasive in some settings (Pratkanis et al., 1988)). The lexicon also suggests that students prefer courses with research project components ("research", "project").

4.3 eCommerce Descriptions

Setup. We consider 59,487 health product listings on the Japanese e-commerce website Rakuten[3]. These data originate from a December 2012 snapshot of the Rakuten marketplace. They were tokenized with the JUMAN morphological analyzer (Kurohashi and Nagao, 1999).

We are interested in identifying words which advertisers could use to increase their sales, regardless of the nature of the product. Therefore, we set log(sales) as our target variable, and control for an item's price (continuous) and seller (207 categories). The category of an item (i.e. toothbrush vs. supplement) is not included in these data. In practice, sellers specialize in particular product types, so this may be indirectly accounted for. For the proposed DR+BOW, DR+ATTN, A+BOW, and A+ATTN models, we set $|e|$ to 4, 64, 4, and 30, respectively.

[3]These data can be obtained from https://rit.rakuten.co.jp/data_release/

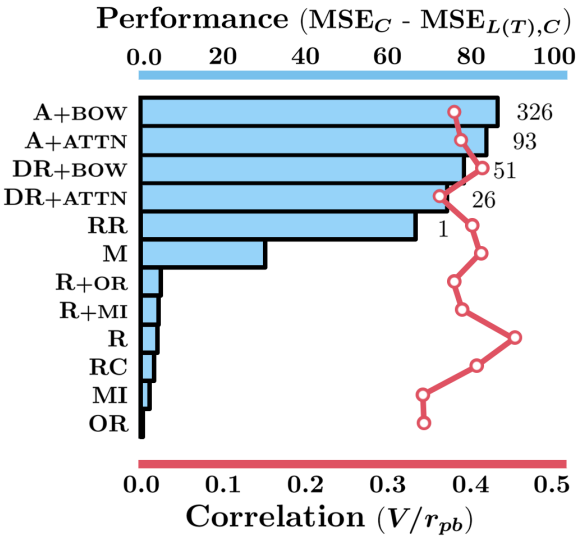

Figure 5: E-commerce comparative performance.

Results. This appears to be a more difficult prediction task, and the confounds are only slightly predictive of sales (MSE_C = 116.34) (Figure 5). Again, lexicons obtained via the proposed methods were the most successful, achieving the highest performance with the lowest correlation (Table 3). When comparing the words selected by A+BOW (proposed) and RR (widely used and well performing), we find that both draw on the rhetorical element of logos and demonstrate informativeness ("nutrition", "size", etc.). A+BOW also draws on ethos by identifying word stems associated with politeness. This quality draws on the authority of shared cultural values, and has been shown to appeal to Japanese shoppers (Pryzant et al., 2017). On the other hand, RR selected sev-

eral numbers and failed to avoid brand indicators: "nichiban", a large company which specializes in medical adhesives, is one of the highest-scoring words.

5 Related Work

There are three areas of related work which we draw on. We address these in turn.

Lexicon induction. Some work in lexicon induction is intended to help interpret the subjective properties of a text or make make machine learning models more interpretable, i.e. so that practitioners can know why their system works. For example, Taboada et al. (2011); Hamilton et al. (2016) induce sentiment lexicons, and Mohammad and Turney (2010); Hu et al. (2009) induce emotion lexicons. Practitioners often get these words by considering the high-scoring features of regressions trained to predict an outcome (McFarland et al., 2013; Chahuneau et al., 2012; Ranganath et al., 2013; Kang et al., 2013). They account for confounds through manual inspection, residualizing (Jaeger et al., 2009; Baayen et al., 2010), hierarchical modeling (Bates, 2010; Gustarini, 2016; Schillebeeckx et al., 2016), log-odds (Szumilas, 2010; Monroe et al., 2008), mutual information (Berg, 2004), or matching (Tan et al., 2014; DiNardo, 2010). Many of these methods are manual processes or have known limitations, mostly due to multicollinearity (Imai and Kim, 2016; Chatelain and Ralf, 2012; Wurm and Fisicaro, 2014). Furthermore, these methods have not been tested in a comparative setting: this work is the first to offer an experimental analysis of their abilities.

Causal inference. Our methods for lexicon induction have connections to recent advances in the causal inference literature. In particular, Johansson et al. (2016) and Shalit et al. (2016) propose an algorithm for counterfactual inference which bear similarities to our Adversarial Selector (Section 3.2), Imai et al. (2013) advocate a lasso-based method related to our Deep Residualization (DR) method (Section 3.1), and Egami et al. (2017) explore how to make causal inferences from text through careful data splitting. Unlike us, these papers are largely unconcerned with the underlying features and algorithmic interpretability. Athey (2017) has a recent survey of machine learning problems where causal modeling is important.

Persuasion. Our experiments touch on the mechanism of *persuasion*, which has been widely studied. Most of this prior work uses lexical, syntactic, discourse, and dialog interactive features (Stab and Gurevych, 2014; Habernal and Gurevych, 2016; Wei et al., 2016), power dynamics (Rosenthal and Mckeown, 2017; Moore, 2012), or diction (Wei et al., 2016) to study *discourse* persuasion as manifested in argument. We study *narrative* persuasion as manifested in everyday decisions. This important mode of persuasion is understudied because researchers have struggled to isolate the "active ingredient" of persuasive narratives (Green, 2008; De Graaf et al., 2012), a problem that the formal framework of deconfounded lexicon induction (Section 2) may help alleviate.

6 Conclusion

Computational social scientists frequently develop algorithms to find words that are related to some information but not other information. We encoded this problem into a formal task, proposed two novel methods for it, and conducted the first principled comparison of algorithms in the space. Our results suggest the proposed algorithms offer better performance than those which are currently in use. Upon linguistic analysis, we also find the proposed algorithms' words better reflect the classic Aristotelian modes of persuasion: logos, pathos, and ethos.

This is a promising new direction for NLP research, one that we hope will help computational (and non-computational!) social scientists better interpret linguistic variables and their relation to outcomes. There are many directions for future work. This includes algorithmic innovation, theoretical bounds for performance, and investigating rich social questions with these powerful new techniques.

7 Appendix: Causal Interpretation of the Informativeness Coefficient

Recall the definition of $\mathcal{I}(L)$:

$$\mathcal{I}(L) = \mathbb{E}\left[\text{Var}\left[\mathbb{E}\left[Y \middle| L(T),\, C\right] \middle| C\right]\right]$$

Here, we discuss how under standard (albeit strong) assumptions that are often made to identify causal effects in observational studies, we can interpret $\mathcal{I}(L)$ with $L(T) = T$ as a measure of the strength of the text's causal effect on Y.

Following the potential outcomes model of Rubin (1974) we start by imagining potential out-

comes $Y(t)$ corresponding to the outcome we would have observed given text t for any possible text $t \in \mathcal{T}$; then we actually observe $Y = Y(T)$. With this formalism, the causal effect of the text is clear, e.g., the effect of using text t' versus t is simply $Y(t') - Y(t)$.

Suppose that T, our observed text, takes on values in $\mathcal{T}$ with a distribution that depends on C. Let's also assume that the observed text T is independent of the potential outcomes $\{Y(t)\}_{t\in\mathcal{T}}$, conditioned on the confounders C (Rosenbaum and Rubin, 1983). So we know what would happen with any given text, but don't yet know which text will get selected (because T is a random variable). Now if we fix C and there is any variance remaining in $Y(T)$ (i.e. $\mathbb{E}\left[\text{Var}\left[Y(T)\middle|C, \{Y(t)\}_{t\in\mathcal{T}}\right]\right] > 0$) then the text has a causal effect on Y.

Now we assume that $Y(t) = f_c(t) + \epsilon$, meaning that the difference in effects of one text t relative to another text t' is always the same given fixed confounders. For example, in a bag of words model, this would imply that switching from using the word "eating" versus "homework" in a course description would always have the same impact on enrollment (conditionally on confounders). With this assumption in hand, then the causal effects of T, $\mathbb{E}\left[\text{Var}\left[Y(T)\middle|C, \{Y(t)\}_{t\in\mathcal{T}}\right]\right]$, matches $\mathcal{I}(L)$ as described in equation (1) (Imbens and Rubin, 2015). In other words, given the same assumptions often made in observational studies, the informativeness coefficient of the full, uncompressed text in fact corresponds to the amount of variation in Y due to the causal effects of T.

Detecting Denial-of-Service Attacks from Social Media Text: Applying NLP to Computer Security

Nathanael Chambers and **Ben Fry** and **James McMasters**

United States Naval Academy
nchamber@usna.edu

Abstract

This paper describes a novel application of NLP models to detect denial of service attacks using only social media as evidence. Individual networks are often slow in reporting attacks, so a detection system from public data could better assist a response to a broad attack across multiple services. We explore NLP methods to use social media as an *indirect* measure of network service status. We describe two learning frameworks for this task: a feed-forward neural network and a partially labeled LDA model. Both models outperform previous work by significant margins (20% F1 score). We further show that the topic-based model enables the first fine-grained analysis of how the public reacts to ongoing network attacks, discovering multiple "stages" of observation. This is the first model that both detects network attacks (with best performance) and provides an analysis of when and how the public interprets service outages. We describe the models, present experiments on the largest twitter DDoS corpus to date, and conclude with an analysis of public reactions based on the learned model's output.

1 Introduction

Distributed Denial of Service (DDoS) attacks have become more frequent and more severe in their impact. Coordinated attacks across several services are now common, yet there are fewer methods to detect multi-network events. Research into detecting and preventing single attacks focuses on *direct* evidence based on characteristics of a network itself, such as monitoring abnormal traffic. This paper instead investigates an aytpical source for multiple attacks with *indirect* evidence: social media text. Do users of attacked systems post on social media? What can be learned from comments? Can NLP learning models extract enough information from user posts to detect attacks? Previous work on attack detection with social media is sparse, and focused on detecting trending words. This paper is the first to learn models of language without 'attack' dictionaries and seed words. The goal is the real-time detection of attacks without network data. Our secondary goal is to illustrate NLP applications to computer security topics.

Research on information extraction from social media has shown that many types of events in the world can be reliably detected from the language that users post. Several approaches have been shown effective in identifying events like earthquakes (Sakaki et al., 2010), concerts and product releases (Ritter et al., 2012), and other natural disasters (Neubig et al., 2011). Detecting DDoS attacks is not too dissimilar from these goals. An attack is a real event in the world, and it takes a community by surprise. This paper thus adopts ideas from NLP, but applies them to the unique application of DDoS detection.

Social media is obviously not the only way (nor the most direct) to monitor network services and attacks. There are several commercial services that directly measure outages, such as norsecorp[1]. These perform *direct* monitoring of network response. We do not propose social media as a better alternative, but rather as an alternative that enhances direct monitoring. Social media also brings its own unique benefits. For instance, social media does not require a priori knowledge of which networks should be monitored. It can also help detect "soft" outages like slowdowns and account blockages, things that direct monitoring cannot always detect. Therefore, this paper is not suggesting a replacement, but rather a new source of valuable information. It is a monitoring architecture that is not constrained by a predefined list of services.

Our goal in using social media is driven by the

Proceedings of NAACL-HLT 2018, pages 1626–1635
New Orleans, Louisiana, June 1 - 6, 2018.

hypothesis that as a network attack unfolds, its users go through a series of observational stages that can be automatically learned and detected. The first stage is a state of confusion and basic symptom observation, as seen in the following real tweets from Twitter:

> *hey linode what's happening? I can't login, my servers are down and you don't reply on mails?*
>
> *is xbox live experiencing some issues?*

These tweets don't discuss an attack even though that is what was occurring. Later stages then develop into direct commentary as the community coelesces to a belief that an attack is the cause:

> *Breaking: Band of America website rumored to be under DDoS attack.*
>
> *Citi Bank & BofA under Massive DDoS attack*

We show that our proposed LDA-based model can effectively identify these stages. There is very little previous work in this area, and that which exists focuses entirely on the second stage. Ritter et al. (2015) proposed models that include hard-coded keywords like 'DDoS' and phrases like '<entity> is down'. Their work helped identify attacks with social media, but these identifications tend to be *after* the news has already reported it. Early symptoms that are discussed don't use words like 'DDoS' because the conclusion has not yet been drawn. We thus propose the first learning models that identify *early* attack discussions: the first is a neural network, and the second is a broader topic model that provides better insight into the evolution of an attack.

Finally, our last goal is to model the themes and topics that users notice during network attacks. This is a somewhat subjective analysis, but it is backed by an empirical model trained from real-world data. Not only do we empirically produce state-of-the-art results, 25% gains over previous work, we also show that our detection system learns topics of discussion previously uninvestigated in the security field.

The core contributions of this paper are as follows: (1) a *25% improvement* over previous work on attack detection, (2) we present the first neural network results on detecting network attacks from social media, (3) we present a partially labeled LDA model for detecting network attacks with state-of-the-art results, (4) the PLDA enables the first analysis of the evolution of an attack as seen through its users, and (5) we make available the largest list of historical DDoS attacks to date.

2 Previous Work

The most relevant line of research to this paper is *event extraction* from social media. Space prohibits describing all work; the major approaches vary in levels of supervision. Ritter et al. (2012) used a Latent Dirichlet Allocation model to identify events in text *without* labeled data. They showed you can cluster and extract events like concerts, movies, and performances into a calendar. General event detection from social media has continued in several threads (Benson et al., 2011; Popescu et al., 2011; Anantharam et al., 2015; Wei, 2016; Zhou et al., 2017). Guo et al. (2013) link tweets to news stories using an annotated dataset. Sakaki et al. (2010) detect earthquake events by monitoring tweets with keywords like 'earthquake'. This is similar in goal to our paper, but different in approach and brittle in its application. We crucially do *not assume* that users use known keywords and phrases.

We take inspiration from the thread of work on flu detection (Lamb et al., 2013; Broniatowski et al., 2013). Their work leverages mentions of an event ('caught', 'sick', 'flu'), and then uses human annotators to label these mentions as relevant to the desired event (flu). We also identify mentions of an event, but we crucially differ by *not knowing* event words a priori. We believe a typical user does not know what a DDoS attack is, so we cannot assume certain language will be used. A major contribution of this work is the first analysis of how the (perhaps uninformed) public perceives DDoS attacks as they occur.

The first work (to our knowledge) on attack detection from Twitter was Motoyama et al. (2010). They tracked a single phrase "X is down" and experimented with whether outages could be detected from its counts. They use a trend detection formula to notice increases of this one phrase to trigger an alert. We compare against this strong baseline later. The work by Kergl et al. (2016) uses social media to identify users who discuss zero-day exploits. While not directly related to the work in this paper, its success reinforces the hypothesis that social media contains useful data for computer security monitoring.

The main thread in this area is the learning model from Ritter et al. (Ritter et al., 2015) and follow-on work (Kergl, 2015; Chang et al., 2016). They proposed a weakly supervised learner to identify cybersecurity events from Twitter. They

Table 1: A sample of 10 DDoS events in our dataset. A 20 day span is collected around each attack date.

collected tweets that contain the word *'DDoS'*, and then collected a set of known network attack days. The known days provided a training set from which they trained this weakly-supervised classifier on the 'DDoS' tweets. An important constraint in their approach, similar to flu research, is the need to use a seed word(s). Seed words enable the collection of a very relevant training set, but it limits the system because it depends on social media posts to use these words, and more importantly, to actually know that a DDoS is happening. We instead hypothesize that attacks are preceded by users who first observe symptoms of the attack, and don't directly discuss a DDoS or use related attack words. Our analysis shows we match several orders of magnitude more tweets.

3 Datasets

We manually created a dataset of historical DDoS attacks that include the entity attacked and the date of attack. Most past attacks are difficult to identify hour ranges, so we used a full 24-hour day as our granularity. We included 6 attacks with sufficient volume from previous work (Ritter et al., 2015), but we grew this set to 50 attacks based on our own investigations into recent years, mostly through web search results for 'DDoS attacks'. Table 1 lists *some* of these for illustration of its diversity. The full list is at `www.usna.edu/Users/cs/nchamber/data/ddos/`

For each of these known attacks, we collected tweets that contained the attacked entity's name in a 20-day period: 17 days prior to the attack, 1 day on the attack, and 2 days following. We wanted a sufficient lead up to the attack to include previous work's trending model (Motoyama et al., 2010), and to provide non-attack days for evaluation. The days surrounding the known attack date are labeled NOT-ATTACK, and the attack day itself as ATTACK. Sometimes an attack lasted longer than a single day, in which case the days following were also labeled as ATTACK, as appropriate.

The historical attacks span the years 2012-2016. We split the data so that years 2012, 2015, and 2016 comprise the training set, 2013 is the development set, and the year 2014 is the test set only used for computing final experiment numbers. Splitting on years (rather than months or entities) guards against test set pollution into our training set. The evaluation on the 2014 test set is thus an unbiased experiment because nothing from the entire year is included in training. For the experiments, we use the union of training and development to train the final models that are then used to evaluate on the test year 2014. There are 200 test days in 2014, 50 in dev, and ˜500 in training.

The full dataset consists of 50 attack days over approximately 800 days and 2 million tweets. The only previous work on this area used seed words to pull out around 9-10 thousand tweets. Our dataset is *more than 2 orders of magnitude larger*. The reason is due to the larger number of attacks we collected, but notably our tweets are more diverse and varied because we don't require hard-coded target words and phrases to match.

Formally, the dataset is 800 labeled datums:

$$d_i = (Entity, Date, Tweets, Label) \quad (1)$$

where $d_i \in D$ and D is the set of all days. $Entity$ is the attacked network service, $Date$ is the calendar date, and $Tweets$ are all tweets on that date mentioning that entity. $Label$ is a binary variable: ATTACK or NOT-ATTACK. Even though the day following an attack often includes attack discussion, it is still labeled NOT-ATTACK. Only if the attack was ongoing is the next day labeled ATTACK.

4 Models

Two primary goals motivate the models we propose and evaluate. The first goal is the automatic classification of attack and non-attack events. We propose the first neural network for this task, and move on to a generative model based on topic models. We evaluate their relative performance and compare against baselines from prior work.

The second goal is a model that enables analysis of user behavior during the evolution of an attack. What do people notice? What do people focus on? These are important questions for the security community that NLP models can help answer. We present a brief subjective study using the generative model, show how learned topics change over time, and discuss the data's implications.

4.1 Task Formulation

As discussed in Section 3, our input is labeled datums: $d_i = (Entity, Date, Tweets, Label)$. Each datum in the training set has a known label of ATTACK or NOTATTACK based on our historical knowledge of which entities were attacked on which days. We thus formulate the task as a binary classification over 24 hour days. We train models with the labeled training set, and report final numbers on test. In order to tune parameters, we use the development set to run grid searches over the models' parameters. The test set was always excluded from these until the final experiments.

4.2 Logistic Regression

Our first baseline model is logistic regression with word-based features. The following were used:

Unigrams. All words in the tweets were lowercased and punctuation stripped.
Bigrams. All bigrams are included & lowercased. Start and stop symbols are used for tweet boundaries, and punctuation included as separate tokens.
Bigram/Trigram Patterns. Since we know the entity, we parameterize the entity's mention in each tweet, and build bigrams and trigrams around them. For instance, the phrase "reddit is slow" is included as a trigram feature "X is slow". This allows learning across instances, so "spamhaus is slow" is included as the same feature.

We use the Stanford CoreNLP toolkit with default settings to train the model. We removed all features that occurred only once. This model is referred to as **LogisticReg** below.

4.3 Neural Network Models

Neural networks have made significant advancements in many NLP areas. Two of the main reasons for this are (1) improved representation of the features, and (2) stacking of hidden layers provides a better data fit.

We experimented with two feed-forward neural networks using word embeddings. We first trained a simple one-layer neural network that is similar to logistic regression, but with embeddings as input (instead of frequency counts). This is the **Neural-1** model. We then trained a two-layer network with hidden layer h of size m, and a softmax output layer to the binary label task. This is the **Neural-2** model.

The input to both of these models is as a Continuous Bag of Words (CBOW) model (Mikolov et al., 2013). Unlike logistic regression, the only features input to the network are unigrams (a tweet's individual tokens). Each unigram u has a word embedding x_u of length n, and they are all input as a weighted average. The reader is referred to Mikolov (2013) for more CBOW background.

We do not use pre-trained word embeddings, but instead learn them from our data. The embedding values are initialized randomly $[0, 1]$ from the uniform distribution. We used DyNet as our modeling toolkit (Neubig et al., 2017).

Overfitting is often a problem with neural networks, and we quickly found our models doing so. We thus applied 0.5 dropout for regularization (Srivastava et al., 2014). We experimented with other dropout values but did not see reliable gains or losses, so kept it at the typical 0.5 value.

We trained other networks without word embeddings, but instead "one-hot vectors" where the vector is the size of the vocabulary. This model did not perform as well and required more memory, so we do not report its results. Additional hidden layers did not improve either, as expected from the observed overfitting.

4.4 Constrained Topic Modeling

While the neural models above improve over previous work and baselines, they are difficult to interpret what is actually learned. One of the applications of this paper is to analyze what people discuss during network attacks. The hidden layers and word embeddings are opaque and difficult from which to draw conclusions.

In contrast, a generative model that represents words explicitly as probability distributions allows for easier post-analysis. It also may generalize better to this task because training data is more sparse and noisy. While we have 2 million tweets, orders of magnitude more than previous work, this is still modest in size with 800 days. To make matters worse, the dataset is biased toward NOTATTACK. 95% of the training set is NOTATTACK, leaving few training instances that are actually labeled as ATTACK. As shown in the next section, the neural models tend to overfit to these small signals. Further, we observed that online discussions go through different stages (Section 5.4), and the neural model merges stages to its detriment.

We thus propose a model inspired by Latent Dirichlet Allocation (LDA) (Blei et al., 2003), but a model carefully designed to the unique applica-

tion at hand. For readers unfamiliar with LDA, the model can be thought of as a clustering algorithm, and an overview of LDA and its variants can be found in Blei's survey (Blei, 2012).

4.4.1 LDA for Security Events

A traditional LDA model can learn general topics on our dataset with the hope that attack topics bubble up. Our initial experiments found this to be insufficient and the non-attack days were full of distracting topics.

For the goal of analyzing attack discussion, we need to encourage the LDA model to learn attack-specific topics. We draw heavily from Labeled LDA (Ramage et al., 2009). Each word is assigned a topic as in standard LDA, but topics can have a known label from the document. This is relevant to this paper because we know which days are attacks (in training). Thus, when a tweet is on an attack day, we assign the tweet a label ATTACK, and bias the Labeled LDA learner to assign its words to an attack-related topic.

What labels do we have in our data? ATTACK and NOTATTACK labels are first, but we also know which entities are mentioned in tweets, providing labels to learn entity-specific topics. We can label a tweet about reddit as REDDIT, and bias the Labeled LDA algorithm to assign a reddit-specific topic. The following tweet is an example:

reddit isn't responding maybe DNS is wrong

This tweet mentions two entities (reddit and dns), and it occurs on a known attack day for reddit in training. This tweet thus has 3 labels (attack, reddit, dns). The tweet's tokens can draw from 1 of 3 topics, which is good but a bit constraining. One of the premises of this paper is that people discuss attacks on social media in a variety of ways (not just one topic). They might discuss hackers, the DDoS attack itself, or just general downtime. The vanilla Labeled LDA (Ramage et al., 2009) is then too strict, but there is a multi-topic extension in the Partially Labeled Dirichlet Allocation (PLDA) (Ramage et al., 2011). PLDA is a version that instead of having one topic per label, it learns N_l topics for each label l. For our example tweet, tokens can now be labeled with 1 of $\sum_l N_l$ topics. We use $N_{attack} = 5$ and $N_{reddit} = N_{dns} = 5$ in our experiments[2], so this tweet would sample from 15 topics.

[2]This is about reddit, but each company has its own 5 topics. Experiments have 40 companies for total 200 topics.

Formally, let a tweet be defined as a document d with words $w \in W_d$. Each document has a set of labels Λ. This set Λ always contains the BACKGROUND label to capture general twitter conversations. Further, if a network or company is mentioned in the document, Λ also contains the company's label (e.g., MICROSOFT). Finally, the label ATTACK is added to Λ if d is an attack day and W_d includes the attacked network's name. Each word $w \in d$ has a latent label l and a latent topic z_l. For readers familiar with plate diagrams, this diagram is shown in Figure 1. Readers will notice its similarity to Ramage et al. (2009) with the addition of a new β parameter and the important change that the attack label is *observed* in training, but *unobserved* in test. When observed (in training), we favor assigning words to attack topics. When unobserved, we want to dissuade but still allow for it when the text strongly favors attack topics. To this end, our PLDA differs from standard use in that ψ is generated from a non-symmetric dirichlet with hyperparameters $\boldsymbol{v}$ (a vector of length $\sum_l N_l$) defined as:

$$v_i = \begin{cases} \alpha, & \text{if } i \notin AttackTopics \\ \beta, & \text{if } i \in AttackTopics \ \ \& \ \ attack \notin \Lambda \\ \beta * 10, & \text{if } i \in AttackTopics \ \ \& \ \ attack \in \Lambda \end{cases}$$

This is a non-symmetric dirichlet prior that enables attack labels to be chosen (β) without an observed attack day. Every tweet must be able to sample from attack topics because we need to label future unknown (unlabeled) attacks. The PLDA in the literature assumes full labeling at all times, but our task is more difficult. When ATTACK is observed, its smoothing parameter's value is $\beta * 10$ because of our heightened certainty, rather than simply β when unobserved.

The number of attack topics N_a and background topics N_b was chosen empirically from dev set performance. For simplicity and to avoid overfitting, we chose a single number $M = 5$ of company topics $\forall_c \, N_c = M$ that is the same across all companies and also $N_{attack} = M$. Only N_b was varied in our parameter tuning stage to discover how many background topics were necessary.

Space prohibits a full mathematical description of PLDA, so we direct the reader to Ramage et al. (2011) for details. Those unfamiliar with the above formalities can think of it as a soft clustering of words that is accomplished through sampling.

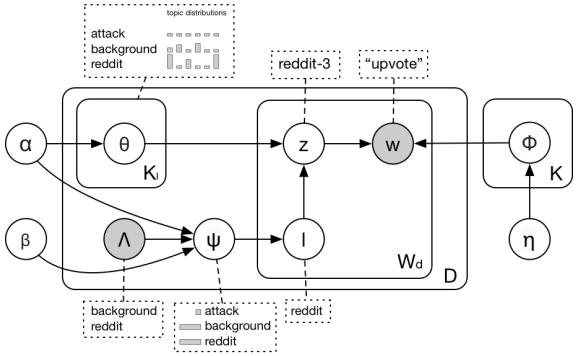

Figure 1: Plate diagram of the partially labeled topic model (PLDAttack). Dotted boxes are example values of a non-attack tweet discussing Reddit.

4.4.2 Inference and Classification

Inference in this model is performed with collapsed Gibbs sampling, sampling l and z_l in turn while holding all other variables constant. A single iteration requires looping over the entire dataset and assigning labels (topics) to each token on each day. We repeat this process until convergence of the joint probability of the model. After convergence, we hold distributions θ, ψ constant and run 20 more sampling iterations. Each word is then assigned the topic that was sampled the most in the 20 iterations.

Once sampling completes, this PLDAttack model provides us two very useful tools. First, the assigned topics enables us to use it as a classifier for our target task: DDoS detection from social media. Second, the topics themselves allow us to create timelines of discussions about DDoS attacks. This provides a higher-level analysis of what people say (Learned Topics).

With all words labeled, we want the model to make a prediction about an entity e on a given day d. Was the entity attacked[3]? We compute the probability of an attack using the labels themselves without any modification:

$$P(attack|d) = \frac{\sum_{w \in W_d} 1\{z_w \in Attack\}}{|W_d|} \quad (2)$$

where $|W_d|$ is the number of words in all tweets on day d and $Attack$ is the set of attack topics. $1\{x\}$ is the indicator function. If this probability is greater than a threshold, the entity/day is labeled as an attack. Otherwise, it is not an attack.

The cutoff threshold depends on a typical probability that is assigned to tweets, and how frequent an entity is actually mentioned on a given day. We use the development set to identify the optimal cutoff to maximize our F1 score.

[3]Or, is the entity currently under attack? This paper is an early detection attempt, leaving live-tracking to future work.

5 Evaluation and Results

All experiments are conducted on the dataset described in Datasets. The task is a binary classification of ATTACK or NOTATTACK given a day of tweets. All parameters are optimized on the development set: we treat attack days as known on training days, but hidden from the development and test days. We calculate F1 score on the development attack days, and optimize parameters using a basic grid search. For the final reported results, we combine train+dev into one observed training set, and the test set is now included in sampling, but with unobserved attack days. Since the PLDAttack model is probabilistic, all reported numbers are an average of 10 independent runs.

We use ATTACK F1 as the main evaluation target; the harmonic mean between precision and recall. Applications overly concerned with missing attacks would optimize to recall R. We chose $F1$ as a happy balance between a quality classifier (good precision P) and a useful classifier (good recall R). We report all three scores for both the ATTACK and NOTATTACK labels, but optimize to F1 during parameter search on the development set.

5.1 Trending Baselines

Entity Trending: This baseline follows the hypothesis that a website under attack is mentioned more than usual, and language analysis is not required. There is credence to this idea. Much of our data includes a spike in discussion on the attack day (however, some non-attack days show similar frequency spikes). We model frequency trending with an exponential decay function similar to that in Motoyama et al. (2010). It uses an Exponentially Weighted Moving Average:

$$A_t = \alpha * n_t + (1 - \alpha) * A_{t-1} \quad (3)$$

where A_t is the EWMA of day t, n_t is the number of tweets on day t, and α determines how the current day's count affects the moving average. We then need a threshold T_t to determine when n_t is trending. This is based on a moving deviation σ^2:

$$D_t = n_t - A_{t-1} \quad (4)$$

	Non-Attack			Attack		
	P	R	F1	P	R	F1
Freq Baseline	.99	.87	.92	.29	**.83**	.43
Motoyama'10	.97	.94	.95	.35	.58	.44
LogisticReg	.97	.75	.85	.14	.67	.24
Neural-1	.96	.97	**.96**	.54	.47	.49
Neural-2	.97	.96	**.96**	.55	.53	.53
PLDAttack	.96	.96	**.96**	**.61**	.52	**.55**

Table 2: Results on the held-out test set of 200 test datums. Motoyama'10 is a trending phrase baseline.

$$\sigma_t^2 = \beta * D_t^2 + (1 - \beta) * \sigma_{n-1}^2 \quad (5)$$

Given this deviation, the threshold is then:

$$T_t = M_{t-1} + \epsilon * \sigma_{t-1} \quad (6)$$

If $n_t > T_t$ for a day, we signal an ATTACK.

Pattern Trending: This modified baseline exactly duplicates Motoyama et al. (2010). Their approach looks for trending mentions that match the pattern, *'X is down'*. The X is substituted with the company's name. We use the same equation 6, but frequency n_t is defined as how many tweets contain the pattern (instead of just 'X').

5.2 Experiment Results

The test set results for baselines and models are shown in Table 2. All improvements are statistically significant as indicated using McNemar's two-tailed test. The trending baselines have high recall. When an attack is happening, the network does indeed trend on social media. Precision is low, however, because non-security events also cause discussions. The neural models outperform the baselines, and a hidden layer (Neural-2) is definitely needed for increased detection. The training set of 500 documents is still small for neural training, though. Neural models have many parameters, and they overfit to our training set despite regularization with dropout, reducing dimensions, and removing hidden layers. Even still, we improved over the Motoyama baseline by 20% relative F1.

PLDA (PLDAttack) showed the highest precision when classifying an ATTACK. Since its recall was similar to the neural models, it produced the best F1 score. This is a 25% relative improvement over previous work. PLDAttack generalizes to the dataset slightly better than the neural models.

Topic 1	Topic 2	Topic 3	Topic 4	Topic 5
issues	after	attack	down	down
working	service	ddos	servers	anonymous
having	#news	under	site	megaupload
issue	hit	twitter	hacked	takes
email	attack	dns	website	sites
update	website	attacks	goes	music
services	hackers	massive	taking	claims
problem	#tech	services	web	doj

Table 3: The top words in each of 5 attack topics learned from the entire train/test dataset.

We now have two good approaches for detecting attacks: neural models and topic modeling. The remaining question is to analyze what people are actually discussing, and it is here that topic modeling further shines.

5.3 Learned Topics

The generative model is attractive because we can use its learned distributions to produce insight into what people discuss. It is more precise in our experiments, and the neural models are simply too difficult to analyze.

Table 3 shows some of the attack topics that were learned on one of our model's runs (results are an average of training runs). As can be seen, though topics are similar, they capture subtle differences in what people discuss during an attack. The first topic represents tweets about news surrounding the event. These often contain links, and show up after the attack is made known to news agencies. In contrast, topic 3 is more general about servers down and specific services such as email. The fourth topic captures discussion about Anonymous and the claims that the group makes about taking sites down. This was obviously learned as an artifact of our data which contains several Anonymous-related events.

One of the most useful analyses we can do with this type of model is track topic evolution over time. Figure 2 illustrates one attack day and the dramatic jump of the attack topics. For simplicity, we plot the 5 attack topics, and hide the others as they are generally flatter across the bottom. This shows that social media became aware on the 9th hour, and only took one more hour to reach peak intensity. What is perhaps most useful with a timeline is understanding the impact of an attack on its users. There is a fair bit of chatter the day following the event, showing that people do not easily forget such attacks and depending on the entity, this could have effects on how people engage. We

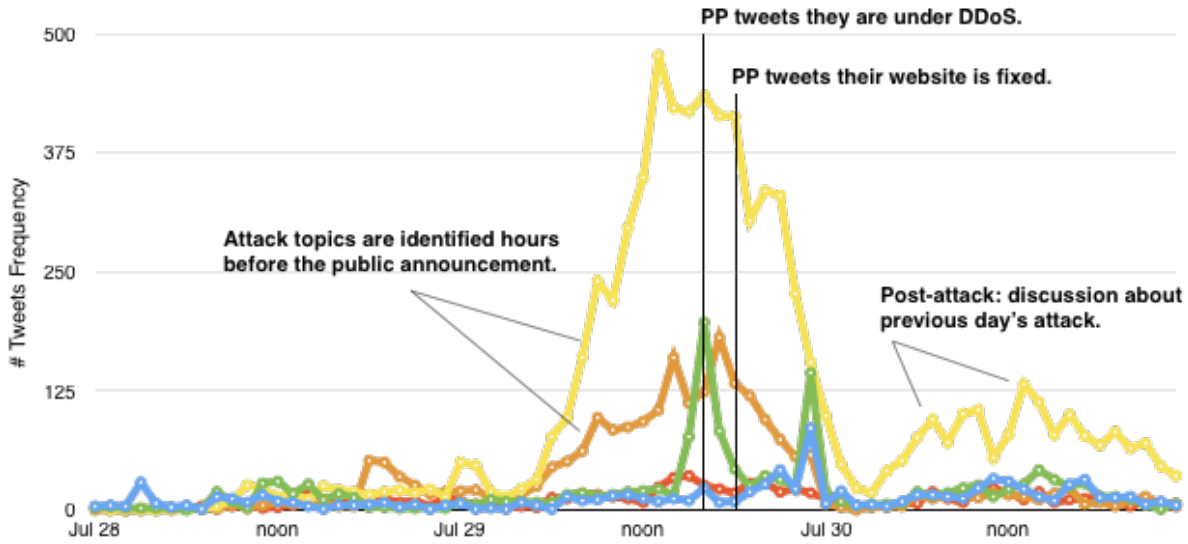

Figure 2: Attack topics during a 3-day period around a DDoS on the Planned Parenthood (PP) website. The attack was announced at 5pm on July 29. The green topic spikes with PP's first tweet about the DDoS. The yellow & brown topics rise hours **before** the announcement. They decrease after the attack, similar to the red 'news' topic.

also see that Planned Parenthood (in this example) delayed in announcing the attack. Whether this is tactical or simply how long it took to realize the event, PLDAttack offers a natural way to discover just how soon patrons (or the public in general) became aware of the issue without an announcement. Decision making around these events might be guided by helpful NLP tools such as this.

Finally, we note previous work tracked tweets with 'DDoS' in it. There were ˜50 such tweets, but our models instead matched *tens of thousands*. Previous seed-based work cannot produce this type of analysis.

5.4 Attack Stages in Online Discussions

To analyze the PLDAttack model's strengths, we split attack days into "spiking" chunks to identify common stages of online chatter. We use topic frequency spikes for Reddit to provide diversity in analysis from the Planned Parenthood Figure 2. Reddit is a community based website attacked on April 19, 2013. We identified four distinct stages of a DDoS attack on social media: (1) Symptom, (2) Inference, (3) Confirmation, and (4) Resumption. Figure 3 shows examples from each stage.

The **Symptom Stage** is the earliest sign of a problem with user observations of the network service. These aren't comments about malicious attacks, but statements about authentication problems and unresponsive websites. This is the most difficult stage for a learner (**false positives**). Services can have trouble for a variety of reasons, not necessarily DDoS attacks. Some of our evaluation data includes inoccuous problems, and these caused a decrease in precision.

The **Inference Stage** includes guesses about the cause of the previous stage's symptoms. These can and do intermix with the Symptom Stage. As seen in the reddit examples in Figure 3, some of the users wonder if they broke reddit rather than a malicious act occurring. We also see an example of someone guessing that it is a DDoS attack, but without actual knowledge of it.

The **Confirmation Stage** occurs when the website publicly announces an attack. Not all attacks have a public announcement. Our error analysis revealed this to be the cause of several **false negatives**. When the public is not directly informed, the learning algorithms must rely on symptoms and inferences only. Previous work largely isolated itself to attacks with a Confirmation Stage, for instance, relying on the 'DDoS' keyword to be present (Ritter et al., 2015).

Finally, the **Resumption Stage** is when the network service is restored. The reddit examples show people commenting on the resumption, and making jokes about the previous situation. Similar to the Symptom Stage, this stage contributes to **false positives** because it also occurs with normal routine network problems, not just malicious acts.

5.5 Error Analysis

Identifying the four stages above led to a natural method of studying errors in our model. We

Symptom Stage
Please come back Reddit! I'm bored.
Reddit won't authenticate me. #lifeisover
Reddit is calling me a robot and won't let me use it

Inference Stage
There is a DDoS attack on Reddit right now?
i broke reddit? wat? I think we crashed Reddit #wow

Confirmation Stage
wow turns out reddit is being DDoS attacked right now
Reddit is experiencing a malicious DDoS attack
Reddit's reward for the Boston bombing? DDOS attacks.

Resumption Stage
@JpDeathBlade Reddit is back and in full force.
Reddit may be returning.
It's ok, Reddit is back up. Go home, nothing to see here.

Figure 3: Examples from the four stages of a social media response to DDoS attacks.

chose a sample of false positives and false negatives, and manually looked at these incorrect decisions to align common mistakes with how they related to the 4 stages. Looking at the false positives, the majority are from the Symptom and Inference Stages. Looking at false negatives, we found attacks where the network did **not** make a public statement, so the Confirmation Stage was missing.

These stages of course do not account for all of the mistakes that are made. Precision is at 61% in our best model, leaving room for improvement. Other reasons for errors included distractor events. For example, the Boston Bombing occurred near the Reddit DDoS. The preceding days included thousands of tweets talking about the *attack* in Boston. This is obviously a different type of attack, and the machine learners were led astray.

5.6 Robustness

A danger in many stochastic processes is finding one good run and only reporting on those results. We thus compare our our model across runs and found the topics to be somewhat robust and steady. We chose five random runs of the best performing model (the one from Figure 2) and focused on the largest attack topic. Is this topic learned in all runs? Not only was the same topic subjectively learned in each run, we graphed the observed frequency of this largest attack topic from 5 of the 10 runs. Not only did it maintain the same frequency, but also the same general shape across the runs. Space prohibits more illustration, but the graph can be found on our data website: `www.usna.edu/Users/cs/nchamber/data/ddos/`

6 Discussion

The core conclusion from our experiments is that social media does indeed contain signals to identify DDoS attacks. Our proposed neural network outperformed previous work (Motoyama et al., 2010) by 20% F1, a very large margin. Even though online users are an *indirect* source of evidence, the 53% F1 from the neural network shows that useful information can be extracted from text.

We further improved results with the generative PLDAttack model based on topic modeling, achieving a smaller 4% increase over the neural net but 25% over the prior trending approach. Although neural networks have significant advantages over LDA-based models, PLDAttack offers advantages by enabling deeper analysis of what people say, what topics are discussed, and how attack discussions evolve over time on Twitter. For instance, it enabled Figure 2 to illustrate the different topics that people discuss during such an event.

Can these results be used in a DDoS detection framework? We believe it can. PLDAttack recall may not be as high as desired, but it can be increased by adjusting the prediction cutoff probability λ. We empirically set the cutoff based on dev set performance to optimize F1. However, a detection system may desire to optimize recall at the expense of precision, thus choosing a lower λ and forcing the system to predict attacks more often. This would increase false positives, but with a human in the loop, it is manageable to monitor.

This paper thus proposed two NLP models for learning to identify DDoS attacks from social media without network data. They leverage *indirect* evidence described by users when they post online about service availability. By identifying the *early topics* before public announcements, we see this as an important step toward a broad-scale monitoring system not dependent on individual network reporting. We hope our datasets and models encourage further efforts in NLP and Computer Security. Models and data are available online: *www.usna.edu/Users/cs/nchamber/data/ddos/*

Abstract

Estimating label proportions in a target corpus is a type of measurement that is useful for answering certain types of social-scientific questions. While past work has described a number of relevant approaches, nearly all are based on an assumption which we argue is invalid for many problems, particularly when dealing with human annotations. In this paper, we identify and differentiate between two relevant data generating scenarios (intrinsic vs. extrinsic labels), introduce a simple but novel method which emphasizes the importance of calibration, and then analyze and experimentally validate the appropriateness of various methods for each of the two scenarios.

1 Introduction

A methodological tool often used in the social sciences and humanities (and practical settings like journalism) is *content analysis* – the manual categorization of pieces of text into a set of categories which have been developed to answer a substantive research question (Krippendorff, 2012). *Automated* content analysis holds great promise for augmenting the efforts of human annotators (O'Connor et al., 2011; Grimmer and Stewart, 2013). While this task bears similarity to text categorization problems such as sentiment analysis, the quantity of real interest is often the *proportion* of documents in a dataset that should receive each label (Hopkins and King, 2010). This paper tackles the problem of estimating label proportions in a target corpus based on a small sample of human annotated data.

As an example, consider the hypothetical question (not explored in this work) of whether hate speech is increasingly prevalent in social media posts in recent years. "Hate speech" is a difficult-to-define category only revealed (at least initially) through human judgments (Davidson et al., 2017). Note that the goal would not be to identify individual instances, but rather to estimate a proportion, as a way of measuring the prevalence of a social phenomenon. Although we assume that trained annotators could recognize this phenomenon with some acceptable level of agreement, relying solely on manual annotation would restrict the number of messages that could be considered, and would limit the analysis to the messages available at the time of annotation.[1]

We thus treat proportion estimation as a *measurement* problem, and seek a way to train an instrument from a limited number of human annotations to measure label proportions in an unannotated target corpus.

This problem can be cast within a supervised learning framework, and past work has demonstrated that it is possible to improve upon a naïve classification-based approach, even without access to any labeled data from the target corpus (Forman, 2005, 2008; Bella et al., 2010; Hopkins and King, 2010; Esuli and Sebastiani, 2015). However, as we argue (§2), most of this work is based on a set of assumptions that we believe are invalid in a significant portion of text-based research projects in the social sciences and humanities.

Our contributions in this paper include:

- identifying two different data-generating scenarios for text data (*intrinsic* vs. *extrinsic* labels) and and establishing their importance to the problem of estimating proportions (§2);
- analyzing which methods are suitable for each setting, and proposing a simple alternative approach for extrinsic labels (§3); and
- an empirical comparison of methods that validates our analysis (§4).

[1] For additional examples see Grimmer et al. (2012), Hopkins and King (2010), and references therein.

Proceedings of NAACL-HLT 2018, pages 1636–1646
New Orleans, Louisiana, June 1 - 6, 2018.

Complicating matters somewhat is the fact that annotation may take place before the entire collection is available, so that the subset of instances that are manually annotated may represent a biased sample (§2). Because this is so frequently the case, all of the results in this paper assume that we must confront the challenges of *transfer learning* or *domain adaptation*. (The simpler case, where we can sample from the true population of interest, is revisited in §5.)

2 Problem Definition

Our setup is similar to that faced in transfer learning, and we use similar terminology (Pan and Yang, 2010; Weiss et al., 2016). We assume that we have a source and a target corpus, comprised of N_S and N_T documents respectively, the latter of which are not available for annotation. We will represent each corpus as a set of documents, i.e., $\boldsymbol{X}^{(S)} = \langle \boldsymbol{x}_1^{(S)}, ..., \boldsymbol{x}_{N_s}^{(S)} \rangle$, and similarly for $\boldsymbol{X}^{(T)}$.

We further assume that we have a set of K mutually exclusive categories, $\mathcal{Y} = \{1, \ldots, K\}$, and that we wish to estimate the proportion of documents in the target corpus that belong to each category. These would typically correspond to a quantity we wish to measure, such as what fraction of news articles frame a policy issue in a particular way, what fraction of product reviews are considered helpful, or what fraction of social media messages convey positive sentiment. Generally speaking, these categories will be designed based on theoretical assumptions, an understanding of the design of the platform that produced the data, and/or initial exploration of the data itself.

In idealized text classification scenarios, it is conventional to assume training data with already-assigned gold-standard labels. Here, we are interested in scenarios where we must generate our labels via an annotation process.[2] Specifically, assume that we have some annotation function, $\mathcal{A}$, which produces a distribution over the K mutually exclusive labels, conditional on text. Given a document, $\boldsymbol{x}_i$, the annotation process samples a label from the annotation function, defined as:

$$\mathcal{A}(\boldsymbol{x}_i, k) \triangleq p(y_i = k \mid \boldsymbol{x}_i). \tag{1}$$

Typically, the annotation function would represent the behavior of a human annotator (or group of annotators), but it could also represent a less controlled real-world process, such as users rating a review's helpfulness. Note that our setup *does* include the special case in which true gold-standard labels are available for each instance (such as the authors of documents in an authorship attribution problem). In such a case, $\mathcal{A}$ is deterministic (assuming unique inputs).

Given that our objective is to mimic the annotation process, we seek to estimate the proportion of documents in the target corpus expected to be categorized into each of the K categories, if we had an unlimited budget and full access to the target corpus at the time of annotation. That is, we wish to estimate $q^{(T)}$, which we define as:

$$q(y = k \mid \boldsymbol{X}^{(T)}) \triangleq \tfrac{1}{N_T} \textstyle\sum_{i=1}^{N_T} p(y_i = k \mid \boldsymbol{x}_i^{(T)}). \tag{2}$$

Given a set of documents sampled from the *source* corpus and L applications of the annotation function, we can obtain, at some cost, a labeled training corpus of L documents, i.e., $D^{(\text{train})} = \langle (\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_L, y_L) \rangle$. Because the source and target corpora are not in general drawn from the same distribution, we seek to make explicit our assumptions about how they differ.[3] Past literature on transfer learning has identified several patterns of dataset shift (Storkey, 2009). Here we focus on two particularly important cases, linking them to the relevant data generating processes, and analyze their relevance to estimating proportions.

Two kinds of distributional shift. There are two natural assumptions we could make about what is constant between the two corpora. We could assume that there is no change in the distribution of text given a document's label, that is $p^{(S)}(\boldsymbol{x} \mid y) = p^{(T)}(\boldsymbol{x} \mid y)$. Alternately, we could assume that there is no change in the distribution of labels given text, i.e., $p^{(S)}(y \mid \boldsymbol{x}) = p^{(T)}(y \mid \boldsymbol{x})$. The former is assumed in the case of *prior probability shift*, where we assume that $p(y)$ differs but $p(\boldsymbol{x} \mid y)$ is constant, and the later is assumed in the case of *covariate shift*, where we assume that $p(\boldsymbol{x})$ differs but $p(y \mid \boldsymbol{x})$ is constant (Storkey, 2009).

These two assumptions correspond to two fundamentally different types of scenarios that we need to consider, which are summarized in Table 1. The first is where we are dealing with what we

[2] This could include gathering multiple independent annotations per instance, but we will typically assume only one.

[3] Clearly, if we make no assumptions about how the source and target distributions are related, there is no guarantee that supervised learning will work (Ben-David et al., 2012).

Label type	Intrinsic	Extrinsic
Data generating process	$\boldsymbol{x} \sim p(\boldsymbol{x} \mid y)$	$y \sim p(y \mid \boldsymbol{x})$
Assumed to differ across domains	$p(y)$	$p(\boldsymbol{x})$
Assumed constant across domains	$p(\boldsymbol{x} \mid y)$	$p(y \mid \boldsymbol{x})$
Corresponding distributional shift	Prior probability shift	Covariate shift

Table 1: Data generating scenarios and corresponding distributional properties.

will call *intrinsic* labels, that is labels which are inherent to each instance, and which in some sense precede and predict the generation of the text of that instance. A classic example of this scenario is the case of authorship attribution (e.g., Mosteller and Wallace, 1964), in which different authors are assumed to have different propensities to use different styles and vocabularies. The identity of the author of a document is arguably an intrinsic property of that document, and it is easy to see a text as having been generated conditional on its author.

The contrasting scenario is what we will refer to as *extrinsic* labels; this scenario is our primary interest. We assume here that the labels are not inherent in the documents, but rather have been externally generated, conditional on the text as a stimulus to some behavioral process.[4] We argue that this is the relevant assumption for most annotation-based projects in the social sciences, where the categories of interest do not correspond to pre-existing categories that might have existed in the minds of authors before writing, or affected the writing process. Rather, these are theorized categories that have been developed specifically to analyze or measure some aspect of the document's *effect* that is of interest to the researcher.

We won't always know the true distributional properties of our datasets, but distinguishing between intrinsic and extrinsic labels provides a guide. The critical point is that these two different labeling scenarios have different implications for robustness to distributional shift. In the case of extrinsic labels, especially when working with trained annotators, it is reasonable to assume that the behavior of the annotation function is determined purely by the text, such that $p(y \mid \boldsymbol{x})$ is unchanged between source and target, and any change in label proportions is explained by a change in the underlying distribution of text, $p(\boldsymbol{x})$. With intrinsic labels, by contrast, it *may* be the case that $p(\boldsymbol{x} \mid y)$ is the same for the source and the target, assuming there are no additional factors influencing the generation of text. In that case, a shift in the distribution of features would be fully explained by a difference in the underlying label proportions.

The idea that there are different data generating processes is obviously not new.[5] What is novel here, however, is asking how these different assumptions affect the estimation of proportions. Virtually all past work on estimating proportions has only considered prior probability shift, assuming that $p(\boldsymbol{x} \mid y)$ is constant.[6] Existing methods take advantage of this assumption, and can be shown empirically to work well when it is satisfied (e.g., through artificial modification of real datasets to alter label proportions in a corpus). We expect them to fail, however, in the case of extrinsic annotations, as there is no reason to think that the required assumption should necessarily hold.

By contrast, the problem of covariate shift is in some sense less of a problem because we directly observe $\boldsymbol{X}^{(T)}$. Since the annotation function is assumed to be unchanging, we could perfectly predict the expected label proportions in the target corpus if we could learn the annotation function using labeled data from the source corpus. The problem thus becomes how to learn a well-calibrated approximation of the annotation function from a limited amount of labeled data.

3 Methods

Given a labeled training set and a target corpus, the naïve approach is to train a classifier through any conventional means, predict labels on the target corpus, and return the relative prevalence of predicted labels. Following Forman (2005), we refer to this approach as **classify and count** (CC). If using a probabilistic classifier, averaging the predicted posterior probabilities rather than predicted labels will be referred to as **probabilistic classify and count** (PCC; Bella et al., 2010).

Both approaches can fail, however. In the case of intrinsic labels, this is because these approaches will not account for the shift in prior label prob-

[4] Fong and Grimmer (2016) also consider this process in attempting to identify the causal effects of texts.

[5] Peters et al. (2014) describe these, somewhat confusingly, as *causal* and *anti-causal* problems.

[6] For example, Hopkins and King (2010) argue that bloggers first decide on the sentiment they wish to convey and then write a blog post conditional on that sentiment.

ability, $p(y)$, which is assumed to have occurred (Hopkins and King, 2010). In the case of covariate shift, the difference in $p(\boldsymbol{x})$ will result in a model that is not optimal (in terms of classification performance) for the target domain. In both cases, there is also the problem of classifier bias or miscalibration. Particularly in the case of unbalanced labels, a standard classifier is likely to be biased, overestimating the probability of the more common labels, and vice versa (Zhao et al., 2017). Here we present a simple but novel method for extrinsic labels, followed by a number of baseline approaches against which we will compare. (See supplementary material for additional details.)

3.1 Proposed method: calibrated probabilistic classify and count (PCC$^{\text{cal}}$)

One simple solution, which we propose here, is to attempt to train a well-calibrated classifier. To be clear, calibration refers to the long-run accuracy of predicted probabilities. That is, a probabilistic classifier, $h_\theta(\boldsymbol{x})$, is well calibrated at the level μ if, among all instances for which the classifier predicts class k with a probability of μ, the proportion that are truly assigned to class k is also equal to μ.[7]

It has previously been shown (DeGroot and Fienberg, 1983; Bröcker, 2009) that any proper scoring rule (e.g., cross entropy, Brier score, etc.) can be factored into two components representing *calibration* and *refinement*, the later of which effectively measures how close predicted probabilities are to zero or one. Minimizing a corresponding loss function thus involves a trade-off between these two components.

Optimizing *only* for calibration is not helpful, as a trivial solution is to simply predict a probability distribution equal to the observed label proportions in the training data for all instances (which is perfectly calibrated on the labeled sample). The alternative we propose here is to train a classifier using a typical objective (here, regularized log loss) but use *calibration on held-out data* as a criterion for *model selection*, i.e., when we tune hyperparameters via cross validation. We refer to this method as **calibrated PCC** (PCC$^{\text{cal}}$). Specifically, we select regularization strength via grid search, choosing the value that leads to the lowest average calibration error across training / held-out splits. Of course, other hyperparameters could be included in model selection as well.

To estimate calibration error (CE) during cross-validation, we use an approximation due to Nguyen and O'Connor (2015), adaptive binning. In the case of binary labels, this is computed as:

$$\text{CE} \triangleq \frac{1}{B} \sum_{j=1}^{B} \left(\frac{1}{|\mathcal{B}_j|} \sum_{i \in \mathcal{B}_j} y_i - p_\theta(\boldsymbol{x}_i) \right)^2, \quad (3)$$

using B bins, where bin $\mathcal{B}_j$ contains instances for which $p_\theta(\boldsymbol{x}_i)$ are in the j^{th} quantile, where $p_\theta(\boldsymbol{x}_i)$ is the predicted probability of a positive label for instance i. For added robustness, we take the average of CE for $B \in \{3, 4, 5, 6, 7\}$.

In our experiments, we consider two variants of PCC: the first, PCC$^{\text{F}_1}$, which is a baseline, is tuned conventionally for classification performance, whereas the other (PCC$^{\text{cal}}$) is tuned for calibration, as measured using CE, but is otherwise identically trained. As a base classifier we make use of l_1-regularized logistic regression, operating on n-gram features.[8]

3.2 Existing methods appropriate for extrinsic labels

The idea of extrinsic labels has not been previously considered by past work on estimating proportions, but it is closely related to the problems of calibration and covariate shift. Here we briefly summarize two representative methods, which we consider as baselines (see supplementary material for details).

Platt scaling. One approach to calibration is to train a model using conventional methods and to then learn a secondary calibration model. One of the most common and successful variations on this approach is Platt scaling, which learns a logistic regression classifier on held-out training data, taking the scores from the primary classifier as input. This model is then applied to the scores returned by the primary classifier on the target corpus (Platt, 1999). To estimate proportions, the predicted probabilities are then averaged, as in PCC.

Reweighting for covariate shift. Although they are not typically thought of in the context of estimating proportions, several methods have been proposed to deal directly with the problem of covariate shift, including kernel mean matching and

[7] For example, a weather forecaster will be well-calibrated if it rains on 60% of days for which the forecaster predicted a 60% chance of rain, etc.

[8] More complex models could be considered, but we use logistic regression because it is a well-understood and widely applicable model that has been shown to be relatively well-calibrated in general (Niculescu-Mizil and Caruana, 2005).

its extensions (Huang et al., 2006; Sugiyama et al., 2011). Here, we consider the two-stage method from Bickel et al. (2009), which uses a logistic regression model to distinguish between source and target domains, and then uses the probabilities from this model to re-weight labeled training instances, to more heavily favor those that are representative of the target domain. The appeal of this method is that all unlabeled data can be used to estimate this shift.

3.3 Existing methods appropriate for intrinsic labels

As previously mentioned, virtually all of the past work on estimating proportions makes the assumption that $p(\boldsymbol{x} \mid y)$ is constant between source and target. Under this assumption, it can be shown that $p(y^{(\theta)} = j \mid y = k)$ is also constant for all j and k, where $y^{(\theta)}$ is the predicted label from h_θ, and y is the true (intrinsic) label. If these values were known, then the label proportions in the target corpus could be found by taking the model's estimate of label proportions in the target corpus, (CC), and then solving a linear system of equations as a post-classification correction. Although a number of variations on this model have been proposed, all are based on the same assumption, thus we take a method known as **adjusted classify and count** (ACC) as an exemplar, which directly estimates the relevant quantities using a confusion matrix (Forman, 2005). In the case of binary classification, this reduces to:

$$\hat{q}_{\text{ACC}}(y = 1 \mid \boldsymbol{X}^{(T)}) = \frac{\frac{1}{N_T}\sum_{i=1}^{N_T} y_i^{(\theta)} - \text{FPR}}{\text{TPR} - \text{FPR}}, \quad (4)$$

where $\text{FPR} = \hat{p}(y^{(\theta)} = 1 \mid y = 0)$ and $\text{TPR} = \hat{p}(y^{(\theta)} = 1 \mid y = 1)$ are both estimated using held-out data.

4 Experiments

For our experiments, we focus on the case of binary classification where the difference between the source and target corpora results from a difference in time—that is, the training documents are sampled from one time period, and the goal is to estimate label proportions on documents from a future time period. We include examples of both intrinsic and extrinsic labels to demonstrate the importance of this distinction to the effectiveness of different methods.

As described below, we create multiple subtasks from each dataset by using different partitions of the data. In all cases, we report absolute error (AE) on the proportion of positive instances, averaged across the subtasks of each dataset.

Although we do not have access to the true annotation function, we approximate the expected label proportions in the target corpus by averaging the available labels, which should be a very close approximation when the number of available labels is large (which informed our choice of datasets for these experiments). For a single subtask, the absolute error is thus evaluated as

$$\text{AE} = \left| \hat{q}(y = 1 \mid \boldsymbol{X}^{(T)}) - \tfrac{1}{N_T}\textstyle\sum_{i=1}^{N_T} y_i^{(T)} \right|. \quad (5)$$

For all experiments, we also report the AE we would obtain from using the observed label proportions in the training sample as a prediction (labeled "Train"). Although this does not correspond to an interesting prediction (as it only says the future will always look exactly like the past), it does represent a fundamental baseline. If a method is unable to do better than this, it suggests that the method has too much measurement error to be useful.

To test for statistically significant differences between methods, we use an omnibus application of the Wilcoxon signed-rank test to compare one method against all others, including a Bonferroni correction for the total number of tests per hypothesis. With 4 datasets, each with 2 sample sizes, comparing against 6 other methods this results in a significance threshold of approximately 0.001.

Finally, in order to connect this work with past literature on estimating proportions, we also include a side experiment with one intrinsically-labeled dataset where we have artificially modified the label proportions in the target corpus by dropping positive or negatively-labeled instances in order to simulate a large prior probability shift between the source and target domains.

4.1 Datasets

We briefly describe the datasets we have used here and provide additional details in the supplementary material. Note that although this work is primarily focused on applications in which the amount of human-annotated data is likely to be small, fair evaluation of these methods requires datasets that are large enough that we can approximate the expected label proportion in the target

corpus using the available labels; as such, the following datasets were chosen so as to have a representative sample of sufficiently large intrinsically and extrinsically-labeled data, where documents were time-stamped, with label proportions that differ between time periods.

Media Frames Corpus (MFC): As a primary example of extrinsic labels, we use a dataset of several thousand news articles that have been annotated in terms of a set of broad-coverage framing dimensions (such as economics, morality, etc.). We treat annotations as indicating the presence or absence of each dimension, and consider each one as a separate sub-task. As with all datasets, we create a source and target corpus by dividing the datasets by year. Particularly for this dataset, it seems reasonable to posit that the annotation function was relatively constant between source and target, as the annotators worked without explicit knowledge of the article's date (Card et al., 2015).

Amazon reviews: As a secondary example of extrinsic labels, we make use of a subset of Amazon reviews for five different product categories, each of which has tens of thousands of reviews. For this dataset, we ignore the star rating associated with the review, and instead focus on predicting the proportion of people that would rate the review as helpful. Here we create separate subtasks for each product category by considering each pair of adjacent years as a source and target corpus, respectively (McAuley et al., 2015).

Yelp reviews: As a primary example of a large dataset with intrinsic labels, we make use of the Yelp10 dataset, treating the source location of the review as the label of interest. Specifically, we create binary classification tasks by choosing pairs of cities with approximately the same number of reviews, and again use year of publication to divide the data into source and target corpora, creating multiple subtasks per pair of cities.

Twitter sentiment: Finally, we include a Twitter sentiment analysis dataset which was collected and automatically labeled, using the presence of certain emoticons as implicit labels indicating positive or negative sentiment (with the emoticons then removed from the text). Because of the way this data was collected, and the relatively narrow time coverage, it seems plausible to treat the sentiment as an intrinsic label. As with the above datasets, we create subtasks by considering all pairs of temporally adjacent days with sufficient tweets, and treating them as a paired source and target corpora, respectively. (Go et al., 2009).

4.2 Results

The results on the datasets with extrinsic and intrinsic labels are presented in Figures 1 and 2, respectively.

As expected, the results differ in important ways between intrinsically and extrinsically labeled datasets, although there are some results which hold in all cases. In all settings, CC is worse on average than predicting the observed proportions in the training data (significantly worse for the Amazon and Twitter datasets), reinforcing the idea that averaging the predictions from a classifier will lead to a biased estimate of label proportions. This same finding holds for PCC^{F_1} when the amount of labeled data is small ($L = 500$), suggesting that simply averaging the predicted probabilities is not reliable without a sufficiently large labeled dataset.

For the datasets with *extrinsic* labels, PCC^{cal} performs best on average in all settings. For the MFC dataset, PCC^{cal} is significantly better than all methods except Platt scaling when $L = 500$ and significantly better than all methods except reweighting and PCC^{F_1} when $L = 2000$ (after a Bonferroni correction, as in all cases). As expected, ACC is actually worse on average than CC on the extrinsic datasets, presumably because of the mismatched assumptions. Reweighting for covariate shift offers mediocre performance in all settings, perhaps because, while it attempts to account for covariate shift, it may still suffer from miscalibration.

On the datasets with *intrinsic* labels, by contrast, no one method dominates the others. As expected, ACC does poorly when the amount of labeled data is small ($L = 500$); it does improve upon CC when $L = 4000$, but not by enough to do significantly better than other methods, perhaps calling into question the validity of the assumption that $p(\boldsymbol{x} \mid y)$ is constant in these datasets.

Surprisingly, both Platt scaling and PCC^{cal} also offer competitive performance in the experiments with intrinsic labels. However, this is likely the case in part because the change in label proportions is relatively small from year to year (or day

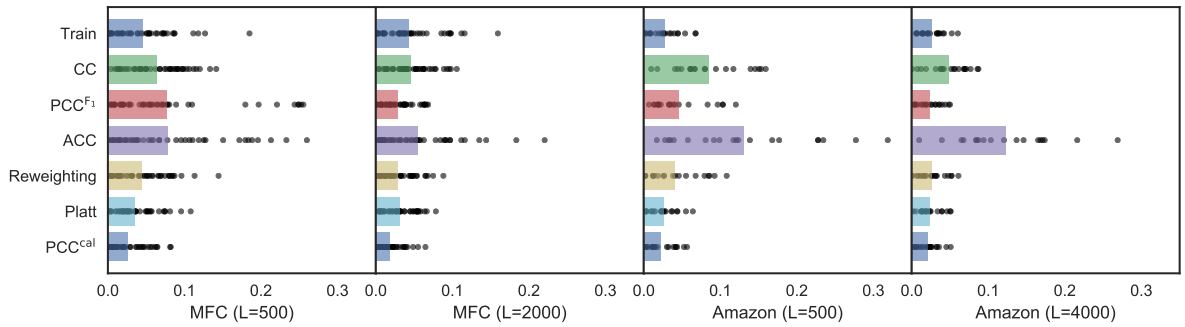

Figure 1: Absolute error (AE) on datasets with extrinsic labels. Each dot represents the result for a single subtask, and bars show the mean. PCC^{cal} (bottom row) performs best on average in all cases and is significantly better than most other methods on MFC.

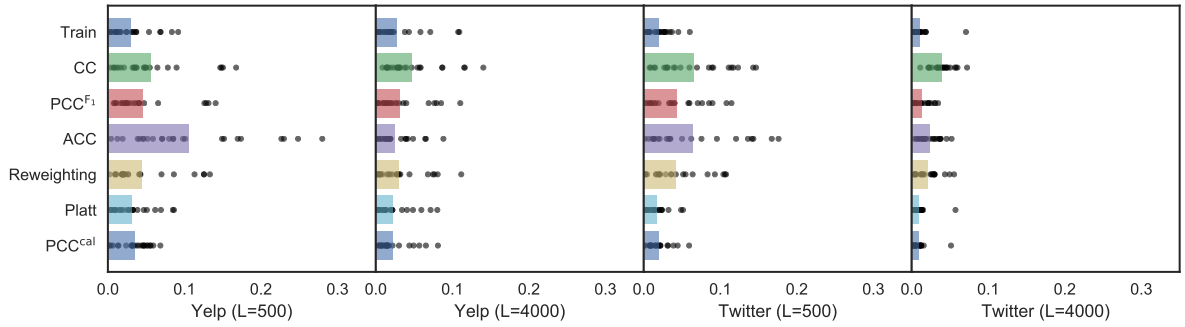

Figure 2: Absolute error (AE) on datasets with intrinsic labels. No method is significantly better than all others.

to day in the case of Twitter). This is illustrated by Figure 3, which presents the results of the side-experiment with artificially modified (intrinsic) label proportions using a subset of the Twitter data. These results confirm past findings, and show that ACC drastically outperforms other methods such as PCC^{F_1}, *if* we selectively drop instances so as to enforce a large difference in label proportions between source and target. This is the expected result, as ACC is the only method tailored to deal with prior probability shift (which is being artificially simulated). Unfortunately, its advantage is not maintained when the difference between source and target is small, which is the case for all of the naturally-occurring differences we found in the Yelp and Twitter datasets. Although past work has relied heavily on these sorts of simulated differences and artificial experiments, it is unclear whether they are a good substitute for real-world data, given that we mostly observed relatively small differences in practice.

Finally, we also tested the effect of using l_2 instead of l_1 regularization, but found that it tended to produce significantly worse estimates of proportions using CC and PCC^{F_1} on the datasets with

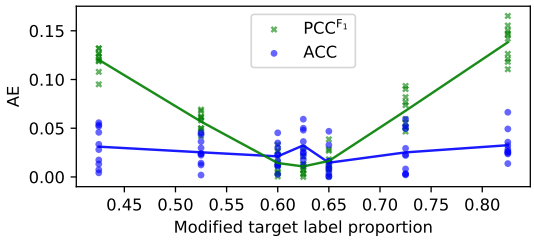

Figure 3: Absolute error (AE) for predictions on one day of Twitter data ($L = 5000$) when artificially modifying target proportions. The proportion of positive labels in the source corpus is 0.625. ACC performs significantly better given an large artificially-created difference in label proportions between source and target, but not when the difference is small.

extrinsic labels, and statistically indistinguishable results using other methods, suggesting that either type of regularization could serve as a basis for PCC^{cal} or Platt scaling.

5 Discussion

As anyone who has worked with human annotations can attest, the process of collecting annotations is messy and time-consuming, and tends to

involve large numbers of disagreements (Artstein and Poesio, 2008). Although it is conventional to treat disagreements as *errors* on the behalf of some subset of annotators, this paper provides an alternative way of understanding these. By treating annotation as a stochastic process, conditional on text, we can explain not only the disagreements between annotators, but also the lack of self-consistency that is also sometimes observed. Although the assumption that $p(y \mid \boldsymbol{x})$ does not change is clearly a simplification, it seems reasonable when working with trained annotators. Certainly this assumption seems much better justified than the conventional assumption that $p(\boldsymbol{x} \mid y)$ is constant, since the latter does not account for differences in the distribution of text arising from differences in subject matter, etc.

Although we have demonstrated that using a method that is appropriate to the data generating process is beneficial, it is important to note that all methods presented here can still result in relatively large errors in the worst cases. In part this is due to the difficulty of learning a conditional distribution involving high-dimensional data (such as text) with only a limited number of annotations. Even with much more annotated data, however, previously unseen features could still have a potentially large impact on future annotations. Ultimately, we should be cautious about all such predictions, and always validate where possible, by eventually sampling and annotating data from the target corpus.

What if we can sample from the target corpus? Although there are many situations in which domain adaptation is unavoidable (such as predicting public opinion from Twitter in real time with models trained on the past), at least some research projects in the humanities and social sciences might reasonably have access to all data of interest from the beginning of the project, such as when working with a historical corpus. Although a full proof is beyond the scope of this paper, in this case, the best approach is almost certainly to simply sample a random set of documents, label them using the annotation function, and report the relative prevalence of each label (Hopkins and King, 2010).

Although this *simple random sampling* (SRS) approach ignores the text, it is an unbiased estimator with variance that can easily calculated, at least

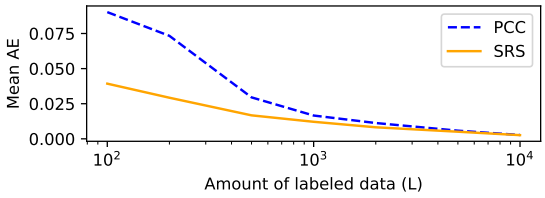

Figure 4: Comparison of SRS and PCC in simulation when we know the true model and sample from the target corpus (averaged over 200 repetitions).

in approximation.[9] More importantly, because it is independent of the dimensionality of the data, it works well on high-dimensional data, such as text, whereas classification-based approaches will struggle. We can illustrate this by comparing SRS and PCC in simulation. Figure 4 shows the mean AE (averaged over 200 trials) for a case in which we know the true model (including the prior on the weights, and thus the appropriate amount of regularization) and only need to learn the values of the weights. Even in this idealized scenario, SRS remains better than PCC for all values of L. (See supplementary material for details).

Depending on the level of accuracy required, simply sampling a few hundred documents and labeling them should be sufficient to get a reasonably reliable estimate of the overall label proportions, along with an approximate confidence interval. Unfortunately, this option is only available when we have full access to the target corpus at the time of annotation.

Additional related work. There is a small literature on the problem of estimating proportions in a target dataset (see §1); as we have emphasized, almost all of it makes the assumption that $p(\boldsymbol{x} \mid y)$ is the same for both source and target. Moreover, most of the methods that have been proposed have been tested using relatively small datasets, or datasets where the target corpus has been artificially modified by altering the label proportions in the target corpus (as we did in the side experiment reported in Figure 3). It

[9] If we were sampling with replacement, the variance in the binary case would be given by the standard formula $\mathbb{V}[\hat{q}^{\text{SRS}}] = \frac{\bar{p}(1-\bar{p})}{L}$, where $\bar{p} = \frac{1}{N_T}\sum_{i=1}^{N_T} p(y_i = 1 \mid \boldsymbol{x}_i)$. This may not be possible, however, as annotators seeing a document for the second or third time would likely be affected by their own past decisions. Nevertheless, using this as the basis for a plug-in estimator should still be a reasonable approximation when the target corpus is large. Please refer to supplementary material for additional details.

seems unclear that this is a good simulation of the kind of shift in distribution that one is likely to encounter in practice. An exception to this is Esuli and Sebastiani (2015), who test their method on the RCV1-v2 corpus, also splitting by time. They perform a large number of experiments, but unfortunately, nearly all of their experiments involve only a very small difference in label proportions between the source and target (with the vast majority < 0.01), which limits the generalizability of their findings. Additional methods for calibration could also be considered, such as the isotonic regression approach of Zadrozny and Elkan (2002), but in practice we would expect the results to be very similar to Platt scaling.

Another line of work has approached the problem of aggregating labels from multiple annotators (Raykar et al., 2009; Hovy et al., 2013; Yan et al., 2013). That is, if we believe that some annotators are more reliable than others, it might make sense to try to determine this in an unsupervised manner, and give more weight to the annotations from the reliable annotators. This seems particularly appropriate when dealing with uncooperative annotators, as might be encountered, for example, in crowdsourcing (Snow et al., 2008; Zhang et al., 2016). However, with a team of trained annotators, we believe that honest disagreements could contain valuable information better not ignored.

Finally, this work also relates to the problem of *active learning*, where the goal is to interactively choose instances to be labeled, in a way that maximizes accuracy while minimizing the total cost of annotation (Beygelzimer et al., 2009; Baldridge and Osborne, 2004; Rai et al., 2010; Settles, 2012). This is an interesting area that might be productively combined with the ideas in this paper. In general, however, the use of active learning involves additional logistical complications and does not always work better than random sampling in practice (Attenberg and Provost, 2011).

6 Conclusions

When estimating proportions in a target corpus, it is important to take seriously the data generating process. We have argued that in the case of data annotated by humans in terms of categories designed to help answer social-scientific research questions, labels should be treated as *extrinsic*, generated probabilistically conditional on text, rather than as a combination of correct and incorrect judgements about a label *intrinsic* to the document. Moreover, it is reasonable to assume in this case that $p(y \mid \boldsymbol{x})$ is unchanging between source and target, and methods that aim to learn a well-calibrated classifier, such as PCC^{cal}, are likely to perform best. By contrast, if $p(\boldsymbol{x} \mid y)$ is unchanging between source and target, then various correction methods from the literature on estimating proportions, such as ACC, can perform well, especially when differences are large. Ultimately, any of these methods can still result in large errors in the worst cases. As such, validation remains important when treating the estimation of proportions as a type of measurement.

Abstract

Peer reviewing is a central component in the scientific publishing process. We present the first public dataset of scientific peer reviews available for research purposes (PeerRead v1),[1] providing an opportunity to study this important artifact. The dataset consists of 14.7K paper drafts and the corresponding accept/reject decisions in top-tier venues including ACL, NIPS and ICLR. The dataset also includes 10.7K textual peer reviews written by experts for a subset of the papers. We describe the data collection process and report interesting observed phenomena in the peer reviews. We also propose two novel NLP tasks based on this dataset and provide simple baseline models. In the first task, we show that simple models can predict whether a paper is accepted with up to 21% error reduction compared to the majority baseline. In the second task, we predict the numerical scores of review aspects and show that simple models can outperform the mean baseline for aspects with high variance such as 'originality' and 'impact'.

1 Introduction

Prestigious scientific venues use peer reviewing to decide which papers to include in their journals or proceedings. While this process seems essential to scientific publication, it is often a subject of debate. Recognizing the important consequences of peer reviewing, several researchers studied various aspects of the process, including consistency, bias, author response and general review quality (e.g., Greaves et al., 2006; Ragone et al., 2011; De Silva and Vance, 2017). For example, the organizers of the NIPS 2014 conference assigned 10% of conference submissions to two different sets of reviewers to measure the consistency of the peer reviewing process, and observed that the two committees disagreed on the accept/reject decision for more than a quarter of the papers (Langford and Guzdial, 2015).

Despite these efforts, quantitative studies of peer reviews had been limited, for the most part, to the few individuals who had access to peer reviews of a given venue (e.g., journal editors and program chairs). The goal of this paper is to lower the barrier to studying peer reviews for the scientific community by introducing the first public dataset of peer reviews for research purposes: PeerRead.

We use three strategies to construct the dataset: (i) We collaborate with conference chairs and conference management systems to allow authors and reviewers to opt-in their paper drafts and peer reviews, respectively. (ii) We crawl publicly available peer reviews and annotate textual reviews with numerical scores for aspects such as 'clarity' and 'impact'. (iii) We crawl arXiv submissions which coincide with important conference submission dates and check whether a similar paper appears in proceedings of these conferences at a later date. In total, the dataset consists of 14.7K paper drafts and the corresponding accept/reject decisions, including a subset of 3K papers for which we have 10.7K textual reviews written by experts. We plan to make periodic releases of PeerRead, adding more sections for new venues every year. We provide more details on data collection in §2.

The PeerRead dataset can be used in a variety of ways. A quantitative analysis of the peer reviews can provide insights to help better understand (and potentially improve) various nuances of the review process. For example, in §3, we analyze correlations between the overall recommendation score and individual aspect scores (e.g., clarity, impact and originality) and quantify how reviews recom-

CoNLL 2016	22	39	✓	11 / 11
arXiv 2007–2017	11,778	—	—	2,891 / 8,887
total	14,784	10,770		

Table 1: The PeerRead dataset. **Asp.** indicates whether the reviews have aspect specific scores (e.g., clarity). Note that ICLR contains the aspect scores assigned by our annotators (see Section 2.4). **Acc/Rej** is the distribution of accepted/rejected papers. Note that NIPS provide reviews only for accepted papers.

mending an oral presentation differ from those recommending a poster. Other examples might include aligning review scores with authors to reveal gender or nationality biases. From a pedagogical perspective, the PeerRead dataset also provides inexperienced authors and first-time reviewers with diverse examples of peer reviews.

As an NLP resource, peer reviews raise interesting challenges, both from the realm of sentiment analysis—predicting various properties of the reviewed paper, e.g., clarity and novelty, as well as that of text generation—given a paper, automatically generate its review. Such NLP tasks, when solved with sufficiently high quality, might help reviewers, area chairs and program chairs in the reviewing process, e.g., by lowering the number of reviewers needed for some paper submission.

In §4, we introduce two new NLP tasks based on this dataset: (i) predicting whether a given paper would be accepted to some venue, and (ii) predicting the numerical score of certain aspects of a paper. Our results show that we can predict the accept/reject decisions with 6–21% error reduction compared to the majority reject-all baseline, in four different sections of PeerRead. Since the baseline models we use are fairly simple, there is plenty of room to develop stronger models to make better predictions.

2 Peer-Review Dataset (PeerRead)

Here we describe the collection and compilation of PeerRead, our scientific peer-review dataset. For an overview of the dataset, see Table 1.

2.1 Review Collection

Reviews in PeerRead belong to one of the two categories:

Opted-in reviews. We coordinated with the Softconf conference management system and the conference chairs for CoNLL 2016[2] and ACL 2017[3] conferences to allow authors and reviewers to opt-in their drafts and reviews, respectively, to be included in this dataset. A submission is included only if (i) the corresponding author opts-in the paper draft, and (ii) at least one of the reviewers opts-in their anonymous reviews. This resulted in 39 reviews for 22 CoNLL 2016 submissions, and 275 reviews for 137 ACL 2017 submissions. Reviews include both text and aspect scores (e.g., calrity) on a scale of 1–5.

Peer reviews on the web. In 2013, the NIPS conference[4] began attaching all accepted papers with their anonymous textual review comments, as well as a confidence level on a scale of 1–3. We collected all accepted papers and their reviews for NIPS 2013–2017, a total of 9,152 reviews for 2,420 papers.

Another source of reviews is the OpenReview platform:[5] a conference management system which promotes open access and open peer reviewing. Reviews include text, as well as numerical recommendations between 1–10 and confidence level between 1–5. We collected all submissions to the ICLR 2017 conference,[6] a total of 1,304 official, anonymous reviews for 427 papers (177 accepted and 255 rejected).[7]

2.2 arXiv Submissions

arXiv[8] is a popular platform for pre-publishing research in various scientific fields including physics, computer science and biology. While arXiv does not contain reviews, we automatically label a subset of arXiv submissions in the years 2007–2017 (inclusive)[9] as accepted or probably-rejected, with

[4]The Conference on Neural Information Processing Systems; `https://nips.cc/`

[5]`http://openreview.net`

[6]The 5th International Conference on Learning Representations; `https://iclr.cc/archive/www/2017.html`

[7]The platform also allows any person to review the paper by adding a comment, but we only use the official reviews of reviewers assigned to review that paper.

[8]`https://arxiv.org/`

[9]For consistency, we only include the first arXiv version of each paper (accepted or rejected) in the dataset.

respect to a group of top-tier NLP, ML and AI venues: ACL, EMNLP, NAACL, EACL, TACL, NIPS, ICML, ICLR and AAAI.

Accepted papers. In order to assign 'accepted' labels, we use the dataset provided by Sutton and Gong (2017) who matched arXiv submissions to their bibliographic entries in the DBLP directory[10] by comparing titles and author names using Jaccard's distance. To improve our coverage, we also add an arXiv submission if its title matches an accepted paper in one of our target venues with a relative Levenshtein distance (Levenshtein, 1966) of < 0.1. This results in a total of 2,891 accepted papers.

Probably-rejected papers. We use the following criteria to assign a 'probably-rejected' label for an arXiv submission:

- The paper wasn't accepted to any of the target venues.[11]
- The paper was submitted to one of the arXiv categories `cs.cl`, `cs.lg` or `cs.ai`.[12]
- The paper wasn't cross-listed in any non-`cs` categories.
- The submission date[13] was within one month of the submission deadlines of our target venues (before or after).
- The submission date coincides with at least one of the arXiv papers accepted for one of the target venues.

This process results in 8,887 'probably-rejected' papers.

Data quality. We did a simple sanity check in order to estimate the number of papers that we labeled as 'probably-rejected', but were in fact accepted to one of the target venues. Some authors add comments to their arXiv submissions to indicate the publication venue. We identified arXiv papers with a comment which matches the term "accept" along with any of our target venues (e.g., "nips"), but not the term "workshop". We found 364 papers which matched these criteria, 352 out of which were labeled as 'accepted'. Manual inspection of the remaining 12 papers showed that one of the papers was indeed a false negative (i.e., labeled as 'probably-rejected' but accepted to one of the target venues) due to a significant change in the paper title. The remaining 11 papers were not accepted to any of the target venues (e.g., "accepted at WMT@ACL 2014").

2.3 Organization and Preprocessing

We organize v1.0 of the PeerRead dataset in five sections: CoNLL 2016, ACL 2017, ICLR 2017, NIPS 2013–2017 and arXiv 2007–2017.[14] Since the data collection varies across sections, different sections may have different license agreements. The papers in each section are further split into standard training, development and test sets with 0.9:0.05:0.05 ratios. In addition to the PDF file of each paper, we also extract its textual content using the `Science Parse` library.[15] We represent each of the splits as a json-encoded text file with a list of paper objects, each of which consists of paper details, accept/reject/probably-reject decision, and a list of reviews.

2.4 Aspect Score Annotations

In many publication venues, reviewers assign numeric aspect scores (e.g., clarity, originality, substance) as part of the peer review. Aspect scores could be viewed as a structured summary of the strengths and weaknesses of a paper. While aspect scores assigned by reviewers are included in the opted-in sections in PeerRead, they are missing from the remaining reviews. In order to increase the utility of the dataset, we annotated 1.3K reviews with aspect scores, based on the corresponding review text. Annotations were done by two of the authors. In this subsection, we describe the annotation process in detail.

Feasibility study. As a first step, we verified the feasibility of the annotation task by annotating nine reviews for which aspect scores are available. The annotators were able to infer about half of the aspect scores from the corresponding review text (the other half was not discussed in the review text). This is expected since reviewer comments often focus on the key strengths or weaknesses of the paper and are not meant to be a comprehensive assessment of each aspect. On average, the absolute difference between our annotated scores and the gold scores originally provided by reviewers is 0.51 (on a 1–5 scale, considering only those cases where the aspect was discussed in the review text).

[10] `http://dblp.uni-trier.de/`

[11] Note that some of the 'probably-rejected' papers may be published at workshops or other venues.

[12] See `https://arxiv.org/archive/cs` for a description of the computer science categories in arXiv.

[13] If a paper has multiple versions, we consider the submission date of the first version.

[14] We plan to periodicly release new versions of PeerRead.

[15] `https://github.com/allenai/science-parse`

Data preprocessing. We used the official reviews in the ICLR 2017 section of the dataset for this annotation task. We excluded unofficial comments contributed by arbitrary members of the community, comments made by the authors in response to other comments, as well as "meta-reviews" which state the final decision on a paper submission. The remaining 1,304 official reviews are all written by anonymous reviewers assigned by the program committee to review a particular submission. We randomly reordered the reviews before annotation so that the annotator judgments based on one review are less affected by other reviews of the same paper.

Annotation guidelines. We annotated seven aspects for each review: appropriateness, clarity, originality, soundness/correctness, meaningful comparison, substance, and impact. For each aspect, we provided our annotators with the instructions given to ACL 2016 reviewers for this aspect.[16] Our annotators' task was to read the detailed review text (346 words on average) and select a score between 1–5 (inclusive, integers only) for each aspect.[17] When review comments do not address a specific aspect, we do not select any score for that aspect, and instead use a special "not discussed" value.

Data quality. In order to assess annotation consistency, the same annotators re-annotated a random sample consisting of 30 reviews. On average, 77% of the annotations were consistent (i.e., the re-annotation was exactly the same as the original annotation, or was off by 1 point) and 2% were inconsistent (i.e., the re-annotation was off by 2 points or more). In the remaining 21%, the aspect was marked as "not discussed" in one annotation but not in the other. We note that different aspects are discussed in the textual reviews at different rates. For example, about 49% of the reviews discussed the 'originality' aspect, while only 5% discussed 'appropriateness'.

3 Data-Driven Analysis of Peer Reviews

In this section, we showcase the potential of using PeerRead for data-driven analysis of peer reviews.

Overall recommendation vs. aspect scores. A critical part of each review is the overall recommendation score, a numeric value which best characterizes a reviewer's judgment of whether the draft should be accepted for publication in this venue. While aspect scores (e.g., clarity, novelty, impact) help explain a reviewer's assessment of the submission, it is not necessarily clear which aspects reviewers appreciate the most about a submission when considering their overall recommendation.

To address this question, we measure pair-wise correlations between the overall recommendation and various aspect scores in the ACL 2017 section of PeerRead and report the results in Table 2.

Aspect	ρ
Substance	0.59
Clarity	0.42
Appropriateness	0.30
Impact	0.16
Meaningful comparison	0.15
Originality	0.08
Soundness/Correctness	0.01

Table 2: Pearson's correlation coefficient ρ between the overall recommendation and various aspect scores in the ACL 2017 section of PeerRead.

The aspects which correlate most strongly with the final recommendation are substance (which concerns the amount of work rather than its quality) and clarity. In contrast, soundness/correctness and originality are least correlated with the final recommendation. These observations raise interesting questions about what we collectively care about the most as a research community when evaluating paper submissions.

Oral vs. poster. In most NLP conferences, accepted submissions may be selected for an oral presentation or a poster presentation. The presentation format decision of accepted papers is based on recommendation by the reviewers. In the official blog of ACL 2017,[18] the program chairs recommend that reviewers and area chairs make this decision based on the expected size of interested audience and whether the ideas can be grasped without back-and-forth discussion. However, it remains unclear what criteria are used by reviewers to make this decision.

To address this question, we compute the mean aspect score in reviews which recommend an oral vs. poster presentation in the ACL 2017 section of

[16] Instructions are provided in Appendix B.

[17] Importantly, our annotators only considered the review text, and did not have access to the papers.

[18] https://acl2017.wordpress.com/2017/03/23/conversing-or-presenting-poster-or-oral/

PeerRead, and report the results in Table 3. Notably, the average 'overall recommendation' score in reviews recommending an oral presentation is 0.9 higher than in reviews recommending a poster presentation, suggesting that reviewers tend to recommend oral presentation for submissions which are holistically stronger.

Presentation format	Oral	Poster	Δ	stdev
Recommendation	3.83	2.92	0.90	0.89
Substance	3.91	3.29	0.62	0.84
Clarity	4.19	3.72	0.47	0.90
Meaningful comparison	3.60	3.36	0.24	0.82
Impact	3.27	3.09	0.18	0.54
Originality	3.91	3.88	0.02	0.87
Soundness/Correctness	3.93	4.18	-0.25	0.91

Table 3: Mean review scores for each presentation format (oral vs. poster). Raw scores range between 1–5. For reference, the last column shows the sample standard deviation based on all reviews.

ACL 2017 vs. ICLR 2017. Table 4 reports the sample mean and standard deviation of various measurements based on reviews in the ACL 2017 and the ICLR 2017 sections of PeerRead. Most of the mean scores are similar in both sections, with a few notable exceptions. The comments in ACL 2017 reviews tend to be about 50% longer than those in the ICLR 2017 reviews. Since review length is often thought of as a measure of its quality, this raises interesting questions about the quality of reviews in ICLR vs. ACL conferences. We note, however, that ACL 2017 reviews were explicitly opted-in while the ICLR 2017 reviews include all official reviews, which is likely to result in a positive bias in review quality of the ACL reviews included in this study.

Another interesting observation is that the mean appropriateness score is lower in ICLR 2017 compared to ACL 2017. While this might indicate that ICLR 2017 attracted more irrelevant submissions, this is probably an artifact of our annotation process: reviewers probably only address appropriateness explicitly in their review if the paper is inappropriate, which leads to a strong negative bias against this category in our ICLR dataset.

4 NLP Tasks

Aside from quantitatively analyzing peer reviews, PeerRead can also be used to define interesting

Measurement	ACL'17	ICLR'17
Review length (words)	531±323	346±213
Appropriateness	4.9±0.4	2.6±1.3
Meaningful comparison	3.5±0.8	2.9±1.1
Substance	3.6±0.8	3.0±0.9
Originality	3.9±0.9	3.3±1.1
Clarity	3.9±0.9	4.2±1.0
Impact	3.2±0.5	3.4±1.0
Overall recommendation	3.3±0.9	3.3±1.4

Table 4: Mean ± standard deviation of various measurements on reviews in the ACL 2017 and ICLR 2017 sections of PeerRead. Note that ACL aspects were written by the reviewers themselves, while ICLR aspects were predicted by our annotators based on the review.

NLP tasks. In this section, we introduce two novel tasks based on the PeerRead dataset. In the first task, given a paper draft, we predict whether the paper will be accepted to a set of target conferences. In the second task, given a textual review, we predict the aspect scores for the paper such as novelty, substance and meaningful comparison.[19]

Both these tasks are not only challenging from an NLP perspective, but also have potential applications. For example, models for predicting the accept/reject decisions of a paper draft might be used in recommendation systems for arXiv submissions. Also, a model trained to predict the aspect scores given review comments using thousands of training examples might result in better-calibrated scores.

4.1 Paper Acceptance Classification

Paper acceptance classification is a binary classification task: given a paper draft, predict whether the paper will be accepted or rejected for a predefined set of venues.

Models. We train a binary classifier to estimate the probability of accept vs. reject given a paper, i.e., $P(\texttt{accept=True} \mid \texttt{paper})$. We experiment with different types of classifiers: logistic regression, SVM with linear or RBF kernels, Random Forest, Nearest Neighbors, Decision Tree, Multilayer Perceptron, AdaBoost, and Naive Bayes. We use hand-engineered features, instead of neural models, because they are easier to interpret.

[19] We also experiment with conditioning on the paper itself to make this prediction.

	ICLR	cs.cl	cs.lg	cs.ai
Majority	57.6	68.9	67.9	92.1
Ours	65.3	75.7	70.7	92.6
(Δ)	+7.7	+6.8	+2.8	+0.5

Table 5: Test accuracies (%) for acceptance classification. Our best model outperforms the majority classifiers in all cases.

We use 22 coarse features, e.g., length of the title and whether jargon terms such as 'deep' and 'neural' appear in the abstract, as well as sparse and dense lexical features. The full feature set is detailed in Appendix A.

Experimental setup. We experiment with the ICLR 2017 and the arXiv sections of the PeerRead dataset. We train separate models for each of the arXiv category: `cs.cl`, `cs.lg`, and `cs.ai`. We use python's sklearn's implementation of all models (Pedregosa et al., 2011).[20] We consider various regularization parameters for SVM and logistic regression (see Appendix A.1 for a detailed description of all hyperparameters). We use the standard test split and tune our hyperparameters using 5-fold cross validation on the training set.

Results. Table 5 shows our test accuracies for the paper acceptance task. Our best model outperforms the majority classifier in all cases, with up to 22% error reduction. Since our models lack the sophistication to assess the quality of the work discussed in the given paper, this might indicate that some of the features we define are correlated with strong papers, or bias reviewers' judgments.

We run an ablation study for this task for the ICLR and arXiv sections. We train only one model for all three categories in arXiv to simplify our analysis. Table 6 shows the absolute degradation in test accuracy of the best performing model when we remove one of the features. The table shows that some features have a large contribution on the classification decision: adding an appendix, a large number of theorems or equations, the average length of the text preceding a citation, the number of papers cited by this paper that were published in the five years before the submission of this paper, whether the abstract contains a phrase "state of the art" for ICLR or "neural" for arXiv, and length of title.[21]

[20] `http://scikit-learn.org/stable/`

[21] Coefficient values of each feature are provided in Appendix A.

ICLR	%
Best model	65.3
– appendix	–5.4
– num_theorems	–3.8
– num_equations	–3.8
– avg_len_ref	–3.8
– $\text{abstract}_{\text{state-of-the-art}}$	–3.5
– #recent_refs	–2.5

arXiv	%
Best model	79.1
– avg_len_ref	–1.4
– num_uniq_words	–1.1
– num_theorems	–1.0
– $\text{abstract}_{\text{neural}}$	–1.0
– num_refmentions	–1.0
– title_length	–1.0

Table 6: The absolute % difference in accuracy on the paper acceptance prediction task when we remove only one feature from the full model. Features with larger negative differences are more salient, and we only show the six most salient features for each section. The features are num_X: number of X (e.g., theorems or equations), avg_len_ref: average length of context before a reference, appendix: does paper have an appendix, abstract_X: does the abstract contain the phrase X, num_uniq_words: number of unique words, num_refmentions: number of reference mentions, and #recent_refs: number of cited papers published in the last five years.

4.2 Review Aspect Score Prediction

The second task is a multi-class regression task to predict scores for seven review aspects: 'impact', 'substance', 'appropriateness', 'comparison', 'soundness', 'originality' and 'clarity'. For this task, we use the two sections of PeerRead which include aspect scores: ACL 2017 and ICLR 2017.[22]

Models. We use a regression model which predicts a floating-point score for each aspect of interest given a sequence of tokens. We train three variants of the model to condition on (i) the paper text only, (ii) the review text only, or (iii) both paper and review text.

We use three neural architectures: convolutional neural networks (CNN, Zhang et al., 2015), recurrent neural networks (LSTM, Hochreiter and Schmidhuber, 1997), and deep averaging networks (DAN, Iyyer et al., 2015). In all three architectures, we use a linear output layer to make the final prediction. The loss function is the mean squared error between predicted and gold scores. We compare against a baseline which always predicts the mean score of an aspect, computed on the training set.[23]

Experimental setup. We train all models on the standard training set for 100 iterations, and

[22] The CoNLL 2016 section also includes aspect scores but is too small for training.

[23] This baseline is guaranteed to obtain mean square errors less than or equal to the majority baseline.

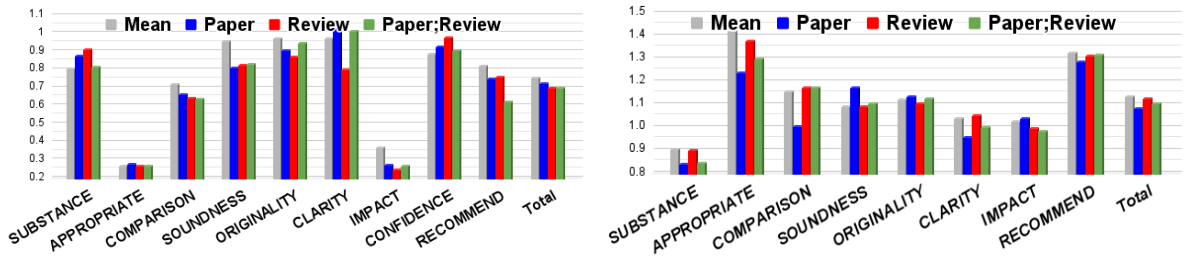

Figure 1: Root mean squared error (RMSE, lower is better) on the test set for the aspect prediction task on the ACL 2017 (left) and the ICLR 2017 (right) sections of PeerRead.

select the best performing model on the standard development set. We use a single 100 dimension layer LSTM and CNN, and a single output layer of 100 dimensions for all models. We use GloVe 840B embeddings (Pennington et al., 2014) as input word representations, without tuning, and keep the 35K most frequent words and replace the rest with an UNK vector. The CNN model uses 128 filters and 5 kernels. We use an RMSProp optimizer (Tieleman and Hinton, 2012) with 0.001 learning rate, 0.9 decay rate, 5.0 gradient clipping, and a batch size of 32. Since scientific papers tend to be long, we only take the first 1000 and 200 tokens of each paper and review, respectively, and concatenate the two prefixes when the model conditions on both the paper and review text.[24]

Results. Figure 1 shows the test set root mean square error (RMSE) on the aspect prediction task (lower is better). For each section (ACL 2017 and ICLR 2017), and for each aspect, we report the results of four systems: 'Mean' (baseline), 'Paper', 'Review' and 'Paper;Review' (i.e., which information the model conditions on). For each variant, the model which performs best on the development set is selected.

We note that aspects with higher RMSE scores for the 'Mean' baseline indicate higher variance among the review scores for this aspect, so we focus our discussion on these aspects. In the ACL 2017 section, the two aspects with the highest variance are 'originality' and 'clarity'. In the ICLR 2017 section, the two aspects with the highest variance are 'appropriateness' and 'meaningful comparison'. Surprisingly, the 'Paper;Review' model outperforms the 'Mean' baseline in all four aspects, and the 'Review' model outperforms the 'Mean' baseline in three out of four. On average, all models slightly improve over the 'Mean' baseline.

5 Related Work

Several efforts have recently been made to collect peer reviews. Publons[25] consolidates peer reviews data to build public reviewer profiles for participating reviewers. Crossref maintains the database of DOIs for its 4000+ publisher members. They recently launched a service to add peer reviews as part of metadata for the scientific articles.[26] Surprisingly, however, most of the reviews are not made publicly available. In contrast, we collected and organized PeerRead such that it is easy for other researchers to use it for research purposes, replicate experiments and make a fair comparison to previous results.

There have been several efforts to analyze the peer review process (e.g., Bonaccorsi et al., 2018; Rennie, 2016). Editors of the British Journal of Psychiatry found differences in courtesy between signed and unsigned reviews (Walsh et al., 2000). Ragone et al. (2011) and Birukou et al. (2011) analyzed ten CS conferences and found low correlation between review scores and the impact of papers in terms of future number of citations. Fang et al. (2016) presented similar observations for NIH grant application reviews and their productivity. Langford and Guzdial (2015) pointed to inconsistencies in the peer review process.

Several recent venues had single vs. double blind review experiments, which pointed to single-blind reviews leading to increased biases towards male authors (Roberts and Verhoef, 2016) and famous institutions (Tomkins et al., 2017). Further, Le Goues et al. (2017) showed that reviewers are unable to

[24] We note that the goal of this paper is to demonstrate potential uses of PeerRead, rather than develop the best model to address this task, which explains the simplicity of the models we use.

[25] publons.com/dashboard/records/review/

[26] https://www.crossref.org/blog/peer-reviews-are-open-for-registering-at-crossref/

successfully guess the identity of the author in a double-blind review. Recently, there have been several initiatives by program chairs in major NLP conferences to study various aspects of the review process, mostly author response and general review quality.[27] In this work, we provide a large scale dataset that would enable the wider scientific community to further study the properties of peer review, and potentially come up with enhancements to current peer review model.

Finally, the peer review process is meant to judge the quality of research work being disseminated to the larger research community. With the ever-growing rates of articles being submitted to top-tier conferences in Computer Science and pre-print repositories (Sutton and Gong, 2017), there is a need to expedite the peer review process. Balachandran (2013) proposed a method for automatic analysis of conference submissions to recommend relevant reviewers. Also related to our acceptance predicting task are (Tsur and Rappoport, 2009) and Ashok et al. (2013), both of which focuses on predicting book reviews. Various automatic tools like Grammerly[28] can assist reviewers in discovering grammar and spelling errors. Tools like Citeomatic[29] (Bhagavatula et al., 2018) are especially useful in finding relevant articles not cited in the manuscript. We believe that the NLP tasks presented in this paper, predicting the acceptance of a paper and the aspect scores of a review, can potentially serve as useful tools for writing a paper, reviewing it, and deciding about its acceptance.

6 Conclusion

We introduced PeerRead, the first publicly available peer review dataset for research purposes, containing 14.7K papers and 10.7K reviews. We analyzed the dataset, showing interesting trends such as a high correlation between overall recommendation and recommending an oral presentation. We defined two novel tasks based on PeerRead: (i) predicting the acceptance of a paper based on textual features and (ii) predicting the score of each aspect in a review based on the paper and review contents. Our experiments show that certain properties of a paper, such as having an appendix, are correlated with higher acceptance rate. Our primary goal is to motivate other researchers to explore these tasks and develop better models that outperform the ones used in this work. More importantly, we hope that other researchers will identify novel opportunities which we have not explored to analyze the peer reviews in this dataset. As a concrete example, it would be interesting to study if the accept/reject decisions reflect author demographic biases (e.g., nationality).

Appendices

A Acceptance Classification Features

Table 7 shows the features used by our acceptance classification model. Figure 2 shows the coefficients of all our features as learned by our best classifier on both datasets.

A.1 Hyperparameters

This section describes the hyperparameters used in our acceptance classification experiment. Unless stated otherwise, we used the sklearn default hyperparameters. For decision tree and random forest, we used maximum depth=5. For the latter, we also used max_features=1. For MLP, we used $\alpha = 1$. For k-nearest neighbors, we used $k = 3$. For logistic regression, we considered both $l1$ and $l2$ penalty.

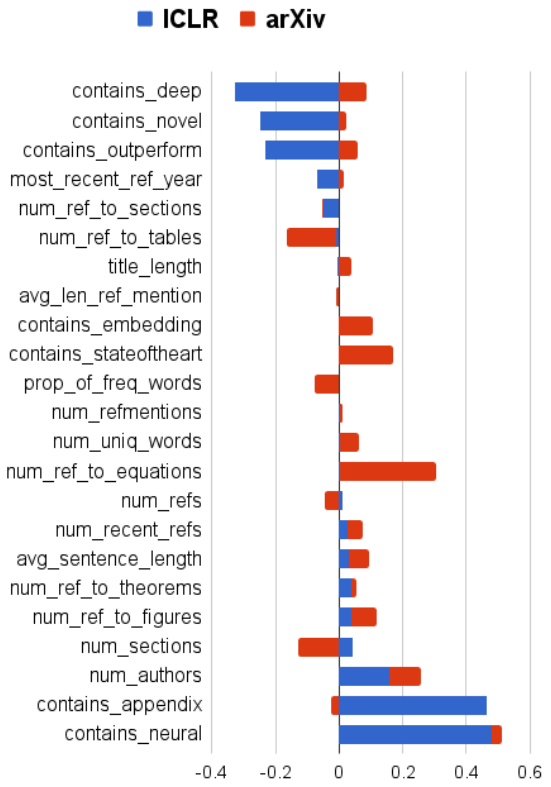

Figure 2: Coefficient values for coarse features in the paper acceptance classification, for ICLR and arXiv.

B Reviewer Instructions

Below is the list of instructions to ACL 2016 reviewers on how to assign aspect scores to reviewed papers.

	Features	Description	Labels
coarse	abstract_contains_X	Whether abstract contains keywords X ⊂ deep, neural, embedding, outperform, outperform, novel, state_of_the_art	boolean
	title_length	Length of title	integer
	num_authors	Number of authors	integer
	most_recent_refs_year	Most recent reference year	2001-2017
	num_refs	Number of references (*sp*)	integer
	num_refmentions	Number of reference mentioned (*sp*)	integer
	avg_length_refs_mention	Average length of references mentioned (*sp*)	float
	num_recent_refs	Number of recent references since the paper submitted (*sp*)	integer
	num_ref_to_X	Number of X ⊂ figures, tables, sections, equations, theorems (*sp*)	integer
	num_uniq_words	Number of unique words (*sp*)	integer
	num_sections	Number of sections (*sp*)	integer
	avg_sentence_length	Average sentence length (*sp*)	float
	contains_appendix	Whether contains an appendix or not (*sp*)	boolean
	prop_of_freq_words	Proportion of frequent words (*sp*)	float
Lexical	BOW	Bag-of-words in abstract	integer
	BOW+TFIDF	TFIDF weighted BOW in abstract	float
	GloVe	Average of GloVe word embeddings in abstract	float
	GloVe+TFIDF	TFIDF weighted average of word embeddings in abstract	float

Table 7: List of *coarse* and *lexical* features used for acceptance classification task. *sp* refers features extracted from science-parse.

APPROPRIATENESS (1-5)

Does the paper fit in ACL 2016? (Please answer this question in light of the desire to broaden the scope of the research areas represented at ACL.)

5: Certainly.
4: Probably. W
3: Unsure.
2: Probably not.
1: Certainly not.

CLARITY (1-5)
For the reasonably well-prepared reader, is it clear what was done and why? Is the paper well-written and well-structured?

5 = Very clear.
4 = Understandable by most readers.
3 = Mostly understandable to me with some effort.
2 = Important questions were hard to resolve even with effort.
1 = Much of the paper is confusing.

ORIGINALITY (1-5)
How original is the approach? Does this paper break new ground in topic, methodology, or content? How exciting and innovative is the research it describes?
Note that a paper could score high for originality even if the results do not show a convincing benefit.

5 = Surprising: Significant new problem, technique, methodology, or insight -- no prior research has attempted something similar.
4 = Creative: An intriguing problem, technique, or approach that is substantially different from previous research.
3 = Respectable: A nice research contribution that represents a notable extension of prior approaches or methodologies.
2 = Pedestrian: Obvious, or a minor improvement on familiar techniques.
1 = Significant portions have actually been done before or done better.

EMPIRICAL SOUNDNESS / CORRECTNESS (1-5)
First, is the technical approach sound and well-chosen? Second, can one trust the empirical claims of the paper -- are they supported by proper experiments and are the results of the experiments correctly interpreted?

5 = The approach is very apt, and the claims are convincingly supported.

4 = Generally solid work, although there are some aspects of the approach or evaluation I am not sure about.
3 = Fairly reasonable work. The approach is not bad, and at least the main claims are probably correct, but I am not entirely ready to accept them (based on the material in the paper).
2 = Troublesome. There are some ideas worth salvaging here, but the work should really have been done or evaluated differently.
1 = Fatally flawed.

THEORETICAL SOUNDNESS / CORRECTNESS (1-5)
First, is the mathematical approach sound and well-chosen? Second, are the arguments in the paper cogent and well-supported?

5 = The mathematical approach is very apt, and the claims are convincingly supported.
4 = Generally solid work, although there are some aspects of the approach I am not sure about or the argument could be stronger.
3 = Fairly reasonable work. The approach is not bad, and at least the main claims are probably correct, but I am not entirely ready to accept them (based on the material in the paper).
2 = Troublesome. There are some ideas worth salvaging here, but the work should really have been done or argued differently.
1 = Fatally flawed.

MEANINGFUL COMPARISON (1-5)
Do the authors make clear where the problems and methods sit with respect to existing literature? Are the references adequate? For empirical papers, are the experimental results meaningfully compared with the best prior approaches?

5 = Precise and complete comparison with related work. Good job given the space constraints.
4 = Mostly solid bibliography and comparison, but there are some references missing.
3 = Bibliography and comparison are somewhat helpful, but it could be hard for a reader to determine exactly how this work relates to previous work.
2 = Only partial awareness and understanding of related work, or a flawed empirical comparison.
1 = Little awareness of related work, or lacks necessary empirical comparison.

SUBSTANCE (1-5)
Does this paper have enough substance, or would it benefit from more ideas or results? Note that this question mainly concerns the amount of work; its quality is evaluated in other categories.

5 = Contains more ideas or results than most publications in this conference; goes the extra mile.
4 = Represents an appropriate amount of work for a publication in this conference. (most submissions)

3 = Leaves open one or two natural questions that should have been pursued within the paper.
2 = Work in progress. There are enough good ideas, but perhaps not enough in terms of outcome.
1 = Seems thin. Not enough ideas here for a full-length paper.

IMPACT OF IDEAS OR RESULTS (1-5)
How significant is the work described? If the ideas are novel, will they also be useful or inspirational? Does the paper bring any new insights into the nature of the problem?

5 = Will affect the field by altering other people's choice of research topics or basic approach.
4 = Some of the ideas or results will substantially help other people's ongoing research.
3 = Interesting but not too influential. The work will be cited, but mainly for comparison or as a source of minor contributions.
2 = Marginally interesting. May or may not be cited.
1 = Will have no impact on the field.

IMPACT OF ACCOMPANYING SOFTWARE (1-5)
If software was submitted or released along with the paper, what is the expected impact of the software package? Will this software be valuable to others? Does it fill an unmet need? Is it at least sufficient to replicate or better understand the research in the paper?

5 = Enabling: The newly released software should affect other people's choice of research or development projects to undertake.
4 = Useful: I would recommend the new software to other researchers or developers for their ongoing work.
3 = Potentially useful: Someone might find the new software useful for their work.
2 = Documentary: The new software useful to study or replicate the reported research, although for other purposes they may have limited interest or limited usability. (Still a positive rating)
1 = No usable software released.

IMPACT OF ACCOMPANYING DATASET (1-5)
If a dataset was submitted or released along with the paper, what is the expected impact of the dataset? Will this dataset be valuable to others in the form in which it is released? Does it fill an unmet need?

5 = Enabling: The newly released datasets should affect other people's choice of research or development projects to undertake.
4 = Useful: I would recommend the new datasets to other researchers or developers for their ongoing work.
3 = Potentially useful: Someone might find the new datasets useful for their work.

2 = Documentary: The new datasets are useful to study or replicate the reported research, although for other purposes they may have limited interest or limited usability. (Still a positive rating)
1 = No usable datasets submitted.

RECOMMENDATION (1-5)
There are many good submissions competing for slots at ACL 2016; how important is it to feature this one? Will people learn a lot by reading this paper or seeing it presented?

In deciding on your ultimate recommendation, please think over all your scores above. But remember that no paper is perfect, and remember that we want a conference full of interesting, diverse, and timely work. If a paper has some weaknesses, but you really got a lot out of it, feel free to fight for it. If a paper is solid but you could live without it, let us know that you're ambivalent. Remember also that the authors have a few weeks to address reviewer comments before the camera-ready deadline.

Should the paper be accepted or rejected?

5 = This paper changed my thinking on this topic and I'd fight to get it accepted;
4 = I learned a lot from this paper and would like to see it accepted.
3 = Borderline: I'm ambivalent about this one.
2 = Leaning against: I'd rather not see it in the conference.
1 = Poor: I'd fight to have it rejected.

REVIEWER CONFIDENCE (1-5)
5 = Positive that my evaluation is correct. I read the paper very carefully and am familiar with related work.
4 = Quite sure. I tried to check the important points carefully. It's unlikely, though conceivable, that I missed something that should affect my ratings.
3 = Pretty sure, but there's a chance I missed something. Although I have a good feel for this area in general, I did not carefully check the paper's details, e.g., the math, experimental design, or novelty.
2 = Willing to defend my evaluation, but it is fairly likely that I missed some details, didn't understand some central points, or can't be sure about the novelty of the work.
1 = Not my area, or paper is very hard to understand. My evaluation is just an educated guess.

Deep Communicating Agents for Abstractive Summarization

Abstract

We present *deep communicating agents* in an encoder-decoder architecture to address the challenges of representing a long document for abstractive summarization. With deep communicating agents, the task of encoding a long text is divided across multiple collaborating agents, each in charge of a subsection of the input text. These encoders are connected to a single decoder, trained end-to-end using reinforcement learning to generate a focused and coherent summary. Empirical results demonstrate that multiple communicating encoders lead to a higher quality summary compared to several strong baselines, including those based on a single encoder or multiple non-communicating encoders.

1 Introduction

We focus on the task of *abstractive* summarization of a *long* document. In contrast to *extractive* summarization, where a summary is composed of a subset of sentences or words lifted from the input text as is, *abstractive* summarization requires the generative ability to rephrase and restructure sentences to compose a coherent and concise summary. As recurrent neural networks (RNNs) are capable of generating fluent language, variants of encoder-decoder RNNs (Sutskever et al., 2014; Bahdanau et al., 2015) have shown promising results on the abstractive summarization task (Rush et al., 2015; Nallapati et al., 2017).

The fundamental challenge, however, is that the strong performance of neural models at encoding short text does not generalize well to long text. The motivation behind our approach is to be able to dynamically attend to different parts of the input to capture salient facts. While recent work in summarization addresses these issues using improved attention models (Chopra et al., 2016), pointer networks with coverage mechanisms (See et al., 2017), and coherence-focused training objectives (Paulus et al., 2018; Jaques et al., 2017), an effective mechanism for representing a long document remains a challenge.

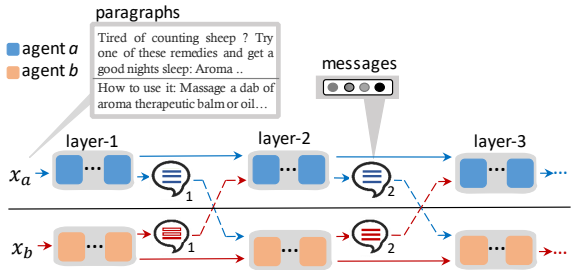

Figure 1: Illustration of deep communicating agents presented in this paper. Each agent a and b encodes one paragraph in multiple layers. By passing new messages through multiple layers the agents are able to coordinate and focus on the important aspects of the input text.

Simultaneous work has investigated the use of deep communicating agents (Sukhbaatar et al., 2016) for collaborative tasks such as logic puzzles (Foerster et al., 2016), visual dialog (Das et al., 2017), and reference games (Lazaridou et al., 2016). Our work builds on these approaches to propose the first study on using communicating agents to encode long text for summarization.

The key idea of our model is to divide the hard task of encoding a long text across multiple collaborating encoder agents, each in charge of a different subsection of the text (Figure 1). Each of these agents encodes their assigned text independently, and broadcasts their encoding to others, allowing agents to share global context information with one another about different sections of the document. All agents then adapt the encoding of their assigned text in light of the global context and re-

Proceedings of NAACL-HLT 2018, pages 1662–1675
New Orleans, Louisiana, June 1 - 6, 2018.

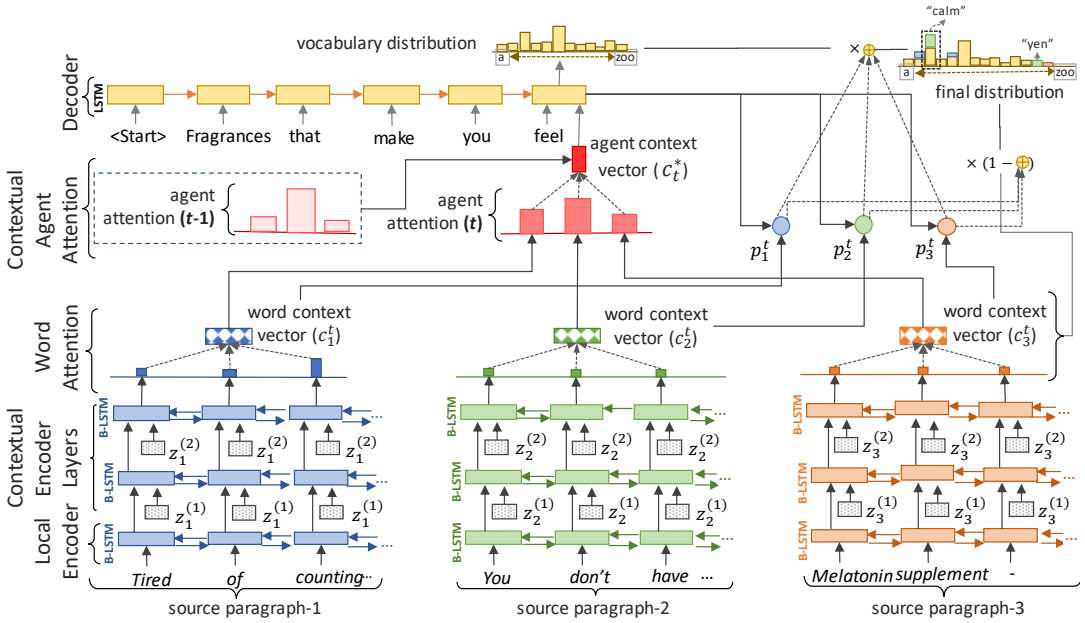

Figure 2: Multi-agent-encoder-decoder overview. Each agent a encodes a paragraph using a local encoder followed by multiple contextual layers with agent communication through concentrated messages $z_a^{(k)}$ at each layer k. **Communication is illustrated in Figure 3**. The word context vectors c_a^t are condensed into agent context c_t^*. Agent specific generation probabilities, p_a^t, enable voting for the suitable out-of-vocabulary words (e.g., '*yen*') in the final distribution.

peat the process across multiple layers, generating new messages at each layer. Once each agent completes encoding, they deliver their information to the decoder with a novel *contextual agent attention* (Figure 2). Contextual agent attention enables the decoder to integrate information from multiple agents smoothly at each decoding step. The network is trained end-to-end using self-critical reinforcement learning (Rennie et al., 2016) to generate focused and coherent summaries.

Empirical results on the CNN/DailyMail and New York Times datasets demonstrate that multiple communicating encoders lead to higher quality summaries compared to strong baselines, including those based on a single encoder or multiple non-communicating encoders. Human evaluations indicate that our model is able to produce more focused summaries. The agents gather salient information from multiple areas of the document, and communicate their information with one another, thus reducing common mistakes such as missing key facts, repeating the same content, or including unnecessary details. Further analysis reveals that our model attains better performance when the decoder interacts with multiple agents in a more balanced way, confirming the benefit of representing a long document with multiple encoding agents.

2 Model

We extend the CommNet model of Sukhbaatar et al. (2016) for sequence generation.

Notation Each document d is a sequence of paragraphs x_a, which are split across multiple encoding agents a=1,..,M (e.g., agent-1 encodes the first paragraph x_1, agent-2 the second paragraph x_2, so on). Each paragraph x_a=$\{w_{a,i}\}^I$, is a sequence of I words. We construct a V-sized vocabulary from the training documents from the most frequently appearing words. Each word $w_{a,i}$ is embedded into a n-dimensional vector $\mathbf{e}_{a,i}$. All W variables are linear projection matrices.

2.1 Multi-Agent Encoder

Each agent encodes the word sequences with the following two stacked encoders.

Local Encoder The first layer is a local encoder of each agent a, where the tokens of the corresponding paragraph x_a are fed into a single layer bi-directional LSTM (bLSTM), producing the local encoder hidden states, $h_i^{(1)} \in \mathcal{R}^H$:

$$\overrightarrow{h}_i^{(1)}, \overleftarrow{h}_i^{(1)} = \texttt{bLSTM}(e_i, \overrightarrow{h}_{i-1}^{(1)}, \overleftarrow{h}_{i+1}^{(1)}) \quad (1)$$

$$h_i^{(1)} = W_1[\overrightarrow{h}_i^{(1)}, \overleftarrow{h}_i^{(1)}] \quad (2)$$

where H is the hidden state dimensionality. The

output of the local encoder layer is fed into the contextual encoder.

Contextual Encoder Our framework enables agent communication cycles across multiple encoding layers. The output of each contextual encoder is an adapted representation of the agent's encoded information conditioned on the information received from the other agents. At each layer k=1,..,K, each agent a jointly encodes the information received from the previous layer (see Figure 3). Each cell of the (k+1)th contextual layer is a bLSTM that takes three inputs: the hidden states from the adjacent LSTM cells, $\overrightarrow{h}_{i-1}^{(k+1)} \in R^H$ or $\overleftarrow{h}_{i+1}^{(k+1)} \in R^H$, the hidden state from the previous layer $h_i^{(k)}$, and the message vector from other agents $z^{(k)} \in R^H$ and outputs $h_i^{(k+1)} \in R^H$:

$$\overrightarrow{h}_i^{(k+1)}, \overleftarrow{h}_i^{(k+1)} = \texttt{bLSTM}(f(h_i^{(k)}, z^{(k)}), \overrightarrow{h}_{i-1}^{(k+1)}, \overleftarrow{h}_{i+1}^{(k+1)}) \quad (3)(4)$$

$$h_i^{(k+1)} = W_2[\overrightarrow{h}_i^{(k+1)}, \overleftarrow{h}_i^{(k+1)}] \quad (5)$$

where i=1..I indicates the index of each token in the sequence.

The message $z^{(k)}$ received by any agent a in layer k is the average of the outputs of the other agents from layer k:

$$z^{(k)} = \frac{1}{M-1} \sum_{m \neq a} h_{m,I}^{(k)} \quad (6)$$

where $h_{m,I}^{(k)}$ is the last hidden state output from the kth contextual layer of each agent where $m \neq a$. Here, we take the average of the messages received from other encoder agents, but a parametric function such as a feed forward model or an attention over messages could also be used.

The message $z^{(k)}$ is projected with the agent's previous encoding of its document:

$$f(h_i^{(k)}, z^{(k)}) = v_1^{\mathrm{T}} \tanh(W_3 h_i^{(k)} + W_4 z^{(k)}) \quad (7)$$

where v_1, W_3, and W_4 are learned parameters shared by every agent. Equation (7) combines the information sent by other agents with the context of the current token from this paragraph. This yields different features about the current context in relation to other topics in the source document. At each layer, the agent modifies its representation of its own context relative to the information received from other agents, and updates the information it sends to other agents accordingly.

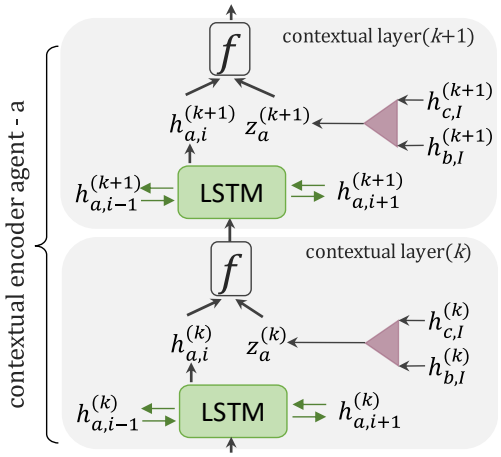

Figure 3: Multi-agent encoder message passing. Agents b and c transmit the last hidden state output (I) of the current layer k as a message, which are passed through an average pool (Eq. (6)). The receiving agent a uses the new message $z_a^{(k)}$ as additional input to its next layer.

2.2 Decoder with Agent Attention

The output from the last contextual encoder layer of each agent $\{h_{a,i}^{(K)}\}^I$, which is a sequence of hidden state vectors of each token i, is sent to the decoder to calculate word-attention distributions. We use a single-layer LSTM for the decoder and feed the last hidden state from the first agent $s_0 = h_{1,I}^{(K)}$ as the initial state. At each time step t, the decoder predicts a new word in the summary w_t and computes a new state s_t by attending to relevant input context provided by the agents.

The decoder uses a new hierarchical attention mechanism over the agents. First, a ***word attention*** distribution l_a^t (Bahdanau et al. (2015)) is computed over every token $\{h_{a,i}^{(K)}\}^I$ for each agent a:

$$l_a^t = \text{softmax}(v_2^{\mathrm{T}} \tanh(W_5 h_a^{(K)} + W_6 s_t + b_1)) \quad (8)$$

where $l_a^t \in [0,1]^I$ is the attention over all tokens in a paragraph x_a and v_2, W_5, W_6, b_1 are learned parameters. For each decoding step t, a new decoder context is calculated for each agent:

$$c_a^t = \sum_i l_{a,i}^t h_{a,i}^{(K)} \quad (9)$$

which is the weighted sum of the encoder hidden states of agent a. Each *word context vector* represents the information extracted by the agent from the paragraph it has read. Here the decoder has to decide which information is more relevant to the

current decoding step t. This is done by weighting each context vector by an agent attention yielding the document global ***agent attention*** distribution g^t (see Figure 2):

$$g^t = \text{softmax}(v_3^{\text{T}}\tanh(W_7 c^t + W_8 s_t + b_2)) \quad (10)$$

where v_3, W_7, W_8, and b_2 are learned, and $g^t \in [0,1]^M$ is a soft selection over M agents. Then, we compute the agent context vector c_t^*:

$$c_t^* = \sum_a g_a^t c_a^t \quad (11)$$

The agent context $c_t^* \in R^H$ is a fixed length vector encoding salient information from the entire document provided by the agents. It is then concatenated with the decoder state s_t and fed through a multi-layer perception to produce a vocabulary distribution (over all vocabulary words) at time t:

$$P^{voc}(w_t|s_t, w_{t-1}) = \text{softmax}(\text{MLP}([s_t, c_t^*])) \quad (12)$$

To keep the topics of generated sentences intact, it is reasonable that the decoder utilize the same agents over the course of short sequences (e.g., within a sentence). Because the decoder is designed to select which agent to attend to at each time step, we introduce contextual agent attention (*caa*) to prevent it from frequently switching between agents. The previous step's agent attention c_{t-1}^* is used as additional information to the decoding step to generate a distribution over words:

$$P^{voc}(w_t|\cdot) = \text{softmax}(\text{MLP}([s_t, c_t^*, c_{t-1}^*])) \quad (13)$$

2.3 Multi-Agent Pointer Network

Similar to See et al. (2017), we allow for copying candidate words from different paragraphs of the document by computing a *generation* probability value for each agent $p_a^t \in [0,1]$ at each timestep t using the context vector c_a^t, decoder state s_t and decoder input y_t:

$$p_a^t = \sigma(v_5^{\text{T}} c_a^t + v_6^{\text{T}} s_t + v_7^{\text{T}} y_t + b) \quad (14)$$

where b is a learned scalar, y_t is the ground-truth/predicted output (depending on the training/testing time). The generation probability determines whether to generate a word from the vocabulary by sampling from $P^{voc}(w|\cdot)$, or copying a word from the corresponding agent's input paragraph x_a by sampling from its attention distribution l_a^t. This produces an extended vocabulary that includes words in the document that are considered out-of-vocabulary (OOV). A probability distribution over the extended vocabulary is computed for each agent:

$$P^a(w_t|\cdot) = p_a^t P^{voc}(w_t|\cdot) + (1 - p_a^t) u_{a,w}^t \quad (15)$$

where $u_{a,w}^t$ is the sum of the attention for all instances where w appears in the source document. The final distribution over the extended vocabulary, from which we sample, is obtained by weighting each agent by their corresponding agent attention values g_a^t:

$$P(w_t|s_t, w_{t-1}) = \sum_a g_a^t P^a(w_t|\cdot) \quad (16)$$

In contrast to a single-agent baseline (See et al., 2017), our model allows each agent to vote for different OOV words at time t (Equation (16)). In such a case, only the word that is relevant to the generated summary up to time t is collaboratively voted as a result of agent attention probability g_a^t.

3 Mixed Objective Learning

To train the deep communicating agents, we use a mixed training objective that jointly optimizes multiple losses, which we describe below.

MLE Our baseline multi-agent model uses maximum likelihood training for sequence generation. Given $y^* = \{y_1^*, y_2^*, ..., y_T^*\}$ as the ground-truth output sequence (human summary word sequences) for a given input document d, we minimize the negative log-likelihood of the target word sequence:

$$L_{\text{MLE}} = -\sum_{t=1}^{N} \log p(y_t^*|y_1^* \ldots y_{t-1}^*, d) \quad (17)$$

Semantic Cohesion To encourage sentences in the summary to be informative without repetition, we include a *semantic cohesion* loss to integrate sentence-level semantics into the learning objective. As the decoder generates the output word sequence $\{y_1, y_2 \ldots y_T\}$, it keeps track of the end of sentence delimiter token ('.') indices. The hidden state vectors at the end of each sentence s'_q, q=1...Q, where $s'_q \in \{s_t : y_t = \text{'.'}, 1 \le t \le T\}$, are used to compute the cosine similarity between two consecutively generated sentences. To minimize the similarity between end-of-sentence hidden states we define a *semantic cohesion* loss:

$$L_{\text{SEM}} = \sum_{q=2}^{Q} \cos(s'_q, s'_{q-1}) \quad (18)$$

The final training objective is then:

$$L_{\text{MLE-SEM}} = L_{\text{MLE}} + \lambda L_{\text{SEM}} \quad (19)$$

where λ is a tunable hyperparameter.

Reinforcement Learning (RL) Loss Policy gradient methods can directly optimize discrete target evaluation metrics such as ROUGE that are non-differentiable (Paulus et al., 2018; Jaques et al., 2017; Pasunuru and Bansal, 2017; Wu et al., 2016). At each time step, the word generated by the model can be viewed as an action taken by an RL agent. Once the full sequence $\hat{y}$ is generated, it is compared against the ground truth sequence y^* to compute the reward $r(\hat{y})$.

Our model learns using a *self-critical training* approach (Rennie et al., 2016), which learns by exploring new sequences and comparing them to the best greedily decoded sequence. For each training example d, two output sequences are generated: $\hat{y}$, which is sampled from the probability distribution at each time step, $p(\hat{y}_t|\hat{y}_1 \dots \hat{y}_{t-1}, d)$, and $\tilde{y}$, the baseline output, which is greedily generated by argmax decoding from $p(\tilde{y}_t|\tilde{y}_1 \dots \tilde{y}_{t-1}, d)$. The training objective is then to minimize:

$$L_{\text{RL}} = (r(\tilde{y}) - r(\hat{y})) \sum_{t=1}^{N} \log p(\hat{y}_t|\hat{y}_1 \dots \hat{y}_{t-1}, d) \quad (20)$$

This loss ensures that, with better exploration, the model learns to generate sequences $\hat{y}$ that receive higher rewards compared to the baseline $\tilde{y}$, increasing overall reward expectation of the model.

Mixed Loss While training with only MLE loss will learn a better language model, this may not guarantee better results on global performance measures. Similarly, optimizing with only RL loss may increase the reward gathered at the expense of diminished readability and fluency of the generated summary (Paulus et al., 2018). A combination of the two objectives can yield improved task-specific scores while maintaining fluency:

$$L_{\text{MIXED}} = \gamma L_{\text{RL}} + (1 - \gamma) L_{\text{MLE}} \quad (21)$$

where γ is a tunable hyperparameter used to balance the two objective functions. We pre-train our models with MLE loss, and then switch to the mixed loss. We can also add the semantic cohesion loss term: $L_{\text{MIXED-SEM}} = \gamma L_{\text{RL}} + (1-\gamma) L_{\text{MLE-SEM}}$ to analyze its impact in RL training.

Intermediate Rewards We introduce sentence-based rewards as opposed to end of summary rewards, using differential ROUGE metrics, to promote generating diverse sentences. Rather than rewarding sentences based on the scores obtained at the end of the generated summary, we compute incremental rouge scores of a generated sentence $\hat{o}_q$:

$$r(\hat{o}_q) = r([\hat{o}_1, \dots \hat{o}_q]) - r([\hat{o}_1, \dots \hat{o}_{q-1}]) \quad (22)$$

Sentences are rewarded for the increase in ROUGE they contribute to the full sequence, ensuring that the current sentence contributed novel information to the overall summary.

4 Experimental Setup

Datasets We conducted experiments on two summarization datasets: CNN/DailyMail (Nallapati et al., 2017; Hermann et al., 2015) and New York Times (NYT) (Sandhaus, 2008). We replicate the preprocessing steps of Paulus et al. (2018) to obtain the same data splits, except that we do not anonymize named entities. For our DCA models, we initialize the number of agents before training, and partition the document among the agents (i.e., three agent $\rightarrow$ three paragraphs). Additional details can be found in Appendix A.1.

Training Details During training and testing we truncate the article to 800 tokens and limit the length of the summary to 100 tokens for training and 110 tokens at test time. We distribute the truncated articles among agents for multi-agent models, preserving the paragraph and sentences as possible. For both datasets, we limit the input and output vocabulary size to the 50,000 most frequent tokens in the training set. We train with up to two contextual layers in all the DCA models as more layers did not provide additional performance gains. We fix $\gamma = 0.97$ for the RL term in Equation (21) and $\lambda = 0.1$ for the SEM term in MLE and MIXED training. Additional details are provided in Appendix A.2.

Evaluation We evaluate our system using ROUGE-1 (unigram recall), ROUGE-2 (bigram recall) and ROUGE-L (longest common sequence).[1] We select the MLE models with the lowest negative log-likelihood and the MLE+RL models with the highest ROUGE-L scores on a sample of validation data to evaluate on the test

[1] We use `pyrouge` (pypi.python.org/pypi/pyrouge/0.1.3).

Model	ROUGE-1	ROUGE-2	ROUGE-L
SummaRuNNer (Nallapati et al., 2017)	39.60	16.20	35.30

set. At test time, we use beam search of width 5 on all our models to generate final predictions.

Baselines We compare our DCA models against previously published models: SummaRuNNer (Nallapati et al., 2017), a graph-based attentional neural model (Tan et al., 2017) an RNN-based extractive summarizer that combines abstractive features during training; Pointer-networks with and without coverage (See et al., 2017), RL-based training for summarization with intra-decoder attention (Paulus et al., 2018)), and Controllable Abstractive Summarization (Fan et al., 2017) which allows users to define attributes of generated summaries and also uses a copy mechanism for source entities and decoder attention to reduce repetition.

Ablations We investigate each new component of our model with a different ablation, producing seven different models. Our first three ablations are: a single-agent model with the same local encoder, context encoder, and pointer network architectures as the DCA encoders trained with MLE loss (**m1**); the same model trained with additional semantic cohesion SEM loss (**m2**), and the same model as the (**m1**) but trained with a mixed loss and end-of-summary rewards (**m3**).

The rest of our models use 3 agents and incrementally add one component. First, we add the semantic cohesion loss (**m4**). Then, we add multi-agent pointer networks (*mpgen*) and agent communication (**m5**). Finally, we add contextual agent attention (caa) (**m6**), and train with the mixed MLE+RL+SEM loss (**m7**). All DCA models use pointer networks.

5 Results

5.1 Quantitative Analysis

We show our results on the CNN/DailyMail and NYT datasets in Table 1 and 2 respectively. Overall, our (**m6**) and (**m7**) models with multi-agent encoders, pointer generation, and communication are the strongest models on ROUGE-1 and ROUGE-2. While weaker on ROUGE-L than the RL model from Paulus et al. (2018), the human evaluations in that work showed that their model received lower *readability* and *relevance* scores than a model trained with MLE, indicating the additional boost in ROUGE-L was not correlated with summary quality. This result can also account for our best models being more abstractive. Our models use mixed loss not just to op-

timize for sentence level structure similarity with the reference summary (to get higher ROUGE as reward), but also to learn parameters to improve semantic coherence, promoting higher abstraction (see Table 4 and Appendix B for generated summary examples).

Model	ROUGE-1	ROUGE-2	ROUGE-L
2-agent	40.94	19.16	37.54
3-agent	**41.69**	**19.47**	37.92
5-agent	40.99	19.02	**38.21**

Table 3: Comparison of multi-agent models varying the number of agents using ROUGE results of model (m7) from Table 1 on CNN/Daily Maily Dataset.

Single vs. Multi-Agents All multi-agent models show improvements over the single agent baselines. On the CNN/DailyMail dataset, compared to MLE published baselines, we improve across all ROUGE scores. We found that the 3-agent models generally outperformed both 2- and 5-agent models (see Table 3). This is in part because we truncate documents before training and the larger number of agents might be more efficient for multi-document summarization.

Independent vs. Communicating Agents When trained on multiple agents with no communication (**m4**), the performance of our DCA models is similar to the single agent baselines (**m1**) and (**m3**). With communication, the biggest jump in ROUGE is seen on the CNN/DailyMail data, indicating that the encoders can better identify the key facts in the input, thereby avoiding unnecessary details.

Contextual Agent Attention (*caa*) Compared to the model with no *contextualized agent attention* (**m5**), the (**m6**) model yields better ROUGE scores. The stability provided by the *caa* helps the decoder avoid frequent switches between agents that would dilute the topical signal captured by each encoder.

Repetition Penalty As neurally generated summaries can be redundant, we introduced the semantic cohesion penalty and incremental rewards for RL to generate semantically diverse summaries. Our baseline model optimized together with SEM loss **(m2)** improves on all ROUGE scores over the baseline **(m1)**. Similarly, our model trained with reinforcement learning uses sentence based intermediate rewards, which also improves ROUGE scores across both datasets.

5.2 Human Evaluations

We perform human evaluations to establish that our model's ROUGE improvements are correlated with human judgments. We measure the communicative multi-agent network with contextual agent attention in comparison to a single-agent network with no communication. We use the following as evaluation criteria for generated summaries: (1) *non-redundancy*, fewer of the same ideas are repeated, (2) *coherence*, ideas are expressed clearly; (3) *focus*, the main ideas of the document are shared while avoiding superfluous details, and (4) *overall*, the summary effectively communicates the article's content. The focus and non-redundancy dimensions help quantify the impact of multi-agent communication in our model, while coherence helps to evaluate the impact of the reward based learning and repetition penalty of the proposed models.

Evaluation Procedure We randomly selected 100 samples from the CNN/DailyMail test set and use workers from Amazon Mechanical Turk as judges to evaluate them on the four criteria defined above. Judges are shown the original document, the ground truth summary, and two model summaries and are asked to evaluate each summary on the four criteria using a Likert scale from 1 (worst) to 5 (best). The ground truth and model summaries are presented to the judges in random order. Each summary is rated by 5 judges and the results are averaged across all examples and judges.

We also performed a head-to-head evaluation (more common in DUC style evaluations) and randomly show two model generated summaries. We ask the human annotators to rate each summary on the same metrics as before without seeing the source document or ground truth summaries.

Results Human evaluators significantly prefer summaries generated by the communicating encoders. In the rating task, evaluators preferred the multi-agent summaries to the single-agent cases for all metrics. In the head-to-head evaluation, humans consistently preferred the DCA summaries to those generated by a single agent. In both the head-to-head and the rating evaluation, the largest improvement for the DCA model was on the *focus* question, indicating that the model learns to generate summaries with more pertinent details by capturing salient information from later portions of the document.

Human	Mr Turnbull was interviewed about his childhood and his political stance. He also admitted he **planned to run for prime minister if Tony Abbott had been successfully toppled in February's leadership spill.** The words 'primed minister' were controversially also printed on the cover.
Single	Malcolm Turnbull is set to feature on the front cover of the GQ Australia in a bold move that will no doubt set senators' tongues wagging. Posing in a suave blue suit with a pinstriped shirt and a contrasting red tie , Mr Turnbull's confident demeanour is complimented by the bold, confronting words printed across the page: 'primed minister'.
Multi	Malcolm Turnbull was set to **run for prime minister if Tony Abbott had been successfully toppled in February's leadership spill**. He is set to feature on the front cover of the liberal party's newsletter.

The shoes are then worn with pieces from the brands ss2015 collection.
Multi	Daphne Selfe, 86, has starred in the campaign for vans and & other stories. The model appears with 22-year-old flo dron & other hair collection . **She was still commanding 1,000 a day for her work.**

Table 4: Comparison of a human summary to best single- and multi-agent model summaries, (m3) and (m7) from CNN/DailyMail dataset. Although single-agent model generates a coherent summary, it is less focused and contains more unnecessary details (highlighed red) and misses **keys facts** that the multi-agent model successfully captures (**bolded**).

	Head-to-Head			Score Based	
Criteria	SA	MA	=	SA	MA
non-redundancy	68	**159**	73	4.384	**4.428**
coherence	89	**173**	38	3.686	**3.754**
focus	83	**181**	36	3.694	**3.884***
overall	102	**158**	40	3.558	**3.682***

Table 5: Head-to-Head and score-based comparison of human evaluations on random subset of CNN/DM dataset. SA=single, MA=multi-agent. * indicates statistical significance at $p < 0.001$ for focus and $p < 0.03$ for the overall.

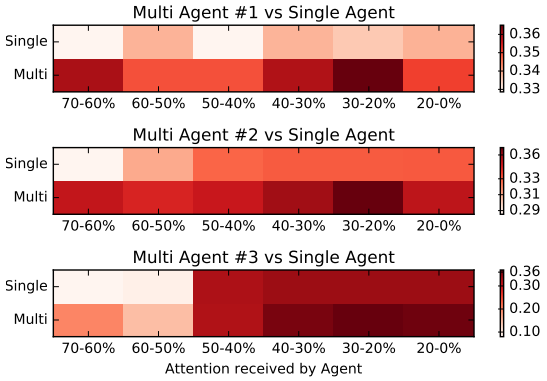

Figure 4: The average ROUGE-L scores for summaries that are binned by each agent's average attention when generating the summary (see Section 5.2). When the agents contribute equally to the summary, the ROUGE-L score increases.

5.3 Communication improves focus

To investigate how much the multi-agent models discover salient concepts in comparison to single agent models, we analyze ROUGE-L scores based on the average attention received by each agent. We compute the average attention received by each agent per decoding time step for every generated summary in the CNN/Daily Mail test corpus, bin the document-summary pairs by the attention received by each agent, and average the ROUGE-L scores for the summaries in each bin.

Figure 4 outlines two interesting results. First, summaries generated with a more distributed attention over the agents yield higher ROUGE-L scores, indicating that attending to multiple areas of the document allows the discovery of salient concepts in the later sections of the text. Second, if we use the same bins and generate summaries for the documents in each bin using the single-agent model, the average ROUGE-L scores for the single-agent summaries are lower than for the corresponding multi-agent summaries, indicating that even in cases where one agent dominates the attention, communication between agents allows the model to generate more focused summaries.

Qualitatively, we see this effect in Table 4, where we compare the human generated summaries against our best single agent model (**m3**) and our best multi-agent model (**m7**). Model (**m3**) generates good summaries but does not capture all the facts in the human summary, while (**m7**) is able to include all the facts with few extra details, generating more relevant and diverse summaries.

6 Related Work

Several recent works investigate attention mechanisms for encoder-decoder models to sharpen the

context that the decoder should focus on within the input encoding (Luong et al., 2015; Vinyals et al., 2015b; Bahdanau et al., 2015). For example, Luong et al. (2015) proposes global and local attention networks for machine translation, while others investigate hierarchical attention networks for document classification (Yang et al., 2016), sentiment classification (Chen et al., 2016), and dialog response selection (Zhou et al., 2016).

Attention mechanisms have shown to be crucial for summarization as well (Rush et al., 2015; Zeng et al., 2016; Nallapati et al., 2017), and pointer networks (Vinyals et al., 2015a), in particular, help address redundancy and saliency in generated summaries (Cheng and Lapata, 2016; See et al., 2017; Paulus et al., 2018; Fan et al., 2017). While we share the same motivation as these works, our work uniquely presents an approach based on CommNet, the deep communicating agent framework (Sukhbaatar et al., 2016). Compared to prior multi-agent works on logic puzzles (Foerster et al., 2017), language learning (Lazaridou et al., 2016; Mordatch and Abbeel, 2017) and starcraft games (Vinyals et al., 2017), we present the first study in using this framework for long text generation.

Finally, our model is related to prior works that address repetitions in generating long text. See et al. (2017) introduce a post-trained coverage network to penalize repeated attentions over the same regions in the input, while Paulus et al. (2018) use intra-decoder attention to punish generating the same words. In contrast, we propose a new semantic coherence loss and intermediate sentence-based rewards for reinforcement learning to discourage semantically similar generations (§3).

7 Conclusions

We investigated the problem of encoding long text to generate abstractive summaries and demonstrated that the use of deep communicating agents can improve summarization by both automatic and manual evaluation. Analysis demonstrates that this improvement is due to the improved ability of covering all and only salient concepts and maintaining semantic coherence in summaries.

Table 6: Summary statistics of CNN/DailyMail (DM) and New York Times (NYT) Datasets.

A.1 Datasets

CNN/DailyMail: CNN/DailyMail dataset (Nallapati et al., 2017; Hermann et al., 2015) is a collection of online news articles along with multi-sentence summaries. We use the same data splits as in Nallapati et al. (2017). While earlier work anonymized entities by replacing each named entity with a unique identifier (e.g., *Dominican Republic*→`entity15`), we opted for non-anonymized version.

New York Times (NYT): Although this dataset has mainly been used to train extractive summarization systems (Hong and Nenkova, 2014; Hong et al., 2015; Li et al., 2016; Durrett et al., 2016), it has recently been used for the abstractive summarization task (Paulus et al., 2018). NYT dataset (Sandhaus, 2008) is a collection of articles published between 1996 and 2007. We use the scripts provided in Li et al. (2016) to extract and preprocess the NYT dataset with some modifications in order to replicate the pre-processing steps presented in Paulus et al. (2018). Similar to (Paulus et al., 2018), we sorted the documents by their publication date in chronological order and used the first 90% for training, the next 5% for validation and last 5% for testing. They also use pointer supervision by replacing all named entities in the abstract if the type is "PERSON", "LOCATION", "ORGANIZATION" or "MISC" using the Stanford named entity recognizer (Manning et al., 2014). By contrast, we did not anonymize the NYT dataset to reduce pre-processing.

A.2 Training Details

We train our models on an NVIDIA P100 GPU machine. We set the hidden state size of the encoders and decoders to 128. For both datasets, we limit the input and output vocabulary size to the 50,000 most frequent tokens in the training set. We initialize word embeddings with 200-d GloVe vectors (Pennington et al., 2014) and fine-tune them during training. We train using Adam with a learning rate of 0.001 for the MLE models and 10^{-5} for the MLE+RL models. We tune the $gamma$ hyper-parameter in the mixed loss by iterating γ={0.95, 0.97, 0.99}. In almost all DCA models, the 0.97 value yielded the best gains. We train our models for 200,000 iterations. which took 4-5 days for 2-3 agents and 5-6 days for 5 agents since it has more encoder parameters to tune.

To avoid repetition, we prevent the decoder from generating the same trigram more than once during test, following Paulus et.al. (2018). In addition, for every predicted out-of-vocabulary token (UNK), we replace it with its most likely origin by choosing the source word w with the largest cascaded attention $w := \arg\max_{a,i} l^t_{a,i} * g^t_a$ (Eq. (8), (10)).

B Generated Summary Examples

This appendix provides example documents from the test set, with side-by-side comparisons of the human generated (golden) summaries and the summaries produced by our models. **Baseline** is a **single-agent** model trained with MLE+RL loss, **(m3)** model in Table 1, while our best **multi-agent** model is optimized by mixed MLE+SEM+RL loss, the **(m7)** model in Table 1.

- red highlights : indicate details that should not appear in the summary but the models generated them.
- red : indicates factual errors in the summary.
- green highlights : indicate key facts in the human (gold) summary that only one of the models manage to capture.

Document	model abbey clancy is helping to target breast cancer , by striking a sultry pose in a new charity campaign . the winner of 2013 's strictly come dancing joins singer foxes , 25 , victoria 's secret angel lily donaldson , 28 , and model alice dellal , 27 , in the new series of pictures by photographer simon emmett for fashion targets breast cancer . clancy , 29 , looks chic as she shows off her famous legs , wearing just a plain white shirt . abbey clancy leads the glamour as she joins forces with her famous friends to target breast cancer , by striking a sultry pose in a new charity campaign the model , who is mother to four - year - old daughter sophia with footballer husband peter crouch , said: ' as a mum , it makes me proud to be part of a campaign that funds vital work towards ensuring the next generation of young women do not have be afraid of a diagnosis of breast cancer . ' i'm wearing my support , and i want everyone across the uk to do the same and get behind this campaign . ' holding onto heaven singer foxes looks foxy in cropped stripy top and jeans . abbey says she is proud to be part of a campaign that funds vital work towards ensuring the next generation of young women do not have be afraid of a diagnosis of breast cancer victoria 's secret angel lily donaldson , who has been in the industry for years , also adds some glamour to the charity campaign holding onto heaven singer foxes dons a stripy top and jeans for the campaign she says she 's ' honoured ' to be a part of she said: ' i'm so honoured to be taking part in this year 's fashion targets breast cancer , and becoming part of the campaign 's awesome heritage . ' fashion is a huge part of my life , and if by taking part i can inspire women to wear their support , join the fight and take on breast cancer head on , then that will be something to be really proud of . ' now in its 19th year , the campaign has so far raised 13 . 5m for breakthrough breast cancer 's research funding . this year the range of clothes and accessories have been produced in conjunction with high street partners m&s , river island , warehouse , topshop , laura ashley , debenhams , superga , baukjen and the cambridge satchel company . they can be viewed online at www . fashiontargetsbreastcancer . org . uk/lookbook the campaign , which also stars alice dellal , has so far raised 13 . 5m for breakthrough breast cancer 's research funding

Table 7: In this example both single- and multi-agent models demonstrate extractive behaviors. However, each select sentences from different sections of the document. While the single model extracts the second and the third sentences, the multi-agent model successfully selects salient sentences from sentences that are further down in the document, specifically sentence 8 and 10. This can be attributed to the fact that agents can successfully encode salient aspects distributed in distant sections of the document. An interesting result is that even though the multi-agent model shows extractive behaviour in this example, it successfully selects the most salient sentences while the single agent model includes superfluous details.

Document	michelle pfeiffer is the latest hollywood star preparing to hit the small screen . the oscar nominated star known for her roles in iconic films such as scarface , dangerous liaisons andthe age of innocence , has teamed up with katie couric to pitch a new television comedy about a morning news program . also involved in the project , in which pfeiffer is attached to star , is diane english , the creator of murphy brown . scroll down for video michelle pfeiffer (left) is set to star in a new television comedy about a morning news program produced by katie couric (right) the series was created by diane english (above with candice bergen) , who was behind the show murphy brown , about a female news anchor according to variety , pfeiffer 's role will be that of a morning news anchor , making it very similar to the real life role couric played as co - host of today for 15 years . **couric will serve as an executive producer and help ' ensure the series strikes realistic notes . ' the creator behind the project , english , was previously the brains behind brown , the show starring candice bergen that centered around a female news anchor and ran for ten seasons , winning 18 emmys . english would also serve as a writer , producer and showrunner on the program**. the ladies are currently in talks with hbo , showtime , amc , netflix and amazon to pick up the program . couric will serve as an executive producer , drawing on her experience as an anchor on today for 15 years pfeiffer would be the one of the biggest stars yet to move to television , joining a group that now includes house of cards stars robin wright and kevin spacey , true detective leads matthew mcconaughey and woody harrelson , and even lady gaga , who recently announced she would be appearing on the next season of american horror story . the actress has kept a low profile for the past 20 years since becoming a mother , only doing a handful of films in that time . she most recently appeared alongside robert de niro in the mob comedy ' the family . '
Human (Gold)	michelle pfeiffer is set to star in a new television comedy about a morning news program . katie couric will serve as an executive producer , drawing on her experience as an anchor on today for 15 years . the series was created by diane english , who was behind the show murphy brown , about a female news anchor . the ladies are currently in talks with hbo , showtime , amc , netflix and amazon to pick up the program .
Single Agent Baseline	the oscar nominated star known for her roles in iconic filmssuch as scarface , dangerous liaisons and the age of innocence , has teamed up with katie couric to pitch a new television comedy about a morning news program . also involved in the project , in which pfeiffer is attached to star , is diane english , the creator of murphy brown .
Multi Agent	michelle pfeiffer is set to star in a new tv comedy about a morning news program . couric will serve as an executive producer and showrunner on the project . the series was created by diane english , the creator of murphy brown . pfeiffer is the one of the biggest stars .

Table 8: The baseline model generates non-coherent summary that references the main character "Michelle Pfeiffer" in an ambiguous way towards the end of the generated summary. In contrast, the multi-agent model successfully captures the main character including the **key facts**. One interesting feature that the multi-agent model showcases is its simplification property, which accounts for its strength in **abstraction**. Specifically, it simplified the **bold** long sentence in the document starting with "*couric will...* and only generated the salient words.

Document	everton manager roberto martinez was forced to defend another penalty fiasco at the club after ross barkley missed from the spot in their 1 - 0 win against burnley at goodison park . the untried barkley inexplicably took the 10th minute kick awarded for a foul by david jones on aaron lennon rather than leighton baines , who has scored 15 penalties from 16 attempts in the premier league . although there was no dispute between the team - mates this time , it brought back memories of everton 's match against west brom in january when kevin mirallas grabbed the ball from baines to take a penalty - and missed . ross barkley steps up to take a 10th minute penalty despite the presence of leighton baines on the pitch barkley 's effort is saved byburnley goalkeeper tom heaton at goodison park martinez insisted barkley was within his rights to request penalty - taking duties on saturday . ' if romelu lukaku had been on the pitch , he would have taken it . otherwise , i am happy to have three or four players who can take penalties and let it depend on how they feel at that moment , ' argued the everton manager . baines (left)has scored 15 penalties from 16 attempts in the premier league ' ross showed incredible responsibility to take it . i love seeing players take control of the big moments and leighton was happy to given him that responsibility . ' barkley 's penalty was well - struck but wasn't put in the corner and burnley goalkeeper tom heaton dived to his right to save . fortunately for the young england player , it didn't prove costly as mirallas went on to score the only goal of the game after 29 minutes . everton boss roberto martinez issues instructions to his players during a break in play against burnley
Human (Gold)	everton defeated burnley 1 - 0 at goodison park on saturday . kevin mirallas scored the only goal of the game in the 29th minute . ross barkley had earlier missed a 10th - minute penalty . leighton baines has scored 15 penalties from 16 attempts this season .
Single Agent Baseline	everton manager roberto martinez was forced to defend another penalty fiasco at the club after ross barkley missed from the spot in their 1 - 0 win against burnley at goodison park . the untried barkley inexplicably took the 10th minute kick awarded for a foul by david jones on aaron lennon rather than leighton baines , who has scored 15 penalties from 16 attempts in the premier league .
Multi Agent	everton beat burnley 1 - 0 at goodison park in the premier league . ross barkley steps up to take a 10th minute penalty but missed it . barkley has scored 15 penalties from 16 attempts in the pitch .

Table 9: The single agent model generates summary with superfluous details and the facts are not clearly expressed. Although it was able to capture the statistics of the player correctly (e.g., *15 penalties*, *16 attempts*), it still missed the player who scored the only goal in the game (i.e., *kevin mirallas*). On the other hand multi-agent model was able to generate a concise summary with several key facts. However, similar to single agent model, it missed to capture the player who scored the only goal in the game. Interestingly, the document contains the word "*defeated*' but the multi-agent model chose to use *beat* instead, which does not exist in the original document.

Encoding Conversation Context for Neural Keyphrase Extraction from Microblog Posts

Abstract

Existing keyphrase extraction methods suffer from data sparsity problem when they are conducted on short and informal texts, especially microblog messages. Enriching context is one way to alleviate this problem. Considering that conversations are formed by reposting and replying messages, they provide useful clues for recognizing essential content in target posts and are therefore helpful for keyphrase identification. In this paper, we present a neural keyphrase extraction framework for microblog posts that takes their conversation context into account, where four types of neural encoders, namely, averaged embedding, RNN, attention, and memory networks, are proposed to represent the conversation context. Experimental results on Twitter and Weibo datasets[1] show that our framework with such encoders outperforms state-of-the-art approaches.

1 Introduction

The increasing popularity of microblogs results in a huge volume of daily-produced user-generated data. As a result, such explosive growth of data far outpaces human beings' reading and understanding capacity. Techniques that can automatically identify critical excerpts from microblog posts are therefore in growing demand. Keyphrase extraction is one of the techniques that can meet this demand, because it is defined to identify salient phrases, generally formed by one or multiple words, for representing key focus and main topics for a given collection (Turney, 2000; Zhao et al., 2011). Particularly for microblogs, keyphrase extraction has been proven useful to downstream applications such as information retrieval (Choi et al., 2012), text summarization (Zhao et al., 2011), event tracking (Ribeiro et al., 2017), etc.

Target post for keyphrase extraction:
"I will curse you in that forum" is the lowest of low. You are an embarrassment **president Duterte**. Childish!
Messages forming a conversation:
[R1]: any *head of state* will be irked if asked to report to *another head of state*
[R2]: Really? Did *Obama* really asked *Duterte* to report to him? LOL

Table 1: An example conversation about "president Duterte" on Twitter. [Ri]: The i-th message in conversation ordered by their positing time. **president Duterte**: keyphrase to be detected; *Italic words*: words that are related to the main topic in conversations and can indicate the keyphrase.

To date, most efforts on keyphrase extraction on microblogs treat messages as independent documents or sentences, and then apply ranking-based models (Zhao et al., 2011; Bellaachia and Al-Dhelaan, 2012; Marujo et al., 2015) or sequence tagging models (Zhang et al., 2016) on them. It is arguable that these methods are suboptimal for recognizing salient content from short and informal messages due to the severe data sparsity problem. Considering that microblogs allow users to form conversations on issues of interests by *reposting with comments*[2] and *replying to messages* for voicing opinions on previous discussed points, these conversations can enrich context for short messages (Chang et al., 2013; Li et al., 2015), and have been proven useful for identifying topic-related content (Li et al., 2016). For example, Table 1 displays a target post with keyphrase "*president Duterte*" and its reposting and replying messages forming a conversation.

Easily identified, critical words are mentioned multiple times in conversations. Such as in [R2], keyword "*Duterte*" re-occurs in the conversation.

[*]Work was done during the internship at Tencent AI Lab.

[1]Our datasets are released at: http://ai.tencent.com/ailab/Encoding_Conversation_Context_for_Neural_Keyphrase_Extraction_from_Microblog_Posts.html

[2]On Twitter, reposting behavior is named as retweet.

Proceedings of NAACL-HLT 2018, pages 1676–1686
New Orleans, Louisiana, June 1 - 6, 2018.

Also, topic-relevant content, e.g., "*head of state*", "*another head of state*", "*Obama*", helps to indicate keyphrase "*president Duterte*". Such contextual information embedded in a conversation is nonetheless ignored for keyphrase extraction in existing approaches.

In this paper, we present a neural keyphrase extraction framework that exploits conversation context, which is represented by neural encoders for capturing salient content to help in indicating keyphrases in target posts. Conversation context has been proven useful in many NLP tasks on social media, such as sentiment analysis (Ren et al., 2016), summarization (Chang et al., 2013; Li et al., 2015), and sarcasm detection (Ghosh et al., 2017). We use four context encoders in our model, namely, averaged embedding, RNN (Pearlmutter, 1989), attention (Bahdanau et al., 2014), and memory networks (Weston et al., 2015), which are proven useful in text representation (Cho et al., 2014; Weston et al., 2015; Huang et al., 2016; Nie et al., 2017). Particularly in this task, to the best of our knowledge, we are the first to encode conversations for detecting keyphrases in microblog posts. Experimental results on Twitter and Sina Weibo datasets demonstrate that, by effectively encoding context in conversations, our proposed approach outperforms existing approaches by a large margin. Quantitative and qualitative analysis suggest that our framework performs robustly on keyphrases with various length. Some encoders such as memory networks can detect salient and topic-related content, whose occurrences are highly indicative of keyphrases. In addition, we test ranking-based models with and without considering conversations. The results also confirm that conversation context can boost keyphrase extraction of ranking-based models.

2 Keyphrase Extraction with Conversation Context Encoding

Our keyphrase extraction framework consists of two parts, i.e., a keyphrase tagger and a conversation context encoder. The keyphrase tagger aims to identify keyphrases from a target post, and the context encoders captures the salient content in conversations, which would indicate keyphrases in the target post. The entire framework is learned synchronously with the given target posts and their corresponding conversation context. In prediction, the keyphrase tagger identifies keyphrases in a post with the help of representations generated by the encoder. Figure 1 shows the overall structure of our keyphrase extraction framework. In the rest of this section, Section 2.1 describes the keyphrase taggers used in our framework; Section 2.2 gives the details of different context encoders.

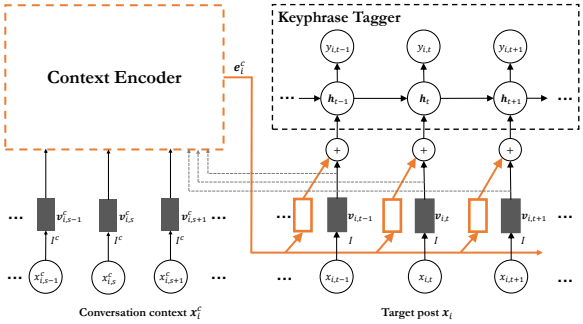

Figure 1: The overall structure of our keyphrase extraction framework with context encoder. Grey dotted array refer to the inputs of target posts that are also used in context encoding.

SINGLE	$x_{i,t}$ is a one-word keyphrase (keyword).
BEGIN	$x_{i,t}$ is the first word of a keyphrase.
MIDDLE	$x_{i,t}$ is part of a keyphrase but it is neither the first nor the last word of the keyphrase.
END	$x_{i,t}$ is the last word of a keyphrase
NOT	$x_{i,t}$ is not a keyword or part of a keyphrase.

Table 2: Definitions of different $y_{i,t}$.

2.1 Keyphrase Taggers

We follow Zhang et al. (2016) to cast keyphrase extraction into the sequence tagging task. Formally, given a target microblog post $\mathbf{x}_i$ formulated as word sequence $< x_{i,1}, x_{i,2}, ..., x_{i,|\mathbf{x}_i|} >$, where $|\mathbf{x}_i|$ denotes the length of $\mathbf{x}_i$, we aim to produce a tag sequence $< y_{i,1}, y_{i,2}, ..., y_{i,|\mathbf{x}_i|} >$, where $y_{i,t}$ indicates whether $x_{i,t}$ is part of a keyphrase. In detail, $y_{i,t}$ has five possible values:

$$y_{i,t} \in \{\text{SINGLE, BEGIN, MIDDLE, END, NOT}\}$$

Table 2 lists the definition of each value. Zhang et al. (2016) has shown that keyphrase extraction methods with this 5-value tagset perform better than those with binary outputs, i.e., only marked with yes or no for a word to be part of a keyphrase.

To predict keyphrase tags, we use four state-of-the-art neural sequence taggers, namely, recurrent neural networks (RNN) (Pearlmutter, 1989), RNN with gated recurrent units (GRU) (Chung et al., 2014), long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997), and bidirectional LSTM (BiLSTM) (Graves and Schmidhuber, 2005).

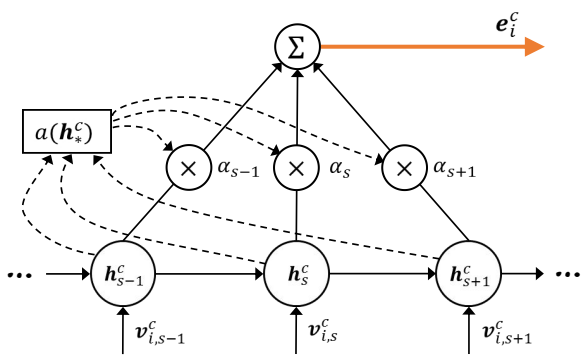

Figure 2: The structure of attention-based conversation context encoder.

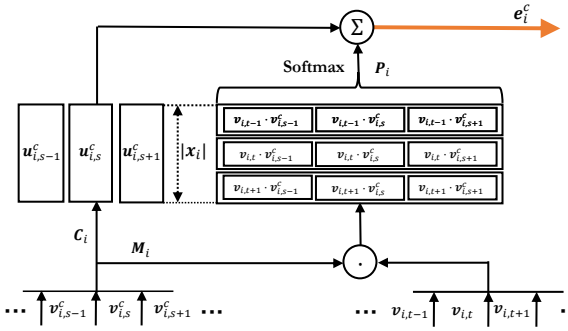

Figure 3: The structure of the conversation context encoder based on memory networks.

In addition to one-type output, we also use joint-layer RNN proposed by Zhang et al. (2016), which is demonstrated to be the state-of-the-art keyphrase tagger in previous work without modeling conversation context. As a multi-task learner (Collobert and Weston, 2008), joint-layer RNN tackles two tasks with two types of outputs, $y_{i,t}^1$ and $y_{i,t}^2$. $y_{i,t}^1$ has a binary tagset, which indicates whether word $x_{i,t}$ is part of a keyphrase or not. $y_{i,t}^2$ employs the 5-value tagset defined in Table 2. Besides the standard RNN version, in implementation, we also build the joint-layer RNN with its GRU, LSTM, and BiLSTM counterparts. To be consistent, taggers with one-type output with the 5-value tagset are named as single-layer taggers.

As shown in Figure 1, our keyphrase tagger is built upon input feature map $I(\cdot)$, which embeds each word $x_{i,t}$ in target post into a dense vector format, i.e., $I(x_{i,t}) = \boldsymbol{\nu}_{i,t}$. We initialize input feature map by pre-trained embeddings, and update embeddings during training.

2.2 Context Encoders

We aggregate all reposting and replying messages in conversations to form a pseudo-document as *context* by their posting time, and input context in forms of word sequences into context encoder. Let $\mathbf{x}_i^c$ denote the context word sequence of the target post $\mathbf{x}_i$, we propose four methods to encode $\mathbf{x}_i^c$, namely, *averaged embedding*, *RNN*, *attention*, and *memory networks*. Similar to keyphrase taggers (see Section 2.1), each word $x_{i,s}^c$ in context $\mathbf{x}_i^c$ takes the form of a vector $\boldsymbol{\nu}_{i,s}^c$ mapped by an input layer $I^c(\cdot)$, which is also initialized by pre-trained embeddings, and updated in the training process.

2.2.1 Averaged Embedding

As a straightforward sentence representation technique, averaged embedding simply takes the average embeddings of words in a context, i.e., $\boldsymbol{\nu}_{i,s}^c$, as the encoding of context representation, i.e.,

$$\mathbf{e}_i^c = \frac{1}{|\mathbf{x}_i^c|} \sum_{s=1}^{|\mathbf{x}_i^c|} \boldsymbol{\nu}_{i,s}^c \tag{1}$$

where $|\mathbf{x}_i^c|$ is the length of $\mathbf{x}_i^c$ in the context.

2.2.2 RNN

RNN encoders employ the recurrent neural network model for the embedded context sequence $< \boldsymbol{\nu}_{i,1}^c, \boldsymbol{\nu}_{i,2}^c, ..., \boldsymbol{\nu}_{i,|\mathbf{x}_i^c|}^c >$, through the recurrent functions over all the states:

$$\mathbf{h}_{i,s}^c = \delta_h(\mathbf{W}_h^1 \mathbf{h}_{i,s-1}^c + \mathbf{W}_h^2 \boldsymbol{\nu}_{i,s}^c) \tag{2}$$

where $\mathbf{W}_h^1$ and $\mathbf{W}_h^2$ are learnable weight matrices, and δ_h is the component-wise sigmoid function. The encoder representation is thus given by the hidden units at the last state:

$$\mathbf{e}_i^c = \mathbf{h}_{|\mathbf{x}_i^c|}^c \tag{3}$$

In this paper, RNN-based encoders have four variants, namely, RNN, GRU, LSTM, and BiLSTM. Particularly, as BiLSTM has two opposite directions, its context representation takes the concatenation of the last states from both directions, which come from two ends of a given context.

2.2.3 Attention

Attention-based encoders put attention mechanism (Bahdanau et al., 2014) upon RNN model for "soft-addressing" important words in the conversation context. In this paper, we use the feed-forward attention (Raffel and Ellis, 2015; SØnderby et al., 2015), as shown in Figure 2. The encoder is thus represented as

$$\mathbf{e}_i^c = \sum_{s=1}^{|x_i^c|} \alpha_{i,s}^c \mathbf{h}_{i,s}^c \tag{4}$$

where $\alpha^c_{i,s}$ is the attention coefficient obtained for word $\mathbf{x}^c_s$, which implicitly reflects its importance for helping keyphrase identification. $\alpha^c_{i,s}$ is computed via a softmax over the hidden states by

$$\alpha^c_{i,s} = softmax(a(\mathbf{h}^c_{i,s})) \quad (5)$$

where $a(\cdot)$ is a learnable function formulated as:

$$a(\mathbf{h}^c_{i,s}) = tanh(\mathbf{W}_a \mathbf{h}^c_{i,s}) \quad (6)$$

which takes input only from on $\mathbf{h}^c_{i,s}$. $\mathbf{W}_a$ are parameters of the function $a(\cdot)$ to be learned.

2.2.4 Memory Networks

The encoder based on memory networks (MemNN) (Weston et al., 2015) stores and updates the representations of conversation contexts in a memory module. The updated representations are used to guide the keyphrase tagger. Figure 3 illustrates its structure.

Formally, each embedded context sequence $\mathbf{V}^c_i =< \boldsymbol{\nu}^c_{i,1}, \boldsymbol{\nu}^c_{i,2}, ..., \boldsymbol{\nu}^c_{i,|\mathbf{x}^c_i|} >$ is stored into memory $\mathbf{M}_i$. We then yield the match between embedded target post $\mathbf{V}_i =< \boldsymbol{\nu}_{i,1}, \boldsymbol{\nu}_{i,2}, ..., \boldsymbol{\nu}_{i,|\mathbf{x}_i|} >$ and context memory $\mathbf{M}_i$ by their inner product activated by softmax:

$$\mathbf{P}_i = softmax(\mathbf{V}_i \cdot \mathbf{M}_i) \quad (7)$$

where $\mathbf{P}_{i,j,j'}$ captures the similarity between the j-th word in conversation context $\mathbf{x}^c_i$ and the j'-th word in target post $\mathbf{x}_i$.

To transform context input $\mathbf{x}^c_i$ into an aligned form so that it is able to be added with $\mathbf{P}_i$, we include another embedding matrix $\mathbf{C}_i =< \boldsymbol{\mu}_{i,1}, ..., \boldsymbol{\mu}_{i,|\mathbf{x}^c_i|} >$. Similar to attention encoder, the MemNN encoder aims to generate a representation, which addresses the important part in the conversation context that helps tagging keyphrases in target post $\mathbf{x}_i$. The sum of $\mathbf{C}_i$ and matching matrix $\mathbf{P}_i$ serves as the encoded representation for conversation context:

$$\mathbf{e}^c_i = \mathbf{P}_i + \mathbf{C}_i \quad (8)$$

In particular, both attention and MemNN explores salient words in conversations that describe main focus of the conversation, which helps indicate keyphrases of a target post. In comparison, MemNN explicitly exploits the affinity of target posts and conversations in matching each other, while attention implicitly highlights certain context without taking target posts into account.

Dataset	# of annot. msgs	# of msgs in context	Context length	Vocab
Twitter				
Train	3,976	3.38	49.74	34,412
Dev	497	3.19	46.44	7,186
Test	497	3.30	48.09	8,779
Weibo				
Train	13,816	1.97	55.77	25,259
Dev	1,727	2.01	45.00	9,106
Test	1,727	1.82	51.95	9,305

Table 3: Statistics of two datasets. Train, Dev, and Test denotes training, development, and test set, respectively. # of annot. msgs: number of messages with keyphrase annotation, each containing conversation context. # of msgs in context: average count of message in conversation context. Context length: average count of words in conversation context. Vocab: vocabulary size.

3 Experiment Setup

3.1 Datasets

Our experiments are conducted on two datasets collected from Twitter and Weibo[3], respectively. The **Twitter** dataset is constructed based on TREC2011 microblog track[4]. To recover conversations, we used Tweet Search API[5] to retrieve full information of a tweet with its "in reply to status id" included. Recursively, we searched the "in reply to" tweet till the entire conversation is recovered. Note that we do not consider retweet relations, i.e., reposting behaviors on Twitter, because retweets provide limited extra textual information for the reason that Twitter did not allow users to add comments in retweets until 2015. To build the **Weibo** dataset, we tracked real-time trending hashtags[6] on Weibo and used the hashtag-search API[7] to crawl the posts matching the given hashtag queries. In the end, a large-scale Weibo corpus is built containing Weibo messages posted during January 2nd to July 31st, 2014.

For keyphrase annotation, we follow Zhang et al. (2016) to use microblog hashtags as gold-

[3]Weibo is short for Sina Weibo, the biggest microblog platform in China and shares the similar market penetration as Twitter (Rapoza, 2011). Similar to Twitter, it has a length limitation of 140 Chinese characters.

Table 4: Comparisons of the average F1 scores (%) and their standard deviations measured on Twitter over the results of models with 5 sets of parameters for random initialization. The left half reports results of single-layer taggers; The right half reports results of joint-layer taggers. Each column: results of the same tagger with different encoders. Each row: results of different taggers with the same encoder. No Encoder: taggers without encoding context. Abbreviations for context encoders: Avg Emb – averaged embedding; Att (LSTM) – attention on LSTM; Att (BiLSTM) – attention on BiLSTM; MemNN – memory networks.

standard keyphrases[8] and filtered all microblog posts by two rules: first, there is only one hashtag per post; second, the hashtag is inside a post, i.e., containing neither the first nor the last word of a post. Then, we removed all the "#" symbols in hashtags before keyphrase extraction. For both Twitter and Weibo dataset, we randomly sample 80% for training, 10% for development, and the rest 10% for test. Table 3 reports the statistics of the two datasets. The dataset released by Zhang et al. (2016) is not used because it does not contain conversation information.

We preprocessed Twitter dataset with Twitter NLP tool[9] (Gimpel et al., 2011; Owoputi et al., 2013) for tokenization. For Weibo dataset, we used NLPIR tool[10] (Zhang et al., 2003) for Chinese word segmentation. In particular, Weibo conversations have an relatively wide range (from 3 to 8,846 words), e.g., one conversation could contain up to 447 messages. If use the maximum length of all conversations as the input length for encoders, padding the inputs will lead to a sparse matrix. Therefore, for long conversations (with more than 10 messages), we use KLSum (Haghighi and Vanderwende, 2009) to produce summaries with a length of 10 messages and then encode the produced summaries. In contrast, we do not summarize Twitter conversations because their length range is much narrower (from 4 to 1,035 words).

[8] Zhang et al. (2016) proves that 90% of the hashtag-annotated keyphrases match human annotations.

3.2 Model Settings

For keyphrase taggers based on RNN, GRU, and LSTM, we follow Zhang et al. (2016) and set their state size to 300. For the BiLSTM tagger, which has two directions, we set the state size for each direction to 150. The joint-layer taggers employ the same hyper-parameters according to Zhang et al. (2016). The state size of context encoders shares the same settings with keyphrase taggers. In training, the entire keyphrase extraction framework uses cross-entropy loss and RMSprop optimizer (Graves, 2013) for parameter updating.

We initialize input feature map I for target post and I_c for conversation context by embeddings pre-trained on large-scale external microblog collections from Twitter and Weibo. Twitter embeddings are trained on 99M tweets with 27B tokens and 4.6M words in the vocabulary. Weibo embeddings are trained on 467M Weibo messages with 1.7B words and 2.5M words in the vocabulary.

In comparison, we employ neural taggers without encoding conversation context, which are based on RNN, GRU, LSTM, and BiLSTM. We also compare our models with the state-of-the-art joint-layer RNN (Zhang et al., 2016) and its GRU, LSTM, and BiLSTM variations.

To further illustrate the effectiveness of leveraging conversation context for keyphrase extraction, we also evaluate some ranking-based models, namely, TF-IDF (Salton and Buckley, 1988), TextRank (Mihalcea and Tarau, 2004), and KEA implemented by KEA-3.0[11] (Witten et al., 1999).

Table 5: Comparisons of F1 scores on Weibo. The abbreviations are defined the same as those in Table 4.

We design two experiment settings when running these models: 1) each target post is treated as a document; 2) each conversation (containing the target post) is treated as a document. We select the top N words for each target post by their ranked-orders and the threshold N is tuned on the development set. As a result, N ranges from 2 to 7 for various methods. Particularly, since TF-IDF and TextRank extract keywords instead of keyphrases, we aggregate the selected keywords according to Bellaachia and Al-Dhelaan (2012).

4 Experimental Results

Section 4.1 to 4.5 present quantitative and qualitative analysis of our neural keyprhase extraction models. Section 4.6 reports the performance of ranking-based models where we test the general applicability of incorporating conversation context to non-neural keyphase extraction methods.

4.1 Overall Comparisons

Table 4 and Table 5 report F1 scores on Twitter and Weibo, respectively.[12] We have the following observations.

Conversation context is useful for keyphrase extraction. By combining the encoded context in conversations, the F1 scores of all taggers are better than their basic versions without context encoders. It confirms that content in conversations helps in indicating keyphrases in target posts.

Selecting the correct context encoder is important. Encoding context simply by RNN or GRU yields poor results. The reason for RNN is that it suffers from gradient vanishing problem when encoding long conversations (conversions in our two datasets have over 45 words on average). The reason for GRU is that its forget gates may be not well trained to process important content when the training set is small.

The results of AvgEmb are the worst on Twitter while competitive to other encoders on Weibo. The performance of AvgEmb is competitive to other complex context encoders on Weibo. The reason may be that incorrect word orders generally do not affect the understanding in Chinese, where word order misuse is prevalent in Chinese Weibo messages. As a result, encoding word orders, as is done by the encoders except AvgEmb, might bring noise to keyphrase extraction on Weibo dataset. In contrast, AvgEmb is the worst encoder on Twitter dataset, as word order is crucial in English.

Identifying salient content in context is important. Four types of context encoders have different behaviors. Avg Emb considers all words in conversation context are equally important. RNN-variant context encoders, i.e., RNN, GRU, LSTM, and BiLSTM, additionally explore the relations between succeeded words without distinguishing salient and non-salient words. Attention (Att (LSTM) and Att (BiLSTM)) and MemNN can recognize critical content in conversations, which would indicate keyphrases in target posts. Therefore, our keyphrase extraction framework with attention or MemNN encoder has generally better F1 scores than those with other encoders.

MemNN can effectively capture salient content in context. On Twitter dataset, MemNN achieves the best F1 scores when combining with various keyphrase taggers except for single-layer GRU and BiLSTM. On Weibo dataset, although MemNN does not always outperform other encoders, its performance is close to the best ones.

[12] We also tried BiRNN and BiGRU as keyphrase taggers and as context encoders. They are outperformed by BiLSTM. We don't report these results due to the space limitation.

	SL BiLSTM		JL BiLSTM	
	Twitter	Weibo	Twitter	Weibo
No encoder	60.8	74.8	62.5	76.8
Avg Emb	61.0	75.7	63.3	79.2
RNN	58.8	72.7	63.1	71.1
GRU	56.4	73.1	62.7	76.0
LSTM	61.3	75.2	63.9	77.8
BiLSTM	62.0	75.4	62.3	78.0
Att (LSTM)	**62.6**	75.6	63.7	79.2
Att (BiLSTM)	62.0	76.5	63.9	**79.9**
MemNN	61.6	**77.4**	**65.1**	79.2

Table 6: The F1 scores of BiLSTM taggers measured on test instances without conversation context (%). SL BiLSTM and JL BiLSTM denote keyphrase tagger as single-layer and joint-layer BiLSTM, respectively. The other abbreviations are defined the same as those in Table 4.

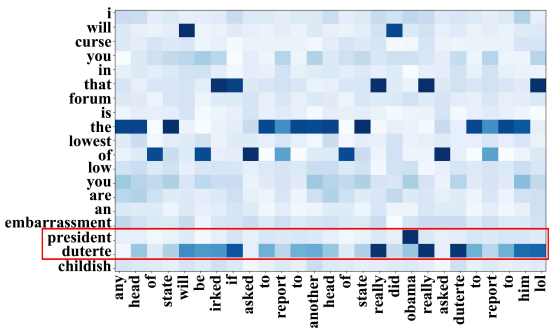

Figure 4: The heatmap of the context representation generated by MemNN (see Eq. 8). The horizontal axis refers to words in the conversation context, while the vertical axis refers to words in the target post. Darker colors indicate higher weights. The red box indicates the keyphrase to be detected.

4.2 Test without Conversation Context

Although we have shown in the previous section that conversation context is useful for training effective models for keyphrase extraction on microblog posts, it is necessary to consider that conversation context might be unavailable to some microblog posts, which do not sparking any repost or reply message. Under this circumstance, the models trained on messages with conversation context might be affected in extracting the keyphrases for messages without conversation context. To study whether conversation context is critical in testing process, we assume that the conversations are only available for training data, while all the target posts in the test set have no context to be leveraged. To this end, we apply the models trained for the experiment in Section 4.1 on the test posts without using their conversation context. In prediction, context encoders of the trained models take the target posts instead of conversation as input. Results are reported in Table 6, where models with context encoders yield better F1 scores than their counterparts without such encoders no matter providing conversation to test data or not. This observation indicates that encoding conversations in training data helps in learning effective keyphrase extraction models, which is beneficial to detect keyphrases in a microblog post with or without its conversation context. In addition, by comparing Table 6 with Table 4 and 5, we find that, for each model with context encoder, higher F1 scores are observed when conversation context is used in testing process. This observation confirms that, conversation context of target posts helps in indicating keyphrases in prediction.

4.3 Qualitative Analysis

To qualitatively analyze why MemNN encoder generally performs better in comparison, we conduct a case study on the sample instance in Table 1. Recall that the keyphrase should be "*president Duterte*". We compare the keyphrases produced by the joint-layer BiLSTM tagger with various context encoders, given in Table 7. Of all models, only the one with MemNN encoder tags correctly. Interestingly, Avg Emb does not extract any keyphrase. The reason might be that it considers each word in conversations independent and equally important. Therefore, when using this encoder, non-topic words like "*if*" and "*LOL*" may distract the keyphrase tagger in identifying the key information. Models with BiLSTM, Att (BiLSTM), and the basic model without encoder mistakenly extract the sentiment word "*childish*" since sentiment words are prominent on Twitter.

We also visualize context representation generated by MemNN for conversation context in a heatmap shown in Figure 4. It is observed that MemNN highlights different types of words for keyphrases and non-keyphrases. For keyphrases, MemNN highlights topical words such as "*Obama*". For non-keyphrases, MemNN highlights non-topic words, e.g., "*be*", "*to*". Therefore, features learned for keyphrases and non-keyphrases are different, which can thus benefit keyphrase tagger to correctly distinguish keyphrases from non-keyphrases.

4.4 Keyphrases with Various Lengths

To further evaluate our methods, we investigate them on keyphrases with various lengths. Figure 5

	Extracted keyphrase
Gold-standard	*president duterte*
No encoder	*duterte childish*
Context Encoder	
Avg Emb	*NULL*
BiLSTM	*duterte childish*
Att (BiLSTM)	*president duterte childish*
MemNN	*president duterte*

Table 7: Outputs of joint-layer BiLSTM combined with various context encoders given the example illustrated in Table1. "*NULL*": Avg Emb did not produce any keyphrase.

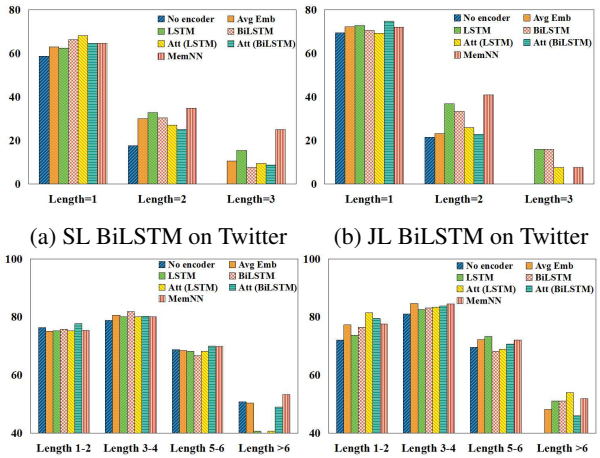
shows the histograms of F1 scores yielded by a single-layer and a joint-layer tagger on Twitter and Weibo when keyphrase lengths are different. Note that we only report the results of BiLSTM taggers because their overall F1 scores are the best according to Table 4 and Table 5.

In general, the F1 scores of all models decrease when keyphrases becomes longer, which implies that detecting longer keyphrases is harder than short ones. In comparison of different context encoders, we observe that MemNN obtained the best F1 score in detection of long keyphrases. This is because MemNN highlights salient content in conversation context by jointly considering its similarities with keyphrases in target posts. When the keyphrases become longer, there are more words in context highlighted, which hence helps keyphrase tagger. For short keyphrases, MemNN is still competitive with other context encoders. The observation suggests that MemNN is robust in detecting various length of keyphrases.

4.5 Error Analysis

In this section, we briefly discuss the errors found in our experiments. It is observed that one major incorrect prediction is additionally extracted neighboring words surrounding a gold-standard keyphrase. For example, in the tweet "*Hillary Clinton accepted gifts from UAE, Saudi Arabia, Oman and others while SOS. CROOKED Podesta Emails 29 ...*", in addition to the gold-standard "*Podesta Emails 29*", our models also extract out "*CROOKED*". In general, these additionally extracted words are mostly modifiers of keyphrases. External features for identifying modifiers can be used to filter these auxiliary parts of a keyphrase.

Another main error comes from the words that are not keyphrases in target posts but reflect the topics in conversations. For example, joint-layer



(a) SL BiLSTM on Twitter (b) JL BiLSTM on Twitter

(c) SL BiLSTM on Weibo (d) JL BiLSTM on Weibo

Figure 5: Histograms of F1 scores on extracting keyphrases with various lengths. SL BiLSTM: tagger based on single-layer BiLSTM. JL BiLSTM: tagger based on joint-layer BiLSTM. Length: count of words in keyphrases. For each length range, histograms from left to right show the results of No encoder, Avg Emb, LSTM, BiLSTM, Att (LSTM), ATT (BiLSTM), and MemNN.

BiLSTM tagger with MemNN encoder mistakenly extracts "*Hillary*" as a keyphrase for "*DOUBLE STANDARD: Obama DOJ Prosecuted Others For Leaking FAR LESS Than Hillary Espionage URL*" whose keyphrase should be "*Espionage*". Because the corresponding conversation of this post is centered around "*Hillary*" instead of "*Espionage*", such information is captured by the context encoder, which leads to incorrect keyphrase prediction. However, this type of error points out the potential of extending our framework to extracting keyphrases from conversations instead of a post, which would be beneficial to generating summary-worthy content for conversations (Fernández et al., 2008; Loza et al., 2014).

4.6 Ranking-based Models

Table 8 reports the results of ranking models on Twitter and Weibo. We have the following observations. First, tagging-based models perform much better than ranking-based ones in keyphrase extraction. Comparing the results in Table 8 with that in Table 4 and Table 5, all neural taggers outperform non-neural ranking-based models by a large margin. This fact, again, confirms that keyphrase extraction is a challenging task on short microblog messages. Compared to ranking-based models, neural tagging models have the ability

	Twitter			Weibo		
	Pre	Rec	F1	Pre	Rec	F1
w/o context						
TF-IDF	6.3	**48.8**	11.1	1.9	7.3	3.0
TextRank	6.6	18.8	9.7	1.0	8.6	1.7
KEA	3.5	0.8	1.3	0.1	0.2	0.1
w/ context						
TF-IDF	7.9	45.6	13.4	2.1	8.3	3.4
TextRank	4.8	20.8	7.8	1.0	9.5	1.8
KEA	**15.4**	12.9	**14.0**	**2.2**	**12.3**	**3.7**

Table 8: Precision, recall, and F1 scores of ranking-based baselines (%). w/o context: each target post is treated as a document; w/ context: each conversation and its corresponding target post is treated as a document.

to capture indicative features. Second, conversation context improves ranking-based models by a large margin. Simply by aggregating conversations to a pseudo-document, the F1 scores of TF-IDF, TextRank, and KEA are generally better than their counterparts that are only performed on target posts. For TF-IDF and TextRank, which are unsupervised, context remarkably improves recall by enriching more topic-related words. While for supervised method KEA, context improves both precision and recall, because supervision helps in identifying good features from conversations.

5 Related Work

Previous work on extracting keyphrases mainly focuses on formal texts like news reports (Wan and Xiao, 2008) and scientific articles (Nguyen and Kan, 2007). Existing keyphrase extraction models can be categorized as ranking-based models and tagging-based models. Ranking-based methods include models based on graph ranking (Mihalcea and Tarau, 2004; Wan and Xiao, 2008), text clustering (Liu et al., 2009), TF-IDF (Jones, 2004; Zhang et al., 2007; Lee and Kim, 2008; Kireyev, 2009; Wu and Giles, 2013), etc. The empirical study provided by Hasan and Ng (2010) shows that TF-IDF has robust performance and can serve as a strong baseline. Tagging models focus on using manually-crafted features for binary classifiers to predict keyphrases (Frank et al., 1999; Tang et al., 2004; Medelyan and Witten, 2006). Our models are in the line of tagging approaches, and provide an alternative choice that incorporates additionally knowledge from conversations.

Recently, keyphrase extraction methods have been extended to social media texts (Zhao et al., 2011; Bellaachia and Al-Dhelaan, 2012; Marujo et al., 2015; Zhang et al., 2016). These work suffers from the data sparsity issue because social media texts are normally short. Also, they only use internal information in the input text and ignore external knowledge in conversation context. Thus our work provides an improved approach that compensates their limitations.

6 Conclusion

This work presents a keyphrase extraction framework for microblog posts with considering conversation context to alleviate the data sparsity in short and colloquial messages. The posts to be tagged are enriched by conversation context through four types of encoders based on averaged embedding, RNN, attention, and memory networks, which are effective in capturing salient content in conversations that is indicative for keyphrase identification. Experimental results on Twitter and Weibo dataset have shown that by effectively encoding conversation context, our proposed models outperform existing approaches by a large margin. Qualitative analysis confirm that our context encoders capture critical content in conversations.

Abstract

Automatic evaluation systems in the field of automatic summarization have been relying on the availability of gold standard summaries for over ten years. Gold standard summaries are expensive to obtain and often require the availability of domain experts to achieve high quality. In this paper, we propose an alternative evaluation approach based on pairwise preferences of sentences. In comparison to gold standard summaries, they are simpler and cheaper to obtain. In our experiments, we show that humans are able to provide useful feedback in the form of pairwise preferences. The new framework performs better than the three most popular versions of ROUGE with less expensive human input. We also show that our framework can reuse already available evaluation data and achieve even better results.

1 Introduction

Due to the huge amount of information contained in texts, the task of automatic text summarization (Mani, 2001; Nenkova and McKeown, 2011) is a pressing challenge nowadays and will become even more important in the future. Building summarization systems is, however, not the only challenge in this field. Evaluation of automatically generated summaries is also an active field of research.

Ideally, we would like to ask humans for their opinion about the quality of automatically generated summaries in an extrinsic evaluation (Halteren and Teufel, 2003). Since summaries are generated for humans, they should also be evaluated directly by humans. Unfortunately, manual evaluation cannot be performed at a large scale because of the huge effort which is necessary for evaluation. (Lin, 2004) reported that 3,000 hours of human effort would be required for a simple evaluation of the summaries for the Document Understanding Conference (DUC) 2003, a popular summarization shared task series. This motivates research of automatic evaluation methods for automatic summarization.

ROUGE (Lin, 2004), the current method of choice for evaluating automated text summarization, relies on the availability of gold standard summaries. The gold standard summaries are used to define the optimal output of a summarization system. Writing high-quality summaries, however, requires the availability of expert writers and takes a lot of effort. (Dang, 2005) reported that creating the reference summaries for the DUC 2005 shared task was a difficult endeavor with an effort of five hours to produce each reference summary. Since ROUGE needs at least four reference summaries to become reasonably reliable, the effort sums up to at least 20 hours of annotation effort per topic. For this reason, gold standard summaries are only available for a few, rather small datasets. Also the more accurate (but also even more expensive) Pyramid method (Nenkova and Passonneau, 2004) requires expensive gold standard summaries.

Lack of larger and diverse evaluation corpora limits research in automatic summarization. Furthermore, currently available automatic evaluation methods are viewed with skepticism (Rankel et al., 2013). Proper evaluation is, however, an indispensable ingredient for good research. Computing the similarity between two summaries as in ROUGE is a very difficult task. This seems to be obvious since estimating the similarity between sentences and even words is still an active field of research.

In this work, we present an alternative evaluation framework which does not use gold standard summaries to estimate the quality of summaries. Instead of comparing automatically generated summaries with gold standard summaries,

Proceedings of NAACL-HLT 2018, pages 1687–1696
New Orleans, Louisiana, June 1 - 6, 2018.

our model is trained with simple and inexpensive pairwise preferences (Thurstone, 1927; Fürnkranz and Hüllermeier, 2010) of sentences. To this end, we provide pairs of sentences from the input document of a summarization task to human annotators and ask which of the two sentences contains more important information. We use here the idea of intrinsic information importance (Hong and Nenkova, 2014; Zopf et al., 2016) which describes that information can be intrinsically important. For example, the information *"Donald Trump won the U.S. presidential election"* is intrinsically important. It is likely that it should also be contained in the generated summary if this information is contained in an input document.

After collecting few preferences, our model uses the preferences to generate a ranking of all sentences according to information importance. Summaries which contain sentences similar the upper part of the ranking are then considered to be better than summaries which contain unimportant sentences from the lower part of the ranking.

Pairwise preferences are an appealing form of annotation, since they are much easier to generate than producing complex gold standard summaries. Not only collecting the annotations is easier, but also using the collected annotations is much simpler. The presented model does not have to solve the difficult task of estimating the similarity between generated and gold standard summaries. Instead, the model uses the ranking to estimate the summary quality.

Figure 1 provides an illustration of the traditional evaluation and our new model. On the left, the input documents are illustrated which should be summarized. In the upper part gold standard summaries are generated by humans and used to estimate the quality of an automatically generated summary. In the lower part, we collect pairwise preferences of sentences and use the preferences for evaluation.

An evaluation on topics from two standard datasets, looking at predicting the relative ratings of automatically generated summaries, shows that our new evaluation model is as good as or better than existing methods, at a much lower annotation cost.

2 Related Work

In this section, we will recapitulate previous work in automated text summarization evaluation, focusing on three important approaches, namely model-free evaluation, ROUGE, and Pyramid. The evaluation methods are ordered according to their annotation requirements from none (model-free evaluation) to high (Pyramid). In addition to the most prominent methods described below, several evaluation models were developed in the Automatically Evaluating Summaries Of Peers (AESOP) shared tasks. The systems in this shared task also considered reference summaries as additional information to evaluate a reference summary and are therefore as expensive as ROUGE in terms of required human annotation. Similarly, Giannakopoulos and Karkaletsis (2013) use machine learning to learn a linear combination of n-gram methods to evaluate summaries. Mackie et al. (2014), Giannakopoulos (2013), and Cohan and Goharian (2016) investigate evaluation for microblog, multilingual, and scientific summarization, respectively. Our evaluation, on contrary, uses newswire datasets since this is the most prominent application domain for automatic summarization. Furthermore, we focus on evaluating the information content of summaries and do not evaluate linguistic quality. This is, for example, captured by Pitler et al. (2004).

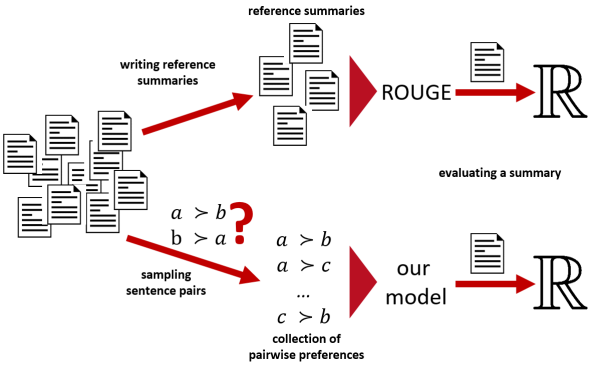

Figure 1: Illustration of traditional evaluation models based on reference summaries (top) and the new model (bottom) which is based on pairwise preferences.

2.1 Model-free Evaluation

Model-free evaluation methods Jensen-Shannon divergence (Louis and Nenkova, 2013) do not require human input such as gold standard summaries and can therefore be applied without additional cost. The quality of model-free evaluation methods is however limited, which is validated in our experiments (see Section 5).

2.2 ROUGE

ROUGE (Lin, 2004) was first used in the Document Understanding Conference (DUC) (Over et al., 2007) and is nowadays the method of choice for automatic evaluation in text summarization. Many popular summarization systems were evaluated with ROUGE (Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Gillick et al., 2009; Lin and Bilmes, 2011). It is inspired from the BLEU evaluation method (Papineni et al., 2002) and is based on measuring lexical n-gram overlap of (stemmed) tokens between generated and gold standard summaries. Researchers usually report the n-gram recall of a summary to evaluate the quality of a summary. The quality of ROUGE is often criticized in the research community. Sjöbergh (2007), for example, shows nicely how the ROUGE recall scoring can be fooled easily. A simple greedy language model based on the source documents extracts frequent bi-grams which are likely to occur in the reference summaries. The generated texts are merely lists of bi-grams and not meaningful sentences which cannot be considered to be summaries. However, they achieve superhuman ROUGE recall scores. In the TAC 2008 shared task (Dang and Owczarzak, 2008), both ROUGE-2 and ROUGE-SU4 score automatic systems higher than human summaries, which would lead to the conclusion that these systems are able to produce better summaries than humans. Furthermore, studies show that the correlation between ROUGE scores and human judgments may not be significant in non-newswire genres and other summary types (Liu and Liu, 2008). ROUGE also has many parameters (Graham, 2015), which makes reproduction and comparison of results problematic. Last but not least, ROUGE computes text similarity only based on simple string matching. Expressing the same information with different words is not rewarded by ROUGE. In addition to Graham (2015), Owczarzak et al. (2012) and Rankel et al. (2013) analyze ROUGE in more detail.

Agreement with human judgments (Owczarzak et al., 2012) can be used instead of Pearson's correlation to validate an automatic evaluation model. Measuring agreement allows to obtain a better understanding of the performance of an evaluation model compared to the Pearson correlation. We will also use agreement similarly to Owczarzak et al. (2012) in our experiments.

2.3 Pyramid

The Pyramid method (Nenkova et al., 2007) (similar to (Teufel and Van Halteren, 2004)) was used in the Text Analysis Conference (TAC) (Dang and Owczarzak, 2008) and goes beyond lexical comparisons. It is based on *Summarization Content Units* (SCUs, later also called Summary Content Units). An SCU is a set of lexical expressions with same meaning (e.g. {"2 people passed away", "two persons died"}). After generating the gold standard summaries, SCUs are extracted from these summaries and are weighted by their occurrence frequency in an additional annotation step. Furthermore, every generated summary has to be annotated individually with SCUs before the Pyramid method can be applied. (Nenkova and Passonneau, 2004) have already reported that a large-scale application of the Pyramid method is infeasible. (Over et al., 2007) report a huge effort for the annotation process in the DUC challenges. This additional annotation effort is unattractive for researchers, who prefer automatic methods such as ROUGE. This is validated by the few applications of the Pyramid method until today. The need for more human annotation also introduces an additional source for annotation mistakes. Inspecting the annotations in the TAC 2008 dataset in detail reveals that this is not only a theoretical issue but has practical implications.[1] PEAK (Yang et al., 2016) is an attempt to automate the Pyramid evaluation (similar to (Passonneau et al., 2013)). PEAK also requires reference summaries and is therefore as expensive as ROUGE.

2.4 Qualitative Feedback in Other NLP Tasks

Simple and inexpensive qualitative human feedback has already been used in the field of machine translation (Callison-Burch, 2009; Callison-Burch et al., 2012; Guzmán et al., 2015). (Snow et al., 2008) showed that in a wide variate of NLP tasks, cheap non-expert labels can replace expensive expert annotations. In comparison to our work, we are not asking non-experts to perform the same task as expert annotators (namely writing references summaries) but replace the complex task with a simpler tasks (providing qualitative feedback in form of pairwise preferences).

[1] We found several issues such as not annotating parent SCUs, missing SCUs in sentences, and different annotations for equal sentences.

3 Problem Definition

First, we define T to be the set of all possible texts which can be considered to be summaries. For a given set of source documents D, we define a binary relation $>_D \subset T \times T$ with the intuition that $\mathbf{a} >_D \mathbf{b}$ holds for two texts $\mathbf{a}, \mathbf{b} \in T$ if and only if $\mathbf{a}$ is considered to be the better summary of document collection D than $\mathbf{b}$. Whenever the context is clear, we will omit D and write $\mathbf{a} > \mathbf{b}$ for short. The relation $>$ induces a strict total order (given that ties are not allowed) over T. A text which ranks high according to $>_D$ is a good summary of the document collection D.

How good summaries are is annotated in summarization corpora only for a very small subset of assessed texts $T^+ \subset T$ by human annotators. We use the relation $>^*$ to express in which order summaries are ranked by humans in summarization corpora for each document set D (also called topic or cluster). The relation $>^*$ therefore models the human judgments. For not assessed texts $T^- = T \setminus T^+$ the human judgment is unknown.

The quality of an evaluation method E can be assessed by measuring the agreement with the human judgments. Evaluation models define (implicitly) a ranking $>^E$ by assigning scores to summaries or predicting the ranking directly. Calculating the agreement of the ranking $>^E$ with the human ranking defined by $>^*$ provides a scores which can be used to assess the performance of evaluation models. Measuring the agreement between two relations (which are sets) can be easily done by computing the intersection of both sets:[2]

$$\text{Agreement}(>^*, >^E) = \frac{|>^* \cap >^E|}{|>^*|} \quad (1)$$

This evaluation of evaluation models is similar to the definition of *Agreement* and *Contradiction* in Owczarzak et al. (2012): *"Agreements occur when the two evaluation metrics make the same distinction between System A and System B (...). Contradictions occur when both metrics find a (...) difference between A and B, but in opposite directions."* A perfect evaluation model, which predicts the preference for all pairs of summaries correctly, will have an agreement of 1 whereas a random evaluation model, which always predicts the preference randomly, will have an expected value of 0.5 according to this measure.

[2]We require that an evaluation metric has to make a decision for two summaries if the two summaries are different according to the human judgment. Formally: $\mathbf{a} >^* \mathbf{b} \rightarrow \mathbf{a} >^E \mathbf{b}$ or $\mathbf{b} >^E \mathbf{a}$.

Donald Trump won the election and became president. $\succ$ *The U.S. Congress certified the results on January 6.*

Figure 2: Example of a pairwise preference annotation of two sentences. The first sentence is preferred over the second sentence because the first sentence contains more important information given that the information is not already known.

We prefer to use the agreement as defined in Equation 1 for evaluation since it can be much better interpreted (Owczarzak et al., 2012). Furthermore, Pearson's correlation is known to be sensitive to outliers, is only able to measure linear correlations, and requires normally distributed, interval scaled residuals (Anscombe, 1973). These properties cannot be assumed to be given when comparing human scores and automated evaluation measures. We therefore prefer to use the agreement according to human judgments as defined in Equation 1 instead of calculating Pearson's correlation.

4 Preference-based Evaluation of Summaries

In this section, we present a novel framework which does not infer a ranking of automatically generated summaries based on gold standard summaries but based on pairwise preferences. The fundamental idea is not to rely on expensive gold standard summaries as previous work does, but to ask annotators for their preferences about sentences. Annotates label pairs of sentences with a preference label which indicates which sentence contains more important information. Figure 2 illustrates such a pairwise preference annotation. A human would likely prefer the first sentence to be included in a summary instead of the second sentence because the first sentence contains, compared to the second sentence, relatively important information. Based on the preferences, our model generates a ranking which reflects the importance of information which is contained in the sentences. Sentences with important information will be ranked high whereas sentences containing only less important information will be ranked low.

4.1 Sampling Preference Annotations

The easiest strategy to select pairs of sentences for which preferences should be annotated is to sample pairs of sentences randomly and to ask annotators to provide a preference label for each sampled pair (i.e. annotating whether $a \succ b$ or $b \succ a$ for two randomly sampled $a, b \in S^*$). The sentences are sampled from all source document of a topic and are therefore independent from the automatically generated summaries. Our model will therefore not only be able to evaluate already generated summaries but also summaries which will be generated in the future.

All preferences are stored in a matrix M. An entry of n at position M_{i_j} indicates that sentence with index i was preferred n-times over sentence with index j. To reduce the number of annotations, we apply a *smooth propagation of knowledge*. The idea is that we do not only obtain information about the sampled sentence pair but also about pairs which are similar to the sampled pair.

To estimate how much information can be transfered from one to another pair, we calculate the similarities between all sentences. As similarity measure we use the average of the well-known and simple Cosine similarity of TF-IDF vectors and Jaccard similarities. The combination allows to both rely the similarity computation on lexical similarity (Jaccard) and on important content words (Cosine). We define the set of all sentences in the source documents of a topic as S^*. Let (a, b), $a, b \in S^*$ be one annotated sentence pair and $\dot{a}, \dot{b}$ the vector of similarities between a and b and all sentences (i.e. $\dot{a}_i$ denotes the similarity between a and the i-th sentence in S^*).

We define the similarity of the pair (a_1, b_1) and the pair (a_2, b_2) as $\text{sim}(a_1, a_2) * \text{sim}(b_1, b_2)$. If a_1 is the exact same sentence as a_2 and b_1 is similar with a degree of 0.7 to b_2, we will transfer 0.7 of the information from (a_1, b_1) to the pair (a_2, b_2). Transferring information means that we generate additional preferences based on human preferences. If a_1 was preferred over b_1 by a human annotator, we will additionally generate a weighted preferences of with a weight of 0.7 between a_2 and b_2. This can be modeled by the outer product $\dot{a}_1 \otimes \dot{b}_1$ of a_1 and b_1. For each annotated pair (a, b), in which a was preferred by a human over b, we update matrix M by $M \leftarrow M + \dot{a} \otimes \dot{b}$.

4.2 Sentence Score Prediction

The proposed usage of pairwise preferences between sentences is close to the idea of generating a ranking of sports teams by playing individual matches. Instead of competitions between teams, we observe competitions between sentences. The outcome of a match between teams equals to the annotation of a pair of sentences by a human annotator. Since different people can have different opinions about the importance of information (Gambhir and Gupta, 2016), we expect that one sentence will not always be preferred by humans similarly to the situation that the better sports team does not always win against a weaker opponent. This is expressed by the winning probability between teams (or sentences).

In sports, the term *power ranking* is used to describe a ranking which does not only rank the individual teams but also assigns a score to each team, the *skill*. A well-known method to generate a power ranking is the Bradly-Terry (BT) model (Bradley and Terry, 1952). It estimates the utilities $v(a), v(b)$ of two teams (or two sentences) a and b so that the winning probability of a against b equals the score of a divided by the sum of the scores of a and b:

$$p(a \text{ is prefered over } b) = \frac{v(a)}{v(a) + v(b)} \quad (2)$$

An algorithm to find a maximum-likelihood estimator (MLE) has already been proposed in (Zermelo, 1929). To find the MLE, we iteratively perform Equation 3 for all sentences s_i until the difference between two iterations is sufficiently small.[3] $\text{wins}(s_i)$ denotes the total number of wins of s_i and $\text{duels}(s_i, s_j)$ the number of duels played between sentences s_i and s_j. This information was collected in the previous step and is stored in matrix M.

$$v(s_i) \leftarrow \text{wins}(s_i) \sum_{i \neq j} \frac{\text{duels}(s_i, s_j)}{v(s_i) + v(s_j)} \quad (3)$$

We normalize the resulting skill vector after each iteration since every multiple of the solution is also a correct solution and therefore restrict the model to converge to one particular solution.

[3] We initialize all scores $v(s_i)$ equally with $v(s_i) \leftarrow \frac{1}{|\mathbf{s}|}$.

4.2.1 Summary Score Prediction

We estimate the score of summary $\mathbf{s}$ with function $u : T \rightarrow \mathbb{R}$ as follows:

$$u(\mathbf{s}) = \sum_{i=1}^{|\mathbf{s}|} w_{s_i} \cdot v(\arg\max_{s \in S^*} \text{sim}(s, s_i)) \quad (4)$$

The utility of a summary is therefore defined as the weighted sum of the sentence utilities v. Since we do not want to restrict our model to purely extractive summaries (which would mean that all sentences contained in the automatic summary have to be exactly contained in the source documents), we estimate the score of a sentence s_i in the summary by searching for the most similar sentence s in the source documents with similarity function $\text{sim} : S \times S \rightarrow [0, 1]$. As weight of s_i, we use $\frac{|s_i|}{|\mathbf{s}|}$ where $|.|$ denotes the length of the summary and sentence measured in number of characters. The intuition of the weight is that a sentence contributes more to the overall score of a summary if it is longer. The score of a summary will decrease if a large fraction of the summary is occupied with a poor sentence. By using a similarity function instead of a hard matching, our method is able to generalize to unseen sentences.

The definition of u in Equation 4 does not consider redundancy. Including a sentence s twice would result in adding the score of s twice to the summary score. This behavior of the evaluation measure is not desirable. We therefore include a redundancy penalization which does not reward redundant information. For a summary $\mathbf{s}$, we reduce the score of sentence s by

$$v_{\text{red}}(s) = v(s) \frac{1}{|s|} \sum_{g \in s} \frac{\text{num}(g, s)}{\text{num}(g, \mathbf{s})} \quad (5)$$

where $\text{num}(g, s)$ and $\text{num}(g, \mathbf{s})$ denote the number of occurrences of the bi-gram g in s and $\mathbf{s}$, respectively. $|s|$ denotes the number of bi-grams in s.

4.3 Reusing Available Annotation Information

For already existing summarization corpora, reference summaries and/or Pyramid annotations have already been created. Instead of generating new preference annotations by asking human annotators, we can also reuse the available data to simulate annotations. To this end, we define functions w_{r} and w_{p} which estimate the score of a single sentence based on reference summaries (r) and Pyramid scores (p), respectively. We will use the scores generated by w_{r} and w_{p} to simulate annotations of sentence pairs. For two sentence a, b we can simulate a human preference annotation of $a \succ b$ if $w_{\text{r}}(a) > w_{\text{r}}(b)$ and a win of b over a otherwise (equivalent for w_{p}).

For a set of gold standard summaries R, we define $w_{\text{r}} : S \rightarrow \mathbb{R}$ simply to be the maximum similarity to the sentences in the gold standard summaries:

$$w_r(s) = \max_{t \in \mathbf{r}, \mathbf{r} \in R} (\text{sim}(s, t)) \quad (6)$$

If a very similar sentence appears in a gold standard summary, s will receive a high score. If no similar sentences are in the gold standard summaries the sentence will receive a low score.

Given that Pyramid annotations are available (as in the TAC 2009 corpus, for example), we can define the score of a sentence as the sum of the weights of the matched unique SCUs (similar to the Pyramid method). Annotations are, unfortunately, only available for all sentences in the documents in T^+ and not for sentences in S^*. We therefore search for sentence s in S^* for the most similar sentence $\hat{s}$ in the documents in T^+

$$\hat{s} = \arg\max_{t \in \mathbf{t}, \mathbf{t} \in T^+} \text{sim}(s, t) \quad (7)$$

and set the score of s to

$$w_p(s) = \sum_{scu \in \hat{s}} \text{weight}(scu) \quad (8)$$

where $scu \in t$ are all unique SCUs contained in t and $\text{weight}(scu)$ denotes the weight of an SCU as defined in (Nenkova and Passonneau, 2004). As described above, we will observe wins and losses between pairs based on the estimated scores.

5 Experiments

We provide in this section a detailed analysis of our proposed evaluation method. For the experiment, we use eight topics from two popular multi-document summarization datasets, the DUC 2004 (DUC04) and TAC 2009 (TAC09) corpora, which are freely available upon request.[4] Each topic in the datasets contains ten source documents. Each topic contains automatically generated summaries which were generated in the DUC 2004 and TAC 2009 shared tasks. All automatically

	JS	R1	R2	R3	R4	SU4	man
DUC04	0.480	0.651	0.639	0.649	0.606	0.558	**0.673**
TAC09	0.565	0.638	0.668	0.660	0.674	0.663	**0.688**

Table 1: Agreement of preference based evaluation as defined in Equation 1 of different versions of Jensen-Shannon, ROUGE and our novel model based on manually labeled pairwise preferences.

generated summaries were evaluated by humans. Each summary was labeled with a score from 1 to 5 (DUC04) or 1 to 10 (TAC09) indicating the information content of the summary. Evaluation of grammatically, writing style, etc. is not included in the scores. An evaluation model predicts the preference for two selected summaries correctly if the model predicts the same preference according to the annotated reference scores and incorrectly otherwise. We do not consider ties in the experiments. In the following, we report the agreement as described in Equation 1 for various experiments. We use the abbreviations **JS** (Jensen-Shannon), **R1** - R4 (ROUGE-1 - ROUGE-4), **SU4** (ROUGE-SU4), and **PY** (Pyramid (Nenkova and Passonneau, 2004)) to denote the reference systems.

5.1 Manual Annotations

In the first experiment, we investigate whether humans are able to provide useful feedback in the form of pairwise preferences.

To evaluate our model, we annotated 200 randomly sampled sentence pairs for the first four topics in the DUC04 and the first four topics in the TAC09 corpus with pairwise preferences. The preferences were used (including the previously described smoothed sampling) as input for the proposed model. The results are shown in Table 1. Column **man** denotes the performance of our now model and column **Time (min)** indicates how much time was required to generate the annotations. This information is in particular important for this paper since our main aim is to develop a cheap evaluation framework. In average, our model achieves an agreement of 0.673 in DUC04 and 0.688 in TAC09. This means, that 67.3/68.8 percent of all pairs of manually rated summaries were predicted correctly. This outperforms the best versions of ROUGE in the respective corpora (SU4 with 65.1 percent in DUC04 and R2 with 66.0 percent in TAC09).

With an average annotation time per topic of 53 and 54 minutes our model needs much less annotation effort than ROUGE.

	R1	R2	R4	PY	man +ref	man +py	man +ref +py

TAC09	0.638	0.668	0.674	0.715	0.682	0.707	**0.717**

Table 2: Agreement of different versions of ROUGE and Pyramid (PY) and our novel models based on human and automatically generated pairwise preferences in addition to manually labeled preferences.

5.2 Weak Supervision with Additionally Simulated Annotations

In the next experiment, we are interested whether we can simulate additional annotations based on already available reference summaries and Pyramid annotations. The automatically annotated pairs can be considered to be an additional weak supervision for the model. We simulated 200 additional annotations based on reference summaries and/or Pyramid annotations in addition to the 200 manual annotations per topic. To this end, we randomly sampled 200 additional pairs and annotated the pairs with a preference label based on reference summaries and/or Pyramid annotations. Table 2, column **man+ref** contains the results for 200 manual + 200 simulated reference summary-based annotations; column **man+py** contains the results for 200 manual + 200 simulated Pyramid score-based annotations; and column **man+ref+py** contains results for 200 manual + 200 reference summary-based + 200 Pyramid score-based annotations. The results show that we can improve the agreement with additional simulated annotations based on reference summaries in DUC04 by 5 percent points. Additional annotations increased Agreement in TAC09 by 3 percent points. This leads to the conclusion that we can use already available reference summaries in order to substitute more human preference annotations, which makes the trade-off between performance and annotations effort of our model even better.

5.3 Solely Using Simulated Annotations

Now, we investigate if simulated preferences are already sufficient to produce reasonable good results. Table 3, columns **ref** and **py** contain the results of an experiment where we sampled 1,000 simulated pairwise annotations. Without any additional annotation effort, the new model is able to

	R1	R2	R4	PY	ref	py
DUC04	0.651	0.639	0.606	n/a	**0.716**	n/a
TAC09	0.638	0.668	0.674	**0.715**	0.644	0.709

Table 3: Agreement with human judgments for reference systems and our model fed with only automatically generated preferences labels.

perform much better than ROUGE at DUC 2004. In TAC 2009, our model achieves similar performance as the best performing evaluation based on Pyramid annotations. We conclude that automatically generating pairwise preferences based on already available reference summaries is already sufficient to outperform ROUGE. Pairwise preferences generated based on the more expensive Pyramid annotations do not improve the performance.

5.4 Convergence

In the next experiment, we investigate how agreement changes with an increasing amount of annotations. Figure 3 shows how agreement improves with more annotations. We sampled n annotations (horizontal axis) randomly from the human annotations and averaged the resulting agreement scores (vertical axis) of 100 runs to obtain reliable results. We observe a continuous improvement of agreement in all four topics in the TAC 2009 dataset which indicates that sampling more annotations can further improve the performance of our system.

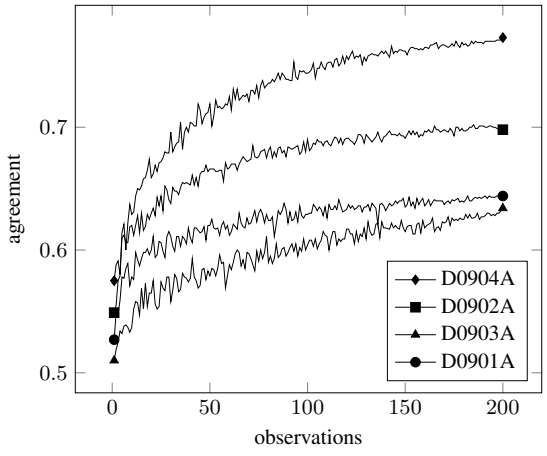

Figure 3: Agreement trajectories averaged over 100 runs per topic in the TAC 2009 corpus.

5.5 Ranking Evaluation

We now investigate the ranking generated by our model directly. Since individual sentences are annotated in the TAC 2009 corpus with SCUs, we can generate a ranking of the sentences and directly compare this ranking with the ranking generated by our model. Table 4 shows the percentage of correctly ordered sentence pairs (similar to Kendall's τ) for our model without and with smoothed sampling.

non-smoothed			smoothed		
man	pyr	ref	man	pyr	ref
0.683	0.987	0.661	0.727	0.941	0.698

Table 4: Percentage of correctly ordered sentence pairs in the TAC 2009 corpus for both a non-smoothed and a smoothed sampling.

Smoothed sampling improves the raking of the model if we use 200 manual or 200 reference summary-based preferences in the TAC 2009 corpus. Given that we can sample pairs based on Pyramid scores, the model is able to reconstruct the ranking almost perfectly if we do not use smoothed sampling. With smoothed sampling, the performance decreases in this case. The result confirms the previously observed performance at summary scoring where preferences based on Pyramid annotations performed best followed by manually generated preference annotations.

6 Conclusions & Outook

Evaluating automatically generated summaries is a challenging task and creating annotations which are required by applications such as ROUGE or Pyramid is laborious and expensive. We presented an alternative model which does not rely on reference summaries or Pyramid annotations but only on simple pairwise preferences of sentences.

We showed in our experiments that the proposed model is able to perform better than the current state-of-the-art ROUGE method with less expensive annotations and that humans are able to provide useful feedback in the form of pairwise preferences. In combination with already available references summaries and Pyramid annotations, we were able to simulate more annotations, which improved performance further.

We conclude that gold standard summaries are not the only usable human feedback which can be used for summary evaluation. Investigating other kinds of feedback such as pairwise preferences might be a promising future research direction.

In future work, we would like to investigate whether we can use crowd-sourcing platforms to

collect pairwise preferences on a large scale. Furthermore, we want to investigate whether we can reduce the number of required preferences with smarter sampling methods. Active learning methods can be used to replace the simple random sampling strategy. Additionally, the investigation of more sophisticated similarity functions can potentially improve the model's performance.

Generating topic-oriented summaries using neural attention

Abstract

Summarizing a document requires identifying the important parts of the document with an objective of providing a quick overview to a reader. However, a long article can span several topics and a single summary cannot do justice to all the topics. Further, the interests of readers can vary and the notion of importance can change across them. Existing summarization algorithms generate a single summary and are not capable of generating multiple summaries tuned to the interests of the readers. In this paper, we propose an attention based RNN framework to generate multiple summaries of a single document tuned to different topics of interest. Our method outperforms existing baselines and our results suggest that the attention of generative networks can be successfully biased to look at sentences relevant to a topic and effectively used to generate topic-tuned summaries.

1 Introduction

Automatic text summarization is the task of generating/extracting short text snippet that embodies the content of a larger document or a collection of documents in a concise fashion. Traditionally, researchers have used extractive methods for summarization - where a set of sentences is selected from an article and concatenated *as-is* to form the summary. Extractive methods are limited by their inability to paraphrase the content of the article using new sentences and hence are very different from the summaries created by humans, who paraphrase a given article to generate summaries. Recent works on summarization have come up with sequence-to-sequence models for generating summaries in a word-by-word fashion, thus 'generating' new sentences.

As articles get longer, it might span several topics and therefore, a single summary is often insufficient to satisfy the interests of the reader. In these cases, it is desirable to produce summaries that are aligned to the topical interests of reader to enable better consumption. Extractive summarization uses sentence-level features (Yang et al., 2017) that have been leveraged for producing query-focused or topic-based summaries. However, for RNN-based frameworks, such tuned summary generation is non-obvious due to the absence of explicit content based features.

To extend the advantages of abstractive summarization and generate topic-tuned summaries, we propose a neural encoder-decoder based framework which takes an article along with a topic of interest as input and generates a summary tuned to the target topic of interest. Our method works by training a neural framework to pay higher attention to parts of the input articles relevant to given topic. To overcome the lack of dataset containing articles with multiple topic-oriented summaries, we use a novel approach to artificially create a topic-centric training corpus from the CNN/Dailymail dataset (Hermann et al., 2015; Nallapati et al., 2016) for training our model.

Table 1 shows an article with different summaries generated by the proposed approach tuned towards the topics of politics, finance and social aspects. It can be seen that the *business* oriented summary talks about IMF's estimates about increase in taxes and the summary for *politics* talks about how it relates to the government's upcoming budget. The summary for the *social* topic elaborates on universal basic income and social security. Thus, for the same article, the proposed approach is capable of generating different summaries tuned to the input topic of interest.

2 Related Work

Traditional methods for summarization (Nenkova and McKeown, 2011) extract key sentences from the source text to construct the summary. Early works on abstractive summarization were focused on sentence compression based approaches (Filippova, 2010; Berg-Kirkpatrick et al., 2011; Banerjee et al., 2015) which connected fragments from multiple sentences to generate novel sentences for the summary or template based approaches that generated summaries by fitting content into a template (Wang and Cardie, 2013; Genest and Lapalme, 2011).

With the advent of deep sequence to sequence models which generated text word-by-word (Sutskever et al., 2014), attention based neural network models have been proposed for summarizing long sentences. Rush et al. (2015) first demonstrated the use of neural networks to generate shorter forms of long sentences. Nallapati et al. (2016) proposed a neural approach for abstractive summarization of large articles by applying the sequence to sequence model. See et al. (2017) further improved the performance on abstractive summarization of articles by introducing the ability to copy words from the source article (Gulcehre et al., 2016) using a pointer network (Vinyals et al., 2015), in addition to generating new words. However, all these frameworks focus on generating a single summary, and do not support topic-tuned summary generation. We use the architecture by See et al. as the starting point for our work and develop a method to generate topic-tuned summaries.

There have been some works on extending extractive summarization towards topical tuning. Lin and Hovy (2000) proposed the idea of extracting topic-based *signature terms* for summarization. Given a topic and a corpus of documents relevant and not relevant to the topic, a set of words characterizing each topic is extracted using a log-likelihood based measure. Sentences which contain these chosen words are assigned more importance while summarizing. Conroy et al. (2006) further extended the method for query-based multi-document summarization by considering sentence overlap with both query terms and topic signature words.

However, all these works rely on identifying sentence level features to compute topic affinities that are leveraged for choosing topic specific sentences for the summary. Since sequence-to-sequence frameworks generate text in a word-by-word fashion, incorporating sentence level statistics is not feasible in this framework. Therefore, we modify the attention of the network to focus on topic-specific parts of the input text to generate the tuned summaries.

3 Topic aware pointer-generator network

Our method builds on top of the pointer-generator network of See et al. which consists of an encoder and a decoder both based on LSTM architecture. Our contribution is a modified encoder to encode the article in a topic-sensitive manner. However, for the sake of completeness, we shall provide an overview of the entire network, and will reuse notations from their work to a large extent.

Given an input article as a sequence of words $a = w_1, w_2 \dots w_n$, and a scaled one-hot topic vector u_t, where t is a topic in a predefined set of topics T, the network produces a summary $s = s_1, s_2, \dots, s_k$ pertaining to the topic t. The topic-vector u_t has a non-zero value $c > 0$ only for the entry corresponding to the desired topic t of the summary. c designates the amount of bias that should be put towards the topic while generating the summary, higher values suggesting higher bias. The input article is passed through an embedding layer to transform them to lower-dimensional embedding $m_1, m_2, \dots, m_n$. The topic one-hot vector u_t is concatenated to each of the embedding to create the sequence $(m_1, u_t), (m_2, u_t), \dots, (m_n, u_t)$. This sequence is passed to a bidirectional LSTM encoder which computes a sequence of hidden states $h_1, h_2, ..h_n$. The final hidden state is passed to a decoder which

is also a LSTM, and it serves as the initial hidden state of the decoder. At each decoding step of the decoder, an attention distribution a^t is calculated over all words of the input article,

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + b_{att}) \quad (1)$$
$$a^t = \text{softmax}(e^t) \quad (2)$$

Here, s_t is the hidden state of the decoder at timestep t, and v, W_h, W_s and b_{att} are model parameters.

The attention model can be thought of as a probability distribution over words in the source text, which aids the decoder in generating the next word in the summary using words in the source text that have higher attention. Since the encoder has information about what is the topic of interest, the h_i are calculated in such a way that the corresponding areas of the article receiving high attention are relevant to the topic. We demonstrate this later in Section 4.2. The decoder uses this attention to calculate a context vector h_t^* as a weighted sum of the encoder hidden states to determine the next word that is to be generated.

$$h_t^* = \sum_{i=1}^{n} a_i^t h_i, \quad (3)$$

At each decoding time step, the decoder network also gets as input y_t, the last word in the summary generated so far and computes a scalar p_{gen} denoting the probability of the network generating a new word from the vocabulary.

$$p_{gen} = \sigma(w_h^T h_t^* + w_s^T s_t + w_y^T y_t + b_{gen}) \quad (4)$$

where w_h, w_s, w_y, b_{gen} are trained vectors. The network probabilistically decides based on p_{gen}, whether to generate a new word from the vocabulary or copy a word from the source text using the attention distribution.

For each word w in the vocabulary, the model calculates $P_{vocab}(w)$, the probability of the word getting newly generated next. P_{vocab} is calculated by passing a concatenation s_t and h_t^* through a linear transformation with sigmoid activation. Also, for each word w' in the input article, its total attention received yields its probability of being copied. Since some words occur in the vocabulary and also the input article, they will have non-zero probabilities of being newly generated as well as being copied. Therefore, the total probability of w being the next word generated in the summary, denoted by $\mathbf{p}$ is given by,

$$\mathbf{p}(w) = p_{gen} P_{vocab}(w) + (1 - p_{gen}) \sum_{i:w_i=w} a_i^t \quad (5)$$

The second term allows the framework to choose a word to copy from the input text using the attention distribution.

The pointer-generator network further employs a coverage mechanism which modifies the loss function to encourage diversity in attention distributions over time steps. This prevents the network from repeating the same phrases again while generating a summary. To handle out-of-vocabulary words, the pointer-generator network also appends them to the vocabulary before the article is encoded.

The training loss is set to be the average negative log-likelihood of the ground truth summaries. The model is trained using back-propagation and the Adagrad gradient descent algorithm (Duchi et al., 2011).

Alternate to the the proposed architecture, one can append the topic vector to the initial hidden state of the encoder, or the initial state of the decoder. However, in our experiments, these approaches did not produce the desired tuning. Another alternative would be to use different W_h attention matrix for each different topic and learn topic specific attention biases. This again did not perform well, perhaps due insufficient data available to train each topic's W_h.

3.1 Generating the training data

The problem of generating *multiple* different summaries of the *same* document based on topics of interest requires a set of articles, each of them (a) annotated with multiple (u_t, s) pairs, where t is a topic, and s is the summary of a oriented to topic t. However, existing datasets for single-document summarization (Over et al., 2007; Hermann et al., 2015) do not have multiple ground truth summaries oriented to different topics for each document. Moreover, existing datasets for topic-based summarization are focused on multi-document summarization and contain multiple articles tagged with a relevant topic. For example, DUC 2005 dataset (Dang, 2005) for topic based multi-document summarization contains 50 topics with each topic having 25 to 50 documents in it. To address the lack of datasets with multiple summaries of a single document, we propose

an approach create such a dataset artificially. The dataset is created in two steps.

We begin with fixing the set of topics for consideration and learn a word frequency based representation for each topic by using a corpus of articles where each article is labelled with a topic. For our experiment, we use the dataset of news articles tagged with topics like *politics*, *sports*, *education* etc. released at the 2017 KDD Data Science + Journalism Workshop (VoxMedia). We group the articles by the topics, so that all articles having topic t are represented by the set S_t. We represent each topic t as a vector $e_t = (n_1, n_2, \ldots, n_v)$ where $v = |V|$ is the size of vocabulary of words $V = \{w_1, w_2, ..., w_v\}$ and n_i is the number of times word w_i occurs in S_t. We normalize e_t to sum to 1.

We then take a corpus of articles with human generated summaries as a collection of (a, s) pairs. For our purposes, we use the CNN-Dailymail dataset which has articles with summaries. We create an *intermediate* dataset which consists of (a, u_t, s) pairs, where u_t is a one-hot representation of the topic t of summary s. We begin with labeling each summary with a topic by computing the dot-product between summary (in its bag-of-words representation) and the topic vectors extracted in the previous step. Let $< v_s, e_t >$ indicate the dot-product between the bag of words representation of summary s and the topic vector for topic t. For each topic t_i, $sim(s, t_i) =< v_s, e_{t_i} >$ is the similarity of summary s to the topic t_i. Let's say that t_i has the highest similarity to summary s and t_j has the second highest similarity. Then we say that summary s has topic t_i with confidence $c = \frac{sim(s,t_i)}{sim(s,t_j)}$. If the confidence is less than a threshold (set to 1.2 in our experiments), we drop the article and summary from our dataset. This enures that the intermediate dataset does not include summaries with more than one dominant topic. If the confidence is greater than the threshold, we add the triple (a, u_{t_i}, s) to the intermediate dataset, where the vector u_{t_i} keeps the value corresponding to t_i equal to the confidence c, instead of 1 as commonly done in one-hot vectors. This allows us to retain the confidence of s being of topic t_i while training our model.

To generate the final dataset, we follow the steps below:

1. Randomly pick (a_1, u_{t_1}, s_1) and (a_2, u_{t_2}, s_2) from the intermediate dataset such that $t_1 \neq t_2$.

2. Make a new article a' by sequentially picking up lines from a_1 and a_2. Each addition of a new line is done by randomly selecting one of a_1 or a_2 and extracting out a new line from the beginning of it. This ensures that the lines from a_1 occur in the same order in a' as originally in a_1, and the same thing is true for a_2 too. This ensures that the sequential flow of content is retained in the merger.

3. Add (a', u_{t_1}, s_1) to the final dataset.

4. Repeat step 2 to get a new article a'' and add (a'', u_{t_2}, s_2) to the final dataset.

5. Discard (a_1, u_{t_1}, s_1) and (a_2, u_{t_2}, s_2) from the intermediate dataset.

6. Repeat steps $1 - 5$ until the entire intermediate dataset is exhausted or all remaining instances in it have the same topic.

The created final dataset is used to train the proposed neural network for summarization. Since every article in the final dataset is a combination of two original articles, and the target summary to be generated is of one of them, the model must learn to distinguish between content coming from the two original articles. The randomization of position of sentences from each original article while merging, ensures that there is no position-specific bias that the model can use either. Since the two original articles have different topics, and the only information given to the model to hint whose summary is to be generated is the topic of one of them, the model is forced to learn what content is more relevant to the given topic and generate a summary accordingly.

We ended up with $112,360$ articles in our final dataset since many article-summary pairs from the CNNDailymail dataset were dropped due to insufficient confidence about their topics. Out of this, $103,666$ were used for training, $4,720$ for validation, and $3,974$ for testing.

4 Experimental Evaluation

To position our method against existing works, we use the following summarizers as our baselines.

Our first baseline is the **vanilla pointer generator (PG)** described in the original work of See et al. (2017). This method does not consider the

desired topic of summary when generating a summary. For an unbiased evaluation, we use exactly those unmerged article-summary pairs of the CNN/Dailymail dataset for training and validation which were eventually incorporated in the final dataset. Then the trained model is applied to generate summaries of the test set of the final dataset.

Our next baseline is a **frequency-based extraction** method that selects lines from the input article which are strongly aligned to the desired topic u_t. For each sentence, the relevance to each of the predefined topics is calculated using a dot product between their vector representations. The sentence is designated to the topic having the maximum relevance score, and the strength of alignment is the ratio of the the highest and the second highest relevance scores.

We extract all the sentences in the article which are aligned to the target topic, and run it through the pointer-generator network to create the summary. We refer to this baseline as **abstractive summarizer with frequency based extraction (*Freq-Abs*)**. Alternatively, we take k sentences which have the highest strength of alignment with the target topic to create a purely extractive summary. k was set to 3 in accordance with the average number of sentences in the summaries of the training set (2.83). We call this method **extractive summarizer with frequency based extraction (*Freq-Ext*)**.

Our last baseline is a **topic-signature based approach** which also works by extracting sentences from the article which are aligned to the target topic. However, the selection of sentences is based on topic signatures as described by Lin and Hovy (2000) and Conroy et al. (2006) instead of word frequencies. A topic signature is a set of words relevant to the topic. For any given sentence, the number of signature terms of each topic is computed. The sentence is designated to belong to the topic which has the highest number of its signature terms occurring in it.

The topic signature is determined based a set of documents T relevant to the topic, and a set of background documents T' that is indicative of general topics. It is assumed that in T and T', the occurrence of each word w follows a binomial distribution with probability of occurrence p. The likelihood of observing T and T' is calculated under two hypotheses - one where the probability of occurrence of w is p_1 in T and p_2 in T' such that $p_1 > p_2$, and the other where it is p in both T and T'. The ratio of likelihoods is calculated and words for which this ratio is the highest are included as part of the topic's signature.

We extracted topic signatures using the summaries of the training dataset as our corpus. For each topic t, the corresponding summaries form the topic specific corpus T, and the remaining summaries make the background corpus. Table 2 shows a subset of the topic signatures.

Topic	Signature words
business	stock, firm, rate, google, worth, companies
education	children, teacher, parents, schools, test
entertainment	actor, star, league, movie, will, taylor
health	disease, brain, people, risk, league, infection, blood
military	arrested, police, car, officer, year, officers, killed, charged
politics	party, campaign, secretary, democrats, bill, congress
social	church, rich, life, woman, sex, identity, gender, will
sports	scored, united, league, nfl, cup, england, beat, game
technology	app, solar, launch, ipod, app, earth, energy, oil

Table 2: Words from signatures of different topics

Analogous to Freq-Abs and Freq-Ext, we try two alternatives here as well - **abstractive summarizer with signature based extraction (*Sign-Abs*)** and **extractive summarizer with signature based extraction (*Sign-Ext*)**.

4.1 Performance on the created dataset

We used the $3,974$ article-topic-summary tuples from our final dataset to evaluate the performance of the summarizers. The models were given the input article and topic and the generated summary was compared with the ground truth summary. We use ROUGE scores to measure the quality of summaries. ROUGE scores measure the precision, recall and f-measure for the occurrence of n-grams in the generated summary with respect to the reference human generated summary. We use the ROUGE-1, ROUGE-2 and ROUGE-L variants (Lin and Och, 2004) which look at unigram, bigram and longest common subsequence overlaps between generated and reference summaries. Table 3 shows the ROUGE F1 scores for the topic-based summaries generated by different methods. It is easy to see that the proposed method yields the best performance across all the baselines.

Further, we also observed that the summaries generated by our system show abstractive nature as noted in See et al. (2017). Table 4 shows some instances where our model used new words unseen in the article.

Algorithm	ROUGE-1	ROUGE-2	ROUGE-L
PG	26.8	9.2	24.5
Freq-Abs	25.8	8.4	23.4
Freq-Ext	25.5	8.5	22.9
Sign-Abs	26.1	8.5	23.7
Sign-Ext	25.9	8.7	23.3
Our method	**34.1**	**13.6**	**31.2**

Table 5: Topic oriented summaries generated by our method for articles from CNN-Dailymail dataset

4.2 Performance on multi-topic articles

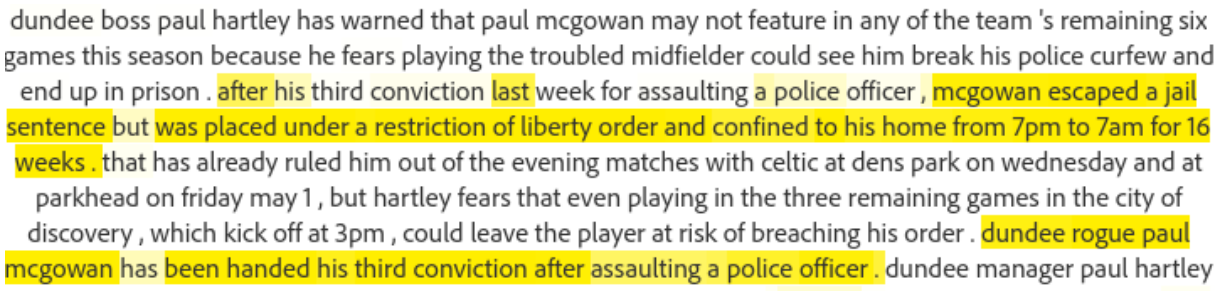
We ran the proposed model on original articles from CNN-DailyMail dataset which were not part of the final dataset used for training. Since the articles were not annotated with topics, we generated summaries for all the different topics. We then detected articles where the method generated different summaries for different topics suggesting the presence of more than one topic in the article. Table 5 shows a few summaries generated by the proposed approach where different summaries were generated aligned to the input topics. The first article talks about the dropping of a player from a football squad. The summary oriented to the *military* topic talks about the assault of a police officer by the player and his criminal history. The *sports* summary talks about the player's fate in the remaining games of the season.

Similarly, we have different summaries for the second article, where the *education* oriented summary talks about the educational affiliations of the suspects and disciplinary procedures, whereas the *military* summary talks about the arrests. Note that these are among the original articles in the dataset which were not used for creating any of the articles in our final data used for training the model.

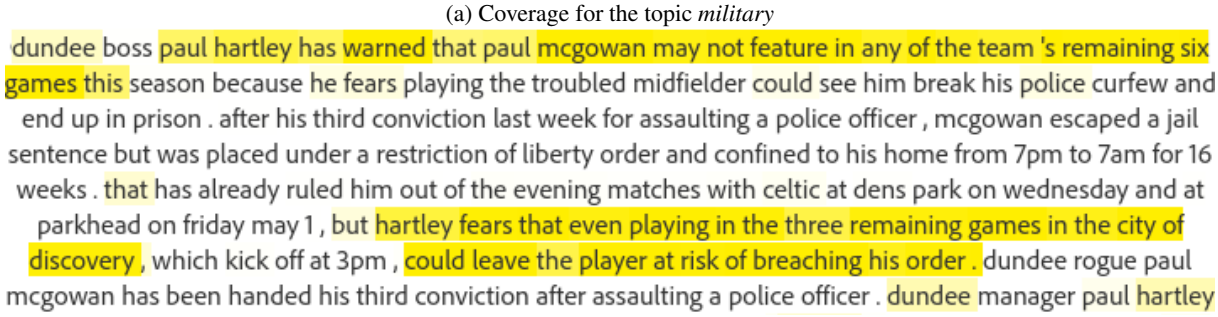
We also observe that the attention distribution varies according to the input topic of summary. We investigate the amount of cumulative attention (defined as coverage by See et al.) that is received by each term summed over all the decoding steps during generation. An example of the variation in attention over an input article is shown in Figure 1. The degree of yellow hue is used to represent the value of coverage for each term. For the topic *military*, words like *jail* and *assualting* receive higher attention, whereas for the topic *sports* words like *games* and *player* are highlighted. Figure 1(b) also shows an example where our model summarizes by skipping a clause (*"which kick off at 3pm"*).

4.3 Human evaluation of performance

Finally, we performed human evaluations of summaries to compare the quality of our method against the baselines. We restrict ourselves to



(a) Coverage for the topic *military*



(b) Coverage for the topic *sports*

Figure 1: Variation in the attention coverage while summarizing an article for different topics

the best performing baseline - the topic signature based abstractive summarizer (Sign-Abs), and the vanilla pointer-generator.

We fetched articles touching multiple topics using the NYTimes Search API[1], which allows to search for articles on NYTimes which appear in the news desk for a topic (the major topic) and are tagged with another topic (the minor topic). For different pairs of topics, we retrieved relevant articles using the API and randomly selected few of them to generate summaries tuned to the two topics using our method and the baselines. We retrieved 18 total articles for the evaluation. Each article had two topics leading to 36 (article,topic) pairs for the summary generation. For each (article,topic) pair, annotators were shown two summaries - one generated by our method and the other by one of the baselines. The task was to choose the summary more relevant to the topic. Each such task was annotated by 10 different annotators. Every annotator was assigned 9 tasks and 1 extra dummy task to check if they were paying attention. Annotations from evaluators who answered incorrectly to the dummy task were discarded. We had a total of 720 annotations from the human evaluation and their summary is shown in Table 6.

The value under "Overall annotations" refers to the fraction of all human responses across all documents which rated the summary produced by our method better than the alternate summary produced by the compared baseline method. Understandably, the proposed approach is comparable in the preference to both the baselines for the major topic (0.5667) - since most standard summaries will cover the primary topic of the input. However, for the minor topic, it can be seen that the proposed approach is better than the baselines.

The value under "Document annotations" indicates the fraction of times the proposed method was preferred by half or more of the annotators for a document-topic pair. It is easy to see that the proposed approach clearly outperforms the baselines under this scenario. The difference in performance is even more significant for summaries generated for the non-major topic since our approach is capable of efficiently generating tuned summaries for minor topics as well.

5 Conclusion

We proposed a method for generating multiple abstractive summaries of a given document oriented towards different topics of interest. Our method works by modifying the attention mechanism of a pointer-generator neural network to make it focus on text relevant to a topic. For training our network, we devised a novel way to create a dataset where articles are tagged with topic oriented summaries. Our method outperformed previous fea-

Abstract

In order to alleviate data sparsity and overfitting problems in maximum likelihood estimation (MLE) for sequence prediction tasks, we propose the Generative Bridging Network (GBN), in which a novel bridge module is introduced to assist the training of the sequence prediction model (the generator network). Unlike MLE directly maximizing the conditional likelihood, the bridge extends the point-wise ground truth to a bridge distribution conditioned on it, and the generator is optimized to minimize their KL-divergence. Three different GBNs, namely uniform GBN, language-model GBN and coaching GBN, are proposed to penalize confidence, enhance language smoothness and relieve learning burden. Experiments conducted on two recognized sequence prediction tasks (machine translation and abstractive text summarization) show that our proposed GBNs can yield significant improvements over strong baselines. Furthermore, by analyzing samples drawn from different bridges, expected influences on the generator are verified.

1 Introduction

Sequence prediction has been widely used in tasks where the outputs are sequentially structured and mutually dependent. Recently, massive explorations in this area have been made to solve practical problems, such as machine translation (Bahdanau et al., 2014; Ma et al., 2017; Norouzi et al., 2016), syntactic parsing (Vinyals et al., 2015), spelling correction (Bahdanau et al., 2014), image captioning (Xu et al., 2015) and speech recognition (Chorowski et al., 2015). Armed with modern computation power, deep LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Chung et al., 2014) based neural sequence prediction models have achieved the state-of-the-art performance.

The typical training algorithm for sequence prediction is Maximum Likelihood Estimation (MLE), which maximizes the likelihood of the target sequences conditioned on the source ones:

$$\theta^* = \arg\max_{\theta} \mathop{\mathbb{E}}_{(X,Y^*)\sim D} \log p_\theta(Y^*|X) \quad (1)$$

Despite the popularity of MLE or teacher forcing (Doya, 1992) in neural sequence prediction tasks, two general issues are always haunting: 1). data sparsity and 2). tendency for overfitting, with which can both harm model generalization.

To combat data sparsity, different strategies have been proposed. Most of them try to take advantage of monolingual data (Sennrich et al., 2015; Zhang and Zong, 2016; Cheng et al., 2016). Others try to modify the ground truth target based on derived rules to get more similar examples for training (Norouzi et al., 2016; Ma et al., 2017). To alleviate overfitting, regularization techniques,

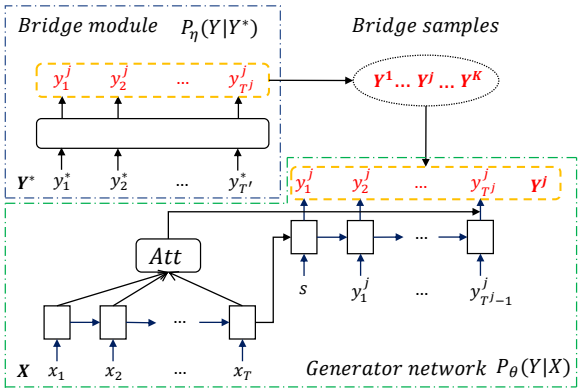

Figure 1: The overall architecture of our novel Generative Bridging Network (GBN). Two main components, namely the generator network and the bridge module, are connected through samples ($Y^1 \dots Y^K$ in red) from the bridge module during training time. (We sometimes call them generator and bridge in brief respectively in the following discussion.) The generator is implemented through an attentive encoder-decoder, where in the figure *Att* represents the attention module.

Proceedings of NAACL-HLT 2018, pages 1706–1715
New Orleans, Louisiana, June 1 - 6, 2018.

such as confidence penalization (Pereyra et al., 2017) and posterior regularization (Zhang et al., 2017), are proposed recently.

As shown in Figure 1, we propose a novel learning architecture, titled Generative Bridging Network (GBN), to combine both of the benefits from synthetic data and regularization. Within the architecture, the bridge module (bridge) first transforms the point-wise ground truth into a bridge distribution, which can be viewed as a target proposer from whom more target examples are drawn to train the generator. By introducing different constraints, the bridge can be set or trained to possess specific property, with which the drawn samples can augment target-side data (alleviate data sparsity) while regularizing the training (avoid overfitting) of the generator network (generator).

In this paper, we introduce three different constraints to build three bridge modules. Together with the generator network, three GBN systems are constructed: 1). a uniform GBN, instantiating the constraint as a uniform distribution to penalize confidence; 2). a language-model GBN, instantiating the constraint as a pre-trained neural language model to increase language smoothness; 3). a coaching GBN, instantiating the constraint as the generator's output distribution to seek a close-to-generator distribution, which enables the bridge to draw easy-to-learn samples for the generator to learn. Without any constraint, our GBN degrades to MLE. The uniform GBN is proved to minimize KL-divergence with a so-called payoff distribution as in reward augmented maximum likelihood or RAML (Norouzi et al., 2016).

Experiments are conducted on two sequence prediction tasks, namely machine translation and abstractive text summarization. On both of them, our proposed GBNs can significantly improve task performance, compared with strong baselines. Among them, the coaching GBN achieves the best. Samples from these three different bridges are demonstrated to confirm the expected impacts they have on the training of the generator. In summary, our contributions are:

- A novel GBN architecture is proposed for sequence prediction to alleviate the data sparsity and overfitting problems, where the bridge module and the generator network are integrated and jointly trained.
- Different constraints are introduced to build GBN variants: uniform GBN, language-model GBN and coaching GBN. Our GBN architecture is proved to be a generalized form of both MLE and RAML.
- All proposed GBN variants outperform the MLE baselines on machine translation and abstractive text summarization. Similar relative improvements are achieved compared to recent state-of-the-art methods in the translation task. We also demonstrate the advantage of our GBNs qualitatively by comparing ground truth and samples from bridges.

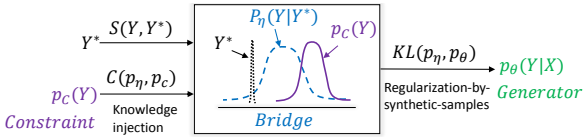

Figure 2: Conceptual interpretation of our Generative Bridging Network (GBN). See detailed discussion in the beginning of Sec. 2.

2 Generative Bridging Network

In this section, we first give a conceptual interpretation of our novel learning architecture which is sketched in Figure 2. Since data augmentation and regularization are two golden solutions for tackling data sparsity and overfitting issues. We are willing to design an architecture which can integrate both of their benefits. The basic idea is to use a so-called bridge which transforms Y^* to an easy-to-sample distribution, and then use this distribution (samples) to train and meanwhile regularize the sequence prediction model (the generator).

The bridge is viewed as a conditional distribution[1] $p_\eta(Y|Y^*)$ to get more target Ys given Y^* so as to construct more training pairs (X, Y). In the meantime, we could inject (empirical) prior knowledge into the bridge through its optimization objective which is inspired by the design of the payoff distribution in RAML. We formulate the optimization objective with two parts in Equation (2): a) an expected similarity score computed through a similarity score function $S(\cdot, Y^*)$ interpolated with b) a knowledge injection constraint[2] $\mathcal{C}(p_\eta(Y|Y^*), p_c(Y))$ where α controls the

[1] η should be treated as an index of the bridge distribution, so it is not necessarily the parameters to be learned.

[2] Note that, in our paper, we specify $\mathcal{C}$ to be KL-divergence between the bridge distribution p_η and certain constraint dis-

strength of the regularization, formally, we write the objective function $L_B(\eta)$ as follows:

$$L_B(\eta) = \mathop{\mathbb{E}}_{Y\sim p_\eta(Y|Y^*)}[-S(Y,Y^*)] + \alpha\mathcal{C}(p_\eta(Y|Y^*), p_c(Y)) \tag{2}$$

Minimizing it empowers the bridge distribution not only to concentrate its mass around the ground truth Y^* but also to adopt certain hope property from $p_c(Y)$. With the constructed bridge distribution, we optimize the generator network $P_\theta(Y|X)$ to match its output distribution towards the bridge distribution by minimizing their KL-divergence:

$$L_G(\theta) = KL(p_\eta(Y|Y^*)||p_\theta(Y|X)) \tag{3}$$

In practice, the KL-divergence is approximated through sampling process detailed in Sec. 2.3. As a matter of fact, the bridge is the crux of the integration: it synthesizes new targets to alleviate data sparsity and then uses the synthetic data as regularization to overcome overfitting. Thus a regularization-by-synthetic-example approach, which is very similar to the prior-incorporation-by-virtual-example method (Niyogi et al., 1998).

2.1 Generator Network

Our generator network is parameterized with the commonly used encoder-decoder architecture (Bahdanau et al., 2014; Cho et al., 2014). The encoder is used to encode the input sequence X to a sequence of hidden states, based on which an attention mechanism is leveraged to compute context vectors at the decoding stage. The context vector together with previous decoder's hidden state and previously predicted label are used, at each time step, to compute the next hidden state and predict an output label.

As claimed in Equation (3), the generator network is not trained to maximize the likelihood of the ground truth but tries best to match the bridge distribution, which is a delegate of the ground truth. We use gradient descent to optimize the KL-divergence with respect to the generator:

$$\nabla L_G(\theta) = \mathop{\mathbb{E}}_{Y\sim p_\eta(Y|Y^*)} \log \nabla p_\theta(Y|X) \tag{4}$$

The optimization process can be viewed as the generator maximizing the likelihood of samples drawn from the bridge. This may alleviate data sparsity and overfitting by posing more unseen scenarios to the generator and may help the generator generalize better in test time.

2.2 Bridge Module[3]

Our bridge module is designed to transform a single target example Y^* to a bridge distribution $p_\eta(Y|Y^*)$. We design its optimization target in Equation (2) to consist of two terms, namely, a concentration requirement and a constraint. The constraint is instantiated as KL-divergence between the bridge and a contraint distribution $p_c(Y)$. We transform Equation (2) as follows, which is convenient for mathematical manipulation later:

$$L_B(\eta) = \mathop{\mathbb{E}}_{Y\sim p_\eta}[-\frac{S(Y,Y^*)}{\tau}] + KL(p_\eta(Y|Y^*)||p_c(Y)) \tag{5}$$

$S(Y,Y^*)$ is a predefined score function which measures similarity between Y and Y^* and peaks when $Y = Y^*$, while $p_c(Y)$ reshapes the bridge distribution. More specifically, the first term ensures that the bridge should concentrate around the ground truth Y^*, and the second introduces willing property which can help regularize the generator. The hyperparameter τ can be interpreted as a temperature which scales the score function. In the following bridge specifications, the score function $S(Y,Y^*)$ is instantiated according to Sec. 3.1.

1. Delta Bridge The delta bridge can be seen as the simplest case where $\alpha = 0$ or no constraint is imposed. The bridge seeks to minimize $\mathop{\mathbb{E}}_{Y\sim p_\eta(Y|Y^*)}[-\frac{S(Y,Y^*)}{\tau}]$. The optimal solution is when the bridge only samples Y^*, thus the Dirac delta distribution is described as follows:

$$p_\eta(Y|Y^*) = \delta_{Y^*}(Y) \tag{6}$$

This exactly corresponds to MLE, where only examples in the dataset are used to train the generator. We regard this case as our baseline.

2. Uniform Bridge The uniform bridge adopts a uniform distribution $U(Y)$ as constraint. This

tribution p_c, however, we believe mathematical form of $\mathcal{C}$ is not restricted, which could motivate further development.

[3] Although we name it bridge module, we explicitly learn it with the generator when a closed-form static solution exists in terms of Equation (5). Otherwise, we will adopt an encoder-decoder to construct a dynamic bridge network.

bridge motivates to include noise into target example, which is similar to label smoothing (Szegedy et al., 2016). The loss function can be written as:

$$L_B(\eta) = \mathop{\mathbb{E}}_{Y\sim p_\eta}[-\frac{S(Y,Y^*)}{\tau}] + KL(p_\eta(Y|Y^*)||U(Y)) \tag{7}$$

We can re-write it as follows by adding a constant to not change the optimization result:

$$L_B(\eta) + C = KL(p_\eta(Y|Y^*)||\frac{\exp\frac{S(Y,Y^*)}{\tau}}{Z}) \tag{8}$$

This bridge is static for having a closed-form solution:

$$p_\eta(Y|Y^*) = \frac{\exp\frac{S(Y,Y^*)}{\tau}}{Z} \tag{9}$$

where Z is the partition function. Note that our uniform bridge corresponds to the payoff distribution described in RAML (Norouzi et al., 2016).

3. Language-model (LM) Bridge The LM bridge utilizes a pretrained neural language model $p_{LM}(Y)$ as constraint, which motivates to propose target examples conforming to language fluency.

$$L_B(\eta) = \mathop{\mathbb{E}}_{Y\sim p_\eta(Y|Y^*)}[-\frac{S(Y,Y^*)}{\tau}] + KL(p_\eta(Y|Y^*)||p_{LM}) \tag{10}$$

Similar to the uniform bridge case, we can re-write the loss function to a KL-divergence:

$$\begin{aligned} &L_B(\eta) + C \\ =&KL(p_\eta(Y|Y^*)||\frac{p_{LM}(Y)\cdot\exp\frac{S(Y,Y^*)}{\tau}}{Z}) \end{aligned} \tag{11}$$

Thus, the LM bridge is also static and can be seen as an extension of the uniform bridge, where the exponentiated similarity score is re-weighted by a pretrained LM score, and renormalized:

$$p(Y|Y^*) = \frac{p_{LM}(Y)\exp\frac{S(Y,Y^*)}{\tau}}{Z} \tag{12}$$

where Z is the partition function. The above equation looks just like the payoff distribution, whereas an additional factor is considered.

4. Coaching Bridge The coaching bridge utilizes the generator's output distribution as constraint, which motivates to generate training samples which are easy to be understood by the generator, so as to relieve its learning burden. The coaching bridge follows the same spirit as the coach proposed in Imitation-via-Coaching (He et al., 2012), which, in reinforcement learning vocabulary, advocates to guide the policy (generator) with easy-to-learn action trajectories and let it gradually approach the oracle when the optimal action is hard to achieve.

$$L_B(\eta) = \mathop{\mathbb{E}}_{Y\sim p_\eta}[-\frac{S(Y,Y^*)}{\tau}] + KL(p_\theta(Y|X)||p_\eta(Y|Y^*)) \tag{13}$$

Since the KL constraint is a moving target when the generator is updated, the coaching bridge should not remain static. Therefore, we perform iterative optimization to train the bridge and the generator jointly. Formally, the derivatives for the coaching bridge are written as follows:

$$\begin{aligned} \nabla L_B(\eta) = &\mathop{\mathbb{E}}_{Y\sim p_\eta}[-\frac{S(Y,Y^*)}{\tau}\nabla\log p_\eta(Y|Y^*)] \\ &+ \mathop{\mathbb{E}}_{Y\sim p_\theta}\nabla\log p_\eta(Y|Y^*) \end{aligned} \tag{14}$$

The first term corresponds to the policy gradient algorithm described in REINFORCE (Williams, 1992), where the coefficient $-S(Y,Y^*)/\tau$ corresponds to reward function. Due to the mutual dependence between bridge module and generator network, we design an iterative training strategy, i.e. the two networks take turns to update their own parameters treating the other as fixed.

2.3 Training

The training of the above three variants is illustrated in Figure 3. Since the proposed bridges can be divided into static ones, which only require pretraining, and dynamic ones, which require continual training with the generator, we describe their training process in details respectively.

2.3.1 Stratified-Sampled Training

Since closed-formed optimal distributions can be found for uniform/LM GBNs, we only need to draw samples from the static bridge distributions to train our sequence generator. Unfortunately,

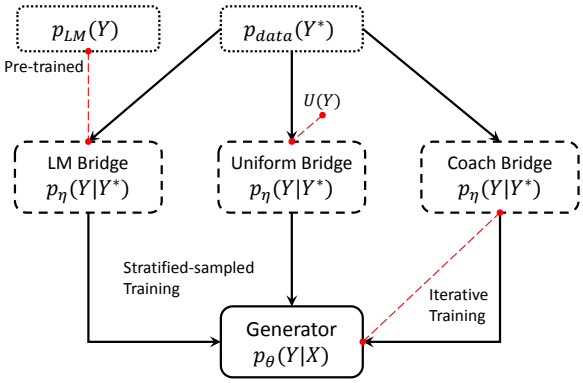

Figure 3: The training processes of the three different variants of our GBN architecture (Sec. 2.3).

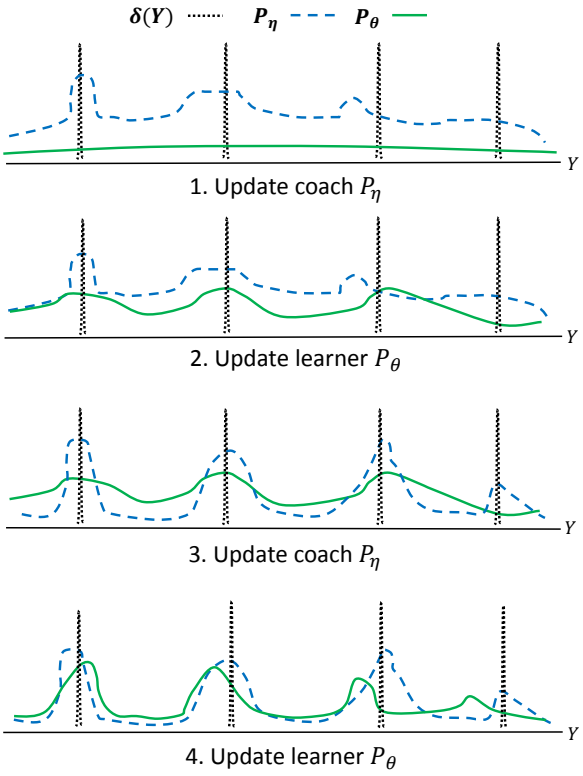

Figure 4: Four iterative updates of the coaching bridge and the generator. In an early stage, the pre-trained generator P_θ may not put mass on some ground truth target points within the output space, shown by $\delta(Y)$. The coaching bridge is first updated with Equation (14) to locate in between the Dirac delta distribution and the generator's output distribution. Then, by sampling from the coaching bridge for approximating Equation (4), target samples which demonstrate easy-to-learn sequence segments facilitate the generator to be optimized to achieve closeness with the coaching bridge. Then this process repeats until the generator converges.

due to the intractability of these bridge distributions, direct sampling is infeasible. Therefore, we follow Norouzi et al. (2016); Ma et al. (2017) and adopt stratified sampling to approximate the direct sampling process. Given a sentence Y^*, we first sample an edit distance m, and then randomly select m positions to replace the original tokens. The difference between the uniform and the LM bridge lies in that the uniform bridge replaces labels by drawing substitutions from a uniform distribution, while LM bridge takes the history as condition and draws substitutions from its step-wise distribution.

2.3.2 Iterative Training

Since the KL-constraint is a moving target for the coaching bridge, an iterative training strategy is designed to alternately update both the generator and the bridge (Algorithm 1). We first pre-train both the generator and the bridge and then start to alternately update their parameters. Figure 4 intuitively demonstrates the intertwined optimization effects over the coaching bridge and the generator. We hypothesize that iterative training with easy-to-learn guidance could benefit gradient update, thus result in better local minimum.

3 Experiment

We select machine translation and abstractive text summarization as benchmarks to verify our GBN framework.

3.1 Similarity Score Function

In our experiments, instead of directly using BLEU or ROUGE as reward to guide the bridge network's policy search, we design a simple surrogate n-gram matching reward as follows:

$$S(Y, Y^*) = 0.4{*}N_4{+}0.3{*}N_3{+}0.2{*}N_2{+}0.1{*}N_1 \quad (15)$$

N_n represents the n-gram matching score between Y and Y^*. In order to alleviate reward sparsity at sequence level, we further decompose the global reward $S(Y, Y^*)$ as a series of local rewards at every time step. Formally, we write the step-wise reward $s(y_t|y_{1:t-1}, Y^*)$ as follows:

$$s(y_t|y_{1:t-1}, Y^*) = \begin{cases} 1.0; N(y_{1:t}, y_{t-3:t}) \leq N(Y^*, y_{t-3:t}) \\ 0.6; N(y_{1:t}, y_{t-2:t}) \leq N(Y^*, y_{t-2:t}) \\ 0.3; N(y_{1:t}, y_{t-1:t}) \leq N(Y^*, y_{t-1:t}) \\ 0.1; N(y_{1:t}, y_t) \leq N(Y^*, y_t) \\ 0.0; otherwise \end{cases} \quad (16)$$

where $N(Y, \tilde{Y})$ represents the occurrence of subsequence $\tilde{Y}$ in whole sequence Y. Specifically, if

Algorithm 1 Training Coaching GBN

procedure PRE-TRAINING
Initialize $p_\theta(Y|X)$ and $p_\eta(Y|Y^*)$ with random weights θ and η
Pre-train $p_\theta(Y|X)$ to predict Y^* given X

end if
end while
end procedure

a certain sub-sequence $y_{t-n+1:t}$ from Y appears less times than in the reference Y^*, y_t receives reward. Formally, we rewrite the step-level gradient for each sampled Y as follows:

$$
\begin{aligned}
&-\frac{S(Y,Y^*)}{\tau}\nabla \log p_\eta(Y|Y^*) \\
&=\sum_t -\frac{s(y_t|y_{1:t-1},Y^*)}{\tau}\cdot\nabla \log p_\eta(y_t|y_{1:t-1},Y^*)
\end{aligned}
\tag{17}
$$

3.2 Machine Translation

Dataset We follow Ranzato et al. (2015); Bahdanau et al. (2016) and select German-English machine translation track of the IWSLT 2014 evaluation campaign. The corpus contains sentence-wise aligned subtitles of TED and TEDx talks. We use Moses toolkit (Koehn et al., 2007) and remove sentences longer than 50 words as well as lower-casing. The evaluation metric is BLEU (Papineni et al., 2002) computed via the multi-bleu.perl.

System Setting We use a unified GRU-based RNN (Chung et al., 2014) for both the generator and the coaching bridge. In order to compare with existing papers, we use a similar system setting with 512 RNN hidden units and 256 as embedding size. We use attentive encoder-decoder to build our system (Bahdanau et al., 2014). During training, we apply ADADELTA (Zeiler, 2012) with $\epsilon = 10^{-6}$ and $\rho = 0.95$ to optimize parameters of the generator and the coaching bridge. During decoding, a beam size of 8 is used to approximate the full search space. An important hyper-parameter for our experiments is the temperature τ. For the uniform/LM bridge, we follow Norouzi et al. (2016) to adopt an optimal temperature $\tau = 0.8$. And for the coaching bridge, we test hyper-parameters from $\tau \in \{0.8, 1.0, 1.2\}$. Besides comparing with our fine-tuned baseline, other systems for comparison of relative BLEU improvement are: MIXER (Ranzato et al., 2015), BSO (Wiseman and Rush, 2016), AC (Bahdanau et al., 2016), Softmax-Q (Ma et al., 2017).

Methods	Baseline	Model
MIXER	20.10	21.81 +1.71
BSO	24.03	26.36 +2.33
AC	27.56	28.53 +0.97
Softmax-Q	27.66	28.77 +1.11
Uniform GBN ($\tau = 0.8$)	29.10	29.80 +0.70
LM GBN ($\tau = 0.8$)		29.90 +0.80
Coaching GBN ($\tau = 0.8$)		29.98 +0.88
Coaching GBN ($\tau = 1.2$)		30.15 +1.05
Coaching GBN ($\tau = 1.0$)		**30.18** +1.08

competing other systems and our proposed GBN can yield a further improvement. We also observe that LM GBN and coaching GBN have both achieved better performance than Uniform GBN, which confirms that better regularization effects are achieved, and the generators become more robust and generalize better. We draw the learning curve of both the bridge and the generator in Figure 5 to demonstrate how they cooperate during training. We can easily observe the interaction between them: as the generator makes progress, the coaching bridge also improves itself to propose harsher targets for the generator to learn.

3.3 Abstractive Text Summarization

Dataset We follow the previous works by Rush et al. (2015); Zhou et al. (2017) and use the same corpus from Annotated English Gigaword dataset (Napoles et al., 2012). In order to be comparable, we use the same script [4] released by Rush et al. (2015) to pre-process and extract the training and validation sets. For the test set, we use the English Gigaword, released by Rush et al. (2015), and evaluate our system through ROUGE (Lin, 2004). Following previous works, we employ ROUGE-1, ROUGE-2, and ROUGE-L as the evaluation metrics in the reported experimental results.

[4]https://github.com/facebookarchive/NAMAS

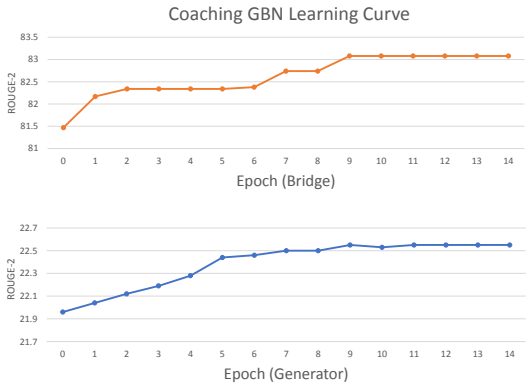

Figure 6: Coaching GBN's learning curve on Abstractive Text Summarization Dev set.

System Setting We follow Zhou et al. (2017); Rush et al. (2015) to set input and output vocabularies to 119,504 and 68,883 respectively, and we also set the word embedding size to 300 and all GRU hidden state size to 512. Then we adopt dropout (Srivastava et al., 2014) with probability $p = 0.5$ strategy in our output layer. We use attention-based sequence-to-sequence model (Bahdanau et al., 2014; Cho et al., 2014) as our baseline and reproduce the results of the baseline reported in Zhou et al. (2017). As stated, the attentive encoder-decode architecture can already outperform existing ABS/ABS+ systems (Rush et al., 2015). In coaching GBN, due to the fact that the input of abstractive summarization X contains more information than the summary target Y^*, directly training the bridge $p_\eta(Y|Y^*)$ to understand the generator $p_\theta(Y|X)$ is infeasible. Therefore, we re-design the coaching bridge to receive both source and target input X, Y and we enlarge its vocabulary size to 88,883 to encompass more information about the source side. In Uniform/LM GBN experiments, we also fix the hyper-parameter $\tau = 0.8$ as the optimal setting.

Results The experimental results are summarized in Table 2. We can observe a significant improvement via our GBN systems. Similarly, the coaching GBN system achieves the strongest performance among all, which again reflects our assumption that more sophisticated regularization can benefit generator's training. We draw the learning curve of the coaching GBN in Figure 6 to demonstrate how the bridge and the generator promote each other.

4 Analysis

By introducing different constraints into the bridge module, the bridge distribution will propose different training samples for the generator to learn. From Table 3, we can observe that most samples still reserve their original meaning. The uniform bridge simply performs random replacement without considering any linguistic constraint. The LM bridge strives to smooth reference sentence with high-frequent words. And the coaching bridge simplifies difficult expressions to relieve generator's learning burden. From our experimental results, the more rational and aggressive diversification from the coaching GBN clearly benefits generator the most and helps the generator generalize to more unseen scenarios.

5 Related Literature

5.1 Data Augmentation and Self-training

In order to resolve the data sparsity problem in Neural Machine Translation (NMT), many works have been conducted to augment the dataset. The most popular strategy is via self-learning, which incorporates the self-generated data directly into training. Zhang and Zong (2016) and Sennrich et al. (2015) both use self-learning to leverage massive monolingual data for NMT training. Our bridge can take advantage of the parallel training data only, instead of external monolingual ones to synthesize new training data.

5.2 Reward Augmented Maximum Likelihood

Reward augmented maximum likelihood or RAML (Norouzi et al., 2016) proposes to integrate task-level reward into MLE training by using an exponentiated payoff distribution. KL divergence between the payoff distribution and the generator's output distribution are minimized to achieve an optimal task-level reward. Following this work, Ma et al. (2017) introduces softmax Q-Distribution to interpret RAML and reveals its relation with Bayesian decision theory. These two works both alleviate data sparsity problem by augmenting target examples based on the ground truth. Our method draws inspiration from them but seeks to propose the more general Generative Bridging Network, which can transform the ground truth into different bridge distributions, from where samples are drawn will account for different interpretable factors.

5.3 Coaching

Our coaching GBN system is inspired by imitation learning by coaching (He et al., 2012). Instead of directly behavior cloning the oracle, they advocate learning hope actions as targets from a coach which is interpolated between learner's policy and the environment loss. As the learner makes progress, the targets provided by the coach will become harsher to gradually improve the learner. Similarly, our proposed coaching GBN is motivated to construct an easy-to-learn bridge distribution which lies in between the ground truth and the generator. Our experimental results confirm its effectiveness to relieve the learning burden.

6 Conclusion

In this paper, we present the Generative Bridging Network (GBN) to overcome data sparsity and overfitting issues with Maximum Likelihood Estimation in neural sequence prediction. Our implemented systems prove to significantly improve the performance, compared with strong baselines. We believe the concept of bridge distribution can be applicable to a wide range of distribution matching tasks in probabilistic learning. In the future, we intend to explore more about GBN's applications as well as its provable computational and statistical guarantees.

Abstract

Sentence compression methods based on LSTM can generate fluent compressed sentences. However, the performance of these methods is significantly degraded when compressing long sentences since it does not explicitly handle syntactic features. To solve this problem, we propose a higher-order syntactic attention network (HiSAN) that can handle higher-order dependency features as an attention distribution on LSTM hidden states. Furthermore, to avoid the influence of incorrect parse results, we train HiSAN by maximizing the probability of a correct output together with the attention distribution. Experiments on the Google sentence compression dataset show that our method achieved the best performance in terms of F_1 as well as ROUGE-1,2 and L scores, 83.2, 82.9, 75.8 and 82.7, respectively. In subjective evaluations, HiSAN outperformed baseline methods in both readability and informativeness.

1 Introduction

Sentence compression is the task of compressing long sentences into short and concise ones by deleting words. To generate compressed sentences that are grammatical, many researchers (Jing, 2000; Knight and Marcu, 2000; Berg-Kirkpatrick et al., 2011; Filippova and Altun, 2013) have adopted tree trimming methods. Even though Filippova and Altun (2013) reported the best results on this task, automatic parse errors greatly degrade the performances of these tree trimming methods.

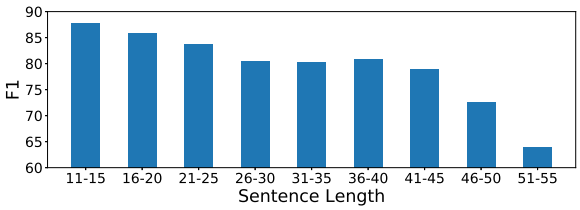

Figure 1: F_1 scores of LSTM-based sentence compression method for each sentence length.[1]

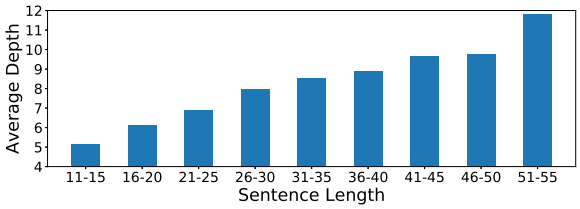

Figure 2: Average tree depths for each sentence length.[2]

Recently, Filippova et al. (2015) proposed an LSTM sequence-to-sequence (Seq2Seq) based sentence compression method that can generate fluent sentences without utilizing any syntactic features. Therefore, Seq2Seq based sentence compression is a promising alternative to tree trimming.

However, as reported for a machine translation task (Cho et al., 2014; Pouget-Abadie et al., 2014; Koehn and Knowles, 2017), the longer the input sentences are, the worse the Seq2Seq performances become. We also observed this problem in the sentence compression task. As shown in Figure 1, the performance of Seq2Seq is degraded when compressing long sentences. In particular, the performance significantly falls if sentence length exceeds 26 words. This is an important problem, because sentences longer than the average sentence length (=28 words) accounts for 42% of the Google sentence compression dataset.

As shown in Figure 2, long sentences have deep

[1] We used an LSTM-based sentence compression method (Filippova et al., 2015) in the evaluation setting as described in Section 4.1.

[2] We treat the maximum distance from root node to the leaf node as dependency tree depth.

Proceedings of NAACL-HLT 2018, pages 1716–1726
New Orleans, Louisiana, June 1 - 6, 2018.

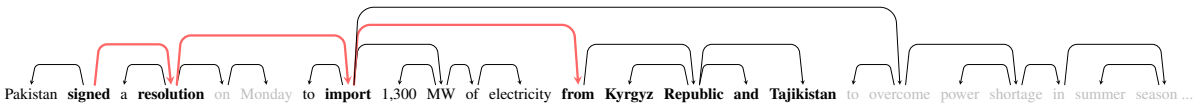

Figure 3: An example compressed sentence and its dependency tree. The words colored by gray represent deleted words.

dependency trees, which have long distances from root node to words at leaf nodes. Therefore, improving compression performance for sentences with such deep dependency trees can help to compress longer sentences.

To deal with sentences that have deep dependency trees, we focus on the chains of dependency relationships. Figure 3 shows an example of a compressed sentence with its dependency tree. The topic of this sentence is *import agreement related to electricity*. Thus, to generate informative compression, the compressed sentence must retain the *country name*. In this example, the compressed sentence should keep the phrase "from Kyrgyz Republic and Tajikistan". Thus, the compressed sentence must also keep the dependency chain "import", "resolution" and "signed" because the phrase is a child of this chain. By considering such higher-order dependency chains, the system can implement informative compression. As can be seen from the example in Figure 3, tracking a higher-order dependency chain for each word would help to compress long sentences. This paper refers to such dependency relationships by the expression "d-length dependency chains".

To handle a d-length dependency chain for sentence compression with LSTM, we propose the higher-order syntactic attention network (HiSAN). HiSAN computes the deletion probability for a given word based on the d-length dependency chain starting from the word. The d-length dependency chain is represented as an attention distribution, learned using automatic parse trees. To alleviate the influence of parse errors in automatic parse trees, we learn the attention distribution together with deletion probability.

Evaluation results on the Google sentence compression dataset (Filippova and Altun, 2013) show that HiSAN achieved the best F_1, ROUGE-1,2 and L scores 83.2, 82.9, 75.8 and 82.7, respectively. In particular, HiSAN attained remarkable compression performance with long sentences. In human evaluations, HiSAN also outperformed the baseline methods.

2 Baseline Sequence-to-Sequence Method

Sentence compression can be regarded as a tagging task, where given a sequence of input tokens $\mathbf{x} = (x_0, ..., x_n)$, a system assigns output label y_t, which is one of three types of specific labels ("keep,""delete," or"end of sentence") to each input token x_t $(1 \leq t \leq n)$.

The LSTM-based approaches for sentence compression are mostly based on the bi-LSTM based tagging method (Tagger) (Klerke et al., 2016; Wang et al., 2017; Chen and Pan, 2017) or Seq2Seq (Filippova et al., 2015; Tran et al., 2016). Tagger independently predicts labels in a point estimation manner, whereas Seq2Seq predicts labels by considering previously predicted labels. Since Seq2Seq is more expressive than Tagger, we built HiSAN on the baseline Seq2Seq model.

Our baseline Seq2Seq is a version of Filippova et al. (2015) extended through the addition of bi-LSTM, an input feeding approach (Vinyals et al., 2015; Luong et al., 2015), and a monotonic hard attention method (Yao and Zweig, 2015; Tran et al., 2016). As described in the evaluations section, this baseline achieved comparable or even better scores than the state-of-the-art scores reported in Filippova et al. (2015). The baseline Seq2Seq model consists of embedding, encoder, decoder, and output layers.

In the embedding layer, the input tokens $\mathbf{x}$ are converted to the embeddings $\mathbf{e}$. As reported in Wang et al. (2017), syntactic features are important for learning a generalizable embedding for sentence compression. Following their results, we also introduce syntactic features into the embedding layer. Specifically, we combine the surface token embedding w_i, POS embedding p_i, and dependency relation label embedding r_i into a single vector as follows:

$$e_i = [w_i, p_i, r_i], \quad (1)$$

where [] represents vector concatenation, and e_i is an embedding of token x_i.

The encoder layer converts the embedding $\mathbf{e}$ into a sequence of hidden states $\mathbf{h} = (h_0, ..., h_n)$

using a stacked bidirectional-LSTM (bi-LSTM) as follows:

$$h_i = \left[\overrightarrow{h_i}, \overleftarrow{h_i}\right] \quad (2)$$

$$\overrightarrow{h}_i = LSTM_{\overrightarrow{\theta}}(\overrightarrow{h}_{i-1}, e_i) \quad (3)$$

$$\overleftarrow{h}_i = LSTM_{\overleftarrow{\theta}}(\overleftarrow{h}_{i-1}, e_i), \quad (4)$$

where $LSTM_{\overrightarrow{\theta}}$ and $LSTM_{\overleftarrow{\theta}}$ represent forward and backward LSTM, respectively. The final state of the backward LSTM $\overleftarrow{h}_0$ is inherited by the decoder as its initial state.

In the decoder layer, the concatenation of a 3-bit one-hot vector which is determined by previously predicted label y_{t-1}, previous final hidden state d_{t-1} (explained later), and the input embedding of x_t, is encoded into the decoder hidden state $\overrightarrow{s}_t$ using stacked forward LSTMs.

Contrary to the original softmax attention method, we can deterministically focus on one encoder hidden state h_t (Yao and Zweig, 2015) to predict y_t in the sentence compression task (Tran et al., 2016).[3]

In the output layer, label probability is calculated as follows:

$$P(y_t \mid y_{<t}, \mathbf{x}) = softmax(W_o \cdot d_t) \cdot \delta_{y_t}, \quad (5)$$

$$d_t = [h_t, \overrightarrow{s}_t] \quad (6)$$

where W_o is a weight matrix of the softmax layer and δ_{y_t} is a binary vector where the y_t-th element is set to 1 and the other elements to 0.

3 Higher-order Syntactic Attention Network

The key component of HiSAN is its attention module. Unlike the baseline Seq2Seq, HiSAN employs a packed d-length dependency chain as distributions in the attention module. Section 3.1 explains the packed d-length dependency chain. Section 3.2 describes the network structure of our attention module, and Section 3.3 explains the learning method of HiSAN.

3.1 Packed d-length Dependency Chain

The probability for a packed d-length dependency chain is obtained from a dependency graph, which is an edge-factored dependency score matrix (Hashimoto and Tsuruoka, 2017; Zhang et al., 2017). First, we explain the dependency graph. Figure 4 (a) shows an example of the dependency graph. HiSAN represents a dependency graph as an attention distribution generated by the attention module. A probability for each dependency edge is obtained from the attention distribution.

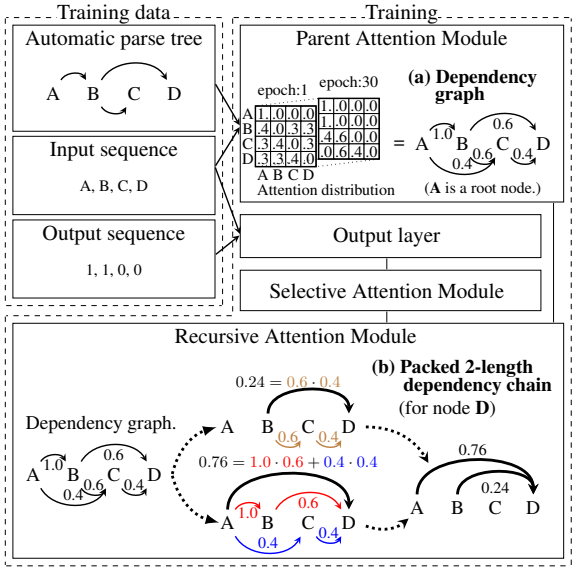

Figure 4: Dependency structures used in our higher-order syntactic attention network.

Figure 4 (b) shows an example of the packed d-length dependency chain. With our recursive attention module, the probability for a packed d-length dependency chain is computed as the sum of probabilities for each path yielded by recursively tracking from a word to its d-th ancestor. The probability for each path is calculated as the product of the probabilities of tracked edges. The probability for the chain can represent several d-length dependency chains compactly, and so alleviates the influence of incorrect parse results. This is the advantage of using dependency graphs.

3.2 Network Architecture

Figure 5 shows the prediction process of HiSAN. In this figure, HiSAN predicts output label y_7 from the input sentence. The prediction process of HiSAN is as follows.

1. **Parent Attention** module calculates $P_{parent}(x_j|x_t, \mathbf{x})$, the probability of x_j being the parent of x_t, by using h_j and h_t. This probability is calculated for all pairs of x_j, x_t. The arc in Figure 5 shows the most probable dependency parent for each child token.

[3] This is because the output length is the same as the input length, and each x_t can be assigned to each y_t in a one-to-one correspondence.

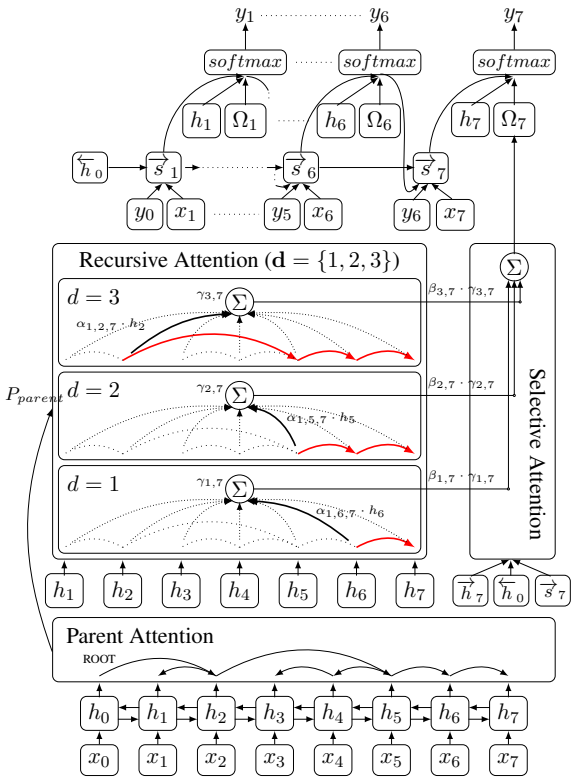

Figure 5: Prediction process of our higher-order syntactic attention network.

2. **Recursive Attention** module calculates $\alpha_{d,t,j}$, the probability of x_j being the d-th order parent (d denotes the chain length) of x_t, by recursively using $P_{parent}(x_j|x_t, \mathbf{x})$. $\alpha_{d,t,j}$ is also treated as an attention distribution, and used to calculate $\gamma_{d,t}$, the weighted sum of $\mathbf{h}$ for each length d. For example, a 3-length dependency chain of word x_7 with highest probability is x_6-x_5-x_2. The encoder hidden states h_6, h_5 and h_2, which correspond to the dependency chain, are weighted by calculated parent probabilities $\alpha_{1,7,6}$, $\alpha_{2,7,5}$ and $\alpha_{3,7,2}$, respectively, and then fed to the selective attention module.

3. **Selective Attention** module calculates weight $\beta_{d,t}$ from its length, $d \in \mathbf{d}$, for each $\gamma_{d,t}$. $\mathbf{d}$ represents a group of chain lengths. $\beta_{d,t}$ is calculated by encoder and decoder hidden states. Each $\beta_{d,t} \cdot \gamma_{d,t}$ is summed to Ω_t, the output of the selective attention module.

4. Finally, the calculated Ω_t is concatenated and input to the output layer.

Details of each module are explained in the following subsection.

3.2.1 Parent Attention Module

Zhang et al. (2017) formalized dependency parsing as the problem of independently selecting the parent of each word in a sentence. They produced a distribution over possible parents for each child word by using the attention layer on bi-LSTM hidden layers.

In a dependency tree, a parent has more than one child. Under this constraint, dependency parsing is represented as follows. Given sentence $S = (x_0, x_1, ..., x_n)$, the parent of x_j is selected from $S \setminus x_i$ for each token $S \setminus x_0$. Note that x_0 denotes the root node. The probability of token x_j being the parent of token x_t in sentence $\mathbf{x}$ is calculated as follows:

$$P_{parent}(x_j|x_t, \mathbf{x}) = softmax(g(h_{j'}, h_t)) \cdot \delta_{x_j}, \quad (7)$$

$$g(h_{j'}, h_t) = v_a^T \cdot tanh(U_a \cdot h_{j'} + W_a \cdot h_t), \quad (8)$$

where v_a, U_a and W_a are weight matrices of g.

Different from the attention based dependency parser, $P_{parent}(x_j|x_t, \mathbf{x})$ is jointly learned with output label probability $P(\mathbf{y} \mid \mathbf{x})$ in the training phase. Training details are given in Section 3.3.

3.2.2 Recursive Attention Module

The recursive attention module recursively calculates $\alpha_{d,t,j}$, the probability of x_j being the d-th order parent of x_t, as follows:

$$\alpha_{d,t,j} = \begin{cases} \sum_{k=1}^{n} \alpha_{d-1,t,k} \cdot \alpha_{1,k,j} & (d > 1) \\ P_{parent}(x_j|x_t, \mathbf{x}) & (d = 1) \end{cases}. \quad (9)$$

Furthermore, in a dependency parse tree, *root* should not have any parent, and a token should not depend on itself. In order to satisfy these rules, we impose the following constraints on $\alpha_{1,t,j}$:

$$\alpha_{1,t,j} = \begin{cases} 1 & (t = 0 \wedge j = 0) \\ 0 & (t = 0 \wedge j > 0) \\ 0 & (t \neq 0 \wedge t = j) \end{cases} \quad (10)$$

The 1st and 2nd lines of Eq. (10) represent the case that the parent of *root* is also *root*. These constraints imply that *root* does not have any parent. The 3rd line of Eq. (10) prevents a token from depending on itself. Because the 1st line of Eq. (9) is similar to the definition of matrix multiplication, Eq. (9) can be efficiently computed on a CPU and GPU[4].

[4]In training, HiSAN with 1- and 3-length dependency chains took 25 and 26 minutes, respectively, per epoch on an Intel Xeon E5-2697 v3 2.60 GHz.

By recursively using the single attention distribution, it is no longer necessary to prepare additional attention distributions for each order when computing the probability of higher order parents. Furthermore, since it is not necessary to learn multiple attention distributions, it becomes unnecessary to use hyper parameters for adjusting the weight of each distribution in training. Finally, this method can avoid the problem of sparse higher-order dependency relations in the training dataset.

The above calculated $\alpha_{d,t,j}$ is used to weight the bi-LSTM hidden layer $\mathbf{h}$ as follows:

$$\gamma_{d,t} = \sum_{k=j}^{n} \alpha_{d,t,j} \cdot h_j. \quad (11)$$

Note that $\gamma_{d,t}$ is inherited by the selective attention module, as explained in the next section.

3.2.3 Selective Attention Module

To select suitable dependency orders of the input sentence, the selective attention module weights and sums the hidden states $\gamma_{d,t}$ to Ω_t by using weighting parameter $\beta_{d,t}$, according to the current context as follows:

$$\beta_{d,t} = softmax(W_c \cdot c_t) \cdot \delta_d, \quad (12)$$

$$\Omega_t = \sum_{d \in \{0, \mathbf{d}\}} \beta_{d,t} \cdot \gamma_{d,t}, \quad (13)$$

where W_c is the weight matrix of the softmax layer, $\mathbf{d}$ is a group of chain lengths, c_t is a vector representing the current context, $\gamma_{0,t}$ is a zero-vector, and $\beta_{0,t}$ indicates the weight when the method does not use the dependency features. Context vector c_t is calculated as $c_t = [\overleftarrow{h}_0, \overrightarrow{h}_n, \overrightarrow{s}_t]$ using the current decoder hidden state $\overrightarrow{s}_t$.

The calculated Ω_t is concatenated and input to the output layer. In detail, d_t in Eq. (5) is replaced by concatenated vector $d'_t = [h_t, \Omega_t, \overrightarrow{s}_t]$; furthermore, instead of d_t, d'_t is also fed to the input of the decoder LSTM at $t+1$.

3.3 Objective Function

To alleviate the influence of parse errors, we jointly update the 1st-order attention distribution $\alpha_{1,t,k}$ and label probability $P(\mathbf{y}|\mathbf{x})$ (Kamigaito et al., 2017). The 1st-order attention distribution is learned by dependency parse trees. If $a_{t,j} = 1$ is an edge between parent word w_j and child w_t on a dependency tree ($a_{t,j} = 0$ denotes that w_j is not a parent of w_t.), the objective function of our method can be defined as:

$$-logP(\mathbf{y}|\mathbf{x}) - \lambda \cdot \sum_{j=1}^{n} \sum_{t=1}^{n} a_{t,j} \cdot log\alpha_{1,t,j}, \quad (14)$$

where λ is a hyper-parameter that controls the importance of the output labels and parse trees in the training dataset.

4 Evaluations

4.1 Evaluation Settings

4.1.1 Dataset

This evaluation used the Google sentence compression dataset (Filippova and Altun, 2013)[5]. This dataset contains information of compression labels, part-of-speech (POS) tags, dependency parents and dependency relation labels for each sentence.

We used the first and last 1,000 sentences of `comp-data.eval.json` as our test and development datasets, respectively. Note that our test dataset is compatible wth that used in previous studies (Filippova et al., 2015; Tran et al., 2016; Klerke et al., 2016; Wang et al., 2017).

In this paper, we trained the following baselines and HiSAN on all sentences of `sent-comp.train*.json` (total 200,000 sentences)[6,7,8].

In our experiments, we replaced rare words that appear fewer than 10 times in our training dataset with a special token ⟨UNK⟩. After this filtering, the input vocabulary size was 23,168.

4.1.2 Baseline Methods

For a fair comparison of HiSAN, we used the input features described in Eq. (1) for the following baseline methods:

[5]https://github.com/google-research-datasets/sentence-compression

[6]Note that Filippova et al. (2015) used 2,000,000 sentences for training their method, but these datasets are not publicly available.

[7]We also demonstrate an experimental evaluation on a small training set (total 8,000 sentences), that was used in previous research. The results of this setting are listed in our supplemental material.

[8]Note that the large training dataset lacks periods at the end of compressed sentences. To unify the form of compressed sentences in small and large settings, we added periods to the end of compressed sentences in the large training dataset.

Tagger: A method that regards sentence compression as a tagging task based on bi-LSTM (Klerke et al., 2016; Wang et al., 2017).

Tagger+ILP: An extension of **Tagger** that integrates ILP (Integer Linear Programming)-based dependency tree trimming (Wang et al., 2017). We set their positive parameter λ to 0.2.

Bi-LSTM: A method that regards sentence compression as a sequence-to-sequence translation task proposed by (Filippova et al., 2015). For a fair comparison, we replaced their one-directional LSTM with the more expressive bi-LSTM in the encoder part. The initial state of the decoder is set to the sum of the final states of the forward and backward LSTMs.

Bi-LSTM-Dep: An extension of Bi-LSTM that exploits features obtained from a dependency tree (named LSTM-PAR-PRES in Filippova et al. (2015)). Following their work, we fed the word embedding and the predicted label of a dependency parent word to the current decoder input of **Bi-LSTM**.

Base: Our baseline Seq2Seq method described in Section 2.

Attn: An extension of the softmax based attention method (Luong et al., 2015). We replaced h_t in Eq. (6) with the weighted sum calculated by the commonly used concat attention (Luong et al., 2015).

HiSAN-Dep: A variant of HiSAN that utilizes the pipeline approach. We fix $\alpha^{1,j,t}$ to 1.0 if x_j is a parent of x_t in the input dependency parse tree, 0.0 otherwise. In this baseline, $\mathbf{d} = \{1\}$ was used.

4.1.3 Training Details

Following the previous work (Wang et al., 2017), the dimensions of the word embeddings, LSTM layers, and attention layer were set to 100. For the Tagger-style methods, the depth of the LSTM layer was set to 3, and for the Seq2Seq-style methods, the depth of the LSTM layer was set to 2. In this setting, all methods have a total of six LSTM-layers. The dimensions of POS and the dependency-relation label embeddings were set to 40. All parameters were initialized by Glorot and Bengio (2010)'s method. For all methods, we applied Dropout (Srivastava et al., 2014) to the input of the LSTM layers. All dropout rates were set to 0.3.

During training, the learning rate was tuned with Adam (Kingma and Ba, 2014). The initial learning rate was set to 0.001. The maximum number of training epochs was set to 30. The hyper-parameter λ was set to 1.0 in the supervised attention setting. All gradients were averaged in each mini-batch. The maximum mini-batch size was set to 16. The order of mini-batches was shuffled at the end of each training epoch. The clipping threshold of the gradient was set to 5.0. We selected trained models with early stopping based on maximizing per-sentence accuracy (i.e., how many compressions could be fully reproduced) of the development data set.

To obtain a compressed sentence, we used greedy decoding, rather than beam decoding, as the latter attained no gain in the development dataset. All methods were written in C++ on Dynet (Neubig et al., 2017).

4.2 Automatic Evaluation

In the automatic evaluation, we used token level F_1-measure ($\mathbf{F_1}$) as well as recall of ROUGE-1, ROUGE-2 and ROUGE-L (Lin and Och, 2004)[9] as evaluation measures. We used $\Delta C = \mathit{system\ compression\ ratio} - \mathit{gold\ compression\ ratio}$ to evaluate how close the compression ratio of system outputs was to that of gold compressed sentences. The average compression ratio of the gold compression for input sentence was 39.8. We used micro-average for F_1-measure and compression ratio[10], and macro-average for ROUGE scores, respectively.

To verify the benefits of our methods on long sentences, we additionally report scores on sentences longer than the average sentence length ($= 28$) in the test set. The average compression ratio of the gold compression for longer input sentences was 31.4.

All results are reported as the average scores of five trials. In each trial, different random choices were used to generate the initial values of the embeddings and the order of mini-batch processing.

Table 1 shows the results. HiSANs outperformed the other methods. In particular, HiSAN ($d = \{1, 2, 4\}$) achieved the best score on F_1,

[9] We used the ROUGE-1.5.5 script with option "-n 2 -m -d -a".

[10] We also report the macro-average of F_1-measure and compression ratio in our supplemental material.

[11] Note that we used average of all metrics to decide the best score of the development dataset. The results are listed in our supplemental material.

	($\mathbf{d} = \{1,2,4\}$)$*$	82.9	82.1	74.9	81.9	-2.4	80.4	79.7	72.1	79.4	-2.1
	($\mathbf{d} = \{1,2,3,4\}$)	82.7	82.1	74.8	81.9	-2.2	80.1	79.6	71.9	79.3	-2.0
HiSAN	($\mathbf{d} = \{1\}$)	83.0	81.7	74.5	81.5	-2.9	80.6	79.6	72.1	79.3	-2.5
	($\mathbf{d} = \{1,2\}$)	83.1	82.3	75.1	82.2	-2.1	**80.9**	80.5	72.8	80.2	-1.9
	($\mathbf{d} = \{1,2,3\}$)	82.9	82.5	75.2	82.1	-2.1	80.7	80.2	72.6	79.9	-2.1
	($\mathbf{d} = \{1,2,4\}$)$*$	**83.2**	**82.9**	**75.8**	**82.7**	**−1.7**	**80.9**	**80.6**	**73.2**	**80.3**	**−1.8**
	($\mathbf{d} = \{1,2,3,4\}$)	82.7	82.0	74.7	81.8	-2.3	80.6	79.8	72.6	79.5	-2.3

Table 1: Results of automatic evaluation. **ALL** and **LONG** represent, respectively, the results in all sentences and long sentences (longer than average length 28) in the test dataset. $\mathbf{d}$ represents the groups of d-length dependency chains. $*$ indicates the model that achieved the best score among the same methods with different $\mathbf{d}$ in the development dataset[11]. Bold values indicate the best scores.

ROUGE, and ΔC in all settings. The F_1 scores of HiSAN (**ALL**) were higher than the current state-of-the-art score of .82, reported by Filippova et al. (2015). The improvements in F_1 and ROUGE scores from the baselines methods in the **LONG** setting are larger than those in the **ALL** setting. ¿From these results, we can conclude that d-length dependency chains are effective for sentence compression, especially in the case of longer than average sentences. HiSAN ($d = \{1\}$) outperformed **HiSAN-Dep** in F_1 scores in **ALL** and **LONG** settings. This result shows the effectiveness of joint learning the dependency parse tree and the output labels.

4.3 Human Evaluation

In the human evaluation, we compared the baselines with our method, which achieved the highest F_1 score in the automatic evaluations. We used the first 100 sentences that were longer than the average sentence length ($= 28$) in the test set for human evaluation. Similar to Filippova et al. (2015), the compressed sentence was rated by five raters who were asked to select a rating on a five-point Likert scale, ranging from one to five for readability (**Read**) and for informativeness (**Info**). We report the average of these scores from the five raters. To investigate the differences between the methods, we also compared the baseline methods and HiSAN using the sentences for which the methods yielded different compressed sentences.

		Read	Info	CR
All *(100)*	Tagger	4.54	3.41	30.9
	Base	4.64	3.45	31.1
	HiSAN (d=$\{1,2,4\}$)	**4.68**	**3.52**	31.6
Diff *(41)*	Base	4.79	3.46	29.4
	HiSAN (d=$\{1,2,4\}$)	**4.89**	**3.64**	30.6

Table 2: Results of human evaluations. *All* denotes results for all sentences in the test set, and *Diff* denotes results for the sentences for which the methods yielded different compressed sentences. Parentheses ( ) denote sentence size. **CR** denotes the compression ratio. The average gold compression ratio for input sentence in *All* and *Diff* were 32.1 and 31.5, respectively. Other notations are similar to those in Table 1.

Table 2 shows the results. HiSAN ($d = \{1,2,4\}$) achieved better results than the baselines in terms of both readability and informativeness. The results agree with those obtained from the automatic evaluations. ¿From the results on the sentences whose compressed sentences were different between Base and HiSAN ($d = \{1,2,4\}$), we can clearly observe the improvement attained by HiSAN (d=$\{1,2,4\}$) in informativeness.

Input	Pakistan signed a resolution on Monday to import 1,300 MW of electricity from Kyrgyz Republic and Tajikistan to overcome power shortage in summer season, said an official press release .
Gold	Pakistan signed a resolution to import 1,300 MW of electricity from Kyrgyz Republic and Tajikistan .
Tagger	Pakistan signed a resolution to import 1,300 MW of electricity Tajikistan to overcome shortage .
Tagger-ILP	Pakistan signed resolution to import MW said .
Base	Pakistan signed a resolution to import 1,300 MW of electricity .
HiSAN-Dep ($d=\{1\}$)	Pakistan signed a resolution to import 1,300 MW of electricity .
HiSAN ($d=\{1,2,4\}$)	Pakistan signed a resolution to import 1,300 MW of electricity from Kyrgyz Republic and Tajikistan .

HiSAN ($d=\{1,2,4\}$)	Bradley Manning received a sentence of 35 years in prison .

Table 3: Example sentences and compressions.

5 Analysis

Table 3 shows examples of source sentences and their compressed variants output by baseline and HiSAN ($d = \{1, 2, 4\}$).

For both examples, the compressed sentence output by **Base** is grammatically correct. However, the informativeness is inferior to that attained by HiSAN ($d = \{1, 2, 4\}$). The compressed sentence output by **HiSAN-Dep** in the second example lacks both readability and informativeness. We believe that this compression failure is caused by incorrect parse results, because **HiSAN-Dep** employs the features obtained from the dependency tree in the pipeline procedure.

As reported in recent papers (Klerke et al., 2016; Wang et al., 2017), the F_1 scores of **Tagger** match or exceed those of the Seq2Seq-based methods. The compressed sentence of the first example in Table 3 output by **Tagger** is ungrammatical. We believe that this is mainly because **Tagger** cannot consider the predicted labels of the previous words. **Tagger-ILP** outputs grammatically incorrect compressed sentences in both examples. This result indicates that THE ILP constraint based on the parent-child relationships between words is insufficient to generate fluent sentences.

Compared with these baselines, HiSAN ($d = \{1, 2, 4\}$) output compressed sentences that were fluent and had higher informativeness. This observation, which confirmed our expectations, is supported by the automatic and human evaluation results.

Table 4: Results of automatic evaluation using sentences with deep dependency trees (deeper than average depth 8). Bold results indicate the best scores.

We confirm that the compression performance of HiSAN actually improves if the sentences have deep dependency trees. Table 4 shows the automatic evaluation results for sentences with deep dependency trees. We can observe that HiSAN

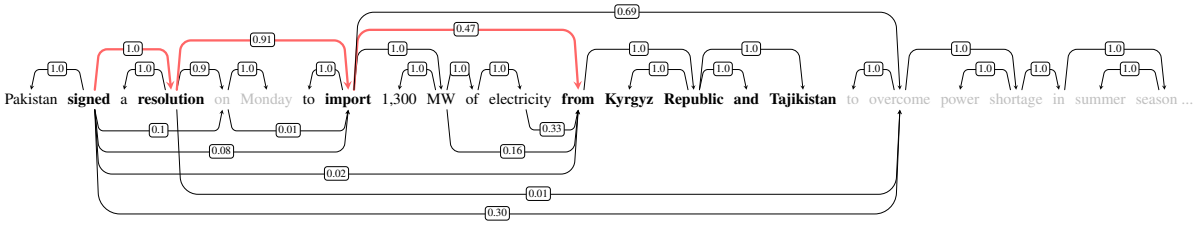

Figure 6: An example compressed sentence and its dependency graph of HiSAN $\mathbf{d} = \{1, 2, 4\}$. The words colored by gray represent deleted words. The numbers for each arc represent a probabilistic weight of a relationship between a parent and child words. The arcs contained in the parsed dependency tree are located on the top side. The arcs not contained in the parsed dependency tree are located on the bottom side.

with higher-order dependency chains has better compression performance if the sentences have deep dependency trees.

Figure 6 shows a compressed sentence and its dependency graph as determined by HiSAN $\mathbf{d} = \{1, 2, 4\}$. Almost all arcs with large probabilistic weights are contained in the parsed dependency trees. Interestingly, some arcs not contained in the parsed dependency trees connecting words which are connected by the dependency chains in the parsed dependency tree (colored by red). Considering the training dataset does not contain such dependency relationships, we can estimate that these arcs are learned in support of compressing sentences. This result meets our expectation that the dependency chain information is necessary for compressing sentences accurately.

6 Related Work

Several neural network based methods for sentence compression use syntactic features. Filippova et al. (2015) employs the features obtained from automatic parse trees in the LSTM-based encoder-decoder in a pipeline manner. Wang et al. (2017) trims dependency trees based on the scores predicted by an LSTM-based tagger. Although these methods can consider dependency relationships between words, the pipeline approach and the 1st-order dependency relationship fail to compress longer than average sentences.

Several recent machine translation studies also utilize syntactic features in Seq2Seq models. Eriguchi et al. (2017); Aharoni and Goldberg (2017) incorporate syntactic features of the target language in the decoder part of Seq2Seq. Both methods outperformed Seq2Seq without syntactic features in terms of translation quality. However, both methods fail to provide an entire parse tree until the decoding phase is finished. Thus, these methods cannot track all possible parents for each word within the decoding process. Similar to HiSAN, Hashimoto and Tsuruoka (2017) use dependency features as attention distributions, but different from HiSAN, they use pre-trained dependency relations, and do not take into account the chains of dependencies. Marcheggiani and Titov (2017); Bastings et al. (2017) consider higher-order dependency relationships in Seq2Seq by incorporating a graph convolution technique (Kipf and Welling, 2016) into the encoder. However, the dependency information of the graph convolution technique is still given in pipeline manner.

Unlike the above methods, HiSAN can capture higher-order dependency features using d-length dependency chains without relying on pipeline processing.

7 Conclusion

In this paper, we incorporated higher-order dependency features into Seq2Seq to compress sentences of all lengths.

Experiments on the Google sentence compression test data showed that our higher-order syntactic attention network (HiSAN) achieved the better performance than baseline methods on F_1 as well as ROUGE-1,2 and L scores 83.2, 82.9, 75.8 and 82.7, respectively. Of particular importance, challenged with longer than average sentences, HiSAN outperformed the baseline methods in terms of F_1, ROUGE-1,2 and L scores. Furthermore, HiSAN also outperformed the previous methods for both readability and informativeness in human evaluations.

From the evaluation results, we conclude that HiSAN is an effective tool for the sentence compression task.

Abstract

Storyline generation aims to extract events described on news articles under a certain topic and reveal how those events evolve over time. Most existing approaches first train supervised models to extract events from news articles published in different time periods and then link relevant events into coherent stories. They are domain dependent and cannot deal with unseen event types. To tackle this problem, approaches based on probabilistic graphic models jointly model the generations of events and storylines without annotated data. However, the parameter inference procedure is too complex and models often require long time to converge. In this paper, we propose a novel neural network based approach to extract structured representations and evolution patterns of storylines without using annotated data. In this model, title and main body of a news article are assumed to share the similar storyline distribution. Moreover, similar documents described in neighboring time periods are assumed to share similar storyline distributions. Based on these assumptions, structured representations and evolution patterns of storylines can be extracted. The proposed model has been evaluated on three news corpora and the experimental results show that it outperforms state-of-the-art approaches accuracy and efficiency.

1 Introduction

With the development of the internet, massive information about current events is generated and propagated continuously on online news media sites. It is difficult for the public to digest such large volumes of information effectively. Storyline generation, aiming at summarizing the development of certain related events, has been intensively studied recently (Diao and Jiang, 2014).

In general, storyline can be considered as an event cluster where event-related news articles are ordered and clustered depending on both content and temporal similarity. Different ways of calculating content and temporal similarity can be used to cluster related events (Yan et al., 2011; Huang and Huang, 2013). Bayesian non-parametric models could also be used to tackle this problem by describing the storyline generating process using probabilistic graphical models (Li and Cardie, 2014; Diao and Jiang, 2014). Nevertheless, most existing approaches extract events independently and link relevant events in a post-processing step. More recently, Zhou et al. (2016) proposed a non-parametric generative model to extract storylines which is combined with Chinese Restaurant Processes (CRPs) to determine the number of storylines automatically. However, the parameter inference procedure is too complex and the model requires long time to converge. This makes it impractical to be deployed in real-world applications.

Recently, deep learning techniques have been successfully applied to various natural language processing tasks. Several approaches (Mikolov et al., 2013; Le and Mikolov, 2014) such as word2vec have been proved efficient in representing rich syntactic and semantic information in text. Therefore, it would be interesting to combine the advantage of both probabilistic graphical model and deep neural networks. There have been some efforts in exploring this in recent years. For example, Yang et al. (2015) proposed a gaussian mixture neural topic model incorporating both the ordering of words and the semantic meaning of sentences into a topic model. Cao et al. (2015) explained topic models from the perspective of neural networks and proposed a neural topic model where the representation of words and documents are combined into a unified framework. However, to the best of our knowledge, there is no attempt in extracting structured repre-

Proceedings of NAACL-HLT 2018, pages 1727–1736
New Orleans, Louisiana, June 1 - 6, 2018.

sentation of storylines from text using neural network based approaches.

In this paper, we propose a novel neural model for storyline generation without the use of any annotated data. In specific, we assume that the storyline distributions of a document's title and its main body are similar. A pairwise ranking approach is used to optimize the model. We also assume that similar documents described in neighboring time periods should share similar storyline distributions. Hence, the model learned in the previous time period can be used for guiding the learning of the model in the current period. Based on the two assumptions, relevant events can be extracted and linked. Furthermore, storyline filtering based on confidence scores is performed. This makes it possible to generate new storylines.

The main contributions of this paper are summarized below:

- We propose a novel neural network based model to extract structured representations and evolution patterns of storylines. To the best of our knowledge, it is the first attempt to perform storyline generation based on neural network without any annotated data.
- The proposed approach has been evaluated on three corpora and a significant improvement on F-measure is achieved when compared to the state-of-the-art approaches. Moreover, the proposed approach only requires a faction of the training time in comparison with the second best approach.

2 Related Work

Considering storyline as hidden topic, storyline extraction can be casted into the topic detection and tracking (TDT) problem. One popular way to deal with TDT is through topic models. However, traditional topic models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) do not detect the dynamics of topic over time. Griffiths and Steyvers (2004) clustered texts using LDA and then mapped the topics into corresponding time periods. Blei and Lafferty (2006) developed a dynamic topic model which captures the evolution of topics in a sequentially organized corpus of documents by using Gaussian time series on the natural parameter of the multinomial topics and logistic normal topic proportion models. Unlike early work that relied on Markov assumptions or discretization of time, Wang and McCallum (2006) proposed a topic-over-time (TOT) model where each topic is associated with a continuous distribution over timestamps. For each document, the mixture distribution over topics is influenced by both word co-occurrences and the document's timestamp. As a storyline might include more than one topic, Kawamae (2011) made an improvement over TOT and proposed a trend analysis model which generates storylines based on the model trained in the previous time period. Ahmed and Xing (2008) employed Recurrent Chinese Restaurant Processes (RCRPs) to cluster texts from discrete time slice while the number of clusters can grows automatically with the data at each epoch. Following this, many approaches were proposed for storyline extraction by combining RCRP with LDA (Ahmed et al., 2011a,b; Ahmed and Xing, 2013). Considering dependencies among clusters in different time periods, a distance-dependent CRP model was proposed by (Blei and Frazier, 2011) which defines a weight function to quantify the dependency in different clusters. Huang et al. (2015) proposed a Dynamic Chinese Restaurant Process (DCRP) model which considers the birth, survival and death of a storyline.

Recently, there have been increasing interests in exploring neural network based approaches for topic detection from text. These approaches can be divided into two categories, solely based on neural networks and a combination of topic models and neural networks. For the first category, topic distributions of documents are modeled by a hidden layer in neural networks. For example, Hinton and Salakhutdinov (2009) proposed a two layer probabilistic graphical model which is a generalization of the restricted Boltzmann machine, called a "Replicate Softmax". It can be used to automatically extract low-dimensional latent semantic representations from a large unstructured collection of documents. Larochelle and Lauly (2012) proposed a neural autoregressive topic model to compute the hidden units of the network efficiently. There are also many approaches trying to combine neural networks with topic models. For example, Yang et al. (2015) presented a Gaussian mixture neural topic model which incorporates both the ordering of words and the semantic meaning of sentences into topic modeling. To make the neural network based model more interpretable, Cao et

al. (2015) explained topic models from the perspective of neural networks and proposed a neural topic model where the representation of words and documents are combined into a unified framework. Tian et al. (2016) proposed a sentence level recurrent topic model assuming the generation of each word within a sentence is dependent on both the topic of the sentence and the the historical context of its preceding words in the sentence. Wan et al. (2012) introduced a hybrid model which combines a neural networks with a latent topic models. The neural network provides a low dimensional embedding for the input data while the subsequent distribution is captured by the topic model. However, most of the aforementioned models are solely for topic detection. They do not consider evolutionary topic clustering for storyline generation.

3 Methodology

To model the generation of a storyline in consecutive time periods from a stream of documents, we propose a neural network based approach, called Neural Storyline Extraction Model (NSEM), as shown in Figure 1. In this model, we have the following assumptions:

Assumption 1: *for a document, the storyline distribution of its title and main body should be similar.*

In general, for any given document, its title and main body should discuss the same storyline. Although title may exist metaphor and metonymy to catch the reader's eye ball, the key entities and words will not change such as name, location and so on. Therefore, it is reasonable to assume that the title h and its main body d of a document share a similar storyline distribution. The storyline distributions of title and main body are denoted as $\boldsymbol{p}(\boldsymbol{s}_h)$ and $\boldsymbol{p}(\boldsymbol{s}_d)$. Hence, $\boldsymbol{p}(\boldsymbol{s}_h)$ and $\boldsymbol{p}(\boldsymbol{s}_d)$ should be similar. Based on this assumption, documents at time period t can be clustered into several storylines in such a way. Let h_{pos} denotes the correct title to the main body d (positive example), and h_{neg} denotes an irrelevant title (negative example), the similarity of the storyline distribution derived from the main body d and that obtained from the correct title h_{pos} should be far more greater than that obtained from irrelevant titles h_{neg}, i.e. $sim(\boldsymbol{p}(\boldsymbol{s}_d), \boldsymbol{p}(\boldsymbol{s}_{h_{pos}})) \gg sim(\boldsymbol{p}(\boldsymbol{s}_d), \boldsymbol{p}(\boldsymbol{s}_{h_{neg}}))$. Different similarity metrics can be used to measure the similarity between two distributions.

Assumption 2: *for similar documents in neighboring time periods, they should share similar storyline distribution.*

It is assumed that similar documents in the neighboring time periods tend to share the same storyline. For example, a document with the title "Indian Election 2014: What are minorities to do?" and another document in the next time period with the title "The efficiency of Indian elections is time tested" should belong to the same storyline "*India election*". Based on this assumption, events extracted in different time period can be linked into storylines. As main body contains more information than title, we only use the storyline distribution of the main body, $\boldsymbol{p}(\boldsymbol{s}_d)$, in order to simplify the model structure. The learned information in the previous time period is used to supervise the learning in the current time period.

Based on the above two assumptions, the proposed NSEM as shown in Figure 1 contains the following four layers: (1) *Input layer* shown at the left bottom part of Figure 1, takes d, h_{pos} and h_{neg} as the input and transforms these texts into vectors; (2) *Main body-Storyline layer* and *Title-Storyline layer*, both are designed to generate storyline distributions; (3) *Similarity layer* aims to calculate the similarity between the storyline distribution of the main body and that of the title. In the top part of Figure 1, the model learned in previous time period is used to guide the storyline distribution learning in current time period. We explain the structure and function of each layer of NSEM in more details below:

Input Layer (d, h): the input layer aims to represent the main body d and title h with distributed embedding $\vec{d}$ and $\vec{h}$. Let the subscript pos denotes the relevant title h_{pos} (positive example) and subscript neg denotes an irrelevant title h_{neg} (negative example). For news articles, we pay more attention to the key elements of events such as location l, person p , organization o and keywords w. Thus an event is described by a quadruple $\langle l, p, o, w\rangle$. We extract these elements from the main body and concatenate their word embeddings as the feature vector $\vec{d} = [\vec{l}, \vec{p}, \vec{o}, \vec{w}]$. We obtain the title feature $\vec{h}$ in the same way.

We first identify named entities and treat those named entities with multi-word expressions (e.g., "Donald Trump") as single tokens. Then we train word2vec (Mikolov et al., 2013) to represent each entity with a 100-dimensional embedding vector. We also filter out less important keywords and en-

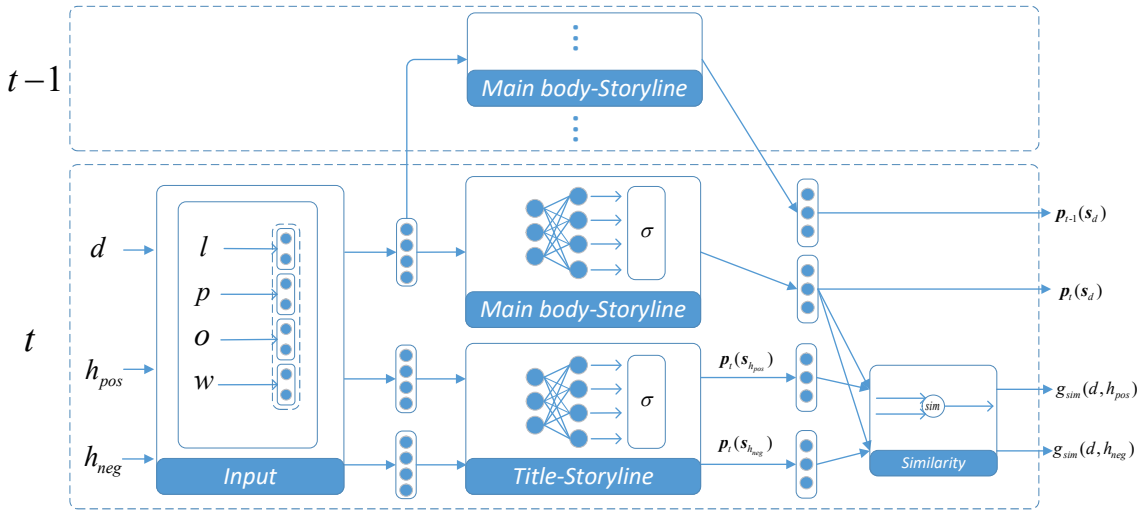

Figure 1: Overall architecture of the Neural Storyline Extraction Model (NSEM).

tities based on some criteria such as TFIDF. For a document containing more than one entity for the same event element type, for example, a document might contain mentions of different locations, we calculate the weighted sum of all location embeddings according to their occurrence number. If a certain event element is missing from a document, we set it to "null". After concatenating the four key event elements, each document or title is represented by a 400-dimensional embedding vector.

Main body-Storyline Layer ($\boldsymbol{p}(\boldsymbol{s}_d) \in \mathbb{R}^{1\times S}$): this layer aims to represent the storyline distribution $\boldsymbol{p}(\boldsymbol{s}_d)$ of main body d. Suppose there are a total of S storylines, the storyline distribution $\boldsymbol{p}(\boldsymbol{s}_d)$ is a S-dimensional vector, denoted as $\boldsymbol{p}(\boldsymbol{s}_d) = \{p(s_d = 1), \cdots, p(s_d = S)\}$. It can be formulated as below:

$$\boldsymbol{p}(\boldsymbol{s}_d) = f(\vec{d} \cdot \boldsymbol{W}_1 + \boldsymbol{b}_1) \quad (1)$$

where $\boldsymbol{W_1} \in \mathbb{R}^{K\times S}$ denotes the weight matrix, $\boldsymbol{b}$ denote the bias, $K = 400$ is the dimension of the document representation, and f denotes the activation function. Here we use the Softmax function. The probability of the main body d belonging to the storyline i can be written below:

$$p(s_d = i) = \frac{\exp(\vec{d} \cdot \boldsymbol{W}_{1i} + \boldsymbol{b}_{1i})}{\sum_{i=1}^{S} \exp(\vec{d} \cdot \boldsymbol{W}_{1i} + \boldsymbol{b}_{1i})} \quad (2)$$

Title-Storyline Layer ($\boldsymbol{p}(\boldsymbol{s}_h) \in \mathbb{R}^{1\times S}$): this layer aims to represent the storyline distribution $\boldsymbol{p}(\boldsymbol{s}_h)$ of title h. Similar to the Main body-Storyline layer, we can obtain $\boldsymbol{p}(\boldsymbol{s}_h)$ and $p(s_h = i)$ of title h in the following way:

$$\boldsymbol{p}(\boldsymbol{s}_h) = f(\vec{h} \cdot \boldsymbol{W}_2 + \boldsymbol{b}_2) \quad (3)$$

$$p(s_h = i) = \frac{\exp(\vec{h} \cdot \boldsymbol{W}_{2i} + \boldsymbol{b}_{2i})}{\sum_{i=1}^{S} \exp(\vec{h} \cdot \boldsymbol{W}_{2i} + \boldsymbol{b}_{2i})} \quad (4)$$

Similarity Layer ($g_{sim} \in \mathbb{R}$): this layer aims to calculate the similarity of the distributions between $\boldsymbol{p}(\boldsymbol{s}_d)$ and $\boldsymbol{p}(\boldsymbol{s}_h)$. The similarity score g_{sim} is calculated by the Kullback-Leibler (KL) divergence:

$$g_{sim}(d, h) = -\sum \boldsymbol{p}(\boldsymbol{s}_d) \log \frac{\boldsymbol{p}(\boldsymbol{s}_h)}{\boldsymbol{p}(\boldsymbol{s}_d)} \quad (5)$$

The similarity can be also calculated by other metric methods.

3.1 Storyline Construction

Different from the common way which link relevant events into storyline, we extract it in a unified framework. According to our second assumption, for the current time period t, we employ the storyline generation results in the previous time period $t-1$ as constraints to guide the storyline generation process in t. For a document d_t (we only use the main body here) in the time period t, we first use the model trained in $t-1$ to predict its storyline distribution $\boldsymbol{p}_{t-1}(\boldsymbol{s}_{d_t})$. Hence when we learn $\boldsymbol{p}_t(\boldsymbol{s}_{d_t})$, we would expect it to be similar to $\boldsymbol{p}_{t-1}(\boldsymbol{s}_{d_t})$. By doing so, we can link relevant events in different time periods together. For cases where intermittent storylines are observed, i.e., the related events occur initially, but disappear in certain time periods and re-occur later, we select

documents randomly from all previous time periods and make them participate in the learning of current model.

3.2 Training

Our first assumption assumes that *for a document, its title and main body should share similar storyline distributions*. Hence, we use a pairwise ranking approach (Collobert et al., 2011) to optimize $\boldsymbol{p}(\boldsymbol{s}_d)$ and $\boldsymbol{p}(\boldsymbol{s}_h)$. The basic idea is that the storyline distribution of the main body d should be more similar to that of the relevant title than irrelevant ones. We first define the loss function as below:

$$\mathcal{L}_1(d, h_{pos}, h_{neg}) = \max(0, \Omega - g_{sim}(d, h_{pos}) + g_{sim}(d, h_{neg})) \quad (6)$$

where Ω denotes the margin parameter, h_{pos} denotes the relevant title and h_{neg} denotes an irrelevant title. We choose titles whose elements $\langle l, p, o, k\rangle$ have no intersection with those positive titles from the current time period as negative examples.

Our second assumption assume that *for similar documents in neighboring time periods, they should share similar storyline distribution*. Hence, the model learned in the previous time period can be used for guiding the learning of the model in the current period. Hence, when constructing storyline for the main body d in current time period t, we use the model in previous time period $t-1$ and predict the storyline distribution $\boldsymbol{p}_{t-1}(\boldsymbol{s}_d)$. Then we measure current storyline distribution $\boldsymbol{p}_t(\boldsymbol{s}_d)$ and predicted distribution $\boldsymbol{p}_{t-1}(\boldsymbol{s}_d)$ by KL divergence which can be defined as below:

$$\mathcal{L}_2(d) = \sum \boldsymbol{p}_{t-1}(\boldsymbol{s}_d) \log \frac{\boldsymbol{p}_t(\boldsymbol{s}_d)}{\boldsymbol{p}_{t-1}(\boldsymbol{s}_d)} \quad (7)$$

Therefore, the final objective function is to minimize:

$$\mathcal{L} = \sum_d (\alpha \mathcal{L}_1(d, h_{pos}, h_{neg}) + \beta \mathcal{L}_2(d)) \quad (8)$$

where α and β are the weights controlling the contributions of the two loss terms.

For the start time period, we only use $\mathcal{L}_1$ to optimize our model. Let Φ_t denote the model parameter in the time period t. Based on the model structure and the loss function described above, the training procedure for NSEM is given in Algorithm 1.

Algorithm 1 Training procedure for NSEM at the time period t

Require: main bodies $\boldsymbol{d}$; titles $\boldsymbol{h}$; model parameter Φ_{t-1} at the time period $t-1$

```
Initialize Φ_t
for d ∈ d do
    Calculate its storyline distribution based on Φ_{t-1}

3.3 Post-processing

As the number of storylines at each time period is assumed to be the same, some newly emerging storylines might be incorrectly linked with previous storylines. Therefore, post-processing is needed to filter out such erroneous linkings. We assume that if a current storyline does not have any key element in common with previously extracted storyline, it should be flagged as a new storyline. We define the **Coverage** of the storyline s as below:

$$Coverage(s, t, M) = (element)_s^t \cap (element)_s^{t-M} \quad (9)$$

where $(element)_s^t$ denotes the set of event elements in the time period t for storyline s and $(element)_s^{t-M}$ denote the set of event elements in the last M time periods for storyline s. If the coverage $Coverage(s, t, M)$ is less than a threshold N, the current storyline s is considered as a new one. For example, if the current storyline' $Coverage$ with index 5 is less than N, then previ-

ous storyline with index 5 stops at current period and the current storyline with index 5 is a new one.

4 Experiments

4.1 Setup

To evaluate the proposed approach, we use the three datasets as in (Zhou et al., 2016). The statistics of the three datasets are presented in Table 4.1. Among which the Dataset III includes 30 different types of manually annotated storylines which are categorized into four types: (1) long-term storylines which last for more than 2 weeks; (2) short-term storylines which last for less than 1 week; (3) intermittent storylines which last for more than 2 weeks in total, but stop for a time and then appear again; (4) new storylines which emerge in the middle of the period, not at the beginning.

Datasets	Documents	Storylines	Dates
I	526,587	N/A	1-30 May 2014
II	101,654	77	1-7 May 2014
III	23,376	30	1-30 May 2014

Table 1: Statistics of the three datasets.

In our experiments, we used the Stanford named entity recognizer [1] for identifying the named entities. In addition, we removed common stopwords and only kept tokens which are verbs, nouns, or adjectives from these news articles.

We chose the following four methods as the baseline approaches.

1. DLDA (Blei and Lafferty, 2006): the dynamic LDA is based on the Markovian assumption that the topic-word distribution at the current time period is only influenced by the topic-word distribution in the previous time period. Moreover, topic-word distributions are linked across time periods by a Markovian chain.

2. RCRP (Ahmed et al., 2011a): it is a non-parametric model for evolutionary clustering based on RCRP, which assumes that the past story popularity is a good prior for current popularity.

3. SDM (Zhou et al., 2015): it assumes that the number of storylines is fixed and the storyline is modeled as a joint distribution over entities and keywords. The dependency of different stories of the same storyline at different time periods is captured by modifying Dirichlet priors.

4. DSEM (Zhou et al., 2016): this model is integrated with CRPs so that the number of storylines can be determined automatically without human intervention. Moreover, per-token Metropolis-Hastings sampler based on light LDA (Yuan et al., 2015) is used to reduce sampling complexity.

For DLDA, SDM and our model NSEM, the storyline number is set to 100 on both Dataset I-I and III. In consideration of the dependency to the historical storyline distributions, the number of past epochs M is set to 7 for both SDM and DSEM. For RCRP, the hyperparameter α is set to 1. For our model NSEM, the threshold Ω is set to 0.5 and the loss weight α and β are set to 1 and 0.5 respectively. In postprocess step, we empirically set the N to 7.

To evaluate the performance of the proposed approach, we use precision, recall and F-measure which are commonly used in evaluating information extraction systems. The precision is calculated based on the following criteria: 1) The entities and keywords extracted refer to the same storyline; 2) The duration of the storyline is correct. We assume that the start date (or end date) of a storyline is the publication date of the first (or last) related news article.

As there is no gold standard available for Dataset I, we do manual examination with the experimental result. We search for the same period of news and compare it with our results in the criteria.

4.2 Experimental Results

The experimental results of the proposed approach in comparison to the baselines on Dataset I, II and III are presented in Table 2. For Dataset I, as it is hard to know the ground-truth of storylines, we only report the precision value by manually examining the extracted storylines.

It can be observed from Table 2 that the proposed approach achieves the best performance on the three datasets. In specific, for Dataset I, NSEM extracts more storylines and with a higher precision value. For Dataset II containing 77 storylines, NSEM extracts 81 storylines among which

[1] https://nlp.stanford.edu/software/CRF-NER.html

Dataset I			
Method	Precision(%)	# of extracted storylines	
SDM	70.20	104	
DSEM	75.43	114	
NSEM	**76.58**	**121**	
Dataset II			
Method	Precision(%)	Recall(%)	F-measure(%)
DLDA	62.67	61.03	61.84
RCRP	67.11	66.23	66.67
SDM	70.67	68.80	69.27
DSEM	73.17	77.92	75.47
NSEM	**75.31**	**79.22**	**77.22**
Dataset III			
Method	Precision(%)	Recall(%)	F-measure(%)
DLDA	46.16	43.33	42.86
RCRP	61.54	53.33	57.14
SDM	54.17	43.33	48.15
DSEM	75.00	70.00	72.41
NSEM	**77.78**	70.00	**73.69**

Table 2: Performance comparison of the storyline extraction results on Dataset I, II and III.

61 are correct and outperforms DSEM with 2% in F-measure. For dataset III consisting of 30 storylines, NSEM extracted 27 storylines among which 21 are correct. Although its recall value is the same as DSEM, its precision value is nearly 3% higher which results in better F-measure.

4.3 Impact of the Number of Storylines S

The proposed approach needs to preset the number of storylines. To study the impact of the number of storylines on the performance of the proposed model, we conducted experiments Dataset III with different numbers of storylines S varying between 25 and 150. Table 3 shows the performance of storyline extraction with different value of S. It can be observed that both precision and recall of NSEM increase with the increasing number of storylines until it reaches 100. If further increasing S, the precision/recall have slight change and the F-measure become relatively stable.

4.4 Structured Browsing

We illustrate the evolution of storylines using structured browsing. The structured information of the storylines such as locations, persons, entities, keywords are presented, together with titles of some related documents. The number of related documents for each storyline is also depicted to allow an easy visualization of storyline popularity over time. Figure 2 illustrates three different types of storylines including "Apple vs Samsung", "Pistorious shoot Steenkamp" and "Egypt election".

Dataset III			
S	Precision(%)	Recall(%)	F-measure(%)
25	66.67	33.33	44.44
50	73.08	46.67	56.96
75	76.92	53.33	62.99
100	77.78	70.00	73.69
125	78.13	73.33	75.65
150	78.79	70.00	74.13

Table 3: The performances of NSEM with different S.

For the first storyline "Apple vs Samsung", it starts at the beginning of the month and only lasts for 9 days. Three representative epochs are highlighted. From the extracted organizations, "Apple, Samsung", and keywords, "patent, infringe", it can be easily deduced that this is about "Apple and Samsung infringed patents".

For the storyline "Pistorious shoot Steenkamp", it is an intermittent storyline which lasts for more than 2 weeks but with no related news articles in some of the days in between. From Figure 2, it can be observed that the storyline ceases for 2 days in Day 10 and 11. From the structured representation of the early storylines, it can be observed that there is a shooting event about Pistorious and Steenkamp in South African. After 2 day's silence, in Day 13, public attention was raised once again since Pistorius applied for mental tests.

For the last storyline "Egypt election", it starts in Day 20 and continues beyond the end of May. From the key event elements, location "Egypt" and keywords "presidential, election", it can be easily inferred that there was a presidential election in Egypt. It can also be observed that Sisi and Morsi were both candidates for the Egypt's presidential election from persons extracted, "Sisi, Morsi" in Day 26. In Day 29, the storyline reached to the climax since Sisi won the election, which can be discovered from the title "Sisi elected #Egypt president by landslide".

4.5 Time Complexity

To explore the efficiency of the proposed approach, we conducted an experiment by comparing the proposed approach NSEM with DSEM. DSEM employs the Metropolis-Hastings sampler to

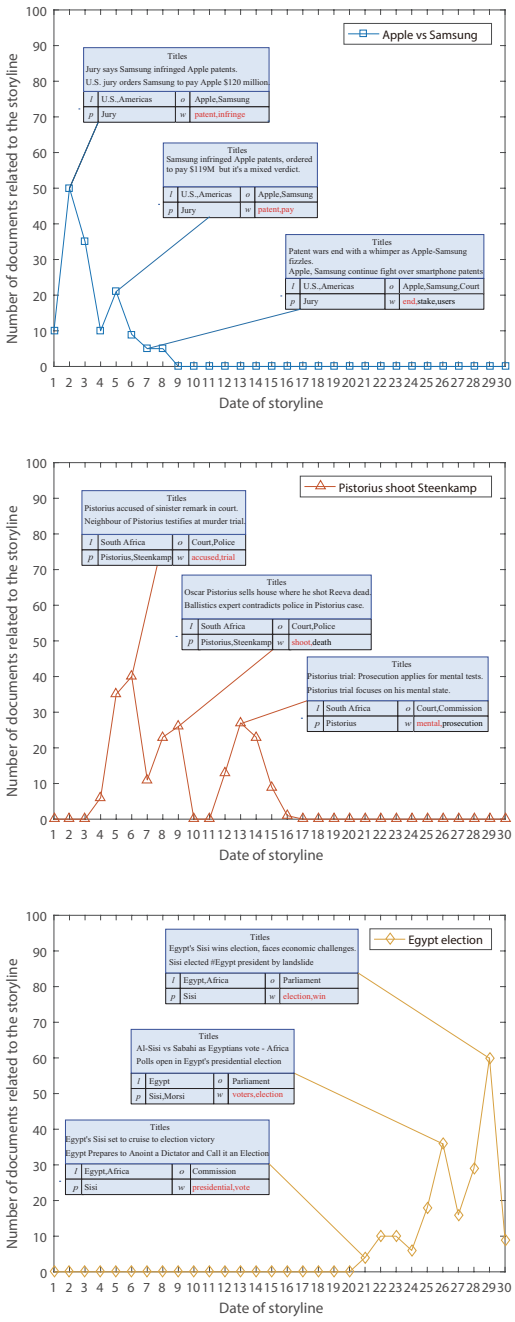

Figure 2: The structured representations of three example storylines.

boost the sampling complexity in order to achieve faster convergence. We train both models on training data varying from 1,000 to 10,000 documents. Figure 3 illustrates the logarithm of time consumed for each training set. It can be observed that NSEM trains 30 times faster compared to DSEM, showing the advantage of using a neural network based approach in comparison with a Bayesian model based method.

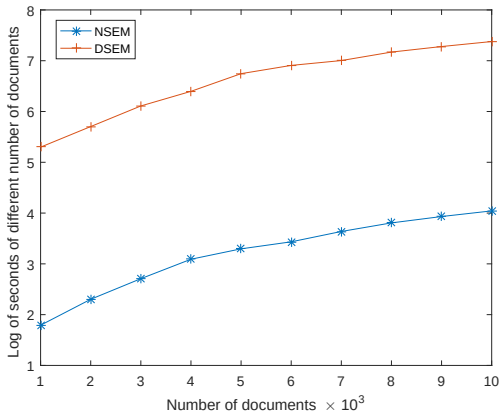

Figure 3: Comparison of training time between NSEM and DSEM.

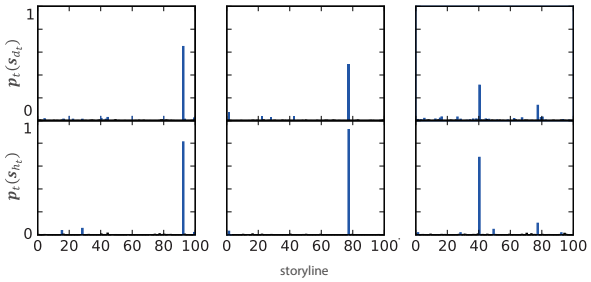
4.6 Visualization of the Learned Distribution

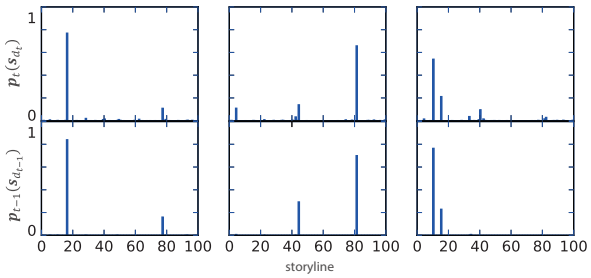
Our proposed model is based on the two distribution similarity assumptions which we presented in the Methodology section. To investigate the quality of the learned storyline distribution, we conducted an experiment on Dataset III where the storyline number S is set to 100. We randomly choose three documents and calculate the storyline distribution of theirs title and main body based on our learned NSEM. We also randomly select three pairs similar documents in different time periods and draw their main body storyline distributions based on the learned NSEM. It can be observed from Figure 4 that the storyline distributions of the title and the main body of a document are similar. Moreover, the storyline distributions of two similar documents in different time periods are also similar.

5 Conclusions and Future Work

In this paper, we have proposed a neural network based storyline extraction model, called NSEM, to extract structured representations of storyline from news articles. NSEM was designed based on the two assumptions about the similarity of storyline distributions of the title and the main body of the same document, and the similarity of storyline distributions of similar documents in different time periods. Experimental results show that our proposed model outperforms the state-of-the-art approaches and only requires a fraction of training time. In future work, we will explore the extension of our proposed model to cater for varying number of storylines automatically and also better deal with intermittent storylines.



(a) Storyline distributions of title and main body.



(b) Storyline distributions of similar documents in different time periods.

Abstract

Submodular maximization with the greedy algorithm has been studied as an effective approach to *extractive summarization*. This approach is known to have three advantages: its applicability to many useful submodular objective functions, the efficiency of the greedy algorithm, and the provable performance guarantee. However, when it comes to *compressive summarization*, we are currently missing a counterpart of the extractive method based on submodularity. In this paper, we propose a fast greedy method for compressive summarization. Our method is applicable to any monotone submodular objective function, including many functions well-suited for document summarization. We provide an approximation guarantee of our greedy algorithm. Experiments show that our method is about 100 to 400 times faster than an existing method based on integer-linear-programming (ILP) formulations and that our method empirically achieves more than 95%-approximation.

1 Introduction

Automatic document summarization continues to be a seminal subject of study in natural language processing and information retrieval (Luhn, 1958; Edmundson, 1969; Cheng and Lapata, 2016; Peyrard and Eckle-Kohler, 2017). Owing to the recent advances in data collection, the size of document data to be summarized has been exploding, which has been bringing a drastic increase in the demand for fast summarization systems.

Extractive summarization is a widely used approach to designing fast summarization systems. With this approach, we construct a summary by extracting some sentences from the original document(s). The extractive approach is not only fast but also has the potential to achieve state-of-the-art ROUGE scores (Lin, 2004), which was revealed by Hirao et al. (2017b). In many existing methods, sentences are extracted by solving various subset selection problems: for example, the *knapsack problem* (McDonald, 2007), *maximum coverage problem* (Filatova and Hatzivassiloglou, 2004; Takamura and Okumura, 2009a), *budgeted median problem* (Takamura and Okumura, 2009b), and *submodular maximization problem* (Lin and Bilmes, 2010). Of particular interest, the method based on submodular maximization has three advantages: (1) Many objective functions used for document summarization are known to be *monotone* and *submodular* (Lin and Bilmes, 2011; J Kurisinkel et al., 2016); examples of such functions include the *coverage function*, *diversity reward function*, and ROUGE. Therefore, the method can deliver high performance by using monotone submodular objective functions that are suitable for the given tasks. (2) The efficient greedy algorithm is effective for the submodular maximization problem, which provides fast summarization systems. (3) Theoretical performance guarantees of the greedy algorithm can be proved; for example, a $\frac{1}{2}(1 - e^{-1})$-approximation guarantee can be obtained.

Although the above extractive methods successfully obtain summaries with high ROUGE scores, they have the following shortcoming: A long sentence typically has redundant parts, which means a summary constructed simply by extracting some sentences often includes many redundant parts. As a result, if the limitation placed on summary length is tight, the extractive approach cannot yield an informative summary.

Compressive summarization is known to be effective in overcoming this problem. With this approach, a summary is constructed with some

Proceedings of NAACL-HLT 2018, pages 1737–1746
New Orleans, Louisiana, June 1 - 6, 2018.

compressed sentences, and thus we can obtain a concise and informative summary. To make compressed sentences, the dependency-tree-based approach (Filippova and Strube, 2008) is often used, which is advantageous in that each compressed sentence preserves its original dependency relations. Specifically, given a set of dependency trees constructed for sentences in the original documents, a summary is obtained by extracting some rooted subtrees; each subtree corresponds to a compressed sentence. Different from the extractive summarization, the dependency relations in each sentence must be taken into account, and hence the aforementioned extractive methods cannot be applied to compressive summarization. A number of methods have been proposed for compressive summarization (Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013; Morita et al., 2013; Kikuchi et al., 2014; Hirao et al., 2017a). These methods formulate summarization as a type of combinatorial optimization problem with a tree constraint, and they obtain summaries by solving the problem. Unfortunately, the existing methods have two drawbacks: (1) The class of objective functions to which they are applicable is limited; for example, they work only with the linear function or coverage function. As a result, the performance of these methods cannot be improved by elaborating the objective functions. (2) They contain costly procedures as their building blocks: integer-linear-programming (ILP) solvers, dynamic programming (DP) algorithms, and so on. Therefore, they are not fast enough to be applied to large-scale document data. In a nutshell, compressive summarization is currently missing a fast method that is applicable to a wide variety of objective functions.

1.1 Our Contribution

In this paper, we propose a submodularity-based greedy method for compressive summarization. Our method is, so to speak, a compressive counterpart of the greedy method for extractive summarization (Lin and Bilmes, 2010). Similar to the extractive method, our method has the three key advantages:

1. Our method works with any monotone submodular objective function, a wide class of useful objective functions, examples of which include the coverage function, ROUGE, and many others (Lin and Bilmes, 2011; J Kurisinkel et al., 2016).

2. Our method is faster than existing compressive summarization methods since it employs the efficient greedy algorithm. Specifically, given a set, V, of all textual units contained in the document data and a summary length limitation value, L, our method requires at most $O(L|V|)$ objective function evaluations. Experiments show that our method is about 100 to 400 times faster than the ILP-based method implemented with `CPLEX`.

3. A theoretical guarantee of our method can be proved; specifically, a $\frac{1}{2}(1 - e^{-1/\lambda})$-approximation guarantee can be obtained, where λ is a parameter defined from given document data (a definition is shown later). This result generalizes the $\frac{1}{2}(1 - e^{-1})$-approximation of the greedy algorithm for submodular maximization with a knapsack constraint (Leskovec et al., 2007). In experiments, our method achieved more that 95%-approximation. Furthermore, our method attained ROUGE_1 scores comparable to those of the ILP-based method.

1.2 Related Work

There are many existing methods for compressive summarization (Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013; Morita et al., 2013; Kikuchi et al., 2014; Hirao et al., 2017a), and they attempt to create summaries by solving optimization problems with a tree and length constraints. Unfortunately, these methods accept only a few objective functions.

A common approach is to use ILP formulations. Berg-Kirkpatrick et al. (2011) formulate the problem as an ILP with the coverage objective function, which is solved by using an ILP solver. Almeida and Martins (2013) also employs an ILP formulation and solves the problem via an algorithm based on *dual decomposition*, which runs faster than an ILP solver.[1] These ILP-based methods are optimal in terms of objective function values. However, it is hard to apply them to large-scale document data since to solve ILPs often takes long computation time.

[1]Their method was observed to be about 25 times faster than `GLPK`, a commonly used free ILP solver. On the other hand, `CPLEX`, which is a commercial ILP solver used in our experiments, was observed to be about 3 to 20 times faster than `GLPK`, and our method is about 100 to 400 times faster than `CPLEX`. Consequently, our method is estimated to be about 12 to 320 times faster than their method.

In an attempt to uncover the potential power of dependency-tree-based compressive summarization, Hirao et al. (2017a) solved ILPs with the ROUGE objective function with an ILP solver. Their method obtains summaries by directly maximizing the ROUGE score for given reference summaries (i.e., any other methods cannot achieve higher ROUGE scores than their method). The resulting summaries, called *oracle summaries*, were revealed to attain substantially high rouge scores, which implies that there remains much room for further research into compressive summarization.

A greedy method with a DP algorithm (Morita et al., 2013) is probably the closest one to our idea. Their method iteratively chooses compressed sentences in a greedy manner, for which a DP algorithm is employed. Thanks to the submodularity of their objective function, their method enjoys a $\frac{1}{2}(1-e^{-1})$-approximation guarantee. However, because of the costly DP procedure, their method is less scalable than the standard greedy methods such as the extractive method (Lin and Bilmes, 2010) and ours. Moreover, it is applicable only to objective functions that are designed for their problem settings; for example, it cannot use ROUGE as an objective function.

1.3 Overview of Our Approach

A high-level sketch of our approach is as follows: As in many existing works, we formulate the compressive summarization task as a combinatorial optimization problem with a tree constraint, which we call the *submodular tree knapsack problem* (STKP). STKP is generally NP-hard; in fact, it includes the knapsack problem and maximum coverage problem as special cases. Unfortunately, as we will see later, a naive greedy algorithm for STKP does not offer any approximation guarantee in general. The main difficulty with STKP is that its tree constraint is too complex. To avoid dealing with the complex constraint directly, we transform STKP into a special case of the *submodular cost submodular knapsack problem* (SCSKP) (Iyer and Bilmes, 2013). For general SCSKP, no approximation guarantee has been proved. Fortunately, in our case, a $\frac{1}{2}(1-e^{-1/\lambda})$-approximation can be proved by exploiting the structure of the resulting SCSKP. Thus we obtain a fast greedy method for compressive summarization, which works with various monotone submodular objective functions and enjoys an approximation guarantee.

2 Submodularity

Given finite set V (e.g., a set of chunks), set function $g : 2^V \to \mathbb{R}$ is said to be *submodular* if $g(A \cup B) + g(A \cap B) \leq g(A) + g(B)$ holds for any $A, B \subseteq V$. We define $g(A \mid B) \coloneqq g(A \cup B) - g(B)$. The submodularity is also characterized by the following *diminishing return property*: $g(\{v\} \mid A) \geq g(\{v\} \mid B)$ for any $A \subseteq B$ and $v \in V \backslash B$. Set function g is *monotone* if $g(A) \leq g(B)$ for any $A \subseteq B$. In this paper, we focus on monotone submodular functions such that $g(\emptyset) = 0$. The submodularity and monotonicity are a natural fit for document summarization; intuitively, the marginal gain, $g(\{v\} \mid S)$, of adding new chunk $v \in V$ to summary $S \subseteq V$ is small if S already has many chunks (submodularity), and a summary becomes more informative as it gets more chunks (monotonicity). In fact, as in (Lin and Bilmes, 2011), many objective functions well-suited for document summarization have submodularity and monotonicity; examples of such functions include the coverage function, diversity reward function, and ROUGE, to name a few.

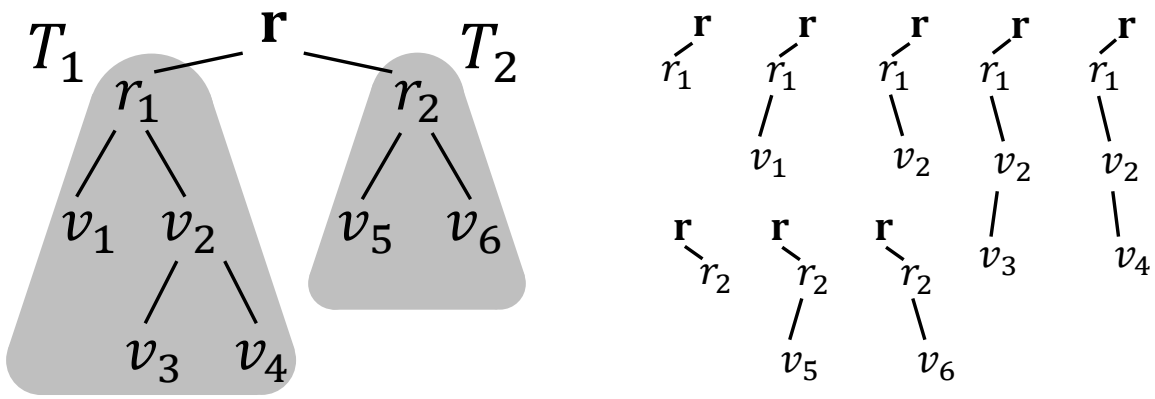
3 Problem Statements

We formulate the summarization task as the following subtree extraction problem called STKP hereafter. In what follows, we let $[M] \coloneqq \{1, \ldots, M\}$ for any positive integer M.

We attempt to summarize document data consisting of N sentences. Each sentence forms a dependency tree, which can be constructed by using existing methods (e.g., (Filippova and Strube, 2008; Filippova and Altun, 2013)). For convenience, we call the dependency tree of a sentence the *sentence tree*. The i-th sentence ($i \in [N]$) yields sentence tree $T_i = (V_i, E_i)$ rooted at $r_i \in V_i$, where V_i is a set of textual units (e.g., words or chunks) contained in the i-th sentence, and edges in E_i represent their dependency relations. We define a *document tree* with a dummy root vertex $\mathbf{r}$ as $\mathbf{T} \coloneqq (\{\mathbf{r}\} \cup V, E)$, where V and E are vertex and edge sets, respectively, defined as follows:

$$V \coloneqq \bigcup_{i \in [N]} V_i, \quad E \coloneqq \bigcup_{i \in [N]} \{E_i \cup \{(\mathbf{r}, r_i)\}\}.$$

Namely, V is the set of all textual units contained in the document data, and edges in E represent the dependency relations as well as the relations between $\mathbf{r}$ and r_i, with which the multiple sentence



(a) Document tree $\mathbf{T} = (\{\mathbf{r}\} \cup V, E)$

(b) Set of all paths rooted at $\mathbf{r}$

Figure 1: Illustration of the problem reformulation. The left figure is a document tree rooted at $\mathbf{r}$; it consists of two sentence trees, T_1 and T_2, rooted at r_1 and r_2, respectively. We have $V = \{r_1, r_2, v_1, \ldots, v_6\}$. The right figure shows $\mathcal{P}$, the set of all paths rooted at $\mathbf{r}$. Note that $|V| = |\mathcal{P}|$ holds. With our method, the greedy algorithm is performed over $\mathcal{P}$, which requires at most $O(|V|)$ objective function evaluations in each iteration.

trees form a single document tree. Figure 1 (a) illustrates an example of a document tree.

Given document tree $\mathbf{T}$, a summary preserves the original dependency relations if it forms a subtree rooted at $\mathbf{r}$ in $\mathbf{T}$. Therefore, our aim is to find a rooted subtree of $\mathbf{T}$ that includes informative textual units. For each $v \in V$, the length of v is denoted by $\ell_v \geq 0$; for example, ℓ_v is the number of words or characters in chunk v. If $S \subseteq V$ is a subset of the textual units included in an obtained summary, its total length must be less than or equal to the given length limitation value $L \geq 0$; namely, the following knapsack constraint must be satisfied: $\sum_{v \in S} \ell_v \leq L$. The quality of summary S is evaluated by a monotone submodular function g. Consequently, compressive summarization is formulated as STKP:

$$\begin{aligned} \underset{S \subseteq V}{\text{maximize}} \quad & g(S) \qquad (1) \\ \text{subject to} \quad & \sum_{v \in S} \ell_v \leq L, \\ & S \cup \{\mathbf{r}\} \text{ forms a subtree in } \mathbf{T}. \end{aligned}$$

At first glance, it may seem that the following naive greedy approach works well for this problem: Starting from root $\mathbf{r}$, we sequentially add the most beneficial child to the current solution until the knapsack constraint is violated. Unfortunately, the approximation ratio of this method can become arbitrarily bad since it may miss beneficial vertices that are far from $\mathbf{r}$; if such missed vertices are more beneficial than those added to the solution by a considerable margin, the resulting approximation ratio is almost equal to zero. To avoid this difficulty, we reformulate STKP in the next section.

4 Proposed Method

We observed that the naive greedy algorithm does not work well for STKP (1) due to the complex tree constraint. We circumvent this difficulty by transforming STKP into a special case of the submodular cost submodular knapsack problem (SCSKP). We then provide a greedy algorithm for SCSKP. An approximation guarantee of the greedy algorithm is also presented.

4.1 Problem Reformulation

We show that STKP can be transformed into SCSKP. Let $\mathcal{P}$ be a set of all paths that connect $v \in V$ to $\mathbf{r}$. Note that there is a one-to-one correspondence between $v \in V$ and $p \in \mathcal{P}$ that connects v to $\mathbf{r}$, and hence $|\mathcal{P}| = |V|$. We define $V_p \subseteq V$ as the set of vertices that are included in $p \in \mathcal{P}$, and we let $V_X \coloneqq \bigcup_{p \in X} V_p$ for any $X \subseteq \mathcal{P}$. If $X \subseteq \mathcal{P}$, then $V_X \cup \{\mathbf{r}\}$ forms a subtree in $\mathbf{T}$. Conversely, if $S \cup \{\mathbf{r}\}$ forms a subtree in $\mathbf{T}$ ($S \subseteq V$), there exists $X \subseteq \mathcal{P}$ such that $V_X = S$. Thus STKP (1) can be transformed into the following maximization

Algorithm 1 Greedy

$U \leftarrow \mathcal{P}$, $X \leftarrow \emptyset$
while $U \neq \emptyset$ **do**
  $p = \mathrm{argmax}_{p' \in U} \frac{f(p'|X)}{c(p'|X)}$
  if $c(X + p) \leq L$ **then**
    $X \leftarrow X + p$
  end if
  $U \leftarrow U - p$
end while
$\hat{p} = \mathrm{argmax}_{p' \in \mathcal{P}} f(p')$
return $Y = \mathrm{argmax}_{X' \in \{X, \hat{p}\}} f(X')$

problem on $\mathcal{P}$:

$$\begin{aligned} \underset{X \subseteq \mathcal{P}}{\text{maximize}} \quad & f(X) \coloneqq g(V_X) \\ \text{subject to} \quad & c(X) \coloneqq \sum_{v \in V_X} \ell_v \leq L. \end{aligned} \tag{2}$$

We here suppose that $c(p) \leq L$ holds for all $p \in \mathcal{P}$; any $p \in \mathcal{P}$ violating this condition can be removed in advance since no feasible solution includes such p. The set functions f and c are monotone submodular functions defined on $\mathcal{P}$ (see the Appendix), and thus the above problem is SCSKP. Figure 1 illustrates how to transform STKP into SCSKP.

4.2 Greedy Algorithm

We provide a greedy algorithm for SCSKP (2). In what follows, given any $X, Y \subseteq \mathcal{P}$, we define the binary operators $+$ and $-$ on $\mathcal{P}$ as

$$\begin{aligned} X + Y &\coloneqq \{p \in \mathcal{P} : p \in X \text{ and/or } p \in Y\}, \\ X - Y &\coloneqq \{p \in \mathcal{P} : p \in X \text{ and } p \notin Y\}. \end{aligned}$$

Namely, they are the union and subtraction of two subsets defined on $\mathcal{P}$. We sometimes abuse the notation and regard $p \in \mathcal{P}$ as a subset of $\mathcal{P}$; for example, we let $X + p = X + \{p\}$ for any $X \subseteq \mathcal{P}$ and $p \in \mathcal{P}$. Furthermore, we define $f(X \mid Y) \coloneqq f(X + Y) - f(Y)$ and $c(X \mid Y) \coloneqq c(X + Y) - c(Y)$ for any $X, Y \subseteq \mathcal{P}$.

Algorithm 1 presents a concise description of the greedy algorithm for SCSKP (2). In practice, function evaluations in the above greedy algorithm can be reduced by using the technique provided in (Leskovec et al., 2007) with some modifications. The resulting greedy algorithm requires at most $O(L|V|)$ function evaluations.

Different from the naive greedy algorithm explained in Section 3, the above greedy algorithm is performed on the set of all rooted paths, $\mathcal{P}$. Thus, even if beneficial vertices are far from $\mathbf{r}$, rooted paths that include such beneficial vertices are considered as candidates to be chosen in each iteration. As a result, we get the following performance guarantee for Algorithm 1; we define λ_i as the number of leaves in T_i for $i \in [N]$, and we let $\lambda \coloneqq \max_{i \in [N]} \lambda_i$.

Theorem 1. *If $Y \subseteq \mathcal{P}$ is the output of Algorithm 1 and $X^* \subseteq \mathcal{P}$ is an optimal solution for SCSKP (2), then we have $f(Y) \geq \frac{1}{2}(1 - e^{-1/\lambda}) f(X^*)$.*

Proof. See the Appendix. □

In other words, Algorithm 1 enjoys a $\frac{1}{2}(1 - e^{-1/\lambda})$-approximation guarantee. Notably, if the values of λ_i ($i \in [N]$) are bounded by a small constant for all N sentences, the performance guarantee does not deteriorate no matter how many sentences are in the document data. This implies that our method works effectively for summarizing large-scale document data that comprises many sentences.

4.3 Relation with Existing Work

We first see some existing results. For submodular maximization with a size constraint (i.e., $|S|$ must be at most a certain value), the greedy algorithm has been proved to achieve $(1 - e^{-1})$-approximation (Nemhauser et al., 1978). Khuller et al. (1999) studied the maximum coverage problem with a knapsack constraint, and proved that the greedy algorithm achieves $(1 - e^{-1/2})$-approximation. They also showed that $(1 - e^{-1})$-approximation can be obtained by executing the greedy algorithm $O(|V|^3)$ times, and this result was generalized to the case with a submodular objective function (Sviridenko, 2004). The greedy algorithm for submodular maximization with a knapsack constraint is known to achieve $\frac{1}{2}(1 - e^{-1})$-approximation (Leskovec et al., 2007). Lin and Bilmes (2010) stated that $(1 - e^{-1/2})$-approximation can be obtained with the greedy algorithm, but a mistake in their proof was pointed out by Morita et al. (2013).[2]

Unlike the above problem settings, submodular maximization with a tree constraint has only a few literatures. Krause et al. (2006) studied submodular maximization over a graph with a knapsack and tree constraints, but their algorithm, called *pSPIEL*,

[2]Probably, this mistake can be fixed with the techniques used in (Khuller et al., 1999).

requires a complicated preprocessing step and imposes some assumptions on the problem, which do not hold in most summarization tasks. Iyer and Bilmes (2013) addressed SCSKP, a more general problem setting. Their algorithm is, however, more expensive than the greedy algorithm, and it only achieves a *bi-criterion* approximation guarantee (i.e., not only the objective value but also the magnitude of constraint violation is approximated); if we use this algorithm for document summarization, a resulting summary may violate the length limitation.

We turn to the relation between our result and the existing ones. We consider submodular maximization with a knapsack constraint. This problem can be formulated as an STKP on a *star graph*, whose vertex and edge sets are $\{\mathbf{r}, r_1, \dots, r_N\}$ and $\{(\mathbf{r}, r_1), \dots, (\mathbf{r}, r_N)\}$, respectively (i.e., every leaf corresponds to an element in $V = \{r_1, \dots, r_N\}$). In this case, we have $\lambda = 1$, and thus we obtain a $\frac{1}{2}(1 - e^{-1})$-approximation guarantee, matching the result of (Leskovec et al., 2007).[3]

5 Objective Functions

As presented in (Lin and Bilmes, 2011), many objective functions used for document summarization are known to be monotone and submodular. Below we list examples of the functions that will be used in the experiments.

Coverage Function

To use the coverage function is a simple but powerful approach to document summarization, and so it appears in many existing works (e.g., (Filatova and Hatzivassiloglou, 2004; Takamura and Okumura, 2009a; Berg-Kirkpatrick et al., 2011)). Let M be the number of distinct words in the document data, and suppose that they are indexed with $j \in [M]$. We let w_j ($j \in [M]$) be the weight value of the j-th word. Given summary $S \subseteq V$, the coverage function $\mathrm{COV}(S)$ is defined as follows:

$$\mathrm{COV}(S) := \sum_{j=1}^{M} w_j z_j,$$

where $z_j \in \{0, 1\}$ is a binary decision variable that indicates whether the j-th word is included in S or not; more precisely, $z_j = 1$ if and only if at least one textual unit in S contains the j-th word.

[3] We also tried to obtain an approximation guarantee that corresponds to the $(1 - e^{-1/2})$-approximation (Khuller et al., 1999; Lin and Bilmes, 2010), but it was not straightforward to apply their techniques to our case.

Coverage Function with Rewords

A summary obtained with the above coverage function often consists of many overly-compressed sentences, which typically leads to low readability. Morita et al. (2013) addressed this problem by adding a positive reward term to the coverage function. Given summary S, let $b_{r_i} \in \{0, 1\}$ ($i \in [N]$) be a binary decision variable that indicates whether r_i, the root node of sentence tree T_i, is included in S or not. Note that, if $S \cup \{\mathbf{r}\}$ forms a rooted subtree in $\mathbf{T}$, we have $b_{r_i} = 1$ if and only if at least one textual unit in the i-th sentence appears in S. With these additional variables, the modified coverage function can be written as

$$\mathrm{COVR}(S) := \mathrm{COV}(S) + \gamma \left(\sum_{v \in S} \ell_v - \sum_{i=1}^{N} b_{r_i} \right),$$

where $\gamma \geq 0$ is a parameter that controls the rate of sentence compression. The value of $\sum_{i=1}^{N} b_{r_i}$ is equal to the number of sentences whose textual unit(s) is used in S. Therefore, a summary that consists of fewer sentences tends to get a higher objective value, thus enhancing readability.

ROUGE

ROUGE (Lin, 2004) is widely used for summarization evaluation, and it is known to be highly correlated with human evaluation. Furthermore, ROUGE is known to be monotone and submodular (Lin and Bilmes, 2011). Specifically, given K reference summaries $R_1, \dots, R_K \subseteq V$ and function $\mathrm{C}_e(S)$, which counts the number of times that n-gram e occurs in summary $S \subseteq V$, the ROUGE_n score function is defined as

$$\mathrm{ROUGE}_n(S) := \frac{\sum_{k=1}^{K} \sum_{e \in R_k} \min\{\mathrm{C}_e(S), \mathrm{C}_e(R_k)\}}{\sum_{k=1}^{K} \sum_{e \in R_k} \mathrm{C}_e(R_k)}.$$

6 Experiments

We applied our method to compressive summarization tasks with the three kinds of objective functions: the coverage function, the one with rewards, and ROUGE_1. To benchmark our method, we also applied the ILP-based method to the tasks. These two methods were compared in terms of achieved approximation ratios, ROUGE_1 scores, and running times.

Objective function	Method	Approximation ratio	ROUGE$_1$	Time (ms)
Coverage	Greedy	0.964	**0.347**	**1.34**
	ILP	**1.00**	0.346	231
Coverage with rewards	Greedy	0.967	**0.334**	**1.44**
	ILP	**1.00**	0.332	552
ROUGE$_1$	Greedy	0.985	0.468	**0.759**
	ILP (oracle)	**1.00**	**0.494**	92.1

Table 1: Approximation ratios, ROUGE$_1$ scores, and running times for our method (Greedy) and the ILP-based method (ILP); the average values over the 50 topics are presented. The two methods are applied to compressive summarization tasks with three types of objective functions: Coverage, Coverage with rewards, and ROUGE$_1$. Summaries obtained with the ILP-based method and ROUGE$_1$ objective function are oracle summaries.

6.1 Settings

In the following experiments, we regard V as the set of all chunks in the document data. For each chunk $v \in V$, we let ℓ_v be the number of words contained in v, and we set the length limitation, L, to 100. For the coverage function and the one with rewards, the weight values w_j ($j \in [M]$) were estimated by logistic regression (Yih et al., 2007) trained on the DUC-2003 dataset. For the coverage function with rewards, we set the parameter, γ, to 0.9.

The experiments were conducted on the DUC-2004 dataset for multiple document summarization evaluation, which is a commonly used benchmark dataset. The dataset consists of 50 topics, each of which has 10 newspaper articles. The dependency trees for this dataset were obtained as follows: We first applied the Stanford parser (de Marneffe et al., 2006) to all sentences in the dataset in order to obtain dependency relations between words. We then applied Filippova's rules (Filippova and Strube, 2008; Filippova and Altun, 2013) to the obtained relations so as to construct trees that represent dependency relations between chunks. To obtain summaries with high readability, we treated a set of chunks connected with certain relations (e.g., subject–object) as a single chunk.

Our algorithm was implemented in C++ and compiled with `GCC version 4.8.5`. The ILP-based method solved ILPs with `CPLEX ver. 12.5.1.0`, a widely used commercial ILP solver. The details of ILP formulations for the three objective functions are presented in the Appendix. All experiments were conducted on a Linux machine (CPU: Intel Xeon E5-2620 v4 2.10GHz and 32GB RAM).

6.2 Results

Table 1 summarizes the comparisons of the achieved approximation ratios, ROUGE$_1$ scores and running times. The ILP-based method are always optimal in terms of objective values (i.e., 100%-approximation is attained), and our method achieved more than 95%-approximation. We observed that the maximum number, λ, of leaves in a sentence tree was about 22 on average, which leads to a 2.2%-approximation guarantee of our algorithm. Therefore, our method empirically performs much better than the theoretical guarantee; this is often the case with the greedy algorithm for submodular maximization problems, in particular when the problems have complex constraints. The ROUGE$_1$ scores of our method are comparable to those of the ILP-based method. With the coverage function and the one with rewards, it happened that our method attained slightly higher ROUGE$_1$ scores than those of ILP-based methods;[4] note that this result is possible since the objective values and ROUGE$_1$ scores are not completely correlated. The results on approximation ratios and ROUGE$_1$ scores imply that our method compares favorably with the ILP-based method in terms of empirical performance. With regard to the running times, our method substantially outperformed the ILP-based method. Specifically, our method was about 170, 380, and 120 times faster than the ILP-based one for the coverage function, the one with rewards, and the ROUGE$_1$ objective function, respectively.

Table 2 shows examples of the summaries obtained by our method and the ILP-based method; both methods used the coverage function with rewards as an objective function. We see that

[4] Similar results were observed in (Takamura and Okumura, 2009a).

Greedy: Yeltsin suffered from disease and had a heart attack followed by multiple bypass surgery in the months. Russian President Boris Yeltsin cut short a trip to Central Asia on Monday due to a respiratory infection that revived questions about his health and ability to lead Russia through a sustained economic crisis. Doctors insisted that Yeltsin fly home ahead of schedule. The prime minister reiterated Wednesday that Yeltsin has plans to resign early elections. Russia's Constitutional Court opened hearings Thursday on whether Boris Yeltsin can seek a term. Sources in Primakov's office said the cancellation was due to concerns.
ILP: Russian President Boris Yeltsin cut short a trip to a respiratory infection that revived questions about his health and ability to lead Russia through a economic crisis. Yeltsin was spending outside Moscow his spokesman Dmitry Yakushkin told reporters. Doctors insisted Monday that Yeltsin fly home from Central Asia ahead of schedule because he was suffering. Yeltsin falls ill speculation arises. The prime minister reiterated Wednesday that Yeltsin has plans to resign early elections. Russia's Constitutional Court opened hearings Thursday on whether Boris Yeltsin can seek a term. Sources in Primakov's office said the cancellation was due to concerns.

Table 2: Summaries obtained with our greedy method (upper) and the ILP-based method (lower) for topic:D31032. To obtain these summaries, both methods used the coverage function with rewards as an objective function.

both methods successfully created informative summaries that preserve original dependency relations. The readability of obtained summaries is unfortunately not high enough. Note that not only our method but also most compressive summarization methods suffer this problem; in fact, there is little difference between the two summaries obtained with our method and the optimal ILP-based method with regard to readability. To conclude, the empirical performance of our method matches that of the ILP-based method, while running about 100 to 400 times faster.

7 Conclusion and Discussion

We proposed a fast greedy method for compressive summarization. Our method works with any monotone submodular objective function; examples of such functions include the coverage function, ROUGE, and many others. The $\frac{1}{2}(1 - e^{-1/\lambda})$-approximation guarantee of our method was proved, which generalizes the $\frac{1}{2}(1 - e^{-1})$-approximation for submodular maximization with a knapsack constraint. Experiments showed that our greedy method empirically achieves more than 95%-approximation and that it runs about 100 to 400 times faster than the ILP-based method implemented with `CPLEX`. With the coverage function and its variant, our method attained as high ROUGE_1 scores as the ILP-based method.

As mentioned above, current compressive summarization systems often fail to achieve high readability, and one possible approach to this problem is to develop better objective functions. Since our method is applicable to various monotone submodular objective functions and can find almost optimal solutions efficiently, our method would be helpful in testing the performance of newly proposed objective functions. Thus we believe that our method is useful for advancing the study into compressive summarization.

Interestingly, STKP can be seen as a variant of *DR-submodular* maximization (Soma and Yoshida, 2017), which is a submodular maximization problem defined over integer lattice. The constraint that appears in DR-submodular maximization is somewhat easier to deal with than that of our problem; exploiting this, Soma and Yoshida (2017) developed a polynomial-time algorithm that achieves roughly $\frac{1}{2}$-approximation. The techniques studied in this field may be useful to develop better algorithms for STKP, which we leave for future work.

Abstract

Single document summarization is the task of producing a shorter version of a document while preserving its principal information content. In this paper we conceptualize extractive summarization as a sentence ranking task and propose a novel training algorithm which globally optimizes the ROUGE evaluation metric through a reinforcement learning objective. We use our algorithm to train a neural summarization model on the CNN and DailyMail datasets and demonstrate experimentally that it outperforms state-of-the-art extractive and abstractive systems when evaluated automatically and by humans.[1]

1 Introduction

Automatic summarization has enjoyed wide popularity in natural language processing due to its potential for various information access applications. Examples include tools which aid users navigate and digest web content (e.g., news, social media, product reviews), question answering, and personalized recommendation engines. Single document summarization — the task of producing a shorter version of a document while preserving its information content — is perhaps the most basic of summarization tasks that have been identified over the years (see Nenkova and McKeown, 2011 for a comprehensive overview).

Modern approaches to single document summarization are data-driven, taking advantage of the success of neural network architectures and their ability to learn continuous features without recourse to preprocessing tools or linguistic annotations. *Abstractive* summarization involves various text rewriting operations (e.g., substitution, deletion, reordering) and has been recently framed as a sequence-to-sequence problem (Sutskever et al., 2014). Central in most approaches (Rush et al., 2015; Chen et al., 2016; Nallapati et al., 2016; See et al., 2017; Tan and Wan, 2017; Paulus et al., 2017) is an encoder-decoder architecture modeled by recurrent neural networks. The encoder reads the source sequence into a list of continuous-space representations from which the decoder generates the target sequence. An attention mechanism (Bahdanau et al., 2015) is often used to locate the region of focus during decoding.

Extractive systems create a summary by identifying (and subsequently concatenating) the most important sentences in a document. A few recent approaches (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2017; Yasunaga et al., 2017) conceptualize extractive summarization as a sequence labeling task in which each label specifies whether each document sentence should be included in the summary. Existing models rely on recurrent neural networks to derive a meaning representation of the document which is then used to label each sentence, taking the previously labeled sentences into account. These models are typically trained using cross-entropy loss in order to maximize the likelihood of the ground-truth labels and do not necessarily *learn to rank* sentences based on their importance due to the absence of a ranking-based objective. Another discrepancy comes from the mismatch between the learning objective and the evaluation criterion, namely ROUGE (Lin and Hovy, 2003), which takes the entire summary into account.

In this paper we argue that cross-entropy training is not optimal for extractive summarization. Models trained this way are prone to generating verbose summaries with unnecessarily long sentences and redundant information. We propose to overcome these difficulties by globally optimizing the ROUGE evaluation metric and learning to rank sentences for summary generation through a reinforcement learning objective. Similar to previous work (Cheng and Lapata, 2016; Narayan et al., 2017; Nallapati et al., 2017), our neural summarization model consists of a hierarchical docu-

Proceedings of NAACL-HLT 2018, pages 1747–1759
New Orleans, Louisiana, June 1 - 6, 2018.

ment encoder and a hierarchical sentence extractor. During training, it combines the maximum-likelihood cross-entropy loss with rewards from policy gradient reinforcement learning to directly optimize the evaluation metric relevant for the summarization task. We show that this global optimization framework renders extractive models better at discriminating among sentences for the final summary; a sentence is ranked high for selection if it often occurs in high scoring summaries.

We report results on the CNN and DailyMail news highlights datasets (Hermann et al., 2015) which have been recently used as testbeds for the evaluation of neural summarization systems. Experimental results show that when evaluated automatically (in terms of ROUGE), our model outperforms state-of-the-art extractive *and* abstractive systems. We also conduct two human evaluations in order to assess (a) which type of summary participants prefer (we compare extractive and abstractive systems) and (b) how much key information from the document is preserved in the summary (we ask participants to answer questions pertaining to the content in the document by reading system summaries). Both evaluations overwhelmingly show that human subjects find our summaries more informative and complete.

Our contributions in this work are three-fold: a novel application of reinforcement learning to sentence ranking for extractive summarization; corroborated by analysis and empirical results showing that cross-entropy training is not well-suited to the summarization task; and large scale user studies following two evaluation paradigms which demonstrate that state-of-the-art abstractive systems lag behind extractive ones when the latter are globally trained.

2 Summarization as Sentence Ranking

Given a document D consisting of a sequence of sentences $(s_1, s_2, ..., s_n)$, an extractive summarizer aims to produce a summary $\mathcal{S}$ by selecting m sentences from D (where $m < n$). For each sentence $s_i \in D$, we predict a label $y_i \in \{0,1\}$ (where 1 means that s_i should be included in the summary) and assign a score $p(y_i|s_i, D, \theta)$ quantifying s_i's relevance to the summary. The model learns to assign $p(1|s_i, D, \theta) > p(1|s_j, D, \theta)$ when sentence s_i is more relevant than s_j. Model parameters are denoted by θ. We estimate $p(y_i|s_i, D, \theta)$ using a neural network model and assemble a summary $\mathcal{S}$ by selecting m sentences with top $p(1|s_i, D, \theta)$ scores.

Our architecture resembles those previously proposed in the literature (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2017). The main components include a sentence encoder, a document encoder, and a sentence extractor (see the left block of Figure 1) which we describe in more detail below.

Sentence Encoder A core component of our model is a convolutional sentence encoder which encodes sentences into continuous representations. In recent years, CNNs have proven useful for various NLP tasks (Collobert et al., 2011; Kim, 2014; Kalchbrenner et al., 2014; Zhang et al., 2015; Lei et al., 2015; Kim et al., 2016; Cheng and Lapata, 2016) because of their effectiveness in identifying salient patterns in the input (Xu et al., 2015). In the case of summarization, CNNs can identify named-entities and events that correlate with the gold summary.

We use temporal narrow convolution by applying a kernel filter K of width h to a window of h words in sentence s to produce a new feature. This filter is applied to each possible window of words in s to produce a feature map $f \in R^{k-h+1}$ where k is the sentence length. We then apply max-pooling over time over the feature map f and take the maximum value as the feature corresponding to this particular filter K. We use multiple kernels of various sizes and each kernel multiple times to construct the representation of a sentence. In Figure 1, kernels of size 2 (red) and 4 (blue) are applied three times each. Max-pooling over time yields two feature lists f^{K_2} and $f^{K_4} \in R^3$. The final sentence embeddings have six dimensions.

Document Encoder The document encoder composes a sequence of sentences to obtain a document representation. We use a recurrent neural network with Long Short-Term Memory (LSTM) cells to avoid the vanishing gradient problem when training long sequences (Hochreiter and Schmidhuber, 1997). Given a document D consisting of a sequence of sentences $(s_1, s_2, \ldots, s_n)$, we follow common practice and feed sentences in reverse order (Sutskever et al., 2014; Li et al., 2015; Filippova et al., 2015; Narayan et al., 2017). This way we make sure that the network also considers the top sentences of the document which are particularly important for summarization (Rush et al., 2015; Nallapati et al., 2016).

Sentence Extractor Our sentence extractor sequentially labels each sentence in a document with 1 (relevant for the summary) or 0 (otherwise).

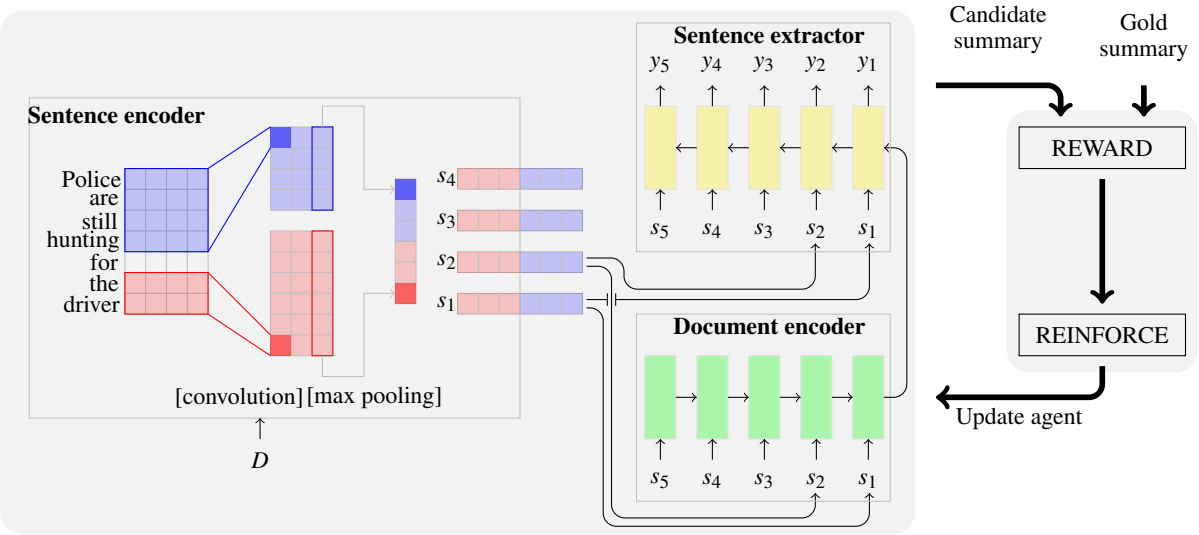

Figure 1: Extractive summarization model with reinforcement learning: a hierarchical encoder-decoder model ranks sentences for their extract-worthiness and a candidate summary is assembled from the top ranked sentences; the REWARD generator compares the candidate against the gold summary to give a reward which is used in the REINFORCE algorithm (Williams, 1992) to update the model.

It is implemented with another RNN with LSTM cells and a softmax layer. At time t_i, it reads sentence s_i and makes a binary prediction, conditioned on the document representation (obtained from the document encoder) and the previously labeled sentences. This way, the sentence extractor is able to identify locally and globally important sentences within the document. We rank the sentences in a document D by $p(y_i = 1|s_i, D, \theta)$, the confidence scores assigned by the softmax layer of the sentence extractor.

We learn to rank sentences by training our network in a reinforcement learning framework, directly optimizing the final evaluation metric, namely ROUGE (Lin and Hovy, 2003). Before we describe our training algorithm, we elaborate on why the maximum-likelihood cross-entropy objective could be deficient for ranking sentences for summarization (Section 3). Then, we define our reinforcement learning objective in Section 4 and show that our new way of training allows the model to better discriminate amongst sentences, i.e., a sentence is ranked higher for selection if it often occurs in high scoring summaries.

3 The Pitfalls of Cross-Entropy Loss

Previous work optimizes summarization models by maximizing $p(y|D,\theta) = \prod_{i=1}^{n} p(y_i|s_i, D, \theta)$, the likelihood of the ground-truth labels $y = (y_1, y_2, ..., y_n)$ for sentences $(s_1, s_2, \ldots, s_n)$, given document D and model parameters θ. This objective can be achieved by minimizing the cross-entropy loss at each decoding step:

$$L(\theta) = -\sum_{i=1}^{n} \log p(y_i|s_i, D, \theta). \quad (1)$$

Cross-entropy training leads to two kinds of discrepancies in the model. The first discrepancy comes from the disconnect between the task definition and the training objective. While MLE in Equation (1) aims to maximize the likelihood of the ground-truth labels, the model is (a) expected to rank sentences to generate a summary and (b) evaluated using ROUGE at test time. The second discrepancy comes from the reliance on ground-truth labels. Document collections for training summarization systems do not naturally contain labels indicating which sentences should be extracted. Instead, they are typically accompanied by abstractive summaries from which sentence-level labels are extrapolated. Cheng and Lapata (2016) follow Woodsend and Lapata (2010) in adopting a rule-based method which assigns labels to each sentence in the document *individually* based on their semantic correspondence with the gold summary (see the fourth column in Table 1). An alternative method (Svore et al., 2007; Cao et al., 2016; Nallapati et al., 2017) identifies the set of sentences which *collectively* gives the highest ROUGE with respect to the gold summary. Sentences in this set are labeled with 1 and 0 otherwise (see the column 5 in Table 1).

Labeling sentences individually often generates too many positive labels causing the model to

sent. pos.	CNN article Sentences	Sent-level ROUGE	Individual Oracle	Collective Oracle	Multiple Collective Oracle

8	Experts say American tourists are bringing Chikungunya back home, and it's just a matter of time before it starts to spread within the United States.	10.6	0	0	(12,13) : 49.3 (7,11,13) : 47.8
9	After all, the Caribbean is a popular one with American tourists, and summer is fast approaching.	13.9	1	0	(0,10,13) : 47.8 (11,12,13):47.7
10	"So far this year we've recorded eight travel-associated cases, and seven of them have come from countries in the Caribbean where we know the virus is being transmitted," Nasci said.	18.4	1	0	(7,13) : 47.6 (9,13) : 47.5 (1,7,13) : 46.9
11	Other states have also reported cases of Chikungunya.	13.4	0	1	(3,7,13) : 46.0
12	The Tennessee Department of Health said the state has had multiple cases of the virus in people who have traveled to the Caribbean.	15.6	1	0	(3,12,13) : 46.0 (3,9,13) : 45.9
13	The virus is not deadly, but it can be painful, with symptoms lasting for weeks.	54.5	1	1	(10,13) : 45.5
14	Those with weak immune systems, such as the elderly, are more likely to suffer from the virus' side effects than those who are healthier.	5.5	0	0	(4,11,13) : 45.3 ...
	Story Highlights • North Carolina reports first case of mosquito-borne virus called Chikungunya • Chikungunya is primarily found in Africa, East Asia and the Caribbean islands • Virus is not deadly, but it can be painful, with symptoms lasting for weeks				

Table 1: An abridged CNN article (only first 15 out of 31 sentences are shown) and its "story highlights". The latter are typically written by journalists to allow readers to quickly gather information on stories. Highlights are often used as gold standard abstractive summaries in the summarization literature.

overfit the data. For example, the document in Table 1 has 12 positively labeled sentences out of 31 in total (only first 10 are shown). Collective labels present a better alternative since they only pertain to the few sentences deemed most suitable to form the summary. However, a model trained with cross-entropy loss on collective labels will underfit the data as it will only maximize probabilities $p(1|s_i, D, \theta)$ for sentences in this set (e.g., sentences $\{0, 11, 13\}$ in Table 1) and ignore all other sentences. We found that there are many candidate summaries with high ROUGE scores which could be considered during training.

Table 1 (last column) shows candidate summaries ranked according to the mean of ROUGE-1, ROUGE-2, and ROUGE-L F_1 scores. Interestingly, multiple top ranked summaries have reasonably high ROUGE scores. For example, the average ROUGE for the summaries ranked second (0,13), third (11,13), and fourth (0,1,13) is 57.5%, 57.2%, and 57.1%, and all top 16 summaries have ROUGE scores more or equal to 50%. A few sentences are indicative of important content and appear frequently in the summaries: sentence 13 occurs in all summaries except one, while sentence 0 appears in several summaries too. Also note that summaries (11,13) and (1,13) yield better ROUGE scores compared to longer summaries, and may be as informative, yet more concise, alternatives.

These discrepancies render the model less efficient at ranking sentences for the summarization task. Instead of maximizing the likelihood of the ground-truth labels, we could train the model to predict the individual ROUGE score for each sentence in the document and then select the top m sentences with highest scores. But sentences with individual ROUGE scores do not necessarily lead to a high scoring summary, e.g., they may convey overlapping content and form verbose and redundant summaries. For example, sentence 3, despite having a high individual ROUGE score (35.6%), does not occur in any of the top 5 summaries. We next explain how we address these issues using reinforcement learning.

4 Sentence Ranking with Reinforcement Learning

Reinforcement learning (Sutton and Barto, 1998) has been proposed as a way of training sequence-

to-sequence generation models in order to directly optimize the metric used at test time, e.g., BLEU or ROUGE (Ranzato et al., 2015). We adapt reinforcement learning to our formulation of extractive summarization to rank sentences for summary generation. We propose an objective function that combines the maximum-likelihood cross-entropy loss with rewards from policy gradient reinforcement learning to globally optimize ROUGE. Our training algorithm allows to explore the space of possible summaries, making our model more robust to unseen data. As a result, reinforcement learning helps extractive summarization in two ways: (a) it directly optimizes the evaluation metric instead of maximizing the likelihood of the ground-truth labels and (b) it makes our model better at discriminating among sentences; a sentence is ranked high for selection if it often occurs in high scoring summaries.

4.1 Policy Learning

We cast the neural summarization model introduced in Figure 1 in the Reinforcement Learning paradigm (Sutton and Barto, 1998). Accordingly, the model can be viewed as an "agent" which interacts with an "environment" consisting of documents. At first, the agent is initialized randomly, it reads document D and predicts a relevance score for each sentence $s_i \in D$ using "policy" $p(y_i|s_i, D, \theta)$, where θ are model parameters. Once the agent is done reading the document, a summary with labels $\hat{y}$ is sampled out of the ranked sentences. The agent is then given a "reward" r commensurate with how well the extract resembles the gold-standard summary. Specifically, as reward function we use mean F_1 of ROUGE-1, ROUGE-2, and ROUGE-L. Unigram and bigram overlap (ROUGE-1 and ROUGE-2) are meant to assess informativeness, whereas the longest common subsequence (ROUGE-L) is meant to assess fluency. We update the agent using the REINFORCE algorithm (Williams, 1992) which aims to minimize the negative expected reward:

$$L(\theta) = -\mathbb{E}_{\hat{y}\sim\, p_\theta}[r(\hat{y})] \tag{2}$$

where, p_θ stands for $p(y|D, \theta)$. REINFORCE is based on the observation that the expected gradient of a non-differentiable reward function (ROUGE, in our case) can be computed as follows:

$$\nabla L(\theta) = -\mathbb{E}_{\hat{y}\sim\, p_\theta}[r(\hat{y})\nabla \log p(\hat{y}|D, \theta)] \tag{3}$$

While MLE in Equation (1) aims to maximize the likelihood of the training data, the objective in Equation (2) learns to discriminate among sentences with respect to how often they occur in high scoring summaries.

4.2 Training with High Probability Samples

Computing the expectation term in Equation (3) is prohibitive, since there is a large number of possible extracts. In practice, we approximate the expected gradient using a single sample $\hat{y}$ from p_θ for each training example in a batch:

$$\begin{aligned}\nabla L(\theta) &\approx -r(\hat{y})\nabla \log p(\hat{y}|D, \theta) \\ &\approx -r(\hat{y}) \sum_{i=1}^{n} \nabla \log p(\hat{y}_i|s_i, D, \theta)\end{aligned} \tag{4}$$

Presented in its original form, the REINFORCE algorithm starts learning with a random policy which can make model training challenging for complex tasks like ours where a single document can give rise to a very large number of candidate summaries. We therefore limit the search space of $\hat{y}$ in Equation (4) to the set of largest probability samples $\hat{\mathbb{Y}}$. We approximate $\hat{\mathbb{Y}}$ by the k extracts which receive highest ROUGE scores. More concretely, we assemble candidate summaries efficiently by first selecting p sentences from the document which on their own have high ROUGE scores. We then generate all possible combinations of p sentences subject to maximum length m and evaluate them against the gold summary. Summaries are ranked according to F_1 by taking the mean of ROUGE-1, ROUGE-2, and ROUGE-L. $\hat{\mathbb{Y}}$ contains these top k candidate summaries. During training, we sample $\hat{y}$ from $\hat{\mathbb{Y}}$ instead of $p(\hat{y}|D, \theta)$.

Ranzato et al. (2015) proposed an alternative to REINFORCE called MIXER (Mixed Incremental Cross-Entropy Reinforce) which first pretrains the model with the cross-entropy loss using ground truth labels and then follows a curriculum learning strategy (Bengio et al., 2015) to gradually teach the model to produce stable predictions on its own. In our experiments MIXER performed worse than the model of Nallapati et al. (2017) just trained on collective labels. We conjecture that this is due to the unbounded nature of our ranking problem. Recall that our model assigns relevance scores to sentences rather than words. The space of sentential representations is vast and fairly unconstrained compared to other prediction tasks operating with fixed vocabularies (Li et al., 2016; Paulus et al., 2017; Zhang and Lapata, 2017). Moreover, our approximation of the gradient allows the model to

converge much faster to an optimal policy. Advantageously, we do not require an online reward estimator, we pre-compute $\hat{\mathbb{Y}}$, which leads to a significant speedup during training compared to MIXER (Ranzato et al., 2015) and related training schemes (Shen et al., 2016).

5 Experimental Setup

In this section we present our experimental setup for assessing the performance of our model which we call REFRESH as a shorthand for **RE**in**F**o**R**cement Learning-based **E**xtractive **S**ummarization. We describe our datasets, discuss implementation details, our evaluation protocol, and the systems used for comparison.

Summarization Datasets We evaluated our models on the CNN and DailyMail news highlights datasets (Hermann et al., 2015). We used the standard splits of Hermann et al. (2015) for training, validation, and testing (90,266/1,220/1,093 documents for CNN and 196,961/12,148/10,397 for DailyMail). We did not anonymize entities or lower case tokens. We followed previous studies (Cheng and Lapata, 2016; Nallapati et al., 2016, 2017; See et al., 2017; Tan and Wan, 2017) in assuming that the "story highlights" associated with each article are gold-standard abstractive summaries. During training we use these to generate high scoring extracts and to estimate rewards for them, but during testing, they are used as reference summaries to evaluate our models.

Implementation Details We generated extracts by selecting three sentences ($m = 3$) for CNN articles and four sentences ($m = 4$) for DailyMail articles. These decisions were informed by the fact that gold highlights in the CNN/DailyMail validation sets are 2.6/4.2 sentences long. For both datasets, we estimated high-scoring extracts using 10 document sentences ($p = 10$) with highest ROUGE scores. We tuned the initialization parameter k for $\hat{\mathbb{Y}}$ on the validation set: we found that our model performs best with $k = 5$ for the CNN dataset and $k = 15$ for the DailyMail dataset.

We used the One Billion Word Benchmark corpus (Chelba et al., 2013) to train word embeddings with the skip-gram model (Mikolov et al., 2013) using context window size 6, negative sampling size 10, and hierarchical softmax 1. Known words were initialized with pre-trained embeddings of size 200. Embeddings for unknown words were initialized to zero, but estimated during training.

LEAD	• A SkyWest Airlines flight made an emergency landing in Buffalo, New York, on Wednesday after a passenger lost consciousness, officials said. • The passenger received medical attention before being released, according to Marissa Snow, spokeswoman for SkyWest. • She said the airliner expects to accommodate the 75 passengers on another aircraft to their original destination – Hartford, Connecticut – later Wednesday afternoon.
See et al.	• Skywest Airlines flight made an emergency landing in Buffalo, New York, on Wednesday after a passenger lost consciousness. • She said the airliner expects to accommodate the 75 passengers on another aircraft to their original destination – Hartford, Connecticut.
REFRESH	• A SkyWest Airlines flight made an emergency landing in Buffalo, New York, on Wednesday after a passenger lost consciousness, officials said. • The passenger received medical attention before being released, according to Marissa Snow, spokeswoman for SkyWest. • The Federal Aviation Administration initially reported a pressurization problem and said it would investigate.
GOLD	• FAA backtracks on saying crew reported a pressurization problem • One passenger lost consciousness • The plane descended 28,000 feet in three minutes
Q_1	Who backtracked on saying crew reported a pressurization problem? (*FAA*)
Q_2	How many passengers lost consciousness in the incident? (*One*)
Q_3	How far did the plane descend in three minutes? (*28,000 feet*)

Figure 2: Summaries produced by the LEAD baseline, the abstractive system of See et al. (2017) and REFRESH for a CNN (test) article. GOLD presents the human-authored summary; the bottom block shows manually written questions using the gold summary and their answers in parentheses.

Sentences were padded with zeros to a length of 100. For the sentence encoder, we used a list of kernels of widths 1 to 7, each with output channel size of 50 (Kim et al., 2016). The sentence embedding size in our model was 350.

For the recurrent neural network component in the document encoder and sentence extractor, we used a single-layered LSTM network with size 600. All input documents were padded with zeros to a maximum document length of 120. We performed minibatch cross-entropy training with a batch size of 20 documents for 20 training epochs. It took around 12 hrs on a single GPU to train. After each epoch, we evaluated our model on the validation set and chose the best performing model for the test set. During training we used the Adam optimizer (Kingma and Ba, 2015) with initial learning rate 0.001. Our system is implemented in TensorFlow (Abadi et al., 2015).

Evaluation We evaluated summarization quality using F_1 ROUGE (Lin and Hovy, 2003). We report unigram and bigram overlap (ROUGE-1 and ROUGE-2) as a means of assessing informativeness and the longest common subsequence

(ROUGE-L) as a means of assessing fluency.[2] We compared REFRESH against a baseline which simply selects the first m leading sentences from each document (LEAD) and two neural models similar to ours (see left block in Figure 1), both trained with cross-entropy loss. Cheng and Lapata (2016) train on individual labels, while Nallapati et al. (2017) use collective labels. We also compared our model against the abstractive systems of Chen et al. (2016), Nallapati et al. (2016), See et al. (2017), and Tan and Wan (2017).[3]

In addition to ROUGE which can be misleading when used as the only means to assess the informativeness of summaries (Schluter, 2017), we also evaluated system output by eliciting human judgments in two ways. In our first experiment, participants were presented with a news article and summaries generated by three systems: the LEAD baseline, abstracts from See et al. (2017), and extracts from REFRESH. We also included the human-authored highlights.[4] Participants read the articles and were asked to rank the summaries from best (1) to worst (4) in order of informativeness (does the summary capture important information in the article?) and fluency (is the summary written in well-formed English?). We did not allow any ties. We randomly selected 10 articles from the CNN test set and 10 from the DailyMail test set. The study was completed by five participants, all native or proficient English speakers. Each participant was presented with the 20 articles. The order of summaries to rank was randomized per article and the order of articles per participant. Examples of summaries our subjects ranked are shown in Figure 2.

Our second experiment assessed the degree to which our model retains key information from the document following a question-answering (QA) paradigm which has been previously used to evaluate summary quality and text compression (Morris et al., 1992; Mani et al., 2002; Clarke and Lapata, 2010). We created a set of questions based on the gold summary under the assumption that it highlights the most important document content. We then examined whether participants were able to answer these questions by reading system summaries alone without access to the article. The more questions a system can answer, the better it is at summarizing the document as a whole.

We worked on the same 20 documents used in our first elicitation study. We wrote multiple fact-based question-answer pairs for each gold summary without looking at the document. Questions were formulated so as to not reveal answers to subsequent questions. We created 71 questions in total varying from two to six questions per gold summary. Example questions are given in Figure 2. Participants read the summary and answered all associated questions as best they could without access to the original document or the gold summary. Subjects were shown summaries from three systems: the LEAD baseline, the abstractive system of See et al. (2017), and REFRESH. Five participants answered questions for each summary. We used the same scoring mechanism from Clarke and Lapata (2010), i.e., a correct answer was marked with a score of one, partially correct answers with a score of 0.5, and zero otherwise. The final score for a system is the average of all its question scores. Answers were elicited using Amazon's Mechanical Turk crowdsourcing platform. We uploaded data in batches (one system at a time) on Mechanical Turk to ensure that same participant does not evaluate summaries from different systems on the same set of questions.

6 Results

We report results using automatic metrics in Table 2. The top part of the table compares REFRESH against related extractive systems. The bottom part reports the performance of abstractive systems. We present three variants of LEAD, one is computed by ourselves and the other two are reported in Nallapati et al. (2017) and See et al. (2017). Note that they vary slightly due to differences in the preprocessing of the data. We report results on the CNN and DailyMail datasets and their combination (CNN+DailyMail).

Cross-Entropy vs Reinforcement Learning The results in Table 2 show that REFRESH is superior to our LEAD baseline and extractive systems across datasets and metrics. It outperforms

[2] We used pyrouge, a Python package, to compute all ROUGE scores with parameters "-a -c 95 -m -n 4 -w 1.2."

[3] Cheng and Lapata (2016) report ROUGE recall scores on the DailyMail dataset only. We used their code (https://github.com/cheng6076/NeuralSum) to produce ROUGE F_1 scores on both CNN and DailyMail datasets. For other systems, all results are taken from their papers.

[4] We are grateful to Abigail See for providing us with the output of her system. We did not include output from Nallapati et al. (2017), Chen et al. (2016), Nallapati et al. (2016), or Tan and Wan (2017) in our human evaluation study, as these models are trained on a named-entity anonymized version of the CNN and DailyMail datasets, and as result produce summaries which are not comparable to ours. We did not include extracts from Cheng and Lapata (2016) either as they were significantly inferior to LEAD (see Table 2).

Models	CNN			DailyMail			CNN+DailyMail		
	R1	R2	RL	R1	R2	RL	R1	R2	RL
LEAD (ours)	29.1	11.1	25.9	40.7	18.3	37.2	39.6	17.7	36.2
LEAD* (Nallapati et al., 2017)	—	—	—	—	—	—	39.2	15.7	35.5
LEAD (See et al., 2017)	—	—	—	—	—	—	**40.3**	17.7	**36.6**
Cheng and Lapata (2016)	28.4	10.0	25.0	36.2	15.2	32.9	35.5	14.7	32.2
Nallapati et al. (2017)*	—	—	—	—	—	—	39.6	16.2	35.3
REFRESH	**30.4**	**11.7**	**26.9**	**41.0**	**18.8**	**37.7**	40.0	**18.2**	**36.6**
Chen et al. (2016)*	27.1	8.2	18.7	—	—	—	—	—	—
Nallapati et al. (2016)*	—	—	—	—	—	—	35.4	13.3	32.6
See et al. (2017)	—	—	—	—	—	—	39.5	17.3	36.4
Tan and Wan (2017)*	30.3	9.8	20.0	—	—	—	38.1	13.9	34.0

Table 2: Results on the CNN and DailyMail test sets. We report ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-L (RL) F_1 scores. Extractive systems are in the first block and abstractive systems in the second. Table cells are filled with — whenever results are not available. Models marked with * are not directly comparable to ours as they are based on an anonymized version of the dataset.

the extractive system of Cheng and Lapata (2016) which is trained on individual labels. REFRESH is not directly comparable with Nallapati et al. (2017) as they generate anonymized summaries. Their system lags behind their LEAD baseline on ROUGE-L on the CNN+DailyMail dataset (35.5% vs 35.3%). Also note that their model is trained on collective labels and has a significant lead over Cheng and Lapata (2016). As discussed in Section 3 cross-entropy training on individual labels tends to overgenerate positive labels leading to less informative and verbose summaries.

Extractive vs Abstractive Systems Our automatic evaluation results further demonstrate that REFRESH is superior to abstractive systems (Chen et al., 2016; Nallapati et al., 2016; See et al., 2017; Tan and Wan, 2017) which are all variants of an encoder-decoder architecture (Sutskever et al., 2014). Despite being more faithful to the actual summarization task (hand-written summaries combine several pieces of information from the original document), abstractive systems lag behind the LEAD baseline. Tan and Wan (2017) present a graph-based neural model, which manages to outperform LEAD on ROUGE-1 but falters when higher order ROUGE scores are used. Amongst abstractive systems See et al. (2017) perform best. Interestingly, their system is mostly extractive, exhibiting a small degree of rewriting; it copies more than 35% of the sentences in the source document, 85% of 4-grams, 90% of 3-grams, 95% of bigrams, and 99% of unigrams.

Human Evaluation: System Ranking Table 3 shows, proportionally, how often participants ranked each system, 1st, 2nd, and so on. Perhaps unsurprisingly human-authored summaries are considered best (and ranked 1st 39% of the time). REFRESH is ranked 2nd best followed by LEAD and See et al. (2017) which are mostly ranked in 3rd and 4th places. We carried out pairwise comparisons between all models in Table 3 to assess whether system differences are statistically significant. There is no significant difference between LEAD and See et al. (2017), and REFRESH and GOLD (using a one-way ANOVA with post-hoc Tukey HSD tests; $p < 0.01$). All other differences are statistically significant.

Models	1st	2nd	3rd	4th	QA
LEAD	0.11	0.21	**0.34**	0.33	36.33
See et al. (2017)	0.14	0.18	0.31	**0.36**	28.73
REFRESH	0.35	**0.42**	0.16	0.07	**66.34**
GOLD	**0.39**	0.19	0.18	0.24	—

Table 3: System ranking and QA-based evaluations. Rankings (1st, 2nd, 3rd and 4th) are shown as proportions. Rank 1 is the best and Rank 4, the worst. The column QA shows the percentage of questions that participants answered correctly by reading system summaries.

Human Evaluation: Question Answering The results of our QA evaluation are shown in the last column of Table 3. Based on summaries generated by REFRESH, participants can answer 66.34% of questions correctly. Summaries produced by LEAD and the abstractive system of See et al. (2017) provide answers for 36.33% and 28.73% of the questions, respectively. Differences between systems are all statistically significant ($p < 0.01$) with the exception of LEAD and See et al. (2017).

Although the QA results in Table 3 follow the same pattern as ROUGE in Table 2, differences among systems are now greatly amplified. QA-based evaluation is more focused and a closer reflection of users' information need (i.e., to find out what the article is about), whereas ROUGE simply captures surface similarity (i.e., n-gram overlap)

between output summaries and their references. Interestingly, LEAD is considered better than See et al. (2017) in the QA evaluation, whereas we find the opposite when participants are asked to rank systems. We hypothesize that LEAD is indeed more informative than See et al. (2017) but humans prefer shorter summaries. The average length of LEAD summaries is 105.7 words compared to 61.6 for See et al. (2017).

7 Related Work

Traditional summarization methods manually define features to rank sentences for their salience in order to identify the most important sentences in a document or set of documents (Kupiec et al., 1995; Mani, 2001; Radev et al., 2004; Filatova and Hatzivassiloglou, 2004; Nenkova et al., 2006; Spärck Jones, 2007). A vast majority of these methods learn to score each sentence independently (Barzilay and Elhadad, 1997; Teufel and Moens, 1997; Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Shen et al., 2007; Schilder and Kondadadi, 2008; Wan, 2010) and a summary is generated by selecting top-scored sentences in a way that is not incorporated into the learning process. Summary quality can be improved heuristically, (Yih et al., 2007), via max-margin methods (Carbonell and Goldstein, 1998; Li et al., 2009), or integer-linear programming (Woodsend and Lapata, 2010; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012; Almeida and Martins, 2013; Parveen et al., 2015).

Recent deep learning methods (Kågebäck et al., 2014; Yin and Pei, 2015; Cheng and Lapata, 2016; Nallapati et al., 2017) learn continuous features without any linguistic preprocessing (e.g., named entities). Like traditional methods, these approaches also suffer from the mismatch between the learning objective and the evaluation criterion (e.g., ROUGE) used at the test time. In comparison, our neural model globally optimizes the ROUGE evaluation metric through a reinforcement learning objective: sentences are highly ranked if they occur in highly scoring summaries.

Reinforcement learning has been previously used in the context of traditional multi-document summarization as a means of selecting a sentence or a subset of sentences from a document cluster. Ryang and Abekawa (2012) cast the sentence selection task as a search problem. Their agent observes a state (e.g., a candidate summary), executes an action (a transition operation that produces a new state selecting a not-yet-selected sentence), and then receives a delayed reward based on tf $*$ idf. Follow-on work (Rioux et al., 2014) extends this approach by employing ROUGE as part of the reward function, while Henß et al. (2015) further experiment with Q-learning. Mollá-Aliod (2017) has adapt this approach to query-focused summarization. Our model differs from these approaches both in application and formulation. We focus solely on extractive summarization, in our case states are documents (not summaries) and actions are relevance scores which lead to sentence ranking (not sentence-to-sentence transitions). Rather than employing reinforcement learning for sentence selection, our algorithm performs sentence ranking using ROUGE as the reward function.

The REINFORCE algorithm (Williams, 1992) has been shown to improve encoder-decoder text-rewriting systems by allowing to directly optimize a non-differentiable objective (Ranzato et al., 2015; Li et al., 2016; Paulus et al., 2017) or to inject task-specific constraints (Zhang and Lapata, 2017; Nogueira and Cho, 2017). However, we are not aware of any attempts to use reinforcement learning for training a sentence ranker in the context of extractive summarization.

8 Conclusions

In this work we developed an extractive summarization model which is globally trained by optimizing the ROUGE evaluation metric. Our training algorithm explores the space of candidate summaries while learning to optimize a reward function which is relevant for the task at hand. Experimental results show that reinforcement learning offers a great means to steer our model towards generating informative, fluent, and concise summaries outperforming state-of-the-art extractive and abstractive systems on the CNN and DailyMail datasets. In the future we would like to focus on smaller discourse units (Mann and Thompson, 1988) rather than individual sentences, modeling compression and extraction jointly.

Relational Summarization for Corpus Analysis

Abram Handler and **Brendan O'Connor**
College of Information and Computer Sciences
University of Massachusetts Amherst
ahandler@cs.umass.edu, brenocon@cs.umass.edu

Abstract

This work introduces a new problem, relational summarization, in which the goal is to generate a natural language summary of the relationship between two lexical items in a corpus, without reference to a knowledge base. Motivated by the needs of novel user interfaces, we define the task and give examples of its application. We also present a new query-focused method for finding natural language sentences which express relationships. Our method allows for summarization of more than two times more query pairs than baseline relation extractors, while returning measurably more readable output. Finally, to help guide future work, we analyze the challenges of relational summarization using both a news and a social media corpus.

1 Introduction

Research on automatic summarization (Nenkova et al., 2011; Das and Martins, 2007) aims to help users understand large document sets. However, the details of how textual summaries might actually be presented to users are often ignored. We propose that user interfaces which display noteworthy terms or concepts present the need for **relational summaries**: descriptions of the relationship between two entities or noun phrases from a corpus.

Examples of such interfaces include: commandline software for examining noteworthy terms or phrases (Squirrell, 2017; Robinson, 2016; Monroe et al., 2008), point-and-click browsers which display named entities and their interconnections on a network diagram (Wright et al., 2009; Görg et al., 2014; Tannier, 2016), concept map browsers (Falke and Gurevych, 2017b) and document search engines which suggest terms relevant to a query, such as the related searches displayed on Wikipedia info boxes from Google. In all such settings a natural question arises: what is the nature of the relationship between the entities or concepts shown in the interface? One particular interface which presents the need for a relational summary is shown in figure 1.

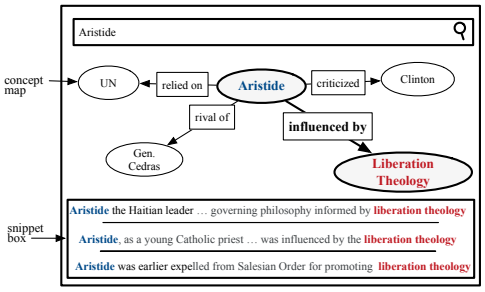

Figure 1: An example interface which requires relational summarization. The user has queried for the entity *Aristide*. The interface shows a *concept map* (top), displaying short summaries of Aristide's important relationships. The user has drilled down to see a more detailed summary of Aristide's relationship with liberation theology, displayed in a *snippet box* (bottom).

Relational questions are ubiquitous and varied. Examples include the following. What is the relationship between the "City of London" and "goal-delivery of Newgate" in 18th century court records (Hitchcock et al., 2012)? What is the relationship between "Advanced Integrated Systems" and "United Arab Emirates" in the Paradise Papers?[1] What does "dad" have to do with "mom" on the subreddit discussion forum *Relationship_Advice*?

This study seeks to answer such questions by examining the problem of **relational summarization**, which lies at the intersection of prior work on summarization and relation extraction. Unlike previous efforts at summarizing relationships (Falke and Gurevych, 2017a), our approach focuses on answering user queries about the connections between two particular terms, without ref-

Proceedings of NAACL-HLT 2018, pages 1760–1769
New Orleans, Louisiana, June 1 - 6, 2018.

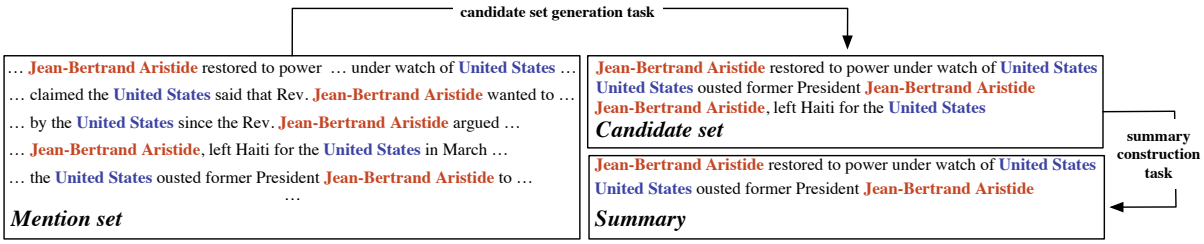

Figure 2: A relational summary is a synopsis of all sentences which mention two terms, denoted (t_1) and (t_2). We refer to such sentences as a *mention set*. In the figure above (t_1) is **Jean-Bertrand Aristide** and (t_2) is **United States**. To create a summary first requires identifying all statements in the mention set which coherently describe some relationship between (t_1) and (t_2). This **candidate set generation task** is a prerequisite for the subsequent **summary construction task**: selecting the top K candidates to create a summary. In this work, we offer a method for the first task and show how the second task will likely require a diversity of summarization techniques (§6).

erencing a knowledge graph (Voskarides et al., 2015).[2] In order to answer such queries we:

- Formally define the problem (§2), which we divide into two subtasks: **candidate set generation** and **summary construction**.
- Provide a new method for the candidate set generation task (§4), which we show outperforms baseline relation extraction techniques (§5) in terms of readability and yield.
- Analyze the summary construction task for future work (§6), demonstrating that different summarization techniques are likely most appropriate for different mention sets.

2 Formal definition and method

We refer to all sentences within a collection of documents which contain two terms, (t_1) and (t_2) as the *mention set*. (t_1) and (t_2) are noun phrases, a syntactic category which encompasses both traditional named entities like people and places, as well as less concrete, but important, entities and concepts like "liberation theology" (Handler et al., 2016).

A relational summary is a synopsis of the mention set. A summary consists of K relation statements, each displayed on its own line. Relation statements are natural language expressions which begin with (t_1) and end with (t_2). We refer to the span of tokens in between (t_1) and (t_2) as a *relation phrase*. We use the notation (t_1) r (t_2) to denote a relation statement, indicating two terms and a relation phrase. In the relation statement, "**Aristide** fled **Haiti**", r is the token "fled", (t_1) is the token **Aristide**, and (t_2) is the token **Haiti**.

Relation statements, which are strings intended for human readers, are similar to the 3-tuples, "*relations*", from prior work on information extraction (Banko et al., 2007). However, in this work, we show that the assumptions underlying the extraction of 3-tuples for machines (§3) leads to poor performance in summarizing mention sets for people (§5).

In this study, we present a strictly extractive method for generating relation statements: each relation statement must be constructed by deleting tokens from some sentence in the mention set.[3] Some relation statements constructed by deleting tokens from a sentence make sense; others do not. We refer to any (t_1) r (t_2) which makes makes sense to a human reader as **acceptable**.[4] Table 1 shows examples of acceptable and unacceptable relation statements, constructed by deletion.

s_1	Aristide fled Haiti ~~in 2004~~. (t_1) r (t_2)
s_2	~~For instance~~ Bush told Aristide ~~to leave~~. (t_1) r (t_2)

Table 1: Two relation statements constructed by deleting tokens from source sentences, s_1 and s_2. The relation statement extracted from s_1 is acceptable; the statement extracted from s_2 is not.

[2] Relational summaries are intended for general-purpose corpus analysis. Existing knowledge bases do not cover topics discussed in many corpora, such as historical court records (Hitchcock et al., 2012). Therefore, our approach does not employ a knowledge base.

[3] In subsequent studies of relation extractors (§5), we allow extractors to lightly introduce new tokens, such as adding the word "is" in relations expressed as noun phrases.

[4] Linguists sometimes use the term "acceptability" to refer to human judgements of the well-formedness of utterance. See Sprouse and Schütze (2014) for an overview.

Only acceptable relation statements are permitted in a summary. The set of all possible acceptable relation statements is called the **candidate set**, denoted $\mathcal{C}$. We refer to the task of identifying all acceptable relation statements as the **candidate set generation task**. Identifying a candidate set presents a subsequent problem of choosing the best collection of K relation statements from $\mathcal{C}$ to create a summary. We refer to this second step as the **summary construction task**.

As in traditional summarization (Das and Martins, 2007; Nenkova et al., 2011), a good relational summary should (i) be readable, (ii) include the most important aspects of the relationship between $(\boldsymbol{t_1})$ and $(\boldsymbol{t_2})$, (iii) avoid redundancy, and (iv) cover the full diversity of topics in the mention set.

Relational summaries might be presented with different kinds of user interfaces. In cases where a user seeks to browse many relationships, a summary might be displayed as a *concept map* (Falke and Gurevych, 2017a), where the two terms are vertexes in a directed graph and their relationship is printed along the edge label between them. In cases where user wants to investigate a specific relationship, a relational summary might be displayed as a *snippet box*: a short list of sentences which begin and end with the two terms. Figure 1 shows a snippet box and concept map. In a snippet box, both the number of lines in the summary and the length of the lines in the summary is longer than in a concept map.

3 Related work

Relational summarization intersects with a diversity of prior work from natural language processing, including work on **relation extraction**, **summarization** and **sentence compression**.

Traditionally, the goal of **relation extraction** is to cull structured facts for knowledge databases from unstructured text. Often, such facts take the form of a 3-tuple which defines a relationship between two arguments, such as (arg1=Angela Merkel, rel=met with, arg2=Theresa May). If extractors do not make use of a predefined schema, the task of finding relations is called Open Information Extraction (OpenIE). OpenIE systems[5] offer an off-the-shelf method for generating a candidate set for a relational summary. Their output can easily be linearized to $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$ statements by simply concatenating the three arguments of the triple to form a string.

However, we find that the recall of relation extractors is often too low to summarize many mention sets. We measure this disadvantage extensively in section §5.1. One reason for their poor performance might be that extractors have goals and assumptions which are poorly suited to the relation summarization task. In relation extraction, the aim is to find relation strings that recur for many different entity pairs, which allows such systems to build knowledge databases. For instance, relation extraction might be used to build tables of world leaders who rel="met with" other world leaders in order to analyze international politics. From this perspective, long, sparse, heterogenous and detailed relation strings which might apply only to a pair of specific arguments are undesirable, as they make it difficult to find general patterns across many different entity pairs. For example, the influential ReVerb OpenIE system (Fader et al., 2011) excludes "overly-specific relation phrases" which apply only to two entities. One way to help ensure that relations generalize across entity pairs is to strive for arguments which are as short as possible, a common goal in OpenIE (Stanovsky and Dagan, 2016).[6]

Our method for generating a candidate set is closer to approaches from **sentence compression** (Knight and Marcu, 2002; Clarke and Lapata, 2008; Filippova and Altun, 2013; Filippova et al., 2015), an NLP task which seeks to make a source sentence shorter while preserving the most important information and producing readable output. We show that our sentence compression approach allows us to achieve higher readability than off-the-shelf relation extractors (§5).

Sentence compression is often used in traditional extractive **summarization** to make more efficient use of a budgeted summary length. We discuss summarization further in §6, where we consider how existing work might be applied to the problem of selecting K statements from the candidate set.

[5]There are many available OpenIE systems. See Stanovsky and Dagan (2016) for an inventory of major work.

[6]Methods from the relation extraction literature which seek to deduce facts from extracted relations, such as Riedel et al. (2013), might also help identify useful summaries in future work. Relations which imply that other relations are true might make good summaries.

Sampled unacceptable compression	**Auburn police** are investigating the death of a **Tuskegee** ~~woman who died ...~~
Known acceptable compression	~~Drug firm~~ **Glenmark** has opened its new facility in **Argentina** ~~which would ...~~

Table 2: Examples of known acceptable and presumed unacceptable training examples, with entities shown in bold. We refer to crossed out spans as *outside of the compression*. Our model uses grammatical information from inside and outside of the compression to predict the acceptability of a compression.

4 Query-focused candidate set generation

Traditionally, relation extraction begins with a fixed notion of what constitutes a desirable "relation" between two arguments, defined by a predefined schema, a syntactic template (Fader et al., 2011), or a collection of seed examples (Angeli et al., 2015). The relation extraction task is then to correctly identify spans in which arguments are joined by a relation.

The relational summarization problem is somewhat different: we begin with a pair of query terms, $(\boldsymbol{t_1})$ and $(\boldsymbol{t_2})$, and we wish to learn the nature of their relationship. Therefore, any statement which coherently describes any relationship between the two query terms is potentially of interest, even if it does not match prior expectations of what constitutes a relation.

We thus approach the candidate set generation task as a specialized form of sentence compression: we attempt to predict if a sentence from the text can be coherently compressed to the form $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$. Table 2 shows examples of sentences which can and cannot be shortened to this form.

We use gold standard sentence–compression pairs from the Filippova and Altun (2013) dataset to supervise this prediction. In sentence compression corpora, gold standard compressions must be acceptable sentences. Therefore, compressions from the dataset which happen to begin and end with a named entity,[7] once extracted from source sentences, can serve as positive examples of acceptable relation statements. On the other hand, randomly chosen spans of the form $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$, which happen to arise in source sentences, are very often not acceptable as standalone sentences. These randomly sampled spans can serve as examples of unacceptable relation statements. We then predict acceptability with supervision from known gold acceptable and sampled, presumed incoherent examples.[8]

Filtering the original dataset in this manner[9] yields 17,529 positive and 30,266 negative sentences. We then downsample negative training examples to create two balanced classes of equal size, and use 81% of data for training, 9% for validation and the remaining 10% for testing.

Let $p(c = 1 \mid s, (\boldsymbol{t_1})\ r\ (\boldsymbol{t_2}))$ indicate the probability that a span of form $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$ extracted from sentence s is coherent. We model $p(c = 1|s, (\boldsymbol{t_1})\ r\ (\boldsymbol{t_2}))$ using logistic regression, with features based on the position of part-of-speech tags and dependency edges in s. Specifically, each sentence in the filtered dataset contains a span of the form $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$. We refer to the tokens in this span as *in the compression* because a user would see these tokens in a relation statement compressed from s. Each sentence also contains spans of tokens which are *outside of the compression* because they are deleted from the original source sentence to create a relation statement. Table 2 displays examples.

Our feature vector records the counts of how many times each part-of-speech tag in the tagset occurs in the compression and also independently records the counts of how many times each part-of-speech tag occurs out of the compression. We refer to the count of each part-of-speech tag in the compression and the count of each part-of-speech tag out of the compression as $\boldsymbol{\Phi}$. We also count the occurrence of each possible dependency edge label in the compression, and the count of each possible dependency edge label out of the compression. If a label's dependent lies in the compres-

[7] https://github.com/google-research-datasets/sentence-compression

[8] We manually inspect 100 negative examples, selected at random, and find that roughly 80% are in fact incoherent.

[9] We also exclude randomly chosen spans which happen to encompass the entire source sentence and exclude randomly chosen spans where $(\boldsymbol{t_1})$ and $(\boldsymbol{t_2})$ are joined by only edges of type compound in the dependency graph of the compression (e.g. "Coup leader Cedras ..."). We use CoreNLP version 3.8 to extract *enhanced++* Universal Dependencies (Manning et al., 2014; Schuster and Manning, 2016; Nivre et al., 2016). We also filter positive and negative examples where the span between $(\boldsymbol{t_1})$ and $(\boldsymbol{t_2})$ is longer than J=75 characters, to simulate a space constraint in a user interface. Finally, we remove all punctuation from the end of the sentence for both positive and negative examples because all gold positive compressions end in punctuation marks. For positive examples, if the compressed version of a sentence deletes tokens between t_1 and t_2, we replace the span between t_1 and t_2 in the source sentence with the compression.

$p(c = 1\|s, (\boldsymbol{t_1})\ r\ (\boldsymbol{t_2}))$	$(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$
.005	**Jean-Bertrand Aristide** that the **United States**
.010	**United States** since the Rev. **Jean-Bertrand Aristide**
...	...
.894	**United States** ousted former President **Jean-Bertrand Aristide**
.976	**Jean-Bertrand Aristide**, left Haiti for the **United States**

Table 3: Highest and lowest coherence predictions from the set **United States – Jean-Bertrand Aristide**

sion, we consider the label in the compression.[10] We refer to these dependency edge counts as $\boldsymbol{\Psi}$. Our final feature vector, $\boldsymbol{\Omega}$, is defined as the concatenation of $\boldsymbol{\Psi}$ and $\boldsymbol{\Phi}$.

Features	Test accuracy
$\boldsymbol{\Phi}$ (pos)	.858
$\boldsymbol{\Psi}$ (deps)	.892
$\boldsymbol{\Omega}$ (deps & pos)	.896

Table 4: Test accuracies.

We implement our model with *scikit-learn* (Pedregosa et al., 2011) and manually tune the inverse regularization constant to the setting, $c = 1$, which achieves the highest accuracy on the validation set. For evaluation, a sentence is presumed coherent if $p(c = 1|s, (\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})) > .5$. Using the feature vector $\boldsymbol{\Omega}$ we achieve an accuracy of .896 on the test set. We also present results using only the $\boldsymbol{\Psi}$ and $\boldsymbol{\Phi}$ features (table 4) because reliable dependency parses are not available in some settings (Blodgett et al., 2016; Bamman, 2017).

Two limitations of this approach suggest areas for future work. First, in some cases, the relationship between $(\boldsymbol{t_1})$ and $(\boldsymbol{t_2})$ might not be expressed in the form, $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$, as in "**Russia** and **France** signed an agreement". In order to generate candidate relation statements it would be helpful to lightly rewrite the sentence, as in "**Russia** signed an agreement with **France**". Additionally, a sentence might express a relationship between two terms but be too long to display on a concept map or a snippet box. In these cases, it would be helpful to compress the sentence to create a more concise relation statement.

5 Experiments

Any relational summarization system should deliver a high-quality summary when a user queries for two terms. Therefore, ideally, a system should generate the largest possible candidate set, without returning incoherent relation statements. We thus evaluate our query-focused generation method in terms of both readability and yield (total relation statements recalled). Our method generates three times more relation statements than OpenIE systems, allowing for summarization of two times more query pairs. We also achieve higher scores in a test of human coherence judgements (table 5).

More concretely, we evaluate our compression-based method for generating candidate sets against two relation extractor baselines on two very different corpora: (1) all comments from the large "relationships"[11] subreddit from June, 2015 – September, 2017[12] and (2) a collection of *New York Times* articles from 1987 to 2007 which mention the country "Haiti" (Sandhaus, 2008). For each corpus, we first find a collection of multi-word phrases using the `phrasemachine` package (Handler et al., 2016) which extracts all multi-word, noun phrase terms from the corpus.

After extracting all terms, we determine the top 100 terms, by count. We then examine all non-empty mention sets for all possible combinations of two top terms. A mention set is a set of sentences which mention two terms (§2). We examine all mention sets because an investigator should be able to investigate any entity she chooses while analyzing a corpus.

In subsequent experiments, we require all relation statements be less than or equal to $J = 75$ characters, which excludes overly verbose relation statements which are unsuitable for many user interfaces.

5.1 Yield experiments

Off-the-shelf relation extractors generate 3-tuples from each mention set. Some of those 3-tuples might have one argument which is equal to $(\boldsymbol{t_1})$ and another argument which is equal to $(\boldsymbol{t_2})$. Each such 3-tuple can be linearized into a string of the form $(\boldsymbol{t_1})\ r\ (\boldsymbol{t_2})$ to generate a candidate set. However, we find that using extractors in this

[10] Enhanced dependencies allow for a token to have more than one incoming edge (i.e., multiple parents). If there is more than one incoming edge, we pick an edge at random.

[11] "relationships" refers to interpersonal relationships

[12] https://medium.com/@jason_82699/pushshift-reddit-api-md-c2d70745c270

manner achieves a low yield (total number of extracted relations). A low yield is undesirable both because it limits the number of mention sets which may be summarized and generates fewer relation statements from which to select an optimal relational summary.

More precisely, we identify the 3-tuples which an OpenIE system extracts from a mention set such that exactly one argument from the triple is equal[13] to (t_1) and exactly one argument from the triple is equal to (t_2). We refer to these 3-tuples as "matching". We then count (1) the total number of mention sets which contain at least one matching 3-tuple and (2) the total number matching 3-tuples across all mention sets. We refer to such counts as the *yield* of a candidate generation system.

We measure the yield of Stanford OpenIE (Angeli et al., 2015) and ClausIE (Del Corro and Gemulla, 2013) on the *New York Times* and *Reddit* corpora, and compare each system to our compression-based approach (§4).[14] We measure these two relation extractors because Stanford OpenIE is included with the popular CoreNLP software and ClausIE achieves the highest recall in two systematic studies of relation extractors (Stanovsky and Dagan, 2016; Zhang et al., 2017).

We find that, for the great majority of sentences, relation extractors do not extract any relations between (t_1) and (t_2). Moreover, for many mention sets, the number of relations extracted with off-the-shelf systems is often zero. We show these results in table 5.

This suggests that although relation summarization is superficially similar to relation extraction, off-the-shelf extractors are poor tools for creating textual units to summarize mention sets. Very often, two terms are related to each other in ways which are simply not captured by relation extractors.

[13]Note that OpenIE systems might not extract the literal string (t_1) or (t_2) as arguments. For instance, if (t_1) is "Merkel" the OpenIE system might extract the argument "Angela Merkel". If some term and some argument from a relational triple share the same head token in the dependency parse of the sentence we say that they are equal. Falke and Gurevych (2017c) employ a similar equality criterion. We tokenize with CoreNLP. In extremely rare cases, tokenization mismatches between CoreNLP and ClausIE make it impossible to apply this criterion.

[14]For our compression-based approach, we count all cases where $p(c = 1 \mid s, (t_1)\ r\ (t_2)) > .5$ as extracting a relation statement.

5.2 Human acceptability judgments

Our compression-based method achieves higher yield than off-the-shelf relation extractors. However, because all sentences in a mention set include (t_1) and (t_2), it is always possible to generate a very large candidate set by simply extracting all spans between (t_1) and (t_2) from the mention set, regardless if such relation statements are coherent. We examine if gains in yield come at the expense of acceptability by presenting randomly selected relation statements to workers on the platform Figure Eight[15] (formerly Crowdflower) and asking workers to rate the extent to which they agree or disagree as to whether a relation statement is a "coherent English sentence" on a scale from 1 to 5. Each relation statement is shown to three workers in total.[16] Our approach is broadly similar to the readability experiments reported in Filippova and Altun (2013).

We solicit 481 total judgements from workers and calculate the mean acceptability score, by method and corpus (table 5). Our method achieves the highest mean acceptability score for both corpora.

Additionally, aggregating judgments across corpora, we observe a statistically significant (p=8 x 10^{-4}) difference between our method ($\mu = 3.89$, $\sigma = 1.38$) and Stanford OpenIE ($\mu = 3.33$, $\sigma = 1.46$) in a two-tailed t-test. Our method also achieves a higher mean score than ClausIE ($\mu = 3.69$, $\sigma = 1.44$), although the difference is not significant.

6 Future work: summary construction task

After a relational summarization system generates a candidate set, the next task is selecting the top K candidate statements for inclusion in a summary (figure 2). In this work, we do not attempt this summary construction task. However, in this section, we analyze the nature of the relational summarization challenge by describing differences among mention sets, and how these differences might affect future efforts at summarization.

We observe that mention sets are inherently heterogenous. Some describe a single, temporally-

[15]https://www.figure-eight.com/

[16]We use seven test questions to filter out careless or bad faith responses. Workers must answer 70% of test questions correctly to be included in a task's results. We construct test questions blindly, without knowledge of the system which generated the relation statement.

	Yield				Coherence	
	Total non-empty pairs		Total rel. stmts.		Mean judgment	
	Haiti	Reddit	Haiti	Reddit	Haiti	Reddit
ClauseIE	128	1,121	279	3,949	3.67	3.71
StanfordOIE	443	1,488	972	5,605	3.69	2.97
This work	**739**	**3,766**	**2,954**	**21,495**	**3.94**	**3.85**
Upper bound	2,472	4,496	43,051	123,760	Range: 1-5	

Table 5: We compare Stanford OpenIE, ClausIE and our headline-based compression method for the candidate set generation task on two different corpora (Haiti articles from *New York Times*, and the *Reddit* relationships forum) in terms of (1) how many entity pairs have a non-empty candidate set, (2) how many total relation statements are generated, and (3) the average human judgment of acceptability (§5.2). For yield measures, the upper bound on the left shows the total number of non-empty entity pairs (i.e. how many pairs actually cooccur in at least one sentence, out of all $\binom{100}{2} = 4950$ theoretically possible pairs) and the upper bound on the right shows the total number of sentences in the corpus which mention at least two of the terms. Our method summarizes more entity pairs across both corpora, and achieves the highest acceptability scores among all techniques (§5.2).

focused event. Others describe a consistent, unchanging relationship. Still others describe intricate sagas unfolding across time. For instance, within the Haiti corpus, one mention set describes events in 1994 when **General Cedras** fled to the **Dominican Republic**. This mention set is quite different from a set of sentences in the Reddit corpus in which users assert that **video games** are a **deal breaker** in interpersonal relationships. Figure 3 displays hand-crafted summarizes for these mention sets.

In general, the properties which guide how a mention set should be summarized are its **size**, **topical diversity**, **temporal focus** and the degree to which the set expresses **states or events**. In this section, we use the notation (t_1) – (t_2) to refer to a mention set. For instance, *New York – London* would refer to all sentences from a corpus which contain the names of both of these cities.

Size. In general, because many word types in a corpus occur infrequently (Zipf, 1949), the number of sentences which mention (t_1) and (t_2) is often small. For instance, of the 320,670 total sentences in the Haiti corpus, only 160 mention "Jean-Bertrand Aristide" and the "United States," which is nonetheless among the larger mention sets in the corpus. In general, larger sets often describe complex and noteworthy relationships, which are more difficult to summarize (figure 3c). Note that although individual mention sets are often small enough to simply read (unlike in some multi-document summarization settings), summarization of mention sets is still quite useful, as practitioners will often seek to understand many different relationships as they investigate a new topic (e.g. figure 1).

Topical diversity. In general, some mention sets are focused on a single topic, others are more diffuse. For instance, after losing power in a second, 2004 coup Haiti's Jean Bertrand Aristide was forced into exile in South Africa. The mention set for *Jean Bertrand Aristide – South Africa* contains twelve sentences which (mostly, but not exclusively) describe Aristide's removal from power and life in exile in South Africa from 2004 onwards. Detecting and including diverse or complex topics is a classic aim of traditional multi document summarization (e.g. Lin and Hovy (2000)), which might be applied in this new setting.

Temporal focus. In timestamped corpora such as news archives or social media posts, some mention sets are focused within certain time periods; others are spread across the span of the corpus. For instance, in the Haiti corpus, *General Cedras – Dominican Republic* are only mentioned together during a few months of 1994 (figure 3b). A good summary for this mention set should describe a central event from this time period: when General Cedras fled to the Dominican Republic. On the other hand, *Jean-Bertrand Aristide – United States* are mentioned together in 67 months in the corpus, covering a number of important events spread across decades (figure 3c). For this mention set, a narrow summary focusing on a single event would be inappropriate.

Many existing methods specialize in detecting (Chaney et al., 2016), tracking (Allan et al., 1998) and summarizing evolving topics in timestamped documents. Some systems focus specifically on summarizing event "spikes": both in news (e.g.

video games and I don't want that to be a **deal breaker**
video games was a **deal breaker**
video games is a **deal breaker**

(a) A hand-crafted summary for the mention set **video games–deal breaker**. The mention set contains many stative descriptions of the relationships between the two terms, indicating that a summary might focus on presenting fixed relationships rather than evolving events.

General Cedras ... last week fled to the **Dominican Republic**
Dominican Republic ... has indicated it will not permit permanent residence by **General Cedras**

(b) A hand-crafted summary for the mention set **General Cedras–Dominican Republic**. The set has a high number of mentions which all fall within a several month span, hinting at a relationship focused on a particular event at a particular point in time.

Aug. 1994 **United States** supports the restoration of the democratically elected president of Haiti, **Jean-Bertrand Aristide**
Oct. 1995 **Jean-Bertrand Aristide** was restored to power a year ago under the watch of **United States**
Sep. 2002 **United States** and other donors withheld contributions, hoping to spur President **Jean-Bertrand Aristide**
Mar. 2004 **Jean-Bertrand Aristide** asserted that he had been driven from power by the **United States**

(c) A hand-crafted summary for the mention set **Jean-Bertrand Aristide–United States**, one of the largest in the Haiti corpus. The mention set describes a complex, shifting relationship; at different times over several decades, Aristide was a beneficiary, opponent and critic of the United States.

Figure 3: Mention sets are heterogenous, requiring a diversity of summarization techniques. In this work, we analyze the diversity of mention sets towards future attempts that the relational summarization problem.

Alfonseca et al. (2013)) and on social media (e.g. Nichols et al. (2012)). In some cases, the event described in a mention set will even match the loose form of a common narrative template (Chambers and Jurafsky, 2008), such as when the two terms are codefendants at a trial.

Mention sets which are more temporally diffuse are also more challenging. Update summarization refers to summarizing changes introduced by new documents, possibly from a high volume stream (Kedzie et al., 2015). This form of summarization is important in cases when a relationship shifts or changes through time, as in figure 3c.

States or events. Mention sets may be coarsely divided into cases where the set expresses a stable state or property of the world in the eyes of the author (e.g. "England is a close ally of the US" or "video games are a deal breaker") and cases where the relation statement expresses a change or event (e.g. "Gen. Cedras fled to the Dominican Republic" or "dad left mom"). In many interesting cases, the mention set contains a mix of stative and eventive relation statements which express a narrative, such as "**America** is an ally of **South Korea**" and "**America** sent a destroyer to **South Korea**".

Defining (Pustejovsky, 1991), extracting (Aguilar et al., 2014) and determining relationships between events (Hovy et al., 2013) is a challenging research area. But a better understanding of states and events would improve future work. For instance, if a summary includes the event "Jolie divorced Pitt", it does not need to include the stative relation phrase "Jolie was married to Pitt". To our knowledge, there is no prior work which considers how fine-grained relations between states and events might be employed for summarization. MacCartney and Manning (2009) offer a framework which might serve as a useful starting catalog.

Conclusion

This work defines a problem which lies at the intersection of typically unrelated fields in natural language processing, summarization and relation extraction. We present a new method which finds large numbers of natural language expressions which coherently describe relationships. We also analyze the challenges of the relational summarization task, by investigating and describing the inherent heterogeneity of mention sets. Because of this heterogeneity, we argue that future attempts to summarize relationships will likely require a diversity of models and techniques.

What's this Movie about?
A Joint Neural Network Architecture for Movie Content Analysis

Abstract

This work takes a first step toward movie content analysis by tackling the novel task of movie overview generation. Overviews are natural language texts that give a first impression of a movie, describing aspects such as its genre, plot, mood, or artistic style. We create a dataset that consists of movie scripts, attribute-value pairs for the movies' aspects, as well as overviews, which we extract from an online database. We present a novel end-to-end model for overview generation, consisting of a multi-label encoder for identifying screenplay attributes, and an LSTM decoder to generate natural language sentences conditioned on the identified attributes. Automatic and human evaluation show that the encoder is able to reliably assign good labels for the movie's attributes, and the overviews provide descriptions of the movie's content which are informative and faithful.

1 Introduction

Movie summarization is the task of automatically summarizing a screenplay in order to gain a general impression of its content. This may include describing the movie's main characters and plot, its genre, artistic style, and so on. As more and more movies are being produced every year[1], there is an ever growing need to facilitate this task. Potential applications include producing shorter versions of scripts to help with the decision making process in a production company, enhancing movie search by generating descriptions of what the movie is about, and notably, supporting movie recommendation engines by abstracting over specific keywords to more general concepts.

Figure 1 gives an example of the type of movie content analysis we would like to obtain automatically. The information is taken from Jinni, a large database (and movie recommendation engine) which indexes movies based on attributes and their values[2] (see the top half of Figure 1) and further aggregates these into a comprehensive overview (see the second half of Figure 1). Jinni's movie attributes were created by film professionals based on analysis of user reviews and metadata. There are hundreds, and they aim to describe aspects such as mood, style, plot, and setting for any released movie or TV show. Although some of these attributes could not be possibly ascribed without information from external sources (e.g., *Praise*, or *Based on*), others could be inferred by watching the movie or reading the

Mood:	Suspenseful, Captivating, Tense, Scary
Plot:	Serial Killer, Special Agents, Investigation, Mind Game, Psychopath, Crimes, Deadly, Law Enforcement, Mind and Soul, Rivalry
Genre:	Crime, Thriller
Style:	Strong Female Presence
Attitude:	Serious, Realistic
Place:	Maryland, USA, Virginia
Period:	20th Century, 90s
Based on:	Based on Book
Praise:	Award Winner, Blockbuster, Critically Acclaimed, Oscar Winner, Modern Classic, Prestigious Awards
Flag:	Brief Nudity, Sexual Content, Strong Violent Content

The Silence of the Lambs can be described as tense, captivating, and suspenseful. The plot revolves around special agents, mind games, and a psychopath. The main genres are thriller and crime. In terms of style, The Silence of the Lambs stars a strong female character. In approach, it is serious and realistic. It is located in Maryland and Virginia. The Silence of the Lambs takes place in the 1990s. It is based on a book. The movie has received attention for being a modern classic, an Oscar winner, and a blockbuster. Note that The Silence of the Lambs involves brief nudity and sexual content.

Figure 1: Jinni attributes, their values, and overview for "The Silence of the Lambs". Underlined attribute values appear in the overview.

[1] According to http://www.boxofficemojo.com/ during 2009–2016, movie releases went up from 536 to 729.

[2] Throughout this paper *attributes* are in italic font and their values in sans serif.

Proceedings of NAACL-HLT 2018, pages 1770–1781
New Orleans, Louisiana, June 1 - 6, 2018.

screenplay (e.g., *Genre, Plot, Flag, Mood, Place*).

This work takes a step toward automatic script summarization by jointly modeling the tasks of movie attribute identification and overview generation. Specifically, we propose a novel neural network architecture which draws insights from encoder-decoder models recently proposed for machine translation (Bahdanau et al., 2015) and related sentence generation tasks (Wen et al., 2015; Mei et al., 2016; Lebret et al., 2016). Our model takes the screenplay as input and generates an overview for it. Rather than representing the script as a sequence, we employ feed-forward neural networks (Zhang and Zhou, 2006; Kurata et al., 2016) to encode the screenplay into various attributes (e.g., *Plot*, *Genre*) and their labels (e.g., thriller, romance), viewing movie content analysis as a multi-label classification problem. Our decoder generates movie overviews using a Long Short-Term Memory network (LSTM; Hochreiter and Schmidhuber, 1997), a type of recurrent neural network with a more complex computational unit which is semantically conditioned (Wen et al., 2015, 2016) on this attribute specific representation. Our model is trained end-to-end using screenplays and movie overviews as the supervision signal.

In both automatic and human-based evaluations our neural network architecture outperforms competitive baselines and generates movie overviews which are well-received by human judges. To the best of our knowledge, this is the first work to automatically analyze and summarize the content of screenplays.

2 Related Work

Recent years have seen increased interest in the computational analysis of movie screenplays. Ye and Baldwin (2008) create animated storyboards using the action descriptions of movie scripts. Danescu-Niculescu-Mizil and Lee (2011) use screenplays to study the coordination of linguistic styles in dialog. Bamman et al. (2013) induce personas of film characters from movie plot summaries. Agarwal et al. (2014a; 2014b; 2015) extract social networks from scripts, create *xkcd* movie narrative charts, and automate the Bechdel test which is designed to assess the presence of women in movies. Gorinski and Lapata (2015) summarize screenplays by selecting important scenes. Our work joins this line of research in an attempt to automatically induce information pertaining to a movie's content such as its genre and plot elements.

There has been a surge of interest recently in repurposing sequence transduction neural network architectures for various generation tasks such as machine translation (Sutskever et al., 2014), sentence compression (Chopra et al., 2016), and simplification (Zhang and Lapata, 2017). Central to these approaches is an encoder-decoder architecture modeled by recurrent neural networks. The encoder reads the source sequence into a list of continuous-space representations from which the decoder generates the target sequence. Previously proposed architectures are not directly applicable to our task for at least two reasons: (a) the correspondence between screenplays and overviews is very loose, and (b) the screenplay is not strictly speaking a sequence (a screenplay is more like a book consisting of thousands of sentences), and cannot be easily compressed into a vector-based representation from which to generate the overview.

Rather than attempting to decode the overview directly from the screenplay, we encode the latter into attribute-value pairs which we then decode into overviews. We conceptualize the generation task as a joint problem of multi-label categorization, where each screenplay is assigned to one or more categories, and content-sensitive natural language generation. Many machine learning techniques have been proposed for building automatic text categorization systems (see Sebastiani, 2002 and Dalal and Zaveri, 2011 for overviews), including neural networks (Belanger and McCallum, 2016; Kurata et al., 2016). Our encoder is a feed-forward neural network, which, however, is able to capture label interactions which are important for our content analysis task. Our decoder employs an enhanced LSTM architecture which directly maximizes the probability of the overview given the screenplay's attribute values. Conditional LSTMs have been applied to various related tasks, including image description generation (Vinyals et al., 2015), the verbalization of database records (Mei et al., 2016; Lebret et al., 2016), and the generation of dialogue acts (Wen et al., 2015, 2016).

3 The Jinni Movie Dataset

Our dataset was built on top of ScriptBase, a collection of 1,276 movie scripts, which Gorinski and

Attribute	Jinni	Frequent	Merged

Plot	406	101	101
Genre	31	31	31
Attitude	8	8	8
Place	173	53	24
Flag	9	9	6

Table 1: Movie attributes and their values.

Lapata (2015) obtained by automatically crawling web-sites such as imsdb.com. We crawled Jinni[3] in order to obtain attributes and overviews (see Figure 1) for each movie in ScriptBase. As mentioned earlier, attributes have values which are essentially labels/tags describing the movie's content, whereas overviews are short summaries giving a first impression of the movie. The crawl resulted in 917 movies which Jinni and ScriptBase had in common. We further split these into training, development and test sets, with 617, 200, and 100 instances, respectively. We concentrate on the six types of attributes shown in Table 1 whose values we hypothesize can be inferred from analyzing the movie's screenplay.

Table 1 provides an overview of the number of labels used in our experiments. Jinni contains a wealth of attribute values varying from nine for *Flag* to more than 400 for *Plot*. Additionally, value names for some attributes are synonyms or near-synonyms (e.g., Nudity and Brief Nudity for *Flag*). We reduced the set of attribute values to those that occurred most frequently (column Frequent in the table) and merged synonyms into a common label (column Merged).

4 Neural Network Architecture

We could approach the movie overview generation task using an attention-based encoder-decoder model (Bahdanau et al., 2015). The encoder would transform the screenplay into a sequence of hidden states with an LSTM (Hochreiter and Schmidhuber, 1997) or another type of computational unit (Cho et al., 2014). The decoder would use another recurrent neural network to generate the overview one word at time, conditioning on all previously generated words and the representation of the input, while an attention mechanism would revisit the input sequence dynamically highlighting pieces of information relevant for the generation task. As mentioned earlier, viewing screenplays as a sequence of sentences is problematic both computationally and conceptually. Even if we used a hierarchical encoder (Tang et al., 2015; Yang et al., 2016) by first building representations of sentences and then aggregating those into a representation of a screenplay, it is doubtful whether a fixed length vector could encode the content of the movie in its entirety or whether the attention mechanism would effectively isolate the parts of the input relevant for generation.

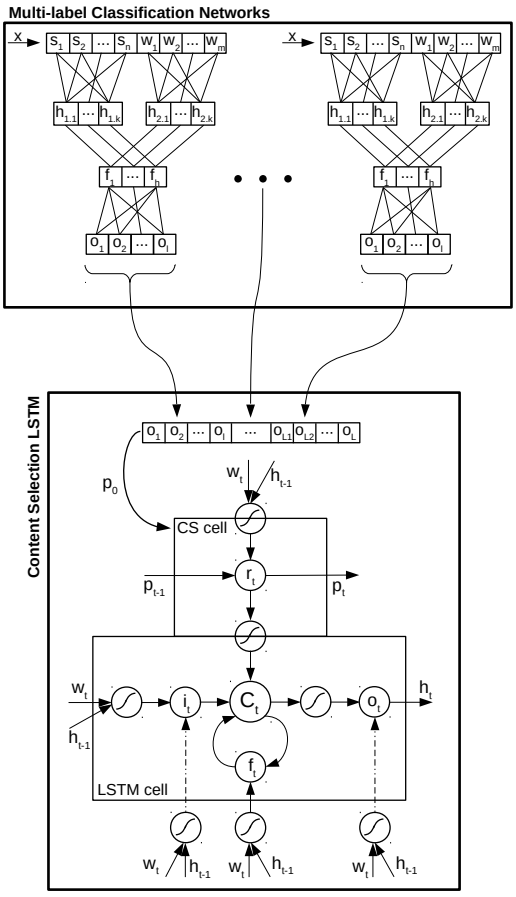

Figure 2: Neural network architecture: given feature vector x representing a screenplay, we employ feed-forward multi-label classification networks to encode the movie into a content vector p_θ representing attribute labels; this encoding is fed into an LSTM with a content selection cell.

We therefore propose an architecture that consists of two stacked neural network models for the tasks of movie attribute identification and overview generation. Figure 2 illustrates our model. We use simple feed-forward neural networks to impose some structure on the input by identifying the labels that most likely apply to the screenplay. We subsequently employ a semantically conditioned LSTM (Wen et al., 2015, 2016)

[3]Dated on 2015/04/18 and available from http://www.jinni.com/.

to select the content for which to generate sentences. This architecture is advantageous for a number of reasons. Firstly, by imposing structure on the screenplays, the generation network is faced with a more compact and informative representation. This allows us to make use of a content selection LSTM similar to Wen et al., (2015; 2016), generating fluent and label-specific outputs. Secondly, it enables us to train the screenplay encoder (aka classification network) and the decoder jointly, in an end-to-end fashion.

4.1 Multi-label Encoder

As shown in Figure 1, the overview highlights various aspects of the movie, essentially devoting a sentence to each attribute. This observation motivates us to encode the screenplay as a set of attributes (with their values) and then decode these into a sentence one by one. We treat attribute encoding as a multi-label classification problem: an attribute (e.g., *Genre* or *Plot*), will typically have multiple values (aka labels) which are suitable for the movie and should occur in the generated sentence. Furthermore, these labels naturally influence each other. For example, a movie whose *Genre* is Crime is also likely to be a Thriller while it is less likely to be a Parody. In traditional multi-label classification such interactions are either ignored (Read et al., 2011; Tsoumakas and Katakis, 2006; Godbole and Sarawagi, 2004; Zhang and Zhou, 2005), or represented by label combinations (Tsoumakas and Vlahavas, 2007; Read et al., 2008). A few approaches assume or impose an existing structure on the label space (Schwing and Urtasun, 2015; Chen et al., 2015; Huang et al., 2015; Jaderberg et al., 2014; Stoyanov et al., 2011; Hershey et al., 2014; Zheng et al., 2015).

We employ a neural network approach with the aim of abstracting the screenplay into a set of meaningful labels whose correlations are discovered automatically, during training. As shown on top of Figure 2, our encoder is a feed-forward neural network where individual neurons represent the labels to be classified. The input to the network is a feature vector x representing the screenplay (we discuss the specific features we use in more detail shortly):

$$h_n = \sigma(W_n x_n) \tag{1}$$

The input is split into k segments by feature type, and the feature segments are fed into k separate fully connected hidden layers. The hidden layer outputs are then combined using simple element-wise addition:

$$f = h_1 \oplus h_2 \oplus \cdots \oplus h_k \tag{2}$$

The combined feature layer is used to compute an l-sized output layer, where l corresponds to the size of the classification label set. The final activation of the output units is obtained by applying the sigmoid function to the output layer:

$$O = \sigma(W_o f) \tag{3}$$

In order to better capture label interactions, we adapt a method of network initialization recently introduced in Kurata et al. (2016). In this approach, instead of initializing the model's output weights W_o from a uniform distribution, the first p rows of the weight matrix are initialized according to λ patterns observed in the data. To this end, we initialize the nth row of W_o with pattern λ_n (equation (4)), which is a vector corresponding to the nth label-assignment observed in the training data:

$$W_o^n = i(\lambda_n) \tag{4}$$

The initialization weight i for unit l of pattern λ_n is set to 0 if the corresponding label is not present in the given instance; or to the upper bound UB of the normalized initialization weights of hidden layer h and output layer o, scaled by the number of times c the pattern occurs in the data:

$$i(\lambda_n^l) = \begin{cases} \sqrt{c} \times UB & \text{if } \lambda_n^l = 1 \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

$$UB = \frac{\sqrt{6}}{\sqrt{|h| + |o|}} \tag{6}$$

We follow Glorot and Bengio (2010) in using $\sqrt{6}$ as normalization factor for UB, and limit the number of patterns λ to the most frequently observed label assignments.

Our model uses three types of features representing the screenplay's lexical make up, its underlying character relations, and interactions.

Lexical Features An obvious feature class is the language of the movie. Comedies will be characterized by a different vocabulary compared to thrillers or historical drama. We thus represent each script as a vector of 7,500 dimensions corresponding to the most frequent words in the training corpus. Vector components were set to the

words' tf-idf values. Words in scripts were further annotated with their sentiment values using the AFINN lexicon (Nielsen, 2011), a list of words scored with sentiment strength within the range $[-5,+5]$. We extracted several features based on these sentiment values such as the sentiment score of the entire movie, the number of scenes with positive/negative sentiment, the ratio of positive to negative scenes, and the minimum and maximum scene sentiment. From scene headings, we were also able to extrapolate the number of internal and external locations per script.

Graph-based Features Our graph-based features are similar to those described in Gorinski and Lapata (2015). Specifically, we view screenplays as weighted, undirected graphs, where vertices correspond to movie characters and edges denote character-to-character interactions (essentially the number of times two characters talk to each other or are involved in a common action). From the graph we extract features corresponding to the number of main and supporting characters, which we identify by measuring their centrality in the movie network (e.g., the number of edges terminating in a given node). We also estimate character polarity by summing the sentiment of each character's utterances as well as the ratio of positive to negative characters in a given script.

Interaction-based Features We extract features based on how often any two characters interact, i.e., whether they are engaged in a conversation or in the same event (e.g., if a character kills another). We identify interactions as described in Gorinski and Lapata (2015) and measure the number of interactions per scene and movie, the number of positive and negative interactions, and their ratio.

4.2 Movie Overview Decoder

Our decoder generates a movie overview from the multi-label encoding described above. For this, we adapt the LSTM architecture of Wen et al. (2015; 2016) which was originally designed for dialogue act generation (e.g., given input inform(type="hotel", count="182", dogsallowed="dontcare"), the network outputs "*there are 182 hotels if you do not care whether dogs are allowed*"). The network performs content selection, i.e., decides which attribute labels to talk about, while generating the sentences describing them.

As outlined in the lower part of Figure 2, a sigmoid control gate feeds a content vector, p_0, into a traditional LSTM cell to generate a natural language surface form. At each timestep t, the output word w_t is drawn from an output distribution conditioned on the previous hidden layer h_{t-1} *as well as* the previous content vector p_{t-1}. The content selection cell effectively acts as a *sentence planner*, retaining or omitting information from the original vector p_0 at every time step t to guide the sentence generating LSTM cell. Our LSTM architecture is defined by the following equations:

$$i_t = \sigma(W_{wi}w_t + W_{hi}h_{t-1}) \quad (7)$$
$$f_t = \sigma(W_{wf}w_t + W_{hf}h_{t-1}) \quad (8)$$
$$o_t = \sigma(W_{wo}w_t + W_{ho}h_{t-1}) \quad (9)$$
$$\hat{c}_t = \tanh(W_{wc}w_t + W_{hc}h_{t-1}) \quad (10)$$
$$r_t = \sigma(W_{wr}w_t + W_{hr}h_{t-1}) \quad (11)$$
$$p_t = r_t \odot p_{t-1} \quad (12)$$
$$c_t = f_t \odot c_{t-1} + i_t \odot \hat{c}_t + \tanh(W_{pc}p_t) \quad (13)$$

where σ is the sigmoid function, $i_t, f_t, o_t, r_t \in [0,1]^n$ are input, forget, output, and reading gates respectively, and $\hat{c}_t$ and c_t are proposed cell value and true cell value at time t.

In the original paper, the input p_0 to the LSTM is a 1-hot representation of the information that should be included in the natural language output. In our setup, we relax this constraint such that each element of $p_0 \in [0,1]$, i.e., we directly use the output of the multi-label encoder just described.

4.3 Training

The proposed architecture is trained jointly in an end-to-end fashion, minimizing the objective:

$$F(\theta) = \sum_t y_t^T \log(\hat{y}_t) + ||p_T|| + \sum_{t=0}^{T-1} \eta\xi^{||p_{t+1}-p_t||} \quad (14)$$

where y_t and $\hat{y}_t$ are the observed and predicted word distributions over the training data, p_T is the content vector at the final time index T, p_0 is the initial content vector as given by the encoder network, and η, ξ are training constants. The second term in the objective penalizes the network for generating output without realizing all required labels, while the third term deters the network from utilizing more than one label at any given time step.

The model is trained on pairs of scripts and sentences extracted from Jinni. To give a concrete example, a training instance for the *Plot* sentence from Figure 1 would consist of the features representing the movie's screenplay, and the overview's

Attributes	ZeroR	NB	DS	SVM	Lib	MLE

All	45.4	50.5	**57.4**

Table 3: Attribute identification (%F1; test set).

Plot sentence "*The plot revolves around special agents, mind games, and a psychopath.*". The *Plot* multi-label network encodes the script into content vector p_0, and the LSTM learns which "labels" represented in p_0 to talk about while its training objective discourages to leave too many labels unmentioned. The observed output error is back-propagated through the LSTM and the embedding network using stochastic gradient descent (Bottou, 1991) with decaying learning rate.

5 Evaluation

In this section we report our evaluation experiments. We begin by assessing how good our encoder is at capturing screenplay content and then proceed to evaluated the generated overviews themselves.

5.1 How Good is the Encoder?

In order to assess encoder's ability to induce structure over screenplays, we focus solely on the top part of the architecture in Figure 2. Specifically, we trained stand-alone models for the six attributes shown in Table 1 on the gold data provided in the Jinni dataset. All networks used the same features introduced earlier and were initialized using the pattern-based method of Kurata et al. (2016). To better capture the fact that we are dealing with multi-label assignments, we used the global error function described in Zhang and Zhou (2006). Given the network output vector $\hat{y}$ for input x, the true bag of label assignments y and its complement $\bar{y}$, the error observed for each instance is computed as:

$$E = \frac{1}{|y||\bar{y}|} \sum_{(k,l)\in y\times\bar{y}} \exp(-(\hat{y}_k - \hat{y}_l)) \qquad (15)$$

The networks were trained with stochastic gradient descent during back propagation, using the same method as for the full model.

We compared our multi-label encoders (MLE) against several baselines. These include assigning the most frequent attribute labels to each movie based on the attributes' mean distribution (ZeroR), Naive Bayes (NB), Decision Stump (DS), LibLinear (Lib; Fan et al., 2008) and Support Vector Machines (SVMs; Chang and Lin, 2011). For each comparison system, we trained a binary classifier per attribute label using features identical to the ones used for the MLE.

Table 2 shows F1 performance on the training data for MLE and comparison systems, averaged over 10 folds. As can be seen, MLE performs best, followed by LibLinear. Table 3 compares MLE, ZeroR, and Lib, the strongest baseline, on the test set using F1 and the best parameters found for each system during cross-validation. As can be seen, MLE outperforms Lib across attributes, and is superior to ZeroR by a large margin. F1 differences between MLE and LibLinear are significant ($p < 0.01$), using approximate randomization testing (Noreen, 1989).

Overall, the results in Tables 2 and 3 indicate that the classification task is hard. This is especially true for *Plot* which has the largest number of labels. Nevertheless, the multi-label encoders introduced here achieve good performance on their own, indicating that they are able to capture the content of the screenplay, albeit approximately.

5.2 How Good is the Decoder?

We next evaluate the performance of the jointly trained system which we call MORGAN as a shorthand for **M**ovie **O**ve**R**view **G**ener**A**tio**N** model. MORGAN is trained on pairs of screenplays and their corresponding verbalizations in the Jinni dataset. Unfortunately, our dataset is relatively small for neural network training; it contains 617 movies only, i.e., there are 617 sentences for each attribute. To alleviate this problem, we augmented the data as follows. We extracted sentence templates from the training set (209 in total), ex-

Mood	T can be described as M_1 and M_2 The mood of T is M_1.
Plot	The plot centers around a P_1, P_2, and P_3 The plot revolves around P_1, P_2, and P_3
Genre	The main genres are G_1, G_2, and G_2 T is M_1 and M_2 movie
Attitude	In approach, T is A_1 The pacing is A_1
Place	The setting is L_1 It is located in L_1
Flag	Note that the movie involves F_1 and F_2 Note that it includes F_1, F_2, and F_3

Table 4: Template sentences extracted from Jinni overviews. Variable T is filled by the movie's title, whereas M, G, P, A, L, F correspond to values for attributes *Mood*, *Genre*, *Plot*, *Attitude*, *Place*, and *Flag*, respectively.

amples of which are shown in Table 5. We replaced the title and attribute values with variables (shown as capital letters in the table). We then used the templates to generate additional data for each movie by substituting attribute variables in template sentences with permutations of the movie's gold-standard labels. We thereby obtained a total of 31,000 training instances.

The model was trained with a learning rate of 0.5, using a decay of 0.01 over 50 epochs, fixing it for subsequent epochs. Constants η and ξ in equation (14) were set to 10^{-4} and 100, respectively. At test time, we used screenplay features as input and generated one sentence per attribute. We arranged these into an overview following the ordering *Mood* $\gg$ *Plot* $\gg$ *Genre* $\gg$ *Attitude* $\gg$ *Place* $\gg$ *Flag* which is fixed and attested in all overviews in our dataset.

We compared MORGAN against several systems: (1) a random baseline, selecting for each movie and attribute type a random sentence from the training set; (2) a nearest-neighbor baseline (NN) which uses the same screenplay features as MORGAN (and cosine similarity) to identify the closest matching script in the training data, and rehashes its overview as output; (3) an attention-based LSTM (Bahdanau et al., 2015) trained on script sentence pairs (31,000 in total); and (4) six attention-based LSTMs, one per attribute type, trained on script sentence pairs (on average 5,200 per LSTM). The attention LSTMs were trained on the same screenplay features as MORGAN, with the attention mechanism at each timestep t focusing on parts of the input. Example overviews generated by MORGAN, the attention LSTMs, and the nearest neighbor system are shown in Table 6.

Models	BLUE	Coherence	Grammaticality
Random	38.0	2.42*	3.83
NN	40.4	3.45	3.93
Attn	23.0	2.93*	3.91
typAttn	37.9	3.20	3.80
MORGAN	**42.0**	**3.72**	**4.08**
Jinni	—	4.27	4.22

Table 5: BLEU scores and mean coherence and grammaticality ratings for movie overviews. * significantly different from MORGAN ($p < 0.05$). Best performing system shown in bold.

We evaluated system output with multi-reference BLEU[4] (Papineni et al., 2002), using sentences from the extended gold-standard as references. Table 5 (first column) summarizes our results. As can be seen, MORGAN outperforms the attention based models, the nearest neighbor system, and the random baseline. The attention-based models cannot succinctly capture the movie's content in order to render it into meaningful sentences. Although the generated sentences are more or less grammatical on their own (see Table 6), the generated overview lacks coherence, and is fairly repetitive. The model does not reliably learn what type of information to focus on for the generation task. For MORGAN this problem is alleviated during the encoding step, which performs content distillation prior to generating overview sentences.

5.3 How are System Overviews Perceived by Humans?

In addition to evaluating system output automatically, we are also interested in how it is perceived by humans. To this end, we ran two judgment elicitation studies on Amazon Mechanical Turk. Both experiments were conducted on 12 movies. In a pre-test we asked 20 workers whether they had seen the movies in our test set and chose the three most popular ones from each of the genres Action, Comedy, Drama, and Romance.

In our first experiment Turkers were presented with an overview taken from the Jinni gold standard, MORGAN or one of the comparison systems and asked to rate its coherence (i.e., whether it was readily comprehensible or difficult to follow) on a scale from 1 (incoherent) to 5 (coherent). Subsequently, they had to rate the grammaticality of

[4]We use NLTK's (http://www.nltk.org/) implementation of BLEU, and report the interpolation of BLEU 1 through 4.

Nearest Neighbor
The mood of Burn after Reading is stylized. The plot revolves around love and romance, motives, buddies, and friends. Its main genres are romance, crime, and comedy. In approach, Burn after Reading is semi serious. It takes place, at least partly, in the USA. Note that Burn after Reading involves violent content, profanity, and sexual content.
attnLSTM
The setting is Europe. It is a sci-fi, adventure, and adventure movie. Note that Burn after Reading includes violent content. Burn after Reading is set in the USA. It is located in the USA. It is set, at least in part, in the USA.
typed attnLSTM
The mood of Burn after Reading is bleak, touching, and feel good. The plot revolves around ambition motives, love and romance, and fall in love. It is an adventure and fantasy, and features thriller themes. In approach, Burn after Reading is serious. Burn after Reading is set, at least in part, in the USA. Note that Burn after Reading involves violent content.
MORGAN
The mood of Burn after Reading is feel good, exciting, and clever. The plot centers around ambition, special agents, and partners. Burn after Reading is a comedy movie. In approach, it is realistic and semi serious. It is set, at least in part, in the USA. Note that it involves profanity.
JINNI
Burn after Reading can be described as cynical, clever, and exciting. The plot revolves around espionage , disorder, and escapades. Burn after Reading's main genres are comedy and crime. In approach, it is not serious and realistic. Burn after reading is set, at least in part, in an urban environment. It is located in Virginia. Note that it involves sexual content, profanity, and violent content.

Nearest Neighbor
Lara Croft: Tomb Raider can be described as touching, offbeat, and humorous. The plot revolves around a psychopath, a chase, and couples motives. Its main genres are drama and comedy. In approach, Lara Croft: Tomb Raider is semi serious. Lara Croft: Tomb Raider is set in the USA.
attnLSTM
Lara Croft: Tomb Raider is set, at least in part, in a dangerous and in a haunted house. The plot centers around buddies, disorder, and criminal heroes motives. The plot centers around escapades, supernatural, and deadly. The setting is a school or college environment. Note that Lara Croft: Tomb raider includes drugs/alcohol and sexual content. The mood of Lara Croft: Tomb Raider is rough, being, and contemplative.
typed attnLSTM
The mood of Lara Croft: Tomb Raider is suspenseful, exciting, and stylized. The plot revolves around a police investigation, cons and scams, and couple relations motives. Lara Croft: Tomb Raider's main genres are fantasy, action, and comedy. In approach, it is serious and fantastic. Lara Croft: Tomb Raider is set, at least in part, in the USA. Note that Lara Croft: Tomb Raider involves profanity and violent content.
MORGAN
Lara Croft: Tomb Raider can be described as suspenseful and rough. The plot centers around danger, a master villain, and deadly. Lara Croft: Tomb raider is an adventure, thriller, and action movie. In approach, it is fantastic. Lara Croft: Tomb Raider takes place, at least partly in Europe. Note that it involves profanity.
JINNI
Lara Croft: Tomb Raider can be described as stylized, exciting, and suspenseful. The plot revolves around time travel, a treasure hunt, and a master villain. The main genres are action, adventure, and fantasy. In approach, it is fantastical and serious. Note that it involves violent content.

Table 6: Overviews generated by MORGAN and comparison systems for "Burn after Reading" (top) and "Lara Croft; Tomb Raider" (bottom).

each overview sentence, again on a scale from 1 (ungrammatical) to 5 (grammatical) and decide whether it appropriately described aspects of the movie's content ("Yes", "No", "Unsure"). We elicited five responses for each overview across six systems (Jinni, typAttn, Attn, Random, NN, and MORGAN) and 12 movies. Finally, participants had to answer a question relating to the movie's content, to make sure that they had actually seen the movie. We discarded responses with wrong answers to the content question. Examples of the overviews participants judged are given in Table 6.

Model	Mood	Plot	Genre	Attitude	Place	Flag	All
Random	37.7	39.6	34.0	43.4	35.8	50.9	19.0*
NN	78.6	67.9	71.4	66.1	58.9	91.1	58.9*
Attn	38.2	38.2	38.2	41.8	51.0	34.5	40.0*
typAttn	60.0	60.0	53.3	57.8	**66.7**	64.4	40.0*
MORGAN	**89.5**	**73.7**	**80.7**	**71.9**	63.2	**89.5**	82.5
Jinni	91.1	89.3	92.9	82.1	67.9	75.0	91.1

Table 7: Proportion of sentences and overviews (All) which describe the movie accurately. * significantly different from MORGAN ($p < 0.05$). Best performing system per attribute is in bold.

Table 5 (columns 2 and 3) summarizes the results of our first judgment elicitation study. All systems perform well with regards to grammaticality. This is not surprising for Random and NN which do not perform any generation. Attn and typAttn also perform well with MORGAN achiev-

ing highest scores for grammaticality amongst automatic systems. Grammaticality differences between the various systems in Table 5 and the Jinni gold standard are not statistically significant (using a one-way ANOVA with post-hoc Tukey HSD tests). Overviews generated by MORGAN are perceived as more coherent in relation to those generated by comparison systems, even though the model does not explicitly take coherence into account. MORGAN overviews are not significantly different in terms of coherence from Jinni, typAttn, and NN, but are significantly better than Random and Attn.

Table 7 shows the percentage of sentences (per attribute and overall) which participants think describe the movie's content felicitously. MORGAN identifies most aspects of the movie successfully, in some cases close to (*Mood, Place*) or even better (*Flag*) than the original Jinni overview. MORGAN is significantly better compared to all other models but not significantly worse than Jinni (using a χ^2 test; see last column in Table 7).

In a second experiment, participants were presented with six overviews for a movie (from Jinni, Attn, typAttn, Random, NN, and MORGAN) and asked to rank them (equal ranks were not allowed) in order of relevance (i.e., whether they express content relevant to the movie). Again, we obtained five responses for each movie. As can be seen in Table 8, while Jinni is ranked first most of the time, MORGAN is ranked second followed by the NN system. We further converted the ranks to ratings on a scale of 1 to 6 (assigning ratings 6...1 to rank placements 1...6) and performed and ANOVA which showed that all systems are significantly ($p < 0.05$) worse than Jinni but MORGAN is significantly better than the comparison systems.

Model	1st	2nd	3rd	4th	5th	6th	AvgRank
Random	1.0	5.8	16.3	22.1	19.2	**35.6**	4.59
NN	5.8	19.2	**24.0**	23.1	15.4	12.5	3.60
Attn	3.8	13.5	20.2	**28.8**	16.3	17.3	3.92
typAttn	1.9	7.7	15.4	10.6	**33.6**	30.8	4.58
MORGAN	8.7	**42.3**	22.1	12.5	12.5	1.9	2.71
Jinni	**78.8**	11.5	1.9	2.9	2.9	1.9	1.45

Table 8: Relevance rankings (shown as proportions) given to overviews by human subjects. Most frequent rank per system and Jinni is in bold.

6 Conclusions

In this work we have presented a novel approach to automatic movie content analysis. We have assembled a new dataset which combines ScriptBase (Gorinski and Lapata, 2015), a corpus of movie scripts, with information gathered from Jinni, a large movie database. We proposed an end-to-end model for movie overview generation via *multi-attribute* encoders and a *semantically conditioned* LSTM decoder. Experimental results show that our encoders are capable of distilling meaningful structures from the screenplay. When applied to the overview generation task, our end-to-end model outperforms a standard attention-based LSTM. Human evaluation also indicates the overviews generated by our model are felicitous, informative, and rated favorably by humans.

In the future, we would like to investigate how attribute-specific features can improve performance compared to our more general feature set which is invariant for each sentence type. It would also be possible to equip the model with a hierarchical decoder which generates a document instead of individual sentences. Although currently our model relies solely on textual information, it would be interesting to incorporate additional modalities such as video (Zhou et al., 2010) or audio (e.g., we expect comedies to be *visually* very different from thrillers, or romantic movies to have a different *score* from superhero movies). Finally, we would like to examine whether the content analysis presented here can extend to different types of fiction such as novels or short stories.

Which Scores to Predict in Sentence Regression for Text Summarization?

Markus Zopf, Eneldo Loza Mencía, and Johannes Fürnkranz

Abstract

The task of automatic text summarization is to generate a short text that summarizes the most important information in a given set of documents. Sentence regression is an emerging branch in automatic text summarizations. Its key idea is to estimate the importance of information via learned utility scores for individual sentences. These scores are then used for selecting sentences from the source documents, typically according to a greedy selection strategy. Recently proposed state-of-the-art models learn to predict ROUGE recall scores of individual sentences, which seems reasonable since the final summaries are evaluated according to ROUGE recall. In this paper, we show in extensive experiments that following this intuition leads to suboptimal results and that learning to predict ROUGE precision scores leads to better results. The crucial difference is to aim not at covering as much information as possible but at wasting as little space as possible in every greedy step.

1 Introduction

More and more data is generated in textual form in newspapers, social media platforms, and microblogging services and it has become impossible for humans to read, comprehend, and filter all the available data. Automatic summarization aims at mitigating these problems by *"taking an information source, extracting content from it, and presenting the most important content to the user in a condensed form and in a manner sensitive to the users or applications needs"* (Mani, 2001).

Very prominent in automatic text summarization is the idea of extractive summarization. In extractive summarization, summaries are not generated from scratch. Instead, sentences in the source documents, which are supposed to be summarized, are extracted and concatenated to form a summary. To be able to select sentences in a meaningful manner, it is crucial for the extractive systems to be able to estimate the utility of individual sentences.

Supervised extractive methods are usually modeled in a regression framework. Hence, this subfield of automatic summarization is called *sentence regression*. The predicted scores are used to generate a ranking of the sentences, and a greedy strategy is often used in combination with additional redundancy avoidance to select sentences which will be added to the iteratively generated summary (Carbonell and Goldstein, 1998). Another method for the selection is solving an integer linear programming (ILP) problem (Gillick et al., 2008; Hong and Nenkova, 2014) which is, however, an NP-hard problem (Filatova and Hatzivassiloglou, 2004). Even though it can be argued that the complexity is not an issue since there are good solvers for ILPs, it remains a problem when large document collections with many sentences have to be summarized or the system should be used on a large scale for many users. The greedy approach is due its simplicity and efficiency very appealing.

Crucial for building sentence regression models is the choice of the regressands which has to be predicted by the models. Most of the recent works try to predict ROUGE recall scores of individual sentences, which seems to be an obvious choice since the final summaries are also evaluated with ROUGE recall metrics (Lin, 2004; Owczarzak et al., 2012). We show in this paper that following this intuition leads to suboptimal results. In extensive experiments, we investigate sentence regression models with perfect and noisy prediction of different regressand candidates with and without redundancy avoidance. In all experiments, we observe the very same result: learning to predict ROUGE precision scores of sentences leads to better results than learning to predict ROUGE recall scores if the scores are selected

Proceedings of NAACL-HLT 2018, pages 1782–1791
New Orleans, Louisiana, June 1 - 6, 2018.

with a greedy algorithm afterwards. Our findings are in particular important for automatic summarization research since the best models currently available are sentence regression models trained to predict ROUGE recall scores. We expect that simply replacing ROUGE recall scores as regressand with ROUGE precision scores can potentially improve these state-of-the-art models further.

We note in passing that the problem is reminiscent of defining heuristics in inductive rule learning: Individual rules are typically evaluated according to their consistency (minimizing the amount of false positives) and completeness (maximizing the amount of true positives), which loosely correspond to precision and recall (Fürnkranz and Flach, 2005). Heuristics such as weighted relative accuracy, which give equal importance to both dimensions, are successfully used for evaluating single rules in subgroup discovery (Lavrač et al., 2004), but tend to over-generalize when being used for selecting rules for inclusion into a predictive rule set. The reason for this is that a lack of completeness can be repaired by adding more rules, whereas a lack of consistency can not, so that consistency or precision of individual rules should receive a higher weight in the selection task. Transferred to summarization, this means that space wasted by recall-oriented selection cannot be used anymore whereas a low recall in a partial summary can be repaired by adding more sentences.

In the following, we will first formalize the problem of extractive summarization and outline the greedy selection strategy (Section 2). Previously extractive summarization systems, in particularly sentence regression models, are summarized in Section 3. We then present an intuition why predicting ROUGE precision scores can potentially give better results in Section 4. In extensive experiments (Section 5), we actually show the previously stated hypothesis which says that selecting sentence according to ROUGE precision instead of ROUGE recall leads to better results if sentence are selected greedily.

2 Extractive Summarization

In this section, we will first formally define the problem of extractive summarization and then describe the greedy sentence selection strategy which is used by many prior works.

2.1 Problem Definition

The task in extractive summarization is to generate a list of sentences S (the summary) from given list of input sentences I (the text to summarize). The size of the generated summary S must not be longer than a predefined length l (usually measured in words or characters).

In order to select sentences, both supervised and unsupervised models are used to predict utility scores of sentences in a first phase. In a second phase, sentences are selected and concatenated to build a summary.

For evaluation, the generated summary is typically compared to human written summaries by automatic means, in many cases by computing so-called ROUGE scores (Lin, 2004).

2.2 Greedy Selection Strategy

A popular strategy to select sentences based on the previously predicted utility scores is the greedy sentence selection strategy which is described in Algorithm 1.

Algorithm 1 Greedy Sentence Selection with Redundancy Avoidance in Extractive Summarization

list of all input sentences $I = s_1, \ldots, s_n$
utility function u
desired summary length l
π = permutation of I s.t. $u(s_{\pi(1)}) \geq \cdots \geq u(s_{\pi(n)})$
$S \leftarrow \emptyset, i \leftarrow 1$
while $|S| < l$ **and** $i < n$ **do**
  if $\text{sim}(s_{\pi(i)}, S) < \theta$ **then**
    $S \leftarrow S + s_{\pi(i)}$
  end if
  $i \leftarrow i + 1$
end while
return S

According to the greedy strategy, the sentence with the highest utility score is selected first. After the best sentence has been selected, it is removed from the input list of available sentences, and the former second best sentence is considered next. Redundancy avoidance strategies are used to ensure that sentences with similar contents are not added multiple times to the summary. A simple strategy computes the similarity of the currently best sentence and all already selected sentences. If the maximum similarity exceeds a predefined threshold θ, the summarizer removes the sentences from the input list without adding it to the summary. The selection process is repeated until the desired summary length is reached. Once a decision is made, it is never revised.

3 Sentence Regression for Extractive Summarization

After the field of automatic summarization has been dominated by unsupervised extractive summarization models for some time (Carbonell and Goldstein, 1998; Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Li et al., 2006), supervised regression models are more commonly used in recent years. The crucial difference is that supervised models learn to predict regressands based on training examples in a training phase whereas unsupervised models do not predict regressands. We focus on supervised extractive regression systems in this paper. Comprehensive overviews of automatic summarization (Nenkova and McKeown, 2011; Gambhir and Gupta, 2016; Yao et al., 2017) also cover unsupervised methods in more detail and include abstractive summarization methods which are out of scope for this paper.

Extractive sentence regression can be described as the task of learning regressands for individual sentences from examples. The general learning problem can be formulated as $y_i = u(x_i) + e_i$ where y_i denotes the regressand (also called dependent variable or target variable) of sentence x_i (the regressor, also called independent variable or features), and e_i denotes the ith residuum (also called error). Sentence regression aims at learning the utility function u from observed sentence-utility pairs in order to minimize the errors for unseen sentences-utility pairs.

Kupiec et al. (1995) proposed one of the first supervised summarization systems, which trains a Bayesian model to predict the probability that a sentence will be included in the summary. They criticized that although a large number of different features had been used in previous unsupervised models, no principled method to select or weight the features had been proposed at this time. Instead of generating summaries, the performance of the model was evaluated based on the classification output of the model for individual sentences. Similarly, Conroy and O'leary (2001) use a Hidden Markov Model to predict the probability that a sentence is included in a reference summary.

The model proposed by Li et al. (2006) already predicts utility scores for individual sentences. The model weights are, however, not learned in a supervised training but assigned by humans. Li et al. (2007) extends this previously proposed unsupervised model and used a support vector regression (SVR) model in the DUC 2007 shared task (Over et al., 2007). Both Li et al. (2006) and Li et al. (2007) use a greedy selection strategy. Instead of learning to predict the probability of appearance of a sentence in a summary (Kupiec et al., 1995; Conroy and O'leary, 2001), Li et al. (2007) use the average and maximum text similarity of candidate sentences and reference summaries as regressands. Ouyang et al. (2011) also applied SVR but used the sum of word probabilities as regressand. Their system therefore also tends to select longer sentences similarly to systems which use ROUGE recall.

PriorSum (Cao et al., 2015b) follows Li et al. (2007) and presents a linear regression framework which uses prior and document dependent features. As regressand, ROUGE-2 recall is used.

Cao et al. (2015a) propose a hierarchical regression process which predicts the importance of sentences based on its constituents. ROUGE-1 recall and ROUGE-2 recall are used as regressand for sentences. For sentence selection, they implement both a greedy selection and a selection based on integer linear programming.

The Redundancy-Aware Sentence Regression (Ren et al., 2016) framework models both importance and redundancy jointly. They train a multi-layer perceptron which then predicts relative importance utilities based on ROUGE-2 recall scores.

REGSUM (Hong and Nenkova, 2014) predicts sentence importance based on word importance and additional features. They use a greedy selection strategy with additional redundancy avoidance which only appends sentences to the summary if the maximum cosine similarity to already selected sentences is lower than a fixed threshold.

We summarize that ROUGE recall is often used in the field of sentence regression in combination with a greedy selection and an additional redundancy avoidance strategy. In the following, we first describe the underlying intuition of using ROUGE recall. Second, we describe why using ROUGE precision instead can be potentially better. Later, we show in the experiments that using ROUGE precision is not only theoretically appealing but also works better in practice than ROUGE recall.

4 ROUGE Recall vs. ROUGE Precision

The ROUGE metric (Lin, 2004) is the method of choice for the evaluation of generated summaries in the field of automatic summarization. Its idea is to compute the similarity between automatically generated summaries and references summaries, which are typically provided by humans.

ROUGE can be viewed as an evaluation measure for an information retrieval task in which precision and recall can be measured. Let E be a set of elements, $R \subset E$ the multiset of desired elements in the reference output, $G \subset E$ is the generated output multiset, and $|.|$ the size of a multiset. Then, the recall is defined as

$$r(G, R) = \frac{|G \cap R|}{|R|} \quad (1)$$

and measures how much of the desired content was returned by the system. On the other hand, precision is defined as

$$p(G, R) = \frac{|G \cap R|}{|G|}, \quad (2)$$

and measures how much of the returned content was actually desirable. We define the intersection $\cap$ of two multisets as the smallest multiset S with $\sigma_S(e) = \min(\sigma_G(e), \sigma_R(e)) \ \forall e \in G, R$, where $\sigma_S(e)$ indicates the number of appearances of element e in set S.

In ROUGE-n, the multiset E is defined as the set of all n-grams, the desired reference multiset R contains all n-grams in a reference summary, and the multiset G contains all n-grams in the system summary. We use multisets and not sets since the same n-gram can be contained multiple times in a text.

When ROUGE was first introduced as the evaluation metric for the DUC 2003 shared task (Over et al., 2007), Lin and Hovy (2003) reported that metrics based on ROUGE recall scores have a good agreement with human judgments. A summary with a high ROUGE recall will contain many n-grams which also appear in the reference summaries. Owczarzak et al. (2012) showed that ROUGE-2 recall is the best variant (highest agreement with human judgments) of ROUGE recall if automatically generated summaries have to be evaluated. ROUGE-2 recall is therefore often used to evaluate automatic summarization systems.

Crucial for the use of ROUGE recall is the length limitation of the generated summaries.

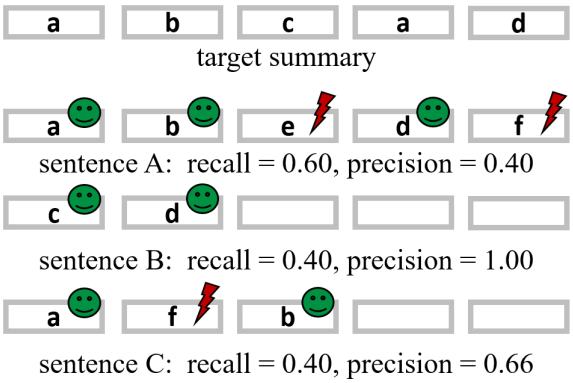

Figure 1: Exemplary illustration of selecting sentences according to precision and recall. The target summary has 5 slots. Sentence A will be selected according to recall since it has a recall scores of 0.6 whereas sentence B and C only have a recall score of 0.4. Sentence A, however, occupies already all available slots in the summary. No more sentence can be selected. Sentence B will be first selected according to precision due to a precision scores of 1.0. After the selection of sentence B, 3 slots are still available in the summary which can be used to fit sentence C to improve the overall summary recall to 0.8.

Usually, the generated summaries are limited to a fixed number of words or characters. Without such a length restriction, systems would be able to generate arbitrary long texts to increase the recall.

Summarization systems aim at maximizing ROUGE recall scores of the generated summaries, since the final summaries are evaluated with ROUGE recall. Greedy extractive summarization approaches try to maximize the overall ROUGE recall of a summary by incrementally adding sentences with a high ROUGE recall to the summary. The idea of this strategy is to pack as much important content as possible into the summary in every step in order to increase the ROUGE recall of the resulting summary. What is usually not considered is the fact that this strategy tends to select longer sentences, since longer sentences tend to have a higher recall. They, however, can contain proportionally more unimportant information, for example in subordinate clauses. As a result, fewer sentences can be selected since the maximum length of the summary is reached earlier.

An alternative strategy, which has not been discussed in the literature so far, is to select sentences according to their ROUGE precision scores. The idea behind this approach is not to cover as much

as information as possible but to waste as little space as possible. Selecting sentences according to precision will not have a bias for longer sentences but for short and dense sentences. Since this strategy tends to selected shorter sentences, more sentence can be included in the summary, which can, in turn, again result in a higher ROUGE recall of the resulting summary.

Figure 1 shows an example in which selecting sentences according to ROUGE precision leads to a higher ROUGE recall score of the resulting summary than selecting sentences according to ROUGE recall. In the following section, we will show that the intuition described in this section is not only appealing in theory, but can also be substantiated in empirical experiments.

We summarize that selecting sentences according to ROUGE precision scores can, intuitively, be better than selecting sentences according to ROUGE recall scores even though the final summaries are always evaluated with ROUGE recall metrics.

5 Experimental Setup

We now present the experimental setups in which we test different regressand candidates for sentence regression in three different, well-known multi-document summarization (MDS) corpora. We used the MDS corpora from the DUC 2004[1], TAC 2008, and TAC 2009[2] summarization shared tasks. All corpora contain 10 input documents and 4 reference summaries for each topic. The number of topics are 50, 46, and 44, respectively. We simulate in the experiments the outcomes of regression models which use different regressands. This will provide us with theoretical insights on which regressand candidates should be considered in regression models and will answer the main question of this paper: *Which scores to predict in sentence regression for text summarization?* For our experiments, we produce summaries containing 665 characters for DUC2004 and summaries containing 100 words for TAC2008 and TAC2009.

5.1 Regressand Candidates

The key ingredient of greedy extractive summarization is the utility function $u(.)$, which is used for sorting the sentences in the first step of Algorithm 1. In this paper, we examine 7 different regressand candidates (**in boldface**) which can be used as regressands when the utility function u is learned via supervised regression.

ROUGE-1 recall (**R1 Rec**) and ROUGE-2 recall (**R2 Rec**) are computed according to Equation 1 for all sentences in the input documents. ROUGE-n recall counts the n-gram overlap of the input sentence and the reference summaries. The more n-grams in the reference documents are covered by a sentence, the higher the score is. These regressands are usually used by prior sentence regression works.

We also compute the ROUGE-1 precision (**R1 Prec**) and ROUGE-2 precision (**R2 Prec**) for all sentences according to Equation 2. A sentence has a high ROUGE-n precision if a high rate of n-grams in the sentence match with n-grams in the reference documents. Sentences with a high density of matching n-grams are therefore preferred by ROUGE precision. The main claim of this paper is that ROGUE precision scores should be primarily considered in sentence regression works instead of ROUGE recall scores. We therefore expect that R1 Prec and R2 Prec will perform better than R1 Rec and R2 Rec.

As a reference point, we compute for each sentence the maximum similarity (**maxADW**) for and the average similarity (**avgADW**) with all sentences in the reference summaries (denoted by list S) according to a state-of-the-art ADW similarity measure (Pilehvar et al., 2013). ADW computes the semantic similarity of two sentences by finding an optimal alignment of word senses contained in the two sentences.

$$\text{maxADW}(s) = \max_{t \in \text{S}} \text{ADWsim}(s, t) \quad (3)$$

$$\text{avgADW}(s) = \frac{1}{|S|} \cdot \sum_{t \in \text{S}} \text{ADWsim}(s, t) \quad (4)$$

Computing the maximum similarity aligns with the idea that a good sentence in the input documents matches well with one sentence in the reference summary. A sentence is representative for the whole summary if it has a high average similarity with all the reference summary sentences. For each sentence, we also randomly generated (**random**) sentence scores which are used as regressand.

6 Results

6.1 Optimal Prediction without Redundancy Avoidance

In the first experiment, we investigate how helpful the predicted scores are under the assumption that the regressand candidates can be predicted perfectly. The experiment therefore shows how a systems will perform in the optimal case. We do not consider redundancy avoidance strategies in this experiment so that observed performance differences are solely due to differences in the used regressand candidates.

random	31.76	04.66	29.58	04.60	29.88	04.63

Table 1: Summarization results in three different multi-document summarization corpora without redundancy avoidance. Columns R-1 and R-2 display the summary quality according to ROUGE-1 recall and ROUGE-2 recall scores, respectively.

The results of the experiment are shown in Table 1. It can be seen that in all corpora the use of ROUGE-1 precision regressands of the sentences leads to better results than using ROUGE-1 recall regressands if ROUGE-1 recall is used as evaluation metric for the final summary. Analogous results can be observed for ROUGE-2 scores. This indicates that using ROUGE recall as regressand in a sentences regression framework is not very promising. Thus, the results are a first confirmation of the previously described intuition that predicting precision scores can be better than predicting recall scores.

Table 2 provides details about the lengths of the produced summaries according to number of stems and number of sentences. The hypothesis that an algorithm that selects sentences according to recall tends to select longer sentences (stated in Section 4) is confirmed. The results therefore also confirm that longer sentences tend to have a higher recall.

In addition to the standard DUC and TAC corpora, we also report results for 2 German datasets, namely the DBS corpus (Benikova et al., 2016) and a subset of the German part of the auto-hMDS corpus (Zopf et al., 2016; Zopf, 2018). The DBS corpus contains topics from the educational domain. auto-hMDS contains heterogeneous topics retrieved from Wikipedia and automatically collected source documents retrieved from web sites. The results are displayed in Table3 and show that the results can be transferred to German. We additionally observe that ROUGE-1 precision seems to be a bit stronger in DBS compared to ROUGE-2 precision even if the resulting summaries are evaluated with ROUGE-2 recall.

6.2 Optimal Prediction of F-Scores

The previous experiment clearly showed that selecting sentences according to ROUGE precision outperforms a selection according to ROUGE recall. In this experiment, we will evaluate if a trade-off between recall and precision can lead to even better results. It is, e.g., known that in inductive rule learning, parametrized measures such as the m-estimate, which may be viewed as a trade-off between precision and weighted relative accuracy, can be tuned to outperform its constituent heuristics (Janssen and Fürnkranz, 2010). In retrieval tasks, the F-measure provides a more commonly

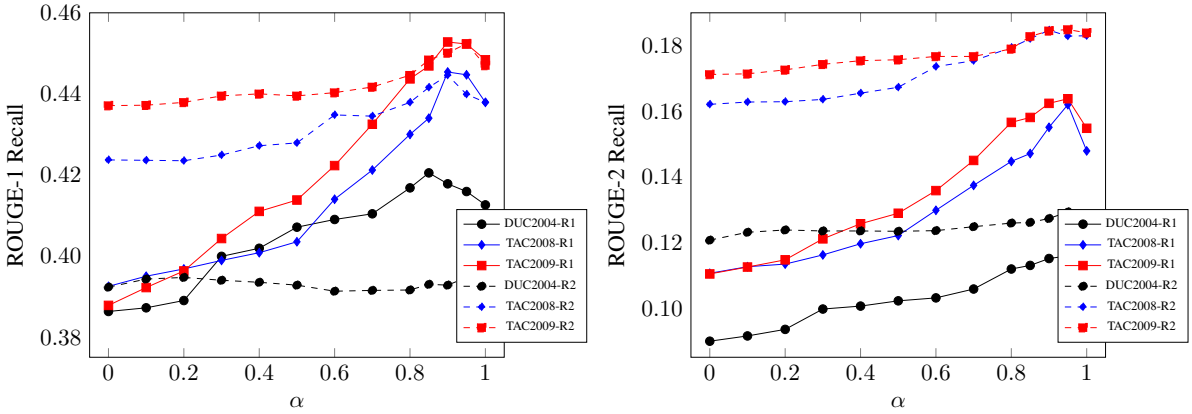

Figure 2: Results of mixing ROUGE-1/2 precision and ROUGE-1/2 recall using $F_\alpha(p, r)$-Measure in different datasets evaluated with ROUGE-1 recall (left) and ROUGE-2 recall (right). For example, the curve labeled DUC2004-R1 shows the results of mixing ROUGE-1 precision and ROUGE-1 recall in the DUC 2004 corpus.

used trade-off between precision and recall, so we chose to use this measure for our experiments. We compute for all sentences the F-measure with $0 \leq \alpha \leq 1$ as

$$F_\alpha(p, r) = \frac{1}{\frac{\alpha}{p} + \frac{1-\alpha}{r}} \quad (5)$$

where a $\alpha = 0$ is equivalent to recall and $\alpha = 1$ equals precision.

The results of the experiment, which are displayed in Figure 2, show that precision ($\alpha = 1.0$) is already close to the optimum but that incorporating also a small fraction of recall ($\alpha \approx 0.9$) leads to the best results which indicates that a slight bias towards longer sentences can improve the result even further. A possible explanation is that there are short sentences in the input documents which are considerably redundant to other high precision sentences. However, overall the trend in the results (increasing evaluation scores with increasing α, which means increasing impact of ROUGE precision) substantiate the general hypothesis of this paper, namely that sentence selection measures should target precision instead of recall.

6.3 Optimal Prediction with Redundancy Avoidance

Summarization systems usually apply a redundancy avoidance strategy in order to avoid including the same information multiple times in the summary. In this experiment, we investigate whether incorporating a simple redundancy avoidance strategy will lead to different results.

During the greedy selection process, we compute the similarity of the currently highest scoring sentence and all already selected sentences (see Algorithm 1, line 4). The highest scoring sentence will be skipped if the maximum similarity of the sentence and the already selected sentences is higher than a predefined threshold θ. We use the state-of-the-art ADW similarity measure to compute the similarities and test the quality of the generated summaries as in the previous experiments with ROUGE-1 and ROUGE-2 recall. The results of the experiment for the thresholds $\theta = 0.4, 0.5, \ldots, 1.0$ are displayed in Figure 3.

We see that sentence selection using ROUGE-1/2 precision scores (red and blue solid lines) consistently leads to better results than with ROUGE-1/2 recall scores (red and blue dashed lines) for all chosen redundancy thresholds. Selecting according to maximum ADW similarity leads to consistently better results than selecting according to the average ADW similarity. This indicates that it is better to search for sentences which align well with a part of the summary than selecting sentences which align relatively well with the whole summary. The best results are achieved with thresholds of $\theta = 0.5$ and $\theta = 0.6$ which worked well for both ROUGE-1 and ROUGE-2 recall in both datasets.

6.4 Noisy Predictions

In the previous experiments, we showed the results of a greedy summarizer which selects sentences according to perfectly predicted scores. Summarization systems are, however, not capable of pre-

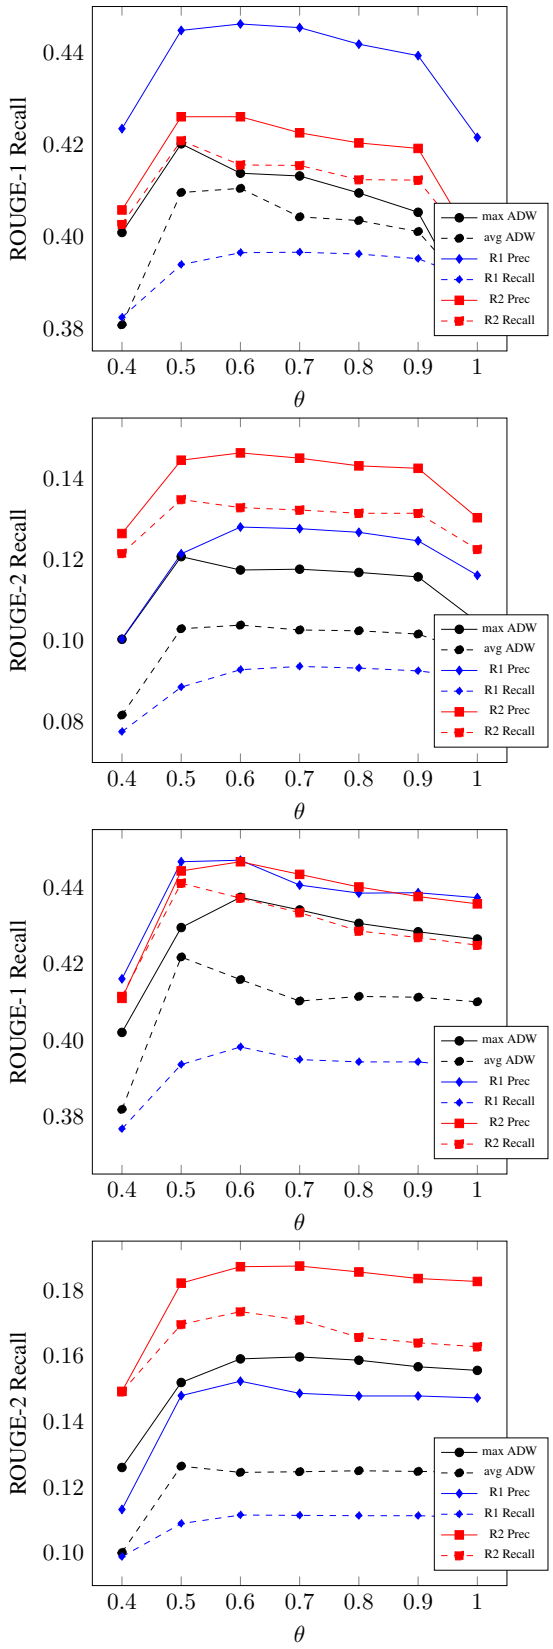

Figure 3: Summary quality assessed with ROUGE-1 recall and ROUGE-2 recall with different redundancy avoidance thresholds θ in the DUC 2004 (top half) and TAC 2008 (bottom half) datasets.

dicting the scores perfectly. We will therefore investigate whether imperfect predictions have an influence on our results in the next experiment. This will also give insights about the robustness of a greedy summarizer in the presence of imprecise predictions.

In order to get model-independent results, we simulate imperfect precisions by adding two different kinds of noise to simulate imperfect predictions, namely additive uniformly distributed continuous noise $\mathcal{U}(a, b)$ and additive Gaussian noise $\mathcal{N}(\mu, \sigma^2)$. For the uniform noise $\mathcal{U}(a, b)$, we test boundaries from $a = -0.2$, $b = 0.2$ to $a = -0.4$, $b = 0.4$. For Gaussian noise, we use mean $\mu = 0$ and variance $\sigma^2 \in \{0.05, 0.1, 0.2\}$. Based on the results in the previous section, we fix the redundancy threshold to 0.6 in this experiment. Due to the random noise, the experiments are no longer deterministic. We therefore run each experiment 10 times and report averaged results.

The results of these experiments (see Table 4) confirm that predicting ROUGE precision is always better than predicting ROUGE recall, in the presence of different kinds of noises and different noise intensities. In case strong Gaussian noise is applied (Table 4, last block), the quality of the

Table 4: Summarization results in three different multi-document summarization corpora with noisy score prediction with uniform noise (top) and Gaussian noise (bottom).

summaries decreases more strongly if ROUGE-2 precision scores are predicted, which means that predicting ROUGE-1 precision might be better than predicting ROUGE-2 precision in the case of low prediction quality.

7 Conclusions

Current state-of-the-art sentence regression systems for automatic summarization learn to predict ROUGE recall scores of individual sentences and apply a greedy sentence selection strategy in order to generate summaries. We show in a wide range of experiments that this design choice leads to suboptimal results. In all experiments, we observed the same pattern. The resulting summaries will have a lower quality if ROUGE recall scores for sentences are used instead of ROUGE precision – no matter whether or not redundancy avoidance is considered and whether or not the scores can be predicted perfectly.

In an experiment where we combined both ROUGE recall and ROUGE precision with an F-score computation, we confirmed the previously described observation that the quality of summaries tends to improve with a growing ratio of ROUGE precision vs. ROUGE recall, with a maximum performance for a ratio of $\alpha \approx 0.9$. Biasing the sentence selection slightly to longer sentences is therefore promising. This goes in line with an often applied pre-processing step in which very short sentences are discarded without further analysis (Erkan and Radev, 2004; Cao et al., 2015b).

We also presented an intuition why a selection according to ROUGE precision leads to better results. A system which selects according to ROUGE recall will tend to select longer sentences, since longer sentences tend to have a higher recall. We conclude that systems should instead of fitting iteratively as much as possible into a summary rather aim at wasting as little space as possible in every step.

For future works, it is very simple to incorporate the findings presented in this paper. Instead of learning to predict ROUGE recall scores, the regressand can simply be exchanged and the ROUGE precision can be used instead. Based on the findings in this paper, we expect that the models will benefit from this modification. We furthermore conclude that comparisons between ILP and greedy methods (Cao et al., 2015a) are biased in favor of ILP. A better comparison is possible if precision scores are used as input for greedy systems instead of recall scores.

Abstract

Variational autoencoders (VAE) combined with hierarchical RNNs have emerged as a powerful framework for conversation modeling. However, they suffer from the notorious degeneration problem, where the decoders learn to ignore latent variables and reduce to vanilla RNNs. We empirically show that this degeneracy occurs mostly due to two reasons. First, the expressive power of hierarchical RNN decoders is often high enough to model the data using only its decoding distributions without relying on the latent variables. Second, the conditional VAE structure whose generation process is conditioned on a context, makes the range of training targets very sparse; that is, the RNN decoders can easily overfit to the training data ignoring the latent variables. To solve the degeneration problem, we propose a novel model named *Variational Hierarchical Conversation RNNs* (VHCR), involving two key ideas of (1) using a hierarchical structure of latent variables, and (2) exploiting an *utterance drop* regularization. With evaluations on two datasets of Cornell Movie Dialog and Ubuntu Dialog Corpus, we show that our VHCR successfully utilizes latent variables and outperforms state-of-the-art models for conversation generation. Moreover, it can perform several new utterance control tasks, thanks to its hierarchical latent structure.

1 Introduction

Conversation modeling has been a long interest of natural language research. Recent approaches for data-driven conversation modeling mostly build upon recurrent neural networks (RNNs) (Vinyals and Le, 2015; Sordoni et al., 2015b; Shang et al., 2015; Li et al., 2017; Serban et al., 2016). Serban et al. (2016) use a hierarchical RNN structure to model the context of conversation. Serban et al. (2017) further exploit an utterance latent variable in the hierarchical RNNs by incorporating the variational autoencoder (VAE) framework (Kingma and Welling, 2014; Rezende et al., 2014).

VAEs enable us to train a latent variable model for natural language modeling, which grants us several advantages. First, latent variables can learn an interpretable holistic representation, such as topics, tones, or high-level syntactic properties. Second, latent variables can model inherently abundant variability of natural language by encoding its global and long-term structure, which is hard to be captured by shallow generative processes (*e.g.* vanilla RNNs) where the only source of stochasticity comes from the sampling of output words.

In spite of such appealing properties of latent variable models for natural language modeling, VAEs suffer from the notorious *degeneration* problem (Bowman et al., 2016; Chen et al., 2017) that occurs when a VAE is combined with a powerful decoder such as autoregressive RNNs. This issue makes VAEs ignore latent variables, and eventually behave as vanilla RNNs. Chen et al. (2017) also note this degeneration issue by showing that a VAE with a RNN decoder prefers to model the data using its decoding distribution rather than using latent variables, from bits-back coding perspective. To resolve this issue, several heuristics have been proposed to weaken the decoder, enforcing the models to use latent variables. For example, Bowman et al. (2016) propose some heuristics, including *KL annealing* and *word drop* regularization. However, these heuristics cannot be a complete solution; for example, we observe that they fail to prevent the degeneracy in VHRED (Serban et al., 2017), a conditional VAE model equipped with hierarchical RNNs for conversation modeling.

The objective of this work is to propose a novel VAE model that significantly alleviates the degen-

Proceedings of NAACL-HLT 2018, pages 1792–1801
New Orleans, Louisiana, June 1 - 6, 2018.

eration problem. Our analysis reveals that the causes of the degeneracy are two-fold. First, the hierarchical structure of autoregressive RNNs is powerful enough to predict a sequence of utterances without the need of latent variables, even with the word drop regularization. Second, we newly discover that the conditional VAE structure where an utterance is generated conditioned on context, *i.e*. a previous sequence of utterances, induces severe data sparsity. Even with a large-scale training corpus, there only exist very few target utterances when conditioned on the context. Hence, the hierarchical RNNs can easily memorize the context-to-utterance relations without relying on latent variables.

We propose a novel model named *Variational Hierarchical Conversation RNN* (VHCR), which involves two novel features to alleviate this problem. First, we introduce a global conversational latent variable along with local utterance latent variables to build a hierarchical latent structure. Second, we propose a new regularization technique called *utterance drop*. We show that our hierarchical latent structure is not only crucial for facilitating the use of latent variables in conversation modeling, but also delivers several additional advantages, including gaining control over the global context in which the conversation takes place.

Our major contributions are as follows:

(1) We reveal that the existing conditional VAE model with hierarchical RNNs for conversation modeling (*e.g*. (Serban et al., 2017)) still suffers from the degeneration problem, and this problem is caused by data sparsity per context that arises from the conditional VAE structure, as well as the use of powerful hierarchical RNN decoders.

(2) We propose a novel variational hierarchical conversation RNN (VHCR), which has two distinctive features: a hierarchical latent structure and a new regularization of utterance drop. To the best of our knowledge, our VHCR is the first VAE conversation model that exploits the hierarchical latent structure.

(3) With evaluations on two benchmark datasets of Cornell Movie Dialog (Danescu-Niculescu-Mizil and Lee, 2011) and Ubuntu Dialog Corpus (Lowe et al., 2015), we show that our model improves the conversation performance in multiple metrics over state-of-the-art methods, including HRED (Serban et al., 2016), and VHRED (Serban et al., 2017) with existing degeneracy solutions such as the word drop (Bowman et al., 2016), and the bag-of-words loss (Zhao et al., 2017).

2 Related Work

Conversation Modeling. One popular approach for conversation modeling is to use RNN-based encoders and decoders, such as (Vinyals and Le, 2015; Sordoni et al., 2015b; Shang et al., 2015). Hierarchical recurrent encoder-decoder (HRED) models (Sordoni et al., 2015a; Serban et al., 2016, 2017) consist of utterance encoder and decoder, and a context RNN which runs over utterance representations to model long-term temporal structure of conversation.

Recently, latent variable models such as VAEs have been adopted in language modeling (Bowman et al., 2016; Zhang et al., 2016; Serban et al., 2017). The VHRED model (Serban et al., 2017) integrates the VAE with the HRED to model Twitter and Ubuntu IRC conversations by introducing an utterance latent variable. This makes a conditional VAE where the generation process is conditioned on the context of conversation. Zhao et al. (2017) further make use of discourse act labels to capture the diversity of conversations.

Degeneracy of Variational Autoencoders. For sequence modeling, VAEs are often merged with the RNN encoder-decoder structure (Bowman et al., 2016; Serban et al., 2017; Zhao et al., 2017) where the encoder predicts the posterior distribution of a latent variable $\mathbf{z}$, and the decoder models the output distributions conditioned on $\mathbf{z}$. However, Bowman et al. (2016) report that a VAE with a RNN decoder easily degenerates; that is, it learns to ignore the latent variable $\mathbf{z}$ and falls back to a vanilla RNN. They propose two techniques to alleviate this issue: *KL annealing* and *word drop*. Chen et al. (2017) interpret this degeneracy in the context of bits-back coding and show that a VAE equipped with autoregressive models such as RNNs often ignores the latent variable to minimize the code length needed for describing data. They propose to constrain the decoder to selectively encode the information of interest in the latent variable. However, their empirical results are limited to an image domain. Zhao et al. (2017) use an auxiliary bag-of-words loss on the latent variable to force the model to use $\mathbf{z}$. That is, they train an auxiliary network that predicts bag-of-words representation of the target utterance based on $\mathbf{z}$. Yet this loss works in an opposite di-

rection to the original objective of VAEs that minimizes the minimum description length. Thus, it may be in danger of forcibly moving the information that is better modeled in the decoder to the latent variable.

3 Approach

We assume that the training set consists of N i.i.d samples of conversations $\{\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_N\}$ where each $\mathbf{c}_i$ is a sequence of utterances (*i.e.* sentences) $\{\mathbf{x}_{i1}, \mathbf{x}_{i2}, ..., \mathbf{x}_{in_i}\}$. Our objective is to learn the parameters of a generative network $\boldsymbol{\theta}$ using Maximum Likelihood Estimation (MLE):

$$\arg\max_{\boldsymbol{\theta}} \sum_i \log p_{\boldsymbol{\theta}}(\mathbf{c}_i) \tag{1}$$

We first briefly review the VAE, and explain the degeneracy issue before presenting our model.

3.1 Preliminary: Variational Autoencoder

We follow the notion of Kingma and Welling (2014). A datapoint $\mathbf{x}$ is generated from a latent variable $\mathbf{z}$, which is sampled from some prior distribution $p(\mathbf{z})$, typically a standard Gaussian distribution $\mathcal{N}(\mathbf{z}|\mathbf{0}, \mathbf{I})$. We assume parametric families for conditional distribution $p_{\boldsymbol{\theta}}(\mathbf{x}|\mathbf{z})$. Since it is intractable to compute the log-marginal likelihood $\log p_{\boldsymbol{\theta}}(\mathbf{x})$, we approximate the intractable true posterior $p_{\boldsymbol{\theta}}(\mathbf{z}|\mathbf{x})$ with a recognition model $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})$ to maximize the *variational lower-bound*:

$$\begin{aligned} &\log p_{\boldsymbol{\theta}}(\mathbf{x}) \geq \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi}; \mathbf{x}) \\ &= \mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})}[-\log q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x}) + \log p_{\boldsymbol{\theta}}(\mathbf{x}, \mathbf{z})] \\ &= -D_{KL}(q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})) + \mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})}[\log p_{\boldsymbol{\theta}}(\mathbf{x}|\mathbf{z})] \end{aligned} \tag{2}$$

Eq. 2 is decomposed into two terms: KL divergence term and reconstruction term. Here, KL divergence measures the amount of information encoded in the latent variable $\mathbf{z}$. In the extreme where KL divergence is zero, the model completely ignores $\mathbf{z}$, *i.e.* it degenerates. The expectation term can be stochastically approximated by sampling $\mathbf{z}$ from the variational posterior $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})$. The gradients to the recognition model can be efficiently estimated using the *reparameterization* trick (Kingma and Welling, 2014).

3.2 VHRED

Serban et al. (2017) propose Variational Hierarchical Recurrent Encoder Decoder (VHRED) model for conversation modeling. It integrates an utterance latent variable $\mathbf{z}_t^{\text{utt}}$ into the HRED structure (Sordoni et al., 2015a) which consists of three RNN components: *encoder RNN*, *context RNN*, and *decoder RNN*. Given a previous sequence of utterances $\mathbf{x}_1, ...\mathbf{x}_{t-1}$ in a conversation, the VHRED generates the next utterance $\mathbf{x}_t$ as:

$$\mathbf{h}_{t-1}^{\text{enc}} = f_{\boldsymbol{\theta}}^{\text{enc}}(\mathbf{x}_{t-1}) \tag{3}$$

$$\mathbf{h}_t^{\text{cxt}} = f_{\boldsymbol{\theta}}^{\text{cxt}}(\mathbf{h}_{t-1}^{\text{cxt}}, \mathbf{h}_{t-1}^{\text{enc}}) \tag{4}$$

$$p_{\boldsymbol{\theta}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_{<t}) = \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t\mathbf{I}) \tag{5}$$

$$\text{where } \boldsymbol{\mu}_t = \text{MLP}_{\boldsymbol{\theta}}(\mathbf{h}_t^{\text{cxt}}) \tag{6}$$

$$\boldsymbol{\sigma}_t = \text{Softplus}(\text{MLP}_{\boldsymbol{\theta}}(\mathbf{h}_t^{\text{cxt}})) \tag{7}$$

$$p_{\boldsymbol{\theta}}(\mathbf{x}_t|\mathbf{x}_{<t}) = f_{\boldsymbol{\theta}}^{\text{dec}}(\mathbf{x}|\mathbf{h}_t^{\text{cxt}}, \mathbf{z}_t^{\text{utt}}) \tag{8}$$

At time step t, the encoder RNN $f_{\boldsymbol{\theta}}^{\text{enc}}$ takes the previous utterance $\mathbf{x}_{t-1}$ and produces an encoder vector $\mathbf{h}_{t-1}^{\text{enc}}$ (Eq. 3). The context RNN $f_{\boldsymbol{\theta}}^{\text{cxt}}$ models the context of the conversation by updating its hidden states using the encoder vector (Eq. 4). The context $\mathbf{h}_t^{\text{cxt}}$ defines the conditional prior $p_{\boldsymbol{\theta}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_{<t})$, which is a factorized Gaussian distribution whose mean $\boldsymbol{\mu}_t$ and diagonal variance $\boldsymbol{\sigma}_t$ are given by feed-forward neural networks (Eq. 5-7). Finally the decoder RNN $f_{\boldsymbol{\theta}}^{\text{dec}}$ generates the utterance $\mathbf{x}_t$, conditioned on the context vector $\mathbf{h}_t^{\text{cxt}}$ and the latent variable $\mathbf{z}_t^{\text{utt}}$ (Eq. 8). We make two important notes: (1) the context RNN can be viewed as a high-level decoder, and together with the decoder RNN, they comprise a hierarchical RNN decoder. (2) VHRED follows a conditional VAE structure where each utterance $\mathbf{x}_t$ is generated conditioned on the context $\mathbf{h}_t^{\text{cxt}}$ (Eq. 5-8).

The variational posterior is a factorized Gaussian distribution where the mean and the diagonal variance are predicted from the target utterance and the context as follows:

$$q_{\boldsymbol{\phi}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_{\leq t}) = \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}_t', \boldsymbol{\sigma}_t' I) \tag{9}$$

$$\text{where } \boldsymbol{\mu}_t' = \text{MLP}_{\boldsymbol{\phi}}(\mathbf{x}_t, \mathbf{h}_t^{\text{cxt}}) \tag{10}$$

$$\boldsymbol{\sigma}_t' = \text{Softplus}(\text{MLP}_{\boldsymbol{\phi}}(\mathbf{x}_t, \mathbf{h}_t^{\text{cxt}})) \tag{11}$$

3.3 The Degeneration Problem

A known problem of a VAE that incorporates an autoregressive RNN decoder is the degeneracy that ignores the latent variable $\mathbf{z}$. In other words, the KL divergence term in Eq. 2 goes to zero and the decoder fails to learn any dependency between the latent variable and the data. Eventually, the model behaves as a vanilla RNN. This problem is

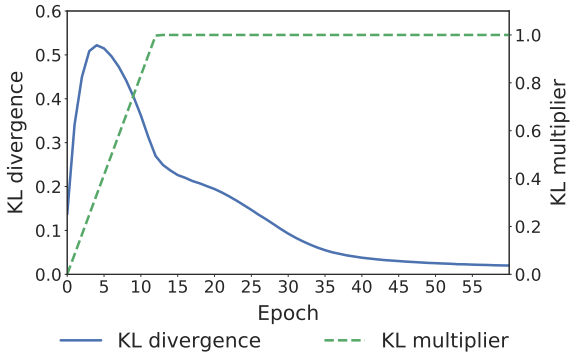

Figure 1: Degeneration of VHRED. The KL divergence term continuously decreases as training proceeds, meaning that the decoder ignores the latent variable $\mathbf{z}^{\text{utt}}$. We train the VHRED on Cornell Movie Dialog Corpus with word drop and KL annealing.

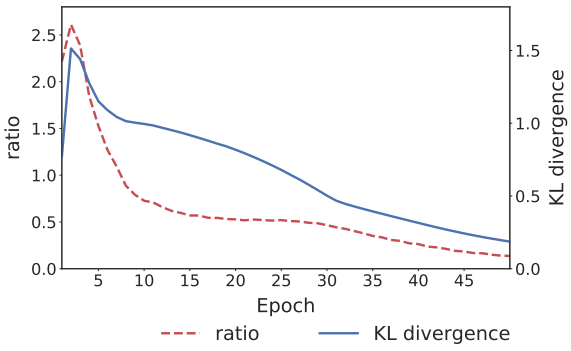

Figure 2: The average ratio $\mathbb{E}[\boldsymbol{\sigma}_t^2]/\text{Var}(\boldsymbol{\mu}_t)$ when the decoder is only conditioned on $\mathbf{z}_t^{\text{utt}}$. The ratio drops to zero as training proceeds, indicating that the conditional priors $p_{\boldsymbol{\theta}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_{<t})$ degenerate to separate point masses.

first reported in the sentence VAE (Bowman et al., 2016), in which following two heuristics are proposed to alleviate the problem by weakening the decoder.

First, the *KL annealing* scales the KL divergence term of Eq. 2 using a KL multiplier λ, which gradually increases from 0 to 1 during training:

$$\tilde{\mathcal{L}}(\boldsymbol{\theta}, \boldsymbol{\phi}; \mathbf{x}) = -\lambda D_{KL}(q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})) + \mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})}[\log p_{\boldsymbol{\theta}}(\mathbf{x}|\mathbf{z})] \quad (12)$$

This helps the optimization process to avoid local optima of zero KL divergence in early training. Second, the *word drop* regularization randomly replaces some conditioned-on word tokens in the RNN decoder with the generic unknown word token (UNK) during training. Normally, the RNN decoder predicts each next word in an autoregressive manner, conditioned on the previous sequence of ground truth (GT) words. By randomly replacing a GT word with an UNK token, the word drop regularization weakens the autoregressive power of the decoder and forces it to rely on the latent variable to predict the next word. The word drop probability is normally set to 0.25, since using a higher probability may degrade the model performance (Bowman et al., 2016).

However, we observe that these tricks do not solve the degeneracy for the VHRED in conversation modeling. An example in Fig. 1 shows that the VHRED learns to ignore the utterance latent variable as the KL divergence term falls to zero.

3.4 Empirical Observation on Degeneracy

The decoder RNN of the VHRED in Eq. 8 conditions on two information sources: deterministic $\mathbf{h}_t^{\text{cxt}}$ and stochastic $\mathbf{z}^{\text{utt}}$. In order to check whether the presence of deterministic source $\mathbf{h}_t^{\text{cxt}}$ causes the degeneration, we drop the deterministic $\mathbf{h}_t^{\text{cxt}}$ and condition the decoder only on the stochastic utterance latent variable $\mathbf{z}^{\text{utt}}$:

$$p_{\boldsymbol{\theta}}(\mathbf{x}_t|\mathbf{x}_{<t}) = f_{\boldsymbol{\theta}}^{\text{dec}}(\mathbf{x}|\mathbf{z}_t^{\text{utt}}) \quad (13)$$

While this model achieves higher values of KL divergence than original VHRED, as training proceeds it again degenerates with the KL divergence term reaching zero (Fig. 2).

To gain an insight of the degeneracy, we examine how the conditional prior $p_{\boldsymbol{\theta}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_{<t})$ (Eq. 5) of the utterance latent variable changes during training, using the model above (Eq. 13). Fig. 2 plots the ratios of $\mathbb{E}[\boldsymbol{\sigma}_t^2]/\text{Var}(\boldsymbol{\mu}_t)$, where $\mathbb{E}[\boldsymbol{\sigma}_t^2]$ indicates the *within variance* of the priors, and $\text{Var}(\boldsymbol{\mu}_t)$ is the *between variance* of the priors. Note that traditionally this ratio is closely related to *Analysis of Variance (ANOVA)* (Lomax and Hahs-Vaughn, 2013). The ratio gradually falls to zero, implying that the priors degenerate to separate point masses as training proceeds. Moreover, we find that the degeneracy of priors coincide with the degeneracy of KL divergence, as shown in (Fig. 2). This is intuitively natural: if the prior is already narrow enough to specify the target utterance, there is little pressure to encode any more information in the variational posterior for reconstruction of the target utterance.

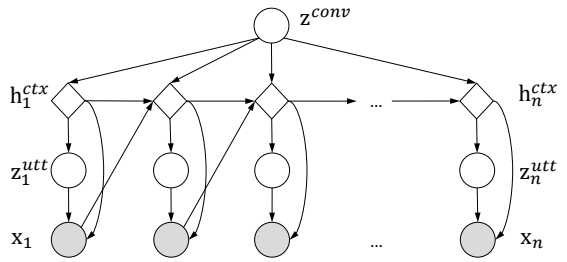

Figure 3: Graphical representation of the Variational Hierarchical Conversation RNN (VHCR). The global latent variable $\mathbf{z}^{\text{conv}}$ provides a global context in which the conversation takes place.

This empirical observation implies that the fundamental reason behind the degeneration may originate from combination of two factors: (1) strong expressive power of the hierarchical RNN decoder and (2) training data sparsity caused by the conditional VAE structure. The VHRED is trained to predict a next target utterance $\mathbf{x}_t$ conditioned on the context $\mathbf{h}_t^{\text{cxt}}$ which encodes information about previous utterances $\{\mathbf{x}_1, \dots, \mathbf{x}_{t-1}\}$. However, conditioning on the context makes the range of training target $\mathbf{x}_t$ very sparse; even in a large-scale conversation corpus such as Ubuntu Dialog (Lowe et al., 2015), there exist one or very few target utterances per context. Therefore, hierarchical RNNs, given their autoregressive power, can easily overfit to training data without using the latent variable. Consequently, the VHRED will not encode any information in the latent variable, i.e. it degenerates. It explains why the word drop fails to prevent the degeneracy in the VHRED. The word drop only regularizes the decoder RNN; however, the context RNN is also powerful enough to predict a next utterance in a given context even with the weakened decoder RNN. Indeed we observe that using a larger word drop probability such as 0.5 or 0.75 only slows down, but fails to stop the KL divergence from vanishing.

3.5 Variational Hierarchical Conversation RNN (VHCR)

As discussed, we argue that the two main causes of degeneration are i) the expressiveness of the hierarchical RNN decoders, and ii) the conditional VAE structure that induces data sparsity. This finding hints us that in order to train a non-degenerate latent variable model, we need to design a model that provides an appropriate way to regularize the hierarchical RNN decoders and alleviate data sparsity per context. At the same time, the model should be capable of modeling complex structure of conversation. Based on these insights, we propose a novel VAE structure named Variational Hierarchical Conversation RNN (VHCR), whose graphical model is illustrated in Fig. 3. Below we first describe the model, and discuss its unique features.

We introduce a global conversation latent variable $\mathbf{z}^{\text{conv}}$ which is responsible for generating a sequence of utterances of a conversation $\mathbf{c} = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$:

$$p_{\boldsymbol{\theta}}(\mathbf{c}|\mathbf{z}^{\text{conv}}) = p_{\boldsymbol{\theta}}(\mathbf{x}_1, \dots, \mathbf{x}_n|\mathbf{z}^{\text{conv}}) \tag{14}$$

Overall, the VHCR builds upon the hierarchical RNNs, following the VHRED (Serban et al., 2017). One key update is to form a hierarchical latent structure, by using the global latent variable $\mathbf{z}^{\text{conv}}$ per conversation, along with local the latent variable $\mathbf{z}_t^{\text{utt}}$ injected at each utterance (Fig. 3):

$$\mathbf{h}_t^{\text{enc}} = f_{\boldsymbol{\theta}}^{\text{enc}}(\mathbf{x}_t) \tag{15}$$

$$\mathbf{h}_t^{\text{cxt}} = \begin{cases} \text{MLP}_{\boldsymbol{\theta}}(\mathbf{z}^{\text{conv}}), & \text{if } t = 0 \\ f_{\boldsymbol{\theta}}^{\text{cxt}}(\mathbf{h}_{t-1}^{\text{cxt}}, \mathbf{h}_{t-1}^{\text{enc}}, \mathbf{z}^{\text{conv}}), & \text{otherwise} \end{cases}$$

$$p_{\boldsymbol{\theta}}(\mathbf{x}_t|\mathbf{x}_{<t}, \mathbf{z}_t^{\text{utt}}, \mathbf{z}^{\text{conv}}) = f_{\boldsymbol{\theta}}^{\text{dec}}(\mathbf{x}|\mathbf{h}_t^{\text{cxt}}, \mathbf{z}_t^{\text{utt}}, \mathbf{z}^{\text{conv}})$$

$$p_{\boldsymbol{\theta}}(\mathbf{z}^{\text{conv}}) = \mathcal{N}(\mathbf{z}|\mathbf{0}, \mathbf{I}) \tag{16}$$

$$p_{\boldsymbol{\theta}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_{<t}, \mathbf{z}^{\text{conv}}) = \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t\mathbf{I}) \tag{17}$$

$$\text{where } \boldsymbol{\mu}_t = \text{MLP}_{\boldsymbol{\theta}}(\mathbf{h}_t^{\text{cxt}}, \mathbf{z}^{\text{conv}}) \tag{18}$$

$$\boldsymbol{\sigma}_t = \text{Softplus}(\text{MLP}_{\boldsymbol{\theta}}(\mathbf{h}_t^{\text{cxt}}, \mathbf{z}^{\text{conv}})). \tag{19}$$

For inference of $\mathbf{z}^{\text{conv}}$, we use a bi-directional RNN denoted by f^{conv}, which runs over the utterance vectors generated by the encoder RNN:

$$q_{\boldsymbol{\phi}}(\mathbf{z}^{\text{conv}}|\mathbf{x}_1, ..., \mathbf{x}_n) = \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}^{\text{conv}}, \boldsymbol{\sigma}^{\text{conv}}I) \tag{20}$$

$$\text{where } \mathbf{h}^{\text{conv}} = f^{\text{conv}}(\mathbf{h}_1^{\text{enc}}, ..., \mathbf{h}_n^{\text{enc}}) \tag{21}$$

$$\boldsymbol{\mu}^{\text{conv}} = \text{MLP}_{\boldsymbol{\phi}}(\mathbf{h}^{\text{conv}}) \tag{22}$$

$$\boldsymbol{\sigma}^{\text{conv}} = \text{Softplus}(\text{MLP}_{\boldsymbol{\phi}}(\mathbf{h}^{\text{conv}})). \tag{23}$$

The posteriors for local variables $\mathbf{z}_t^{\text{utt}}$ are then conditioned on $\mathbf{z}^{\text{conv}}$:

$$q_{\boldsymbol{\phi}}(\mathbf{z}_t^{\text{utt}}|\mathbf{x}_1, ..., \mathbf{x}_n, \mathbf{z}^{\text{conv}}) = \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}_t', \boldsymbol{\sigma}_t'I) \tag{24}$$

$$\text{where } \boldsymbol{\mu}_t' = \text{MLP}_{\boldsymbol{\phi}}(\mathbf{x}_t, \mathbf{h}_t^{\text{cxt}}, \mathbf{z}^{\text{conv}}) \tag{25}$$

$$\boldsymbol{\sigma}_t' = \text{Softplus}(\text{MLP}_{\boldsymbol{\phi}}(\mathbf{x}_t, \mathbf{h}_t^{\text{cxt}}, \mathbf{z}^{\text{conv}})).$$

Our solution of VHCR to the degeneration problem is based on two ideas. The first idea is to build a hierarchical latent structure of $\mathbf{z}^{\text{conv}}$ for

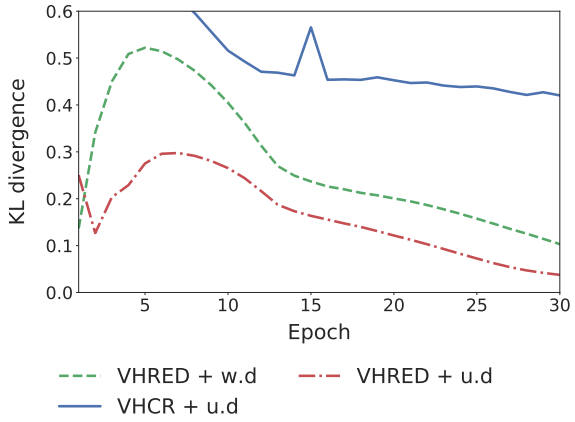

Figure 4: The comparison of KL divergences. The VHCR with the utterance drop shows high and stable KL divergence, indicating the active use of latent variables. w.d and u.d denote the word drop and the utterance drop, respectively.

a conversation and $\mathbf{z}_t^{\text{utt}}$ for each utterance. As $\mathbf{z}^{\text{conv}}$ is independent of the conditional structure, it does not suffer from the data sparsity problem. However, the expressive power of hierarchical RNN decoders makes the model still prone to ignore latent variables $\mathbf{z}^{\text{conv}}$ and $\mathbf{z}_t^{\text{utt}}$. Therefore, our second idea is to apply an *utterance drop* regularization to effectively regularize the hierarchical RNNs, in order to facilitate the use of latent variables. That is, at each time step, the utterance encoder vector $\mathbf{h}_t^{\text{enc}}$ is randomly replaced with a generic unknown vector $\mathbf{h}^{\text{unk}}$ with a probability p. This regularization weakens the autoregressive power of hierarchical RNNs and as well alleviates the data sparsity problem, since it induces noise into the context vector $\mathbf{h}_t^{\text{cxt}}$ which conditions the decoder RNN. The difference with the word drop (Bowman et al., 2016) is that our utterance drop depresses the hierarchical RNN decoders as a whole, while the word drop only weakens the lower-level decoder RNNs. Fig. 4 confirms that with the utterance drop with a probability of 0.25, the VHCR effectively learns to use latent variables, achieving a significant degree of KL divergence.

3.6 Effectiveness of Hierarchical Latent Structure

Is the hierarchical latent structure of the VHCR crucial for effective utilization of latent variables? We investigate this question by applying the utterance drop on the VHRED which lacks any hierarchical latent structure. We observe that the KL divergence still vanishes (Fig. 4), even though the utterance drop injects considerable noise in the context $\mathbf{h}_t^{\text{cxt}}$. We argue that the utterance drop weakens the context RNN, thus it consequently fail to predict a reasonable prior distribution for $\mathbf{z}^{\text{utt}}$ (Eq. 5-7). If the prior is far away from the region of $\mathbf{z}^{\text{utt}}$ that can generate a correct target utterance, encoding information about the target in the variational posterior will incur a large KL divergence penalty. If the penalty outweighs the gain of the reconstruction term in Eq. 2, then the model would learn to ignore $\mathbf{z}^{\text{utt}}$, in order to maximize the variational lower-bound in Eq. 2.

On the other hand, the global variable $\mathbf{z}^{\text{conv}}$ allows the VHCR to predict a reasonable prior for local variable $\mathbf{z}_t^{\text{utt}}$ even in the presence of the utterance drop regularization. That is, $\mathbf{z}^{\text{conv}}$ can act as a *guide* for $\mathbf{z}^{\text{utt}}$ by encoding the information for local variables. This reduces the KL divergence penalty induced by encoding information in $\mathbf{z}^{\text{utt}}$ to an affordable degree at the cost of KL divergence caused by using $\mathbf{z}^{\text{conv}}$. This trade-off is indeed a fundamental strength of hierarchical models that provide *parsimonious* representation; if there exists any shared information among the local variables, it is coded in the global latent variable reducing the code length by effectively reusing the information. The remaining local variability is handled properly by the decoding distribution and local latent variables.

The global variable $\mathbf{z}^{\text{conv}}$ provides other benefits by representing a latent global structure of a conversation, such as a topic, a length, and a tone of the conversation. Moreover, it allows us to control such global properties, which is impossible for models without hierarchical latent structure.

4 Results

We first describe our experimental setting, such as datasets and baselines (section 4.1). We then report quantitative comparisons using three different metrics (section 4.2–4.4). Finally, we present qualitative analyses, including several utterance control tasks that are enabled by the hierarchal latent structure of our VHCR (section 4.5). We defer implementation details and additional experiment results to the supplementary file.

4.1 Experimental Setting

Datasets. We evaluate the performance of conversation generation using two benchmark datasets: 1) Cornell Movie Dialog Corpus (Danescu-

Table 2: KL divergence decomposition. VHRED and VHCR are trained with word drop and utterance drop respectively.

Niculescu-Mizil and Lee, 2011), containing 220,579 conversations from 617 movies. 2) Ubuntu Dialog Corpus (Lowe et al., 2015), containing about 1 million multi-turn conversations from Ubuntu IRC channels. In both datasets, we truncate utterances longer than 30 words.

Baselines. We compare our approach with four baselines. They are combinations of two state-of-the-art models of conversation generation with different solutions to the degeneracy. (i) Hierarchical recurrent encoder-decoder (HRED) (Serban et al., 2016), (ii) Variational HRED (VHRED) (Serban et al., 2017), (iii) VHRED with the word drop (Bowman et al., 2016), and (iv) VHRED with the bag-of-words (bow) loss (Zhao et al., 2017).

Performance Measures. Automatic evaluation of conversational systems is still a challenging problem (Liu et al., 2016). Based on literature, we report three quantitative metrics: i) the negative log-likelihood (the variational bound for variational models), ii) embedding-based metrics (Serban et al., 2017), and iii) human evaluation via Amazon Mechanical Turk (AMT).

4.2 Results of Negative Log-likelihood

Table 1 summarizes the per-word negative log-likelihood (NLL) evaluated on the test sets of two datasets. For variational models, we instead present the variational bound of the negative log-likelihood in Eq. 2, which consists of the reconstruction error term and the KL divergence term. The KL divergence term can measure how much each model utilizes the latent variables.

We observe that the NLL is the lowest by the HRED. Variational models show higher NLLs, because they are regularized methods that are forced to rely more on latent variables. Independent of NLL values, we later show that the latent variable models often show better generalization performance in terms of embedding-based metrics and human evaluation. In the VHRED, the KL divergence term gradually vanishes even with the word drop regularization; thus, early stopping is necessary to obtain a meaningful KL divergence. The VHRED with the bag-of-words loss (bow) achieves the highest KL divergence, however, at the cost of high NLL values. That is, the variational lower-bound minimizes the minimum description length, to which the bow loss works in an opposite direction by forcing latent variables to encode bag-of-words representation of utterances. Our VHCR achieves stable KL divergence without any auxiliary objective, and the NLL is lower than the VHRED + bow model.

Table 2 summarizes how global and latent variable are used in the VHCR. We observe that VHCR encodes a significant amount of information in the global variable $\mathbf{z}^{\text{conv}}$ as well as in the local variable $\mathbf{z}^{\text{utt}}$, indicating that the VHCR successfully exploits its hierarchical latent structure.

4.3 Results of Embedding-Based Metrics

The embedding-based metrics (Serban et al., 2017; Rus and Lintean, 2012) measure the textual similarity between the words in the model response and the ground truth. We represent words using Word2Vec embeddings trained on the Google News Corpus[1]. The *average* metric projects each utterance to a vector by taking the mean over word embeddings in the utterance, and computes the cosine similarity between the model response vector and the ground truth vector. The *extrema* metric is similar to the average metric, only except that it takes the extremum of each di-

(b) Ubuntu Dialog

Table 3: Results of embedding-based metrics. 1-turn and 3-turn responses of models per context.

mension, instead of the mean. The *greedy* metric first finds the best non-exclusive word alignment between the model response and the ground truth, and then computes the mean over the cosine similarity between the aligned words.

Table 3 compares the different methods with three embedding-based metrics. Each model generates a single response (1-turn) or consecutive three responses (3-turn) for a given context. For 3-turn cases, we report the average of metrics measured for three turns. We use the greedy decoding for all the models.

Our VHCR achieves the best results in most metrics. The HRED is the worst on the Cornell Movie dataset, but outperforms the VHRED and VHRED + bow on the Ubuntu Dialog dataset. Although the VHRED + bow shows the highest KL divergence, its performance is similar to that of VHRED, and worse than that of the VHCR model. It suggests that a higher KL divergence does not necessarily lead to better performance; it is more important for the models to balance the modeling powers of the decoder and the latent variables. The VHCR uses a more sophisticated hierarchical latent structure, which better reflects the structure of natural language conversations.

4.4 Results of Human Evaluation

Table 4 reports human evaluation results via Amazon Mechanical Turk (AMT). The VHCR outperforms the baselines in both datasets; yet the performance improvement in Cornell Movie Dialog are less significant compared to that of Ubuntu. We empirically find that Cornell Movie dataset is small in size, but very diverse and complex in content and style, and the models often fail to generate sensible responses for the context. The performance gap with the HRED is the smallest, suggesting that the VAE models without hierarchical latent structure have overfitted to Cornell Movie dataset.

4.5 Qualitative Analyses

Comparison of Predicted Responses. Table 5 compares the generated responses of algorithms. Overall, the VHCR creates more consistent responses within the context of a given conversation. This is supposedly due to the global latent variable $\mathbf{z}^{\text{conv}}$ that provides a more direct and effective way to handle the global context of a conversation. The context RNN of the baseline models can handle long-term context to some extent, but not as much as the VHCR.

Interpolation on $\mathbf{z}^{\text{conv}}$. We present examples of one advantage by the hierarchical latent structure of the VHCR, which cannot be done by the other existing models. Table 6 shows how the generated responses vary according to the interpolation on $\mathbf{z}^{\text{conv}}$. We randomly sample two $\mathbf{z}^{\text{conv}}$ from a standard Gaussian prior as references (*i.e.* the top and the bottom row of Table 6), and interpolate points between them. We generate 3-turn conversations conditioned on given $\mathbf{z}^{\text{conv}}$. We see that $\mathbf{z}^{\text{conv}}$ controls the overall tone and content of conversations; for example, the tone of the response is friendly in the first sample, but gradually becomes hostile as $\mathbf{z}^{\text{conv}}$ changes.

Generation on a Fixed $\mathbf{z}^{\text{conv}}$. We also study how fixing a global conversation latent variable $\mathbf{z}^{\text{conv}}$ affects the conversation generation. Table 7 shows an example, where we randomly fix a reference $\mathbf{z}^{\text{conv}}$ from the prior, and generate multiple examples of 3-turn conversation using randomly sampled local variables $\mathbf{z}^{\text{utt}}$. We observe that $\mathbf{z}^{\text{conv}}$ heavily affects the form of the first utterance; in the examples, the first utterances all start with a "where" phrase. At the same time, responses show

where is she? → she's the only one who knows where she is, she's going to be all right. → oh, you're the only one who's gon na be. she's a <unk>.
where's my wife? → you've got to get out of here, you know? you're the one who's gon na be here. → oh, that's nice.
where are you? → well, i was just thinking about you and i know what you're doing. i'm going to have to go to the <unk> and i'm → i'm sorry.
where are you going? → to get you to the airport. → you're going to be late?
where are you going? → to the <unk>. i am not going to tell you what i am. i am the only one who has to be. i will be the → you've got to stop!

Table 7: An example of 3-turn responses conditioned on sampled $\mathbf{z}^{\text{utt}}$ for a single fixed $\mathbf{z}^{\text{conv}}$.

variations according to different local variables $\mathbf{z}^{\text{utt}}$. These examples show that the hierarchical latent structure of VHCR allows both global and fine-grained control over generated conversations.

5 Discussion

We introduced the variational hierarchical conversation RNN (VHCR) for conversation modeling. We noted that the degeneration problem in existing VAE models such as the VHRED is persistent, and proposed a hierarchical latent variable model with the utterance drop regularization. Our VHCR obtained higher and more stable KL divergences than various versions of VHRED models without using any auxiliary objective. The empirical results showed that the VHCR better reflected the structure of natural conversations, and outperformed previous models. Moreover, the hierarchical latent structure allowed both global and fine-grained control over the conversation generation.

Abstract

Virtual agents are becoming a prominent channel of interaction in customer service. Not all customer interactions are smooth, however, and some can become almost comically bad. In such instances, a human agent might need to step in and salvage the conversation. Detecting bad conversations is important since disappointing customer service may threaten customer loyalty and impact revenue. In this paper, we outline an approach to detecting such *egregious* conversations, using behavioral cues from the user, patterns in agent responses, and user-agent interaction. Using logs of two commercial systems, we show that using these features improves the detection F1-score by around 20% over using textual features alone. In addition, we show that those features are common across two quite different domains and, arguably, universal.

1 Introduction

Automated conversational agents (chatbots) are becoming widely used for various tasks such as personal assistants or as customer service agents. Recent studies project that 80% of businesses plan to use chatbots by 2020[1], and that chatbots will power 85% of customer service interactions by the year 2020[2]. This increasing usage is mainly due to advances in artificial intelligence and natural language processing (Hirschberg and Manning, 2015) along with increasingly capable chat development environments, leading to improvements in conversational richness and robustness.

Still, chatbots may behave extremely badly, leading to conversations so off-the-mark that only a human agent could step in and salvage them. Consequences of these failures may include loss of customer goodwill and associated revenue, and even exposure to litigation if the failures can be shown to include fraudulent claims. Due to the increasing prevalence of chatbots, even a small fraction of such egregious[3] conversations could be problematic for the companies deploying chatbots and the providers of chatbot services.

In this paper we study detecting these egregious conversations that can arise in numerous ways. For example, incomplete or internally inconsistent training data can lead to false classification of user intent. Bugs in dialog descriptions can lead to dead ends. Failure to maintain adequate context can cause chatbots to miss anaphoric references. In the extreme case, malicious actors may provide heavily biased (e.g., the Tay chatbot[4]) or even hacked misbehaviors.

In this article, we focus on customer care systems. In such setting, a conversation usually becomes egregious due to a combination of the aforementioned problems. The resulting customer frustration may not surface in easily detectable ways such as the appearance of all caps, shouting to a speech recognizer, or the use of profanity or extreme punctuation. Consequently, the chatbot will continue as if the conversation is proceeding well, usually

Customer: *I got 2 quotes for the flight ticket, but i'm wondering what the details of each ticket are?*
Agent: *Please select "Buy" next to the ticket you'd like to purchase.*
Customer: *No, I don't want to buy yet till I know the details of the flights.*
Agent: *If you're in the process of renting a car, please continue with by clicking "Next"*
Customer: *Are you a real person?*
Agent: *I am a digital assistant. I've been trained to answer questions about travels. Ask me any questions you have.*
Customer: *I asked a specific question and you gave me a random answer about car rental which I'm not interested in.*
Agent: *I'm not trained on that yet, but I'm still learning. You may want to rephrase your question and try again.*
Customer: *This service is pointless , can i talk to a real live person?*
Agent: *We don't currently have live agents to chat with online.*

Figure 1: Example of an *egregious* conversation.

leading to conversational breakdown.

Consider, for example, the anonymized but representative conversation depicted in Figure 1. Here the customer aims to understand the details of a flight ticket. In the first two turns, the chatbot misses the customer's intentions, which leads to the customer asking "Are you a real person?". The customer then tries to explain what went wrong, but the chatbot has insufficient exposure to this sort of utterance to provide anything but the default response ("I'm not trained on that"). The response seems to upset the customer and leads to a request for a human agent, which is rejected by the system ("We don't currently have live agents"). Such rejection along with the previous responses could lead to customer frustration (Amsel, 1992).

Being able to automatically detect such conversations, either in real time or through log analysis, could help to improve chatbot quality. If detected in real time, a human agent can be pulled in to salvage the conversation. As an aid to chatbot improvement, analysis of egregious conversations can often point to problems in training data or system logic that can be repaired. While it is possible to scan system logs by eye, the sheer volume of conversations may overwhelm the analyst or lead to random sampling that misses important failures. If, though, we can automatically detect the worst conversations (in our experience, typically under 10% of the total), the focus can be on fixing the worst problems.

Our goal in this paper is to study conversational features that lead to egregious conversations. Specifically, we consider customer inputs throughout a whole conversation, and detect cues such as rephrasing, the presence of heightened emotions, and queries about whether the chatbot is a human or requests to speak to an actual human. In addition, we analyze the chatbot responses, looking for repetitions (e.g. from loops that might be due to flow problems), and the presence of "not trained" responses. Finally, we analyze the larger conversational context exploring, for example, where the presence of a "not trained" response might be especially problematic (e.g., in the presence of strong customer emotion).

The main contributions of this paper are twofold: (1) This is the first research focusing on detecting egregious conversations in conversational agent (chatbot) setting and (2) this is the first research using unique agent, customer, and customer-agent interaction features to detect egregiousness.

The rest of this paper is organized as follows. We review related work, then we formally define the methodology for detecting egregious conversations. We describe our data, experimental setting, and results. We then conclude and suggest future directions.

2 Related Work

Detecting egregious conversations is a new task, however, there is related work that aim at measuring the general quality of the interactions in conversational systems. These works studied the complementary problem of detecting and measuring user satisfaction and engagement. Early work by (Walker et al., 1997, 2001) discussed a framework that maximizes the user satisfaction by considering measures such as number of inappropriate utterances, recognition rates, number of times user requests repetitions, number of turns per interaction, etc. Shortcomings of this approach are discussed by (Hajdinjak and Mihelic, 2006). Other works focus on predicting the user engagement in such systems. Examples include (Kiseleva et al., 2016b,a; Jiang et al., 2015). Specifically, these

works evaluated chat functionality by asking users to make conversations with an intelligent agent and measured the user satisfaction along with other features such as the automatic speech recognition (ASR) quality and intent classification quality. In (Sandbank et al., 2017) the authors presented a conversational system enhanced with emotion analysis, and suggested using emotions as triggers for human escalation. In our work, we likewise use emotion analysis as predictive features for egregious conversation. The works of (Sarikaya, 2017; Sano et al., 2017) studied reasons why users reformulated utterances in such systems. Specifically, in (Sarikaya, 2017) they reported on how the different reasons affect the users' satisfaction. In (Sano et al., 2017) they focused on how to automatically predict the reason for user's dissatisfaction using different features. Our work also explores user reformulation (or rephrasing) as one of the features to predict egregious conversations. We build on the previous work by leveraging some of the approaches in our classifier for egregious conversations. In (Walker et al., 2000; Hastie et al., 2002) the authors also looked for problems in a specific setting of spoken conversations. The main difference with our work is that we focus on chat logs for domains for which the expected user utterances are a bit more diverse, using interaction features as well as features that are not sensitive to any architectural aspects of the conversational system (e.g., ASR component). Several other approaches for evaluating chatbot conversations indirectly capture the notion of conversational quality. For example, several prior works borrowed from the field of pragmatics in various metrics around the principles of cooperative conversation (Chakrabarti and Luger, 2013; Saygin A. P., 2002). In (Steidl et al., 2004) they measured dialogue success at the turn level as a way of predicting the success of a conversation as a whole. (Webb et al., 2010) created a measure of dialogue appropriateness to determine its role in maintaining a conversation. Recently, (Liu et al., 2016) evaluated a number of popular measures for dialogue response generation systems and highlighted specific weaknesses in the measures. Similarly, in (Sebastian et al., 2009) they developed a taxonomy of available measures for an end-user's quality of experience for multimodel dialogue systems, some of which touch on conversational quality. All these measures may serve as reasons for a conversation turning egregious, but none try to capture or predict it directly.

In the domain of customer service, researchers mainly studied reasons for failure of such systems along with suggestions for improved design (Mimoun et al., 2012; Gnewuch et al., 2017). In (Mimoun et al., 2012) the authors analyzed reasons sales chatbots fail by interviewing chatbots experts. They found that a combination of exaggerated customer expectations along with a reduction in agent performance (e.g., failure to listen to the consumer, being too intrusive) caused customers to stop using such systems. Based on this qualitative study, they proposed an improved model for sales chatbots. In (Gnewuch et al., 2017) they studied service quality dimensions (i.e., reliability, empathy, responsiveness, and tangibility) and how to apply them during agent design. The main difference between those works and ours is that they focus on qualitative high-level analysis while we focus on automatic detection based on the conversations logs.

3 Methodology

The objective of this work is to reliably detect egregious conversations between a human and a virtual agent. We treat this as a binary classification task, where the target classes are "egregious" and "non-egregious". While we are currently applying this to complete conversations (i.e., the classification is done on the whole conversation), some of the features examined here could likely be used to detect egregious conversations as they were unfolding in real time. To perform egregious conversation detection, features from both customer inputs and agent responses are extracted, together with features related to the combination of specific inputs and responses. In addition, some of these features are *contextual*, meaning that they are dependent on *where* in the conversation they appear.

Using this set of features for detecting egre-

gious conversations is novel, and as our experimental results show, improves performance compared to a model based solely on features extracted from the conversation's text. We now describe the agent, customer, and combined customer-agent features.

3.1 Agent Response Features

A virtual agent is generally expected to closely simulate interactions with a human operator (Reeves and Nass, 1996; Nass and Moon,Y, 2000; Krämer, 2008). When the agent starts losing the context of a conversation, fails in understanding the customer intention, or keeps repeating the same responses, the illusion of conversing with a human is lost and the conversation may become extremely annoying. With this in mind, we now describe the analysis of the agent's responses and associated features (summarized in the top part of Table 1).

3.1.1 Repeating Response Analysis

As typically implemented, the virtual agent's task is to reliably detect the intent of each customer's utterance and respond meaningfully. Accurate intent detection is thus a fundamental characteristic of well-trained virtual agents, and incorrect intent analysis is reported as the leading cause of user dissatisfaction (Sarikaya, 2017). Moreover, since a classifier (e.g., SVM, neural network, etc.) is often used to detect intents, its probabilistic behavior can cause the agent to repeat the same (or semantically similar) response over and over again, despite the user's attempt to rephrase the same intent.

Such agent repetitions lead to an unnatural interaction (Klüwer, 2011). To identify the agent's repeating responses, we measured similarity between agent's subsequent (not necessarily sequential) turns. We represented each sentence by averaging the pre-trained embeddings[5] of each word in the sentence, calculating the cosine similarity between the representations. Turns with a high similarity value[6] are considered as repeating responses.

[5]https://code.google.com/archive/p/word2vec

[6]Empirically, similarity values ≥ 0.8

3.1.2 Unsupported Intent Analysis

Given that the knowledge of a virtual agent is necessarily limited, we can expect that training would not cover all customer intents. If the classifier technology provides an estimate of classification confidence, the agent can respond with some variant of "I'm not trained on that" when confidence is low. In some cases, customers will accept that not all requests are supported. In other cases, unsupported intents can lead to customer dissatisfaction (Sarikaya, 2017), and cascade to an egregious conversation (as discussed below in Section 3.3). We extracted the possible variants of the unsupported intent messages directly from the system, and later matched them with the agent responses from the logs.

3.2 Customer Inputs Features

From the customer's point of view, an ineffective interaction with a virtual agent is clearly undesirable. An ineffective interaction requires the expenditure of relatively large effort from the customer with little return on the investment (Zeithaml et al., 1990; Mimoun et al., 2012). These efforts can appear as behavioral cues in the customer's inputs, and include emotions, repetitions, and more. We used the following customer analysis in our model. Customer features are summarized in the middle part of Table 1.

3.2.1 Rephrasing Analysis

When a customer repeats or rephrases an utterance, it usually indicates a problem with the agent's understanding of the customer's intent. This can be caused by different reasons as described in (Sano et al., 2017). To measure the similarity between subsequent customer turns to detect repetition or rephrasing, we used the same approach as described in Section 3.1.1. Turns with a high similarity value[6] are considered as rephrases.

3.2.2 Emotional Analysis

The customer's emotional state during the conversation is known to correlate with the conversation's quality (Oliver, 2014). In order to analyze the emotions that customers exhibit in each turn, we utilized the IBM Tone Analyzer service, available publicly online[7].

[7]https://ibm.co/2hnYkCv

This service was trained using customer care interactions, and infers emotions such as *frustration*, *sadness*, *happiness*. We focused on negative emotions (denoted as NEG EMO) to identify turns with a negative emotional peak (i.e., single utterances that carried high negative emotional state), as well as to estimate the aggregated negative emotion throughout the conversation (i.e., the averaged negative emotion intensity). In order to get a more robust representation of the customer's negative emotional state, we summed the score of the negative emotions (such as *frustration*, *sadness*, *anger*, etc.) into a single negative sentiment score (denoted as NEG SENT). Note that we used the positive emotions as a filter for other customer features, such as the rephrasing analysis. Usually, high positive emotions capture different styles of "thanking the agent", or indicate that the customer is somewhat satisfied (Rychalski and Hudson, 2017), thus, the conversation is less likely to become egregious.

3.2.3 Asking for a Human Agent

In examining the conversation logs, we noticed that it is not unusual to find a customer asking to be transferred to a human agent. Such a request might indicate that the virtual agent is not providing a satisfactory service. Moreover, even if there are human agents, they might not be available at all times, and thus, a rejection of such a request is sometimes reasonable, but might still lead to customer frustration (Amsel, 1992).

3.2.4 Unigram Input

In addition to the above analyses, we also detected customer turns that contain exactly one word. The assumption is that single word (unigram) sentences are probably short customer responses (e.g., no, yes, thanks, okay), which in most cases do not contribute to the egregiousness of the conversation. Hence, calculating the percentage of those turns out of the whole conversation gives us another measurable feature.

3.3 Customer-Agent Interaction Features

We also looked at features across conversation utterance-response pairs in order to capture a more complete picture of the interaction between the customer and the virtual agent. Here, we considered a pair to be customer utterance followed by an agent response. For example, a pair may contain a turn in which the customer expressed negative emotions and received a response of "not trained" by the agent. In this case, we would leverage the two analyses: emotional and unsupported intent. Figure 1 gives an example of this in the customer's penultimate turn. Such interactions may divert the conversation towards becoming egregious. These features are summarized in the last part of Table 1.

Group	Feature	Description	Contextual?
Agent	AGNT RPT	Similarity of subsequent agent responses	Yes
	#AGNT !TRND	Number of times the agent replied with "not trained"	No
Customer	MAX 3 RPHRS	Max rephrasing similarity score of 3 subsequent turns	Yes
	#RPHRS	Number of customer rephrasing throughout the conversation	Yes
	MAX NEG EMO	Max negative emotion in the conversation	No
	NEG SENT	Aggregated negative sentiment in the conversation	No
	DIFF NEG SENT	Difference between max turn-level negative sentiment and conversation-level	Yes + No
	RPHRS & NEG SENT	Rephrasing of subsequent turns with an average high negative sentiment	Yes
	HMN AGT & NEG SENT	Negative sentiment when asking for a human agent	No
	#1 WRD	Turns that contained only one word	Yes
Customer-Agent Interaction	NEG SENT & AGNT !TRND	Customer negative sentiment with agent replying "not trained"	No
	HMN AGT & AGNT !TRND	Customer asking to talk to a human agent followed by the agent replying "not trained"	No
	LNG SNTNS & AGNT !TRND	Customer long turn followed by an agent "not trained" response	No
	RPHRS & SMLR	The similarity between the customer's turn and the agent's response in case of customer rephrasing	No
	RPHRS & AGNT !TRND	The similarity between the customer's turns when the agent's response is "not trained"	No
	CONV LEN	Total number of customer turns and agent responses	No

Table 1: Features sets description.

3.3.1 Similarity Analysis

We also calculated the similarity between the customer's turn and the virtual agent's response in cases of customer rephrasing. This analysis aims to capture the reason for the customer rephrasing. When a similarity score between the customer's turn and the agent's response is low, this may indicate a misclassified intent, as the agent's responses are likely to share some textual similarity to the customer's utterance. Thus, a low score may indicate a poor interaction, which might lead the conversation to become egregious. Another similarity feature is between two customer's subsequent turns when the agent's response was "not trained".

3.4 Conversation Egregiousness Prediction Classifier

We trained a binary SVM classifier with a linear kernel. A feature vector for a sample in the training data is generated using the scores calculated for the described features, where each feature value is a number between [0,1]. After the model was trained, test conversations are classified by the model, after being transformed to a feature vector in the same way a training sample is transformed. The SVM classification model (denoted *EGR*) outputs a label "egregious" or "non-egregious" as a prediction for the conversation.

4 Experiments

4.1 Dataset

We extracted data from two commercial systems that provide customer support via conversational bots (hereafter denoted as *company A* and *company B*). Both agents are using similar underlying conversation engines, each embedded in a larger system with its own unique business logic. *Company A*'s system deals with sales support during an online purchase, while *company B*'s system deals with technical support for purchased software products. Each system logs conversations, and each conversation is a sequence of tuples, where each tuple consists of {*conversation id, turn id, customer input, agent response*}. From each system, we randomly extracted 10000 conversations. We further removed conversations that contained fewer than 2 turns, as these are too short to be meaningful since the customer never replied or provided more details about the issue at hand. Figure 2 depicts the frequencies of conversation lengths which follow a power-law relationship. The conversations from *company A*'s system tend to be longer, with an average of 8.4 turns vs. an average of 4.4 turns for *company B*.

4.2 Experimental Setup

The first step in building a classification model is to obtain ground truth data. For this purpose, we randomly sampled conversations from our datasets. This sample included 1100 and 200 conversations for *company A* and *company B* respectively. The sampled conversations were tagged using an in-house tagging system designed to increase the consistency of human judgements. Each conversation was tagged by four different expert judges[8]. Given the full conversation, each judge tagged whether the conversation was egregious or not following this guideline: "Conversations which are extraordinarily bad in some way, those conversations where you'd like to see a human jump in and *save* the conversation".

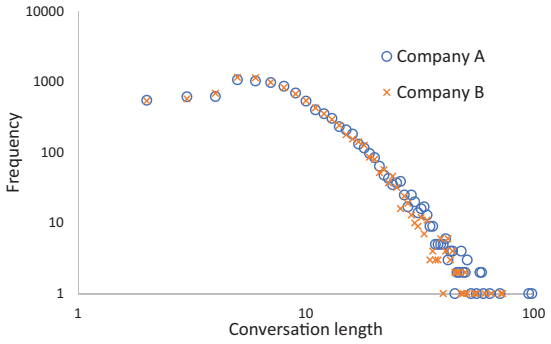

Figure 2: Frequency versus conversation length for *company A* and *company B* on a log-log scale.

We generated true binary labels by considering a conversation to be egregious if at least three of the four judges agreed. The inter-rater reliability between all judges, measured by Cohen's Kappa, was 0.72 which indicates high level agreement. This process generated the egregious class sizes of 95 (8.6%) and 16 (8%) for *company A* and *company B*, respectively. This verifies the unbalanced data expectation as previously discussed.

We also implemented two baseline models, rule-based and text-based, as follows:

Rule-based. In this approach, we look for cases in which the virtual agent responded with a "not trained" reply, or occurrences of the customer requesting to talk to a human agent. As discussed earlier, these may be indicative of the customer's dissatisfaction with the nature of the virtual agent's responses.

Text-based. A model that was trained to predict egregiousness given the conversation's text (all customer and agent's text dur-

[8]judges that are HCI experts and have experience in designing conversational agents systems.

	Egregious			Non-Egregious		
Model	P	R	F	P	R	F
Rule-based	0.28	0.54	0.37	0.95	0.87	0.91
Text-based	0.46	0.56	0.50	0.96	**0.94**	**0.95**
EGR	**0.47**	**0.79**	**0.59**	**0.98**	0.92	**0.95**

Table 2: Cross-validation results for the baselines and *EGR* models.

ing the conversation). This model was implemented using state-of-the-art textual features as in (Herzig et al., 2017). In (Herzig et al., 2017) emotions are detected from text, which can be thought of as similar to our task of predicting egregious conversations.

We evaluated these baseline methods against our classifier using 10-fold cross-validation over *company A*'s dataset (we did not use *company B*'s data for training due to the low number of tagged conversations). Since class distribution is unbalanced, we evaluated classification performance by using precision (P), recall (R) and F1-score (F) for each class. The *EGR* classifier was implemented using an SVM with a linear kernel[9].

4.3 Classification Results

Table 2 depicts the classification results for both classes and the three models we explored. The *EGR* model significantly outperformed both baselines[10]. Specifically, for the egregious class, the precision obtained by the text-based and *EGR* models were similar. This indicates that the text analyzed by both models encodes some information about egregiousness. On the other hand, for the recall and hence the F1-score, the *EGR* model relatively improved the text-based model by 41% and 18%, respectively. We will further analyze the models below.

4.4 Feature Set Contribution Analysis

To better understand the contributions of different sets of features to our *EGR* model, we examined various features in an incremental fashion. Based on the groups of feature sets that we defined in Section 3, we tested the performance of different group combinations, added in the following order: *agent*, *customer* and *customer-agent interactions*.

[9]http://scikit-learn.org/stable/modules/svm.html

[10]*EGR* with $p < 0.001$, using *McNemar's test.*

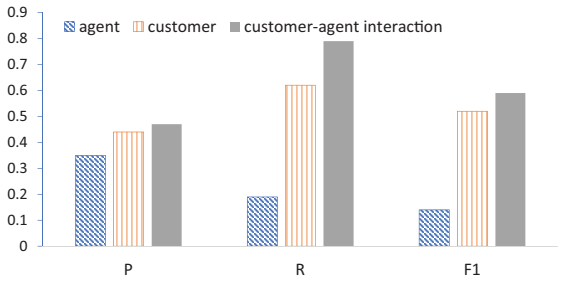

Figure 3: Precision (P), Recall (R), and F1-score (F) for various group combinations.

Figure 3 depicts the results for the classification task. The *x*-axis represents specific combinations of groups, and the *y*-axis represents the performance obtained. Figure 3 shows that adding each group improved performance, which indicates the informative value of each group. The figure also suggests that the most informative group in terms of prediction ability is the *customer* group.

4.5 Cross-Domain Analysis

We also studied how robust our features were: If our features generalize well, performance should not drop much when testing *company B* with the classifier trained exclusively on the data from *company A*. Although *company A* and *company B* share similar conversation engine platforms, they are completely different in terms of objectives, domain, terminology, etc. For this task, we utilized the 200 annotated conversations of *company B* as test data, and experimented with the different models, trained on *company A*'s data. The rule-based baseline does not require training, of course, and could be applied directly.

Table 3 summarizes the results showing that the performance of the *EGR* model is relatively stable (w.r.t the model's performance when it was trained and tested on the same domain), with a degradation of only 9% in F1-score[11]. In addition, the results also show that the text-based model performs poorly when applied to a different domain (F1-score of 0.11). This may occur since textual features are closely tied to the training domain.

[11]*EGR* model results are statistically significant compared to the baselines models with $p < 0.001$, using *McNemar's test.*

	Egregious			Non-Egregious		
Model	P	R	F	P	R	F
Rule-based	0.15	0.12	0.14	0.93	0.94	0.93
Text-based	0.33	0.06	0.11	0.92	**0.99**	**0.96**
EGR	**0.41**	**0.81**	**0.54**	**0.98**	0.90	0.94

Table 3: Cross domain performance (models trained on *company A*'s data, tested on *company B*'s data).

	Egregious	Non-egregious
NLU error	48%	48%
LG limitation	33%	37%
Unsupported intent error	18%	14%

Table 4: Percentage of different customer rephrasing reasons for egregious, and non-egregious conversations.

4.6 Models Analysis

4.6.1 Customer Rephrasing Analysis

Inspired by (Sarikaya, 2017; Sano et al., 2017) we analyzed the customer rephrasing motivations for both the egregious and the non-egregious classes. First, we detected customer rephrasing as described in Section 3.2.1, and then assigned to each its motivation. Specifically, in our setting, the relevant motivations are[12]: (1) *Natural language understanding (NLU) error* - the agent's intent detection is wrong, and thus the agent's response is semantically far from the customer's turn; (2) *Language generation (LG) limitation* - the intent is detected correctly, but the customer is not satisfied by the response (for example, the response was too generic); (3) *Unsupported intent error* - the customer's intent is not supported by the agent.

In order to detect *NLU errors*, we measured the similarity between the first customer turn (before the rephrasing) and the agent response. We followed the methodology presented in (Jovita et al., 2015) claiming that the best answer given by the system has the highest similarity value between the customer turn and the agent answer. Thus, if the similarity was < 0.8 we considered this as an erroneous detection. If the similarity was ≥ 0.8 we considered the detection as correct, and thus the rephrasing occurred due to *LG limitation*. To detect *unsupported intent error* we used the approach described in Section 3.1.2. As reported in table 4, rephrasing due to an unsupported intent is more common in egregious conversations (18% vs. 14%), whereas, rephrasing due to generation limitations (*LG limitation*) is more common in non-egregious conversations (37% vs. 33%). This indicates that customers are more tolerant of cases where the system understood their intent, but the response is not exactly what they expected, rather than cases where the system's response was "not trained". Finally, the percentage of rephrasing due to wrong intent detection (*NLU errors*) is similar for both classes, which is somewhat expected as similar underlying systems provided NLU support.

4.6.2 Recall Analysis

We further investigated why the *EGR* model was better at identifying egregious conversations (i.e., its recall was higher compared to the baseline models). We manually examined 26 egregious conversations that were identified justly so by the *EGR* model, but misclassified by the other models. Those conversations were particularly prevalent with the agent's difficulty to identify correctly the user's intent due to *NLU errors* or *LG limitation*. We did not encounter any *unsupported intent errors* leading to customer rephrasing, which affected the ability of the rule-based model to classify those conversations as egregious. In addition, the customer intents that appeared in those conversations were very diverse. While customer rephrasing was captured by the *EGR* model, for the text-based model some of the intents were new (did not appear in the training data) and thus were difficult for the model to capture.

5 Conclusions and Future Work

In this paper, we have shown how it is possible to detect egregious conversations using a combination of customer utterances, agent responses, and customer-agent interactional features. As explained, the goal of this work is to give developers of automated agents tools to detect and then solve problems cre-

[12]We did not consider other motivations like automatic speech recognition (ASR) errors, fallback to search, and backend failure as they are not relevant to our setting.

ated by exceptionally bad conversations. In this context, future work includes collecting more data and using neural approaches (e.g., RNN, CNN) for analysis, validating our models on a range of domains beyond the two explored here. We also plan to extend the work to detect egregious conversations in real time (e.g., for escalating to a human operators), and create log analysis tools to analyze the root causes of egregious conversations and suggest possible remedies.

Abstract

An enormous amount of conversation occurs online every day, such as on chat platforms where multiple conversations may take place concurrently. Interleaved conversations lead to difficulties in not only following discussions but also retrieving relevant information from simultaneous messages. Conversation disentanglement aims to separate intermingled messages into detached conversations.

In this paper, we propose to leverage representation learning for conversation disentanglement. A Siamese hierarchical convolutional neural network (SHCNN), which integrates local and more global representations of a message, is first presented to estimate the conversation-level similarity between closely posted messages. With the estimated similarity scores, our algorithm for conversation identification by similarity ranking (CISIR) then derives conversations based on high-confidence message pairs and pairwise redundancy. Experiments were conducted with four publicly available datasets of conversations from Reddit and IRC channels. The experimental results show that our approach significantly outperforms comparative baselines in both pairwise similarity estimation and conversation disentanglement.

1 Introduction

With the growth of ubiquitous internet and mobile devices, people now commonly communicate in the virtual world. Among the various methods of communication, text-based conversational media, such as internet relay chat (IRC) (Werry, 1996) and Facebook Messenger[1], has been and remains one of the most popular choices. In addition, many enterprises have started to use conversational chat platforms such as Slack[2] to enhance team collaboration. However, multiple conversations may occur simultaneously when conversations involve three or more participants. Aoki et al. (2006) found an average of 1.79 conversations among eight participants at a time. Moreover, some platforms like chatrooms in Twitch may have more concurrent conversations (Hamilton et al., 2014). Interleaved conversations can lead to difficulties in both grasping discussions and identifying messages related to a search result. For example, Figure 1 shows a segment of conversations from the real-world IRC dataset as an example. Five interleaved threads are involved in only ten messages. Messages in the same thread may not have identical keywords. Moreover, a user (i.e., *Elma*) can participate in multiple threads. Hence, a robust mechanism to disentangle interleaved conversations can improve a user's satisfaction with a chat system.

Thread	Message
⋮	⋮
T31	*Malcolm: If running as root, I need to set up a global config rather than ∼/.fetchmailrc ?*
T38	***Elma:*** *i'm sure i missed something but fonts rendering in my gimp works isn't at its best*
T39	*Sena: is there anyway to see what the CPU temperature is?*
T38	***Elma:*** *is it because of gimp or i missed some tuning or such?*
T31	*Rache: Specify a non-default name run control file.*
T41	*Denny: so how does one enforce a permission set and ownership set on a folder and all its children?*
T31	*Malcolm: in the man page it doesn't mention any global fetchmailrc file... that is what was confusing me...*
T42	*Shenna: hi, are sata drives accessed as sda or hda?*
T41	***Elma:*** *-R for recursive...*
T42	***Elma:*** *sda*
⋮	⋮

One solution for conversation disentanglement is to model the task as a topic detection and tracking (TDT) (Allan, 2002) task by deciding whether each incoming message starts a new topic or belongs to an existing conversation. Messages in the same conversation may have higher similarity

scores (Shen et al., 2006; Mayfield et al., 2012) or similar context messages (Wang and Oard, 2009). However, similarity thresholds for determining new topics vary depending on context. Embedding of earlier messages, resulting in duplication of parts of messages, can alter the similarity score. More specifically, the similarity scores obtained in previous work cannot well represent conversation-level relationships between messages.

Several studies have examined the use of statistical (Du et al., 2017) and linguistic features (Elsner and Charniak, 2008, 2010, 2011; Mayfield et al., 2012) for predicting user annotations of paired message similarity. These studies employed bag-of-words representations which do not capture term similarity and cannot distinguish word importance and relationships between words in a message. Thus, better representations of messages and their relationships are needed.

Recent studies have demonstrated the effectiveness of deep learning methods in representation learning (Bengio et al., 2013), aiming to infer low-dimensional distributed representations for sparse data such as text (Hinton and Salakhutdinov, 2006). These representations can be derived not only for words (Mikolov et al., 2013) but also sentences and documents (Le and Mikolov, 2014). In particular, convolutional neural networks (CNNs) have been shown to efficiently and effectively preserve important semantic and syntactic information from embedded text sequences (Blunsom et al., 2014). It has been demonstrated that CNNs produce state-of-the-art results in many NLP tasks such as text classification (Kim, 2014; Lai et al., 2015; Zhang et al., 2015) and sentiment analysis (Tang et al., 2014; Poria et al., 2015). Existing approaches, however, do not take advantage of deep learning techniques to model relationships between messages for disentangling conversations. (Mehri and Carenini, 2017) defined many statistical features for use with a random forest for in-thread classification and used a recurrent neural network (RNN) only to model adjacent messages with an external dataset as a feature.

In this paper, we aim to leverage deep learning for conversation disentanglement. Our proposed approach consists of two stages: (1) message pair similarity estimation and (2) conversation identification. In the first stage, we propose the Siamese hierarchical convolutional neural network (SHCNN) to estimate conversation-level similarity between pairs of closely posted messages. SHCNN is framed as a Siamese architecture (Mueller and Thyagarajan, 2016) concatenating the outputs of two hierarchical convolutional neural networks and additional features. Compared to other conventional CNN-based Siamese networks (Severyn and Moschitti, 2015; Yin et al., 2016), SHCNN models not only local information in adjacent words but also more global semantic information in a message. In the second stage, the algorithm of conversation identification by similarity ranking (CISIR) ranks messages within a time window paired with each message and constructs a message graph involving high-rank connections with strong confidence. Although only high-confidence relations are represented in the constructed graph, the redundancy of pairwise relationships can capture the connectivity of messages within a conversation.

In summary, the main contributions of this paper are threefold: **(1) Deep similarity estimation for conversation disentanglement:** To the best of our knowledge, this is the first study applying deep learning to estimate similarities between messages for disentangling conversations. SHCNN simultaneously captures and compares local and global characteristics of two messages to estimate their similarity. Message representations are also optimized towards the task of conversation disentanglement. **(2) Efficient and effective method:** The selection of message pairs posted closely in time and the proposed CISIR algorithm significantly reduces the computational time from $O\left(|M|^2\right)$ to $O\left(k|M|\right)$, where $|M|$ is the number of messages, and k is the maximum number of messages posted within a fixed-length time window. When many messages are posted over a long period, the computational time of our approach could be near-linear. **(3) Empirical improvements over previous work:** Extensive experiments have been conducted on four publicly available datasets, including three synthetic conversation datasets and one real conversation dataset from Reddit[3] and IRC conversations. Our approach outperforms all comparative baselines for both similarity estimation and conversation disentanglement.

2 Related Work

Methods for conversation disentanglement can be simply categorized into unsupervised and supervised approaches. Unsupervised approaches (Wang and Oard, 2009) estimate the relationship between messages through unsupervised similarity functions such cosine similarity, and assign messages to conversations based on a predefined

[3]Reddit: `https://www.reddit.com/`

threshold. In contrast, supervised methods exploit a set of user annotations (Elsner and Charniak, 2008; Mayfield et al., 2012; Shen et al., 2006; Du et al., 2017; Mehri and Carenini, 2017) to adapt to different datasets. Our approach can be classified as a supervised approach because a small set of user annotations is used to train the SHCNN.

In addition to conversations, some studies predict the partial structure of threaded data, especially for online forums (Aumayr et al., 2011; Wang et al., 2011b,a). These studies merely classify parent-child relationships in disentangled, independent threads. Moreover, they focus only on comments to the same post. Indeed, conversation disentanglement is a more difficult task.

Estimating the similarity of text pairs is an essential part in our approach. Many studies also focus on similar tasks aside from conversation disentanglement, such as entailment prediction (Mueller and Thyagarajan, 2016; Wang and Jiang, 2017) and question-answering (Severyn and Moschitti, 2015; Amiri et al., 2016; Yin et al., 2016). However, most of their models are complicated and require a larger amount of labeled training data; limited conversational data can lead to unsatisfactory performance as shown in Section 4.

3 Conversation Disentanglement

In this section, we formally define the objective of this work and notations used. A two-stage approach is then proposed to address the problem.

3.1 Problem Statement

Given a set of speakers $\boldsymbol{S}$, a message m is defined as a tuple $m = (\boldsymbol{w}, s, t)$, where $\boldsymbol{w} = \langle w_1, w_2, \cdots, w_n \rangle$ is a word sequence posted by the speaker $s \in \boldsymbol{S}$ at time t in seconds. Each message m is associated with a conversation $z\,(m)$. Messages in different conversations can be posted concurrently, i.e., conversations can be interleaved.

Following the settings of previous work (Elsner and Charniak, 2008, 2010, 2011; Mayfield et al., 2012), a set of pairwise annotations $\boldsymbol{A} = \{(m_i, m_j, y)\}$, where $y \in \{0, 1\}$, is given for training the model. More specifically, a Boolean value y indicates whether two messages m_i and m_j are in the same conversation, i.e., $z(m_i)$ and $z(m_j)$ are identical.

Given a set of messages $\boldsymbol{M}$ and the pairwise annotations $\boldsymbol{A}$ as training data, the goal is to learn a model that can identify whether messages are posted in the same conversation $z(m)$. Note that the number of conversations $|\boldsymbol{Z} = \{z(m) \mid \forall m \in \boldsymbol{M}\}|$ is always unknown to the system.

3.2 Framework Overview

Figure 2 illustrates our two-stage framework. The first stage aims to estimate pairwise similarity among messages. Message pair selection is applied to focus on the similarity between messages that are posted closely in time and thus more likely to be in the same conversation. The Siamese hierarchical CNN (SHCNN) is proposed for learning message representations and estimating pairwise similarity scores. The overlapping hierarchical structure of SHCNN models a message at multiple semantic levels and obtains representations that are more comprehensive.

In the second stage, our conversation identification by similarity ranking (CISIR) algorithm exploits the redundancy and connectivity of pairwise relationships to identify conversations as connected components in a message graph.

3.3 Message Pair Selection

Most of the previous work on conversation disentanglement focused on pairwise relationships between messages (Mayfield et al., 2012). Especially for single-pass clustering approaches, all pairs of messages need to be enumerated during similarity computation (Wang and Oard, 2009). However, if messages have been collected for a long time, the number of message pairs could be too mammoth to be processed in an acceptable amount of time. More precisely, it leads to at least $O(n^2)$ computational time, where n is the number of messages. As shown in Figure 3, the percentage of messages in the same conversation as a given message becomes significantly lower with a longer elapsed time between consecutive messages. In light of this observation, an assumption is made as follows:

Assumption 1 *The elapsed time between two consecutive messages posted in the same conversation is not greater than T hours, where T is a small number.*

More specifically, in our dataset every message m_i is posted within T hours earlier or later than any other message m_j in the same conversation, i.e., $\frac{|t_i - t_j|}{3600} < T$ for all pairs (m_i, m_j), where t is in seconds. For example, in the IRC dataset the average elapsed time between consecutive messages in a conversation is only 7 minutes. If a conversation is ongoing, there may not be an extended silence before a new message; conversely, an extended silence could be treated as the start of a new

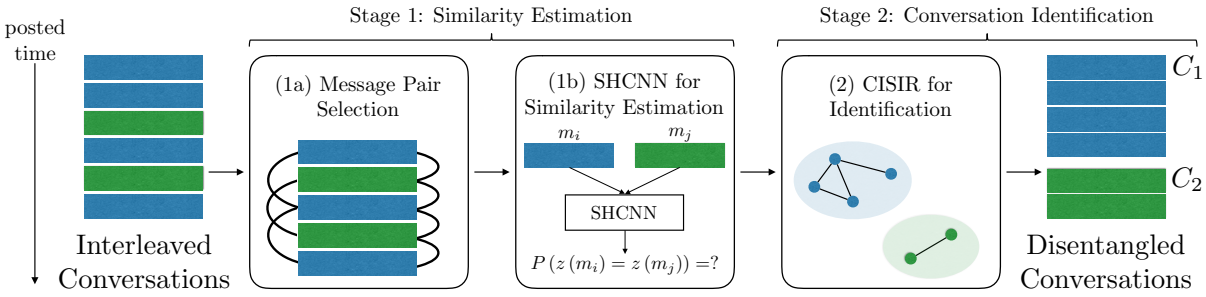

Figure 2: Illustration of our proposed two stage method. In the first stage, (1a) message pairs are selected for (1b) estimating pairwise similarity with a Siamese hierarchical CNN (SHCNN). In the second stage, (2) the algorithm of conversation identification by similarity ranking (CISIR) constructs a graph with strong relationships among messages and finds conversations as connected components.

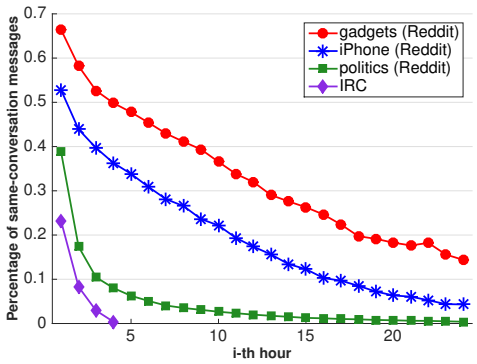

Figure 3: The percentage of messages in the same conversation as a given message with elapsed time between messages no greater than i hours for four experimental datasets.

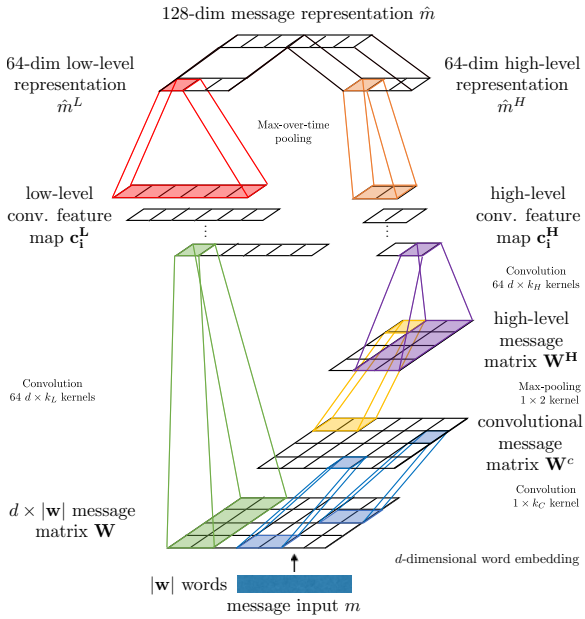

Figure 4: Illustration of hierarchical CNN (HCNN) for message representation. The labels with a larger font size indicate the corresponding tensors, and the labels with a smaller font size explain the operations between tensors.

conversation. With this assumption, the number of pairs can be reduced to $O(kn)$, where k is the maximum number of messages posted in a T-hour time window. By default T is set to 1 hour in our experiments.

In addition, it is worth mentioning that it may be possible to include conversational structure, such as replied-to relations, into the model. For example, after using CISIR to identify conversational threads, structure inference may be performed using methods such as described in (Aumayr et al., 2011) or (Wang et al., 2011b) and the structure used to refine the threads. In this study, we focus on only conversation disentanglement.

3.4 Similarity Estimation with the Siamese Hierarchical CNN (SHCNN)

Given a set of message pairs, we propose the Siamese hierarchical CNN (SHCNN) to estimate the similarity between a pair of messages.

3.4.1 Hierarchical CNN for Message Representation

The effectiveness of CNNs for representing text has already been addressed in previous studies. However, single-layer CNNs (Kim, 2014; Severyn and Moschitti, 2015) may not represent high-level semantics while low-level information could be diluted with multiple-layer CNNs (Yin et al., 2016). The hierarchical CNN (HCNN) is designed to simultaneously capture low- and high-level message meanings as shown in Figure 4.

A message m_i is first represented by a $d \times |\boldsymbol{w}|$ message matrix $\boldsymbol{W} \in \boldsymbol{R}^{d \times |\boldsymbol{w}|}$, where d is the dimension of a word embedding, and $|\boldsymbol{w}|$ is the num-

ber of words in a message. For low-level information, we exploit single-layer CNNs (Kim, 2014; Severyn and Moschitti, 2015) with a set of $d \times k_L$ kernels, where L denotes "Low", to extract n-gram semantics of k_L contiguous words. In this paper, 64 $d \times k_L$ kernels, where $k_L = 5$, are applied to obtain 64 low-level features $\hat{m}^L$. Note that the kernel row dimension is identical to the word embedding dimension to jointly consider the full embedding vector. As a consequence, convolution with each kernel produces a vector $\boldsymbol{c_i^L}$, which is then aggregated by max-over-time pooling (Collobert et al., 2011; Kim, 2014).

To acquire high-level semantics across a message, HCNN uses another multiple-layer CNN for feature extraction. A $1 \times k_C$ kernel is applied to $\boldsymbol{W}$, thereby generating a convolutional message matrix $\boldsymbol{W^C}$. Features covering broader contents are computed by applying a 1×2 kernel to a max-pooling layer with a stride of 2, producing a high-level message matrix $\boldsymbol{W^H}$. The row sizes of the two kernels are set to 1 to capture relations within each embedding dimension, and convolution is performed on $\boldsymbol{W^H}$ with 64 $d \times k_H$ kernels to capture relations across embedding dimensions. The generated convolutional feature maps $\boldsymbol{c_i^H}$ are subject to max-over-time pooling, resulting in 64 features $\hat{m}^H$. Finally, a message representation $\hat{m}$ is constructed by concatenating $\hat{m}^L$ and $\hat{m}^H$, i.e., creating a 128-dimensional feature vector, for characterizing both low- and high-level semantics of a message m. In this paper, both k_C and k_H are set to 5 while computing high-level representations.

3.4.2 Siamese Hierarchical CNN (SHCNN)

A Siamese structure with two identical subnetworks is useful to exploit the affinity between representations of two instances in the same hidden space (Severyn and Moschitti, 2015; Yin et al., 2016; Wang and Jiang, 2017). For similarity estimation, we propose the Siamese hierarchical CNN (SHCNN) using a Siamese structure that blends the outputs from two HCNNs as well as some context features.

Figure 5 shows the structure of the SHCNN for estimating the similarity between two messages m_i and m_j where the message representations $\hat{m}_i$ and $\hat{m}_j$ are generated by two sub-networks HCNNs (See Figure 4). There are many ways to deal with two sub-networks, such as using a similarity matrix (Severyn and Moschitti, 2015) or an attention matrix (Yin et al., 2016). However, both methods lead to an enormous number of parameters for long messages. We propose to independently compute the element-wise absolute differences (Mueller and Thyagarajan, 2016) between a pair of message representations $\hat{m}_i$ and $\hat{m}_j$, each from a sub-network. More formally, the absolute difference d is a vector where the k-th element is computed as $|\hat{m}_i(k) - \hat{m}_j(k)|$. This approach provides not only fewer parameters but also the flexibility to observe interactions among different dimensions in representations. Our experiments also show it outperforms the other two approaches in similarity estimation (See Section 4).

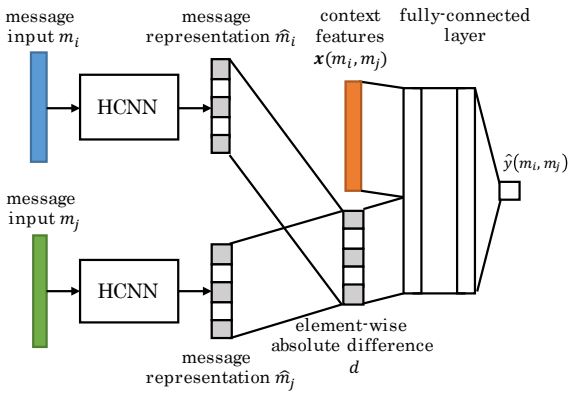

Figure 5: The siamese hierarchical CNN (SHCNN) for similarity estimation. Note that the model structure of an HCNN is shown in Figure 4.

In addition to message contents, contexts such as temporal and user information were also usually considered in previous studies about conversation disentanglement (Wang and Oard, 2009; Elsner and Charniak, 2010, 2011). In this paper, we focus on the performance of message content representations and only incorporate four context features: speaker identicality, absolute time difference and the number of duplicated words with and without weighting by inverse document frequency (Christopher et al., 2008). SHCNN concatenates the context features $\boldsymbol{x}(m_i, m_j)$ with the absolute difference d as the input of a fully-connected layer of the same size.

The final output of SHCNN $\hat{y}(m_i, m_j)$ is normalized by a logistic sigmoid function (Han and Moraga, 1995), representing the probability $P(z(m_i) = z(m_j))$.

3.4.3 Activation Functions

All convolutional layers and the fully-connected layer require activation functions, and the choice affects the performance (Maas et al., 2013). Popular functions include rectified linear units (ReLUs) (LeCun et al., 2015), hyperbolic tangent

units ($\tanh$) and exponential linear units (ELUs) (Clevert et al., 2016). In this study, we conducted informal comparison experiments and ELU was finally chosen for all functions because it performed the best.

3.4.4 Optimization and Implementation Details

Given a set of annotated message pairs $\boldsymbol{A} = \{(m_i, m_j, y)\}$, where y is a Boolean value indicating whether two messages are in the same conversation, SHCNN is optimized with binomial cross entropy (Goodfellow et al., 2016). More formally, the objective function is as follows:

$$\sum_{(m_i,m_j,y)\in A}[y \cdot \log(\hat{y}+\epsilon) + (1-y)\cdot\log(1-\hat{y}+\epsilon)] + \lambda||\boldsymbol{\theta}||^2$$

where $\hat{y}$ simplifies $\hat{y}(m_i, m_j)$, and ϵ is a small number, i.e., 10^{-9} in our experiments, preventing underflow errors. The term λ serves as the weight for L2-regularization for the set of parameters $\boldsymbol{\theta}$.

In our experiments, SHCNN is implemented by TensorFlow (Abadi et al., 2016) and trained by the Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 10^{-3}. The dropout technique (Srivastava et al., 2014) is utilized in the fully-connected layer with a dropout probability of 0.1. Word embeddings are initialized using the publicly available fastText 300-dimensional pretrained embeddings from Facebook (Bojanowski et al., 2016). The batch size is set to 512, and the maximum number of training epochs is 1,000. The final model is determined by evaluating the mean average precision (MAP) on a validation dataset every 100 iterations.

3.5 Conversation Identification by SImilarity Ranking (CISIR)

In the second stage of conversation disentanglement, i.e., part (2) in Figure 2, we aim to separate conversations based on the identified message pairs and their estimated similarity.

3.5.1 Graph-based Methods and Conversation Connectivity

It is intuitive to apply graph-based methods if pairwise relationships of messages are exploited (Elsner and Charniak, 2008). Furthermore, methods based on single-pass clustering (Wang and Oard, 2009) can be also be treated as graph-based methods. However, graph-based methods have a risky drawback: A single false positive connection between two messages can be propagated to several messages from different conversations. As shown in Figure 3, a certain percentage of message pairs are in different conversations, which can lead to numerous false positive connections.

False alarms may be reduced by raising the threshold that determines whether two messages are connected (Wang and Oard, 2009). However, a high threshold can make disentangled conversations fragmented and the best threshold for each pair could vary.

Algorithm 1: The algorithm of conversation disentanglement by similarity ranking (CISIR).

CISIR $(\boldsymbol{M}, \boldsymbol{D}, r, h)$;
Input : Message set $\boldsymbol{M}$, the set of selected message pairs $\boldsymbol{D}$, the threshold of similarity ranks r and the threshold of similarity scores h.
Output: A set of conversations $\boldsymbol{C}$
Let $G = (\boldsymbol{M}, \emptyset)$ be an undirected message graph
for $m \in M$ **do**
  $\boldsymbol{D}_m = \{(m_i, m_j, \hat{y}) \mid m_i = m \vee m_j = m\}$
  Rank entries in $\boldsymbol{D}_m$ by $\hat{y}$ in a descending order
  for $k = 1$ *to* $\min(r, |\boldsymbol{D}_m|)$ **do**
    Let $(m_i, m_j, \hat{y})$ be the k-th entry in ranked $\boldsymbol{D}_m$
    if $\hat{y} < h$ **then**
      break
    Add an edge (m_i, m_j) into G
$\boldsymbol{C}$ = ConnectedComponents(G)
return $\boldsymbol{C}$

3.5.2 The CISIR Algorithm

Instead of setting a high threshold, we propose the algorithm of Conversation Identification by SImilarity Ranking (CISIR). CISIR focuses on the top messages ranked by similarity scores. Based on Assumption 1, for each message, there exists at least one or more other messages in the same conversation posted closely in time. With this redundancy, a few pairs with stronger confidence, i.e., the top-ranked pairs, can be enough to extend a correct connectivity to earlier or later messages, while the low-ranked pairs can be ignored to reduce the risk of error propagation.

Given a set of selected message pairs with estimated similarity scores $\boldsymbol{D} = \{(m_i, m_j, \hat{y})\}$, Algorithm 1 shows the procedure of CISIR with two parameters r and h, where r is a high threshold

of similarity ranks and h is a lower threshold of similarity scores. Note that CISIR filters out pairs with low scores because a message can have more than r same-conversation pairs posted in its T-hour time window. For each message, CISIR ranks all of its associated pairs by the estimated similarity and only retrieves the top-r pairs whose similarity scores are greater than h. These retrieved high-confidence pairs are treated as the edges in a message graph G. Finally, CISIR divides G into connected components, and the messages in each connected component are treated as a conversation. In this paper, we use grid search to set r and h as 5 and 0.5, respectively.

3.5.3 Improvement of Time Complexity

The efficiency of Algorithm 1 can be further improved. The top-r qualified pairs for each message can be pre-processed by a scan of $\boldsymbol{D}$ with $|M|$ min-heaps which always contain at most $r+1$ elements. When r is a small constant number, it only takes $O(|D|) = O(k \cdot |M|)$ for pre-processing, where k is the maximum number of messages posted in a T-hour time window. With pre-processed top pairs, CISIR can do graph construction and find connected components in $O(k|M|)$, which compares favorably to conventional methods in $O(|M|^2)$.

4 Experiments

In this section, we conduct extensive experiments on four publicly available datasets to evaluate SHCNN and CISIR in two stages.

4.1 Datasets and Experimental Settings

4.1.1 Datasets

Three datasets from Reddit and one dataset of IRC are used as the experimental datasets.

- **Reddit Datasets**[4] The Reddit dataset is comprised of all posts and corresponding comments in all sub-reddits (i.e., forums in Reddit.com) from June 2016 to May 2017. Comments under a post can be treated as messages in one conversational thread. Here we manually merge all comments in a sub-reddit to construct a synthetic dataset of interleaved conversations. Note that although it is called a "synthetic dataset," all messages are written by real users. Three subreddits with different popularity levels as shown in Table 1 are selected to build three datasets: gadgets, iPhone and politics.

[4]The organized Reddit dataset is publicly available in `https://files.pushshift.io/reddit/`.

Dataset	Reddit			IRC
	gadgets	iPhone	politics	
Conversations	287	617	3,671	39
Messages	8,518	12,433	105,663	497
Speakers	5,185	5,231	25,289	71
Train/Valid Pairs	3,445	5,556	244,492	5,995
Test Pairs	27,565	44,450	1,955,943	47,966

Table 1: Statistics of four datasets after pre-processing.

- **IRC Dataset.** An annotated IRC dataset used in (Elsner and Charniak, 2008) is also included in our experiments. The IRC dataset consists of about 6 hours of messages in interleaved conversations. Even though the IRC dataset is significantly smaller and shorter than the Reddit datasets, it consists of natural, interleaved conversations with ground truth annotations, including thread id.

4.1.2 Experimental Settings

Humans may not participate in a large number of simultaneous conversations. e.g., an average of 1.79 for eight people (Aoki et al., 2006), but there could be hundreds of concurrent posts in a subreddit. Hence, we adjusted the datasets to be more similar to real conversations. Specifically we removed some conversations so that every dataset has at most ten conversations at any point in time. Short messages with less than five words are also removed because even for humans they are frequently ambiguous. Too short conversations with less than ten messages are also discarded as outliers (Ren et al., 2011). Training and validation data are randomly chosen from only 10% of the selected message pairs, respectively, because in real situations obtaining labels could be very costly. The remaining 80% of pairs are regarded as testing data. As a result, Table 1 shows the statistics of the four datasets after pre-processing.

4.2 Pairwise Similarity Estimation

Message pair similarity estimation is treated as a ranking task and evaluated with three ranking evaluation metrics: precision at 1 (P@1), mean average precision (MAP) and mean reciprocal rank (MRR) (Christopher et al., 2008). We compare the performance with six baseline methods, including the difference of posted time (*TimeDiff*), sameness of speakers (*Speaker*), cosine similarity of text (*Text-Sim*), the approach proposed by Elsner and Charniak (2008) (Elsner), *DeepQA* (Severyn and Moschitti, 2015) and *ABCNN* (Yin et al., 2016). Note that DeepQA and ABCNN are neural network-based models for question-answering. The approach of Mehri and Carenini

Table 2: Performance of pairwise similarity estimation in four datasets. Our approach is denoted as SHCNN.The performance with only low-level or high-level representations are denoted as SHCNN (L) and SHCNN (H). All improvements of SHCNN against the best baseline are significant at the 1% level of significance in a paired t-test.

$z(m_i)$	Message
T16	*"**Arlie:** Wow, maybe we just missed it when we were driving around"*
T18	*"**Arlie:** i've been very close to that situation myself"*

Figure 6: An example message pair in two different conversations from IRC shows how SHCNN discriminates between messages on different topics. The leftmost column is the conversation IDs of the corresponding messages. SHCNN predicts 0.67% of being in the same conversation for this pair while DeepQA with single-layer CNNs predicts 69.81%.

$z(m_i)$	Message
T16	*"Very well, I seem to be trying to show Arlie how its done and am **coding a webserver**."*
T16	*"Arlie: Good enough doesnt cut it! Is **the 'faster' method** a big change in design? Could I **implement** later without wanting to kill myself?"*

Figure 7: An example message pair in a conversation from IRC shows how SHCNN captures similarity in local information. The leftmost column is the conversation IDs of the corresponding messages. SHCNN predicts 70.41% for this pair while ABCNN with multiple-layer CNNs predicts 36.50%.

(2017) was not compared in our experiments because the RNN requires additional message sequences; moreover, its performance was only mildly better than Elsner, which performed poorly on IRC in Table 2.

Table 2 shows the performance of similarity estimation. Among all methods, neural network approaches (Severyn and Moschitti, 2015; Yin et al., 2016) perform better than other methods in most cases, indicating that message content representation has considerable impact on estimating pairwise similarity. SHCNN outperforms most of the baselines even if only low-level (L) or high-level (H) representations are exploited. When SHCNN captures both low- and high-level semantics, it significantly outperforms all baselines across the four datasets. For example, ABCNN can outperform SHCNN using only either low- or high-level representations in the politics dataset; however, SHCNN turns the tables after using both representations. An interesting observation is that ABCNN is the best baseline in every dataset except for IRC; this may be because the IRC data is too small to train complicated attention structures. On the contrary, our SHCNN can precisely capture semantics even with few parameters and limited data.

To shed deeper insights of how SHCNN surpasses other methods, we exhibit the prediction results of the IRC data and demonstrate the capability of SHCNN to simultaneously preserve local and more global information. Figure 6 presents an example to show how SHCNN is better than other methods in capturing more high-level topical information. Even though the main sentences of two messages are clearly on different topics, the baseline method DeepQA (Severyn and Moschitti, 2015) still predicts a high similarity. This could be attributed to the context of author mention (Wang and Oard, 2009) and a bias on the local information, i.e., the exact same term "Arlie", in the Siamese network used in DeepQA. On the contrary, SHCNN can capture more global information that differentiates the topics and correctly predicts a very low score. Figure 7 illustrates another example of how SHCNN outperforms other methods in preserving the similarity of local information. Both of the messages in the example have some segments related to software engineering. A baseline method ABCNN (Yin et al., 2016) with multiple-layer CNNs, however, still predicts a low score. This might be because both sentences are long so that the local information is diluted after processing by multiple CNN layers. Differently, SHCNN is able to seize local information, correctly predicting a high score.

Table 3: Performance of conversation disentanglement in four datasets. Our approach is denoted as CISIR. "Oracle" indicates the optimal performance if CISIR correctly retrieves all message pairs in identical conversations. All improvements of CISIR against the best baseline are significant at the 1% level of significance in a paired t-test.

4.3 Conversation Identification

For conversation identification, three clustering metrics are adopted for evaluation: normalized mutual information (NMI), adjusted rand index (ARI) and F_1 score (F1). Six methods are implemented as the baselines for conversation disentanglement, including *Doc2Vec* (Le and Mikolov, 2014), blocks of 10 messages (*Block-10*), messages of respective speakers (*Speaker*) (Elsner and Charniak, 2011), context-based message expansion (*CBME*) (Wang and Oard, 2009) and a graph-theoretical model with chat- and content-specific features (Elsner and Charniak, 2008) (*GTM*). The embedding-based clustering method, i.e., *Doc2Vec*, applies affinity propagation (Frey and Dueck, 2007) to cluster messages embedded using *Doc2Vec* without being given the number of clusters, with the idea that messages in the same conversation would form a cluster. Note that message pairs in the training and validation data are not utilized in prediction for a fair comparison to all methods.

Table 3 shows the performance of conversation disentanglement. Note that "Oracle" represents the optimal performance for CISIR when all message pairs in identical conversations in $\boldsymbol{D}$ are correctly retrieved. Because pairs in $\boldsymbol{D}$ may not have enough coverage to connect all messages in a coversation, the optimal performance could be lower than 1.0. CISIR performs better than all baseline methods for all datasets, and achieves excellent performance in IRC, due in part to the high-performing similarity estimates from the first stage. Among the baseline methods, GTM performs relatively well on all datasets except for IRC. This is because messages are more frequently posted in the IRC dataset, thereby increasing the number of incorrect pairs in the constructed graph. Examining the graph constructed by GTM, there are only two connected components, indicating that many conversations were incorrectly combined; in contrast, CISIR may be exempt from error propagation because it only relies on top-ranked pairs. Doc2Vec is trained to predict words in a document in an unsupervised manner. Its lowest performance in the experiments may point out a need for supervised learning in the specific task of conversation disentanglement to tackle the variation in semantic patterns. Time and author contextual cues do help conversation disentanglement as seen in the results of Block-10 and Speaker. Both of these contexts are integrated into our model.

5 Conclusions

In this paper, we propose a novel framework for disentangling conversations, including similarity estimation for message pairs and conversation identification. In contrast to previous work, we assume that we do not need to select all message pairs in the first stage, thereby reducing computational time without sacrificing performance too much. To estimate conversation-level similarity, a Siamese Hierarchical Convolutional Neural Network, SHCNN, is proposed to minimize the estimation error as well as preserve both the low- and high-level semantics of messages. In the second stage, we developed the Conversation Identification by SImilarity Ranking, CISIR, algorithm, which exploits the assumption made in the first stage and identifies individual, entangled conversations with high-ranked message pairs. Extensive experiments conducted on four publicly available datasets show that SHCNN and CISIR outperform several existing approaches in both similarity estimation and conversation identification.

Abstract

Inferring missing links in knowledge graphs (KG) has attracted a lot of attention from the research community. In this paper, we tackle a practical query answering task involving predicting the relation of a given entity pair. We frame this prediction problem as an inference problem in a probabilistic graphical model and aim at resolving it from a variational inference perspective. In order to model the relation between the query entity pair, we assume that there exists an underlying latent variable (paths connecting two nodes) in the KG, which carries the equivalent semantics of their relations. However, due to the intractability of connections in large KGs, we propose to use variation inference to maximize the evidence lower bound. More specifically, our framework (DIVA) is composed of three modules, i.e. a posterior approximator, a prior (path finder), and a likelihood (path reasoner). By using variational inference, we are able to incorporate them closely into a unified architecture and jointly optimize them to perform KG reasoning. With active interactions among these sub-modules, DIVA is better at handling noise and coping with more complex reasoning scenarios. In order to evaluate our method, we conduct the experiment of the link prediction task on multiple datasets and achieve state-of-the-art performances on both datasets.

1 Introduction

Large-scaled knowledge graph supports a lot of downstream natural language processing tasks like question answering, response generation, etc. However, there are large amount of important facts missing in existing KG, which has significantly limited the capability of KG's application. Therefore, automated reasoning, or the ability for computing systems to make new inferences from the observed evidence, has attracted lots of attention from the research community. In recent years, there are surging interests in designing machine learning algorithms for complex reasoning tasks, especially in large knowledge graphs (KGs) where the countless entities and links have posed great challenges to traditional logic-based algorithms. Specifically, we situate our study in this large KG multi-hop reasoning scenario, where the goal is to design an automated inference model to complete the missing links between existing entities in large KGs. For examples, if the KG contains a fact like *president*(*BarackObama*, *USA*) and *spouse*(*Michelle, BarackObama*), then we would like the machines to complete the missing link *livesIn*(*Michelle*, *USA*) automatically. Systems for this task are essential to complex question answering applications.

To tackle the multi-hop link prediction problem, various approaches have been proposed. Some earlier works like PRA (Lao et al., 2011; Gardner et al., 2014, 2013) use bounded-depth random walk with restarts to obtain paths. More recently, DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2018), frame the path-finding problem as a Markov Decision Process (MDP) and utilize reinforcement learning (RL) to maximize the expected return. Another line of work along with ours are Chain-of-Reasoning (Das et al., 2016) and Compositional Reasoning (Neelakantan et al., 2015), which take multi-hop chains learned by PRA as input and aim to infer its relation.

Here we frame the KG reasoning task as a two sub-steps, i.e. "Path-Finding" and "Path-Reasoning". We found that most of the related research is only focused on one step, which leads to major drawbacks—lack of interactions between these two steps. More specifically, DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2018) can be interpreted as enhancing the "Path-Finding" step while compositional reasoning (Neelakantan et al., 2015) and chains of rea-

Proceedings of NAACL-HLT 2018, pages 1823–1832
New Orleans, Louisiana, June 1 - 6, 2018.

soning (Das et al., 2016) can be interpreted as enhancing the "Path-Reasoning" step. DeepPath is trained to find paths more efficiently between two given entities while being agnostic to whether the entity pairs are positive or negative, whereas MINERVA learns to reach target nodes given an entity-query pair while being agnostic to the quality of the searched path[1]. In contrast, chains of reasoning and compositional reasoning only learn to predict relation given paths while being agnostic to the path-finding procedure. The lack of interaction prevents the model from understanding more diverse inputs and make the model very sensitive to noise and adversarial samples.

In order to increase the robustness of existing KG reasoning model and handle noisier environments, we propose to combine these two steps together as a whole from the perspective of the latent variable graphic model. This graphic model views the paths as discrete latent variables and relation as the observed variables with a given entity pair as the condition, thus the path-finding module can be viewed as a prior distribution to infer the underlying links in the KG. In contrast, the path-reasoning module can be viewed as the likelihood distribution, which classifies underlying links into multiple classes. With this assumption, we introduce an approximate posterior and design a variational auto-encoder (Kingma and Welling, 2013) algorithm to maximize the evidence lower-bound. This variational framework closely incorporates two modules into a unified framework and jointly train them together. By active cooperations and interactions, the path finder can take into account the value of searched path and resort to the more meaningful paths. Meanwhile, the path reasoner can receive more diverse paths from the path finder and generalizes better to unseen scenarios. Our contributions are three-fold:

- We introduce a variational inference framework for KG reasoning, which tightly integrates the path-finding and path-reasoning processes to perform joint reasoning.
- We have successfully leveraged negative samples into training and increase the robustness of existing KG reasoning model.
- We show that our method can scale up to large KG and achieve state-of-the-art results on two popular datasets.

The rest of the paper is organized as follow. In Section 2 we will outline related work on KG embedding, multi-hop reasoning, and variational auto-encoder. We describe our variational knowledge reasoner DIVA in Section 3. Experimental results are presented in Section 4, and we conclude in Section 5.

2 Related Work

2.1 Knowledge Graph Embeddings

Embedding methods to model multi-relation data from KGs have been extensively studied in recent years (Nickel et al., 2011; Bordes et al., 2013; Socher et al., 2013; Lin et al., 2015; Trouillon et al., 2017). From a representation learning perspective, all these methods are trying to learn a projection from symbolic space to vector space. For each triple (e_s, r, e_d) in the KG, various score functions can be defined using either vector or matrix operations. Although these embedding approaches have been successful capturing the semantics of KG symbols (entities and relations) and achieving impressive results on knowledge base completion tasks, most of them fail to model multi-hop relation paths, which are indispensable for more complex reasoning tasks. Besides, since all these models operate solely on latent space, their predictions are barely interpretable.

2.2 Multi-Hop Reasoning

The Path-Ranking Algorithm (PRA) method is the first approach to use a random walk with restart mechanism to perform multi-hop reasoning. Later on, some research studies (Gardner et al., 2014, 2013) have revised the PRA algorithm to compute feature similarity in the vector space. These formula-based algorithms can create a large fan-out area, which potentially undermines the inference accuracy. To mitigate this problem, a Convolutional Neural Network(CNN)-based model (Toutanova et al., 2015) has been proposed to perform multi-hop reasoning. Recently, DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2018) view the multi-hop reasoning problem as a Markov Decision Process, and leverages REINFORCE (Williams, 1992) to efficiently search for paths in large knowledge graph. These two methods are reported to achieve state-of-the-art results, however, these two models both use heuristic rewards to drive the policy

[1] MINERVA assigns constant rewards to all paths reaching the destination while ignoring their qualities.

search, which could make their models sensitive to noises and adversarial examples.

2.3 Variational Auto-encoder

Variational Auto-Encoder (Kingma and Welling, 2013) is a very popular algorithm to perform approximate posterior inference in large-scale scenarios, especially in neural networks. Recently, VAE has been successfully applied to various complex machine learning tasks like image generation (Mansimov et al., 2015), machine translation (Zhang et al., 2016), sentence generation (Guu et al., 2017a) and question answering (Zhang et al., 2017). Zhang et al. (2017) is closest to ours, this paper proposes a variational framework to understand the variability of human language about entity referencing. In contrast, our model uses a variational framework to cope with the complex link connections in large KG. Unlike the previous research in VAE, both Zhang et al. (2017) and our model uses discrete variables as the latent representation to infer the semantics of given entity pairs. More specifically, we view the generation of relation as a stochastic process controlled by a latent representation, i.e. the connected multi-hop link existed in the KG. Though the potential link paths are discrete and countable, its amount is still very large and poses challenges to direct optimization. Therefore, we resort to variational auto-encoder as our approximation strategy.

3 Our Approach

3.1 Background

Here we formally define the background of our task. Let $\mathcal{E}$ be the set of entities and R be the set of relations. Then a KG is defined as a collection of triple facts (e_s, r, e_d), where $e_s, e_d \in \mathcal{E}$ and $r \in \mathcal{R}$. We are particularly interested in the problem of relation inference, which seeks to answer the question in the format of $(e_s, ?, e_d)$, the problem setting is slightly different from standard link prediction to answer the question of $(e_s, r, ?)$. Next, in order to tackle this classification problem, we assume that there is a latent representation for given entity pair in the KG, i.e. the collection of linked paths, these hidden variables can reveal the underlying semantics between these two entities. Therefore, the link classification problem can be decomposed into two modules – acquire underlying paths (Path Finder) and infer relation from latent representation (Path Reasoner).

Path Finder The state-of-the-art approach (Xiong et al., 2017; Das et al., 2018) is to view this process as a Markov Decision Process (MDP). A tuple $< S, A, P >$ is defined to represent the MDP, where S denotes the current state, e.g. the current node in the knowledge graph, A is the set of available actions, e.g. all the outgoing edges from the state, while P is the transition probability describing the state transition mechanism. In the knowledge graph, the transition of the state is deterministic, so we do not need to model the state transition P.

Path Reasoner The common approach (Lao et al., 2011; Neelakantan et al., 2015; Das et al., 2016) is to encode the path as a feature vector and use a multi-class discriminator to predict the unknown relation. PRA (Lao et al., 2011) proposes to encode paths as binary features to learn a log-linear classifier, while (Das et al., 2016) applies recurrent neural network to recursively encode the paths into hidden features and uses vector similarity for classification.

3.2 Variational KG Reasoner (DIVA)

Here we draw a schematic diagram of our model in Figure 1. Formally, we define the objective function for the general relation classification problem as follows:

$$\begin{aligned} Obj &= \sum_{(e_s,r,e_d)\in D} \log p(r|(e_s,e_d)) \\ &= \sum_{(e_s,r,e_d)\in D} \log \sum_{L} p_\theta(L|(e_s,e_d))p(r|L) \end{aligned} \tag{1}$$

where D is the dataset, (e_s, r, e_d) is the triple contained in the dataset, and L is the latent connecting paths. The evidence probability $p(r|(e_s, e_d))$ can be written as the marginalization of the product of two terms over the latent space. However, this evidence probability is intractable since it requires summing over the whole latent link space. Therefore, we propose to maximize its variational lower bound as follows:

$$\begin{aligned} ELBO = &\underset{L\sim q_\varphi(L|r,(e_s,e_d))}{E}[\log p_\theta(r|L)] - \\ &KL(q_\varphi(L|r,(e_s,e_d))||p_\beta(L|(e_s,e_d))) \end{aligned} \tag{2}$$

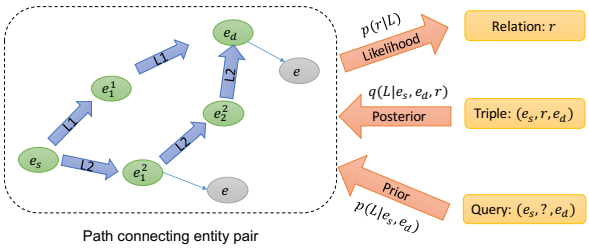

Figure 1: The probabilistic graphical model of our proposed approach. Arrows with dotted border represent the approximate posterior, which is modeled as a multinomial distribution over the whole link space. Arrows with solid border represent the prior and likelihood distributions.

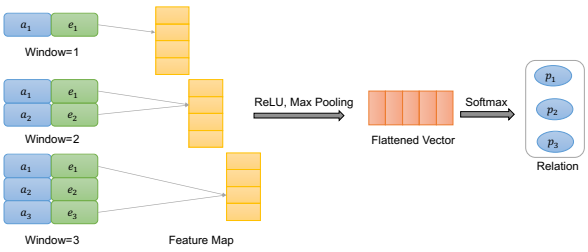

Figure 2: Overview of the CNN Path Reasoner.

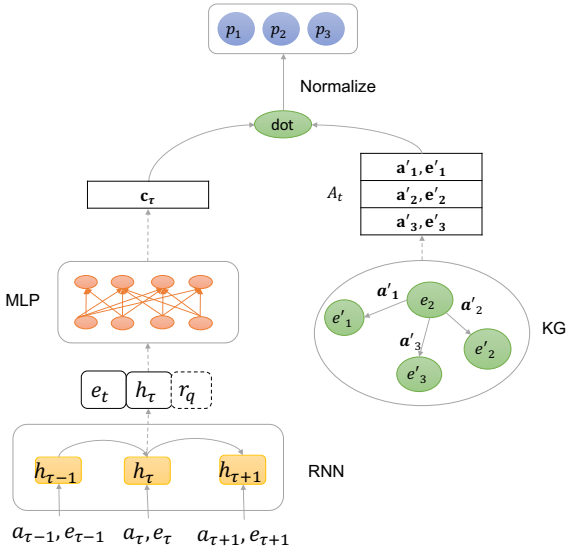

Figure 3: An overview of the path finder model. Note that r_q (query relation) exists in the approximate posterior while disappearing in the path finder model and e_t represents the target entity embedding, c_τ is the output of MLP layer at time step τ, a', e' denotes the connected edges and ends in the knowledge graphs.

Specifically, the ELBO (Kingma and Welling, 2013) is composed of three different terms – likelihood $p_\theta(r|L)$, prior $p_\beta(L|(e_s, e_t))$, and posterior $q_\varphi(L|(e_s, e_d), r)$. In this paper, we use three neural network models to parameterize these terms and then follow (Kingma and Welling, 2013) to apply variational auto-encoder to maximize the approximate lower bound. We describe these three models in details below:

Path Reasoner (Likelihood). Here we propose a path reasoner using Convolutional Neural Networks (CNN) (LeCun et al., 1995) and a feed-forward neural network. This model takes path sequence $L = \{a_1, e_1, \cdots, a_i, e_i, \cdots a_n, e_n\}$ to output a softmax probability over the relations set R, where a_i denotes the i-th intermediate relation and e_i denotes the i-th intermediate entity between the given entity pair. Here we first project them into embedding space and concatenate i-th relation embedding with i-th entity embedding as a combined vector, which we denote as $\{f_1, f_2, \cdots, f_n\}$ and $f_i \in \mathcal{R}^{2E}$. As shown in Figure 2, we pad the embedding sequence to a length of N. Then we design three convolution layers with window size of $(1 \times 2E), (2 \times 2E), (3 \times 2E)$, input channel size 1 and filter size D. After the convolution layer, we use $(N \times 1), (N - 1 \times 1), (N - 2 \times 1)$ to max pool the convolution feature map. Finally, we concatenate the three vectors as a combined vector $F \in \mathcal{R}^{3D}$. Finally, we use two-layered MLP with intermediate hidden size of M to output a softmax distribution over all the relations set R.

$$\begin{aligned} F &= f(f_1, f_2, \cdots, f_N) \\ p(r|L;\theta) &= softmax(W_r F + b_r) \end{aligned} \tag{3}$$

where f denotes the convolution and max-pooling function applied to extract reasoning path feature F, and W_r, b_r denote the weights and bias for the output feed-forward neural network.

Path Finder (Prior). Here we formulate the path finder $p(L|(e_s, e_d))$ as an MDP problem, and recursively predict actions (an outgoing relation-entity edge (a, e)) in every time step based on the previous history h_{t-1} as follows:

$$\begin{aligned} c_t &= ReLU(W_h[h_t; e_d] + b_h) \\ p((a_{t+1}, e_{t+1})|h_t, \beta) &= softmax(A_t c_t) \end{aligned} \tag{4}$$

where the $h_t \in \mathcal{R}^H$ denotes the history embedding, $e_d \in \mathcal{R}^E$ denotes the entity embedding, $A_t \in \mathcal{R}^{|A| \times 2E}$ is outgoing matrix which stacks the concatenated embeddings of all outgoing edges

and $|A|$ denotes the number of outgoing edge, we use W_h and b_h to represent the weight and bias of the feed-forward neural network outputting feature vector $c_t \in \mathcal{R}^{2E}$. The history embedding h_t is obtained using an LSTM network (Hochreiter and Schmidhuber, 1997) to encode all the previous decisions as follows:

$$h_t = LSTM(h_{t-1}, (a_t, e_t)) \tag{5}$$

As shown in Figure 3, the LSTM-based path finder interacts with the KG in every time step and decides which outgoing edge (a_{t+1}, e_{t+1}) to follow, search procedure will terminate either the target node is reached or the maximum step is reached.

Approximate Posterior. We formulate the posterior distribution $q(L|(e_s, e_d), r)$ following the similar architecture as the prior. The main difference lies in the fact that posterior approximator is aware of the relation r, therefore making more relevant decisions. The posterior borrows the history vector from finder as h_t, while the feed-forward neural network is distinctive in that it takes the relation embedding also into account. Formally, we write its outgoing distribution as follows:

$$\begin{aligned} u_t &= ReLU(W_{hp}[h_t; e_d; r] + b_{hp}) \\ q((a_{t+1}, e_{t+1})|h_t; \varphi) &= softmax(A_t u_t) \end{aligned} \tag{6}$$

where W_{hp} and b_{hp} denote the weight and bias for the feed-forward neural network.

3.3 Optimization

In order to maximize the ELBO with respect to the neural network models described above, we follow VAE (Kingma and Welling, 2013) to interpret the negative ELBO as two separate losses and minimize these them jointly using a gradient descent:

Reconstruction Loss. Here we name the first term of negative ELBO as reconstruction loss:

$$J_R = \underset{L \sim q_\varphi(L|r,(e_s,e_d))}{E}[-\log p_\theta(r|L)] \tag{7}$$

this loss function is motivated to reconstruct the relation R from the latent variable L sampled from approximate posterior, optimizing this loss function jointly can not only help the approximate posterior to obtain paths unique to particular relation r, but also teaches the path reasoner to reason over multiple hops and predict the correct relation.

KL-divergence Loss. We name the second term as KL-divergence loss:

$$J_{KL} = KL(q_\varphi(L|r, (e_s, e_d))|p_\beta(L|(e_s, e_d))) \tag{8}$$

this loss function is motivated to push the prior distribution towards the posterior distribution. The intuition of this loss lies in the fact that an entity pair already implies their relation, therefore, we can teach the path finder to approach the approximate posterior as much as possible. During test-time when we have no knowledge about relation, we use path finder to replace posterior approximator to search for high-quality paths.

Derivatives. We show the derivatives of the loss function with respect to three different models. For the approximate posterior, we re-weight the KL-diverge loss and design a joint loss function as follows:

$$J = J_R + w_{KL} J_{KL} \tag{9}$$

where w_{KL} is the re-weight factor to combine these two losses functions together. Formally, we write the derivative of posterior as follows:

$$\frac{\partial J}{\partial \varphi} = \underset{L \sim q_\varphi(L))}{E}[-f_{re}(L)\frac{\partial \log q_\varphi(L|(e_s, e_d), r)}{\partial \varphi} \tag{10}$$

where $f_{re}(L) = \log p_\theta + w_{KL} \log \frac{p_\beta}{q_\varphi}$ denotes the probability assigned by path reasoner. In practice, we found that the KL-reward term $\log \frac{p_\beta}{q_\varphi}$ causes severe instability during training, so we finally leave this term out by setting w_{KL} as 0. For the path reasoner, we also optimize its parameters with regard to the reconstruction as follows:

$$\frac{\partial J_R}{\partial \theta} = \underset{L \sim q_\varphi(L)}{E} - \frac{\partial \log p_\theta(r|L)}{\partial \theta} \tag{11}$$

For the path finder, we optimize its parameters with regard to the KL-divergence to teach it to infuse the relation information into the found links.

$$\frac{\partial J_{KL}}{\partial \beta} = \underset{L \sim q_\varphi(L)}{E} - \frac{\partial \log p_\beta(L|(e_s, e_d))}{\partial \beta} \tag{12}$$

Train & Test During training time, in contrast to the preceding methods like Das et al. (2018); Xiong et al. (2017), we also exploit negative samples by introducing an pseudo "n/a" relation,

Algorithm 1 The DIVA Algorithm.

procedure TRAINING & TESTING
Train:
  for episode ← 1 to N **do**
    Rollout K paths from posterior p_φ
    if Train-Posterior **then**
      $\varphi \leftarrow \varphi - \eta \times \frac{\partial L_r}{\partial \varphi}$
    else if Train-Likelihood **then**
      $\theta \leftarrow \theta - \eta \times \frac{\partial L_r}{\partial \theta}$
    else if Train-Prior **then**
      $\beta \leftarrow \beta - \eta \times \frac{\partial L_{KL}}{\partial \beta}$
    end if
  end for
Test MAP:
  Restore initial parameters θ, β
  Given sample $(e_s, r_q, (e_1, e_2, \cdots, e_n))$
  $L_i \leftarrow BeamSearch(p_\beta(L|e_s, e_i))$
  $S_i \leftarrow \frac{1}{|L_i|} \sum_{l \in L_i} p_\theta(r_q|l)$
  Sort S_i and find positive rank ra^+
  $MAP \leftarrow \frac{1}{1+ra^+}$
end procedure

which indicates "no-relation" between two entities. Therefore, we manage to decompose the data sample $(e_q, r_q, [e_1^-, e_2^-, \cdots, e_n^+])$ into a series of tuples (e_q, r'_q, e_i), where $r'_q = r_q$ for positive samples and $r'_q = n/a$ for negative samples. During training, we alternatively update three submodules with SGD. During test, we apply the path-finder to beam-search the top paths for all tuples and rank them based on the scores assign by path-reasoner. More specifically, we demonstrate the pseudo code in Algorithm 1.

3.4 Discussion

We here interpret the update of the posterior approximator in equation Equation 10 as a special case of REINFORCE (Williams, 1992), where we use Monte-Carlo sampling to estimate the expected return $\log p_\theta(r|L)$ for current posterior policy. This formula is very similar to DeepPath and MINERVA (Xiong et al., 2017; Das et al., 2018) in the sense that path-finding process is described as an exploration process to maximize the policy's long-term reward. Unlike these two models assigning heuristic rewards to the policy, our model assigns model-based reward $\log p_\theta(r|L)$, which is known to be more sophisticated and considers more implicit factors to distinguish between good and bad paths. Besides, our update formula for path reasoner Equation 11 is also similar to chain-of-reasoning (Das et al., 2016), both models are aimed at maximizing the likelihood of relation given the multi-hop chain. However, our model is distinctive from theirs in a sense that the obtained paths are sampled from a dynamic policy, by exposing more diverse paths to the path reasoner, it can generalize to more conditions. By the active interactions and collaborations of two models, DIVA is able to comprehend more complex inference scenarios and handle more noisy environments.

4 Experiments

To evaluate the performance of DIVA, we explore the standard link prediction task on two different-sized KG datasets and compare with the state-of-the-art algorithms. Link prediction is to rank a list of target entities $(e_1^-, e_2^-, \cdots, e_n^+)$ given a query entity e_q and query relation r_q. The dataset is arranged in the format of $(e_q, r_q, [e_1^-, e_2^-, \cdots, e_n^+])$, and the evaluation score (Mean Averaged Precision, MAP) is based on the ranked position of the positive sample.

4.1 Dataset and Setting

We perform experiments on two datasets, and the details of the statistics are described in Table 1. The samples of FB15k-237 (Toutanova et al., 2015) are sampled from FB15k (Bordes et al., 2013), here we follow DeepPath (Xiong et al., 2017) to select 20 relations including Sports, Locations, Film, etc. Our NELL dataset is downloaded from the released dataset[2], which contains 12 relations for evaluation. Besides, both datasets contain negative samples obtained by using the PRA code released by Lao et al. (2011). For each query r_q, we remove all the triples with r_q and r_q^{-1} during reasoning. During training, we set number of rollouts to 20 for each training sample and update the posterior distribution using Monte-Carlo REINFORCE (Williams, 1992) algorithm. During testing, we use a beam of 5 to approximate the whole search space for path finder. We follow MINERVA (Das et al., 2018) to set the maximum reasoning length to 3, which lowers the burden for the path-reasoner model. For both datasets, we set the embedding size E to 200, the history embedding size H to 200, the convolution kernel feature size D to 128, we set the hidden size of MLP for both path finder and path reasoner to 400.

Dataset	#Ent	#R	#Triples	#Tasks
FB15k-237	14,505	237	310,116	20
NELL-995	75,492	200	154,213	12

Table 1: Dataset statistics.

Model	12-rel MAP	9-rel MAP
RPA (Lao et al., 2011)	67.5	-
TransE (Bordes et al., 2013)	75.0	-
TransR (Lin et al., 2015)	74.0	-
TransD (Ji et al., 2015)	77.3	-
TransH (Wang et al., 2014)	75.1	-
MINERVA (Das et al., 2018)	-	**88.2**
DeepPath (Xiong et al., 2017)	79.6	80.2
RNN-Chain (Das et al., 2016)	79.0	80.2
CNN Path-Reasoner	82.0	82.2
DIVA	**88.6**	87.9

Table 2: MAP results on the NELL dataset. Since MINERVA (Das et al., 2018) only takes 9 relations out of the original 12 relations, we report the known results for both version of NELL-995 dataset.

4.2 Quantitative Results

We mainly compare with the embedding-based algorithms (Bordes et al., 2013; Lin et al., 2015; Ji et al., 2015; Wang et al., 2014), PRA (Lao et al., 2011), MINERVA (Das et al., 2018), DeepPath (Xiong et al., 2017) and Chain-of-Reasoning (Das et al., 2016), besides, we also take our standalone CNN path-reasoner from DIVA. Besides, we also try to directly maximize the marginal likelihood $p(r|e_s, e_d) = \sum_L p(L|e_s, e_d)p(r|L)$ using only the prior and likelihood model following MML (Guu et al., 2017b), which enables us to understand the superiority of introducing an approximate posterior. Here we first report our results for NELL-995 in Table 2, which is known to be a simple dataset and many existing algorithms already approach very significant accuracy. Then we test our methods in FB15k (Toutanova et al., 2015) and report our results in Table 3, which is much harder than NELL and arguably more relevant for real-world scenarios.

Besides, we also evaluate our model on FB-15k 20-relation subset with HITS@N score. Since our model only deals with the relation classification problem $(e_s, ?, e_d)$ with e_d as input, so it's hard for us to directly compare with MINERVA (Das et al., 2018). However, here we compare with chain-RNN (Das et al., 2016) and CNN Path-Reasoner model, the results are demonstrated as Table 4. Please note that the HITS@N score is computed against relation rather than entity.

Model	20-rel MAP
PRA (Lao et al., 2011)	54.1
TransE (Bordes et al., 2013)	53.2
TransR (Lin et al., 2015)	54.0
MINERVA (Das et al., 2018)	55.2
DeepPath (Xiong et al., 2017)	57.2
RNN-Chain (Das et al., 2016)	51.2
CNN Path-Reasoner	54.2
MML (Guu et al., 2017b)	58.7
DIVA	**59.8**

Table 3: Results on the FB15k dataset, please note that MINERVA's result is obtained based on our own implementation.

Model	HITS@3	HITS@5
RNN-Chain (Das et al., 2016)	0.80	0.82
CNN Path-Reasoner	0.82	0.83
DIVA	**0.84**	**0.86**

Table 4: HITS@N results on the FB15k dataset

Result Analysis We can observe from the above tables Table 3 and Table 2 that our algorithm has significantly outperformed most of the existing algorithms and achieves a very similar result as MINERVA (Das et al., 2018) on NELL dataset and achieves state-of-the-art results on FB15k. We conclude that our method is able to deal with more complex reasoning scenarios and is more robust to the adversarial examples. Besides, we also observe that our CNN Path-Reasoner can outperform the RNN-Chain (Das et al., 2016) on both datasets, we speculate that it is due to the short lengths of reasoning chains, which can extract more useful information from the reasoning chain.

From these two pie charts in Figure 5, we can observe that in NELL-995, very few errors are coming from the path reasoner since the path length is very small. A large proportion only contains a single hop. In contrast, most of the failures in the FB15k dataset are coming from the path reasoner, which fails to classify the multi-hop chain into correct relation. This analysis demonstrates that FB15k is much harder dataset and may be closer to real-life scenarios.

4.3 Beam Size Trade-offs

Here we are especially interested in studying the impact of different beam sizes in the link prediction tasks. With larger beam size, the path finder can obtain more linking paths, meanwhile, more noises are introduced to pose greater challenges for the path reasoner to infer the relation. With smaller beam size, the path finder will struggle to find connecting paths between positive entity

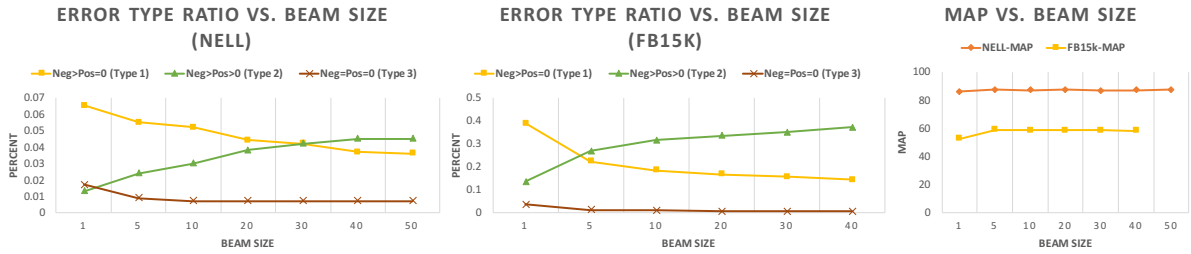

Figure 4: MAP results varying beam size and the error type's occurrence w.r.t to beam size. A beam size that is too large or too small would cause performance to drop.

Type	Reasoning Path	Score
Negative	athleteDirkNowitzki → *(athleteLedSportsteam)* → sportsteamMavericks	0.98
Positive	athleteDirkNowitzki → *(athleteLedSportsteam)* → sportsteamDallasMavericks	0.96
Explanation	*"maverick" is equivalent to "dallas-maverick", but treated as negative sample*	-
Negative	athleteRichHill → *(personBelongsToOrganization)* → sportsteamChicagoCubs	0.88
Positive	athleteRichHill → *(personBelongsToOrganization)* → sportsteamBlackhawks	0.74
Explanation	*Rich Hill plays in both sportsteam but the knowledge graph only include one*	-
Negative	coachNikolaiZherdev → *(athleteHomeStadium)* → stadiumOreventvenueGiantsStadium → *(teamHomestadium^{-1})* → sportsteamNewyorkGiants	0.98
Positive	coachNikolaiZherdev → *(athleteHomeStadium)* → stadiumOreventvenueGiantsStadium → *(teamHomestadium^{-1})* → sportsteam-rangers	0.72
Explanation	*The home stadium accommodates multiple teams, therefore the logic chain is not valid*	-

Table 5: The three samples separately indicates three frequent error types, the first one belongs to "duplicate entity", the second one belongs to "missing entity", while the last one is due to "wrong reasoning". Please note that the parenthesis terms denote relations while the non-parenthesis terms denote entities.

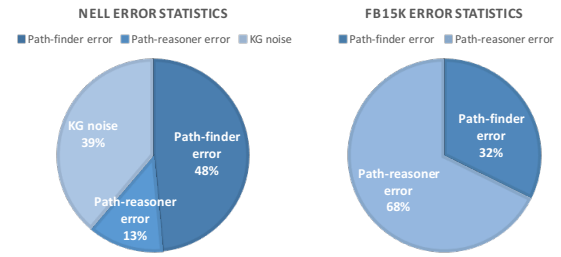

Figure 5: Error analysis for the NELL and FB15k link prediction task. Since FB15k dataset uses placeholders for entities, we are not able to analyze whether the error comes from KG noise.

pairs, meanwhile eliminating many noisy links. Therefore, we first mainly summarize three different types and investigate their changing curve under different beam size conditions:

1. No paths are found for positive samples, while paths are found for negative samples, which we denote as Neg>Pos=0.

2. Both positive samples and negative samples found paths, but the reasoner assigns higher scores to negative samples, which we denote as Neg>Pos>0.

3. Both negative and positive samples are not able to find paths in the knowledge graph, which we denote as Neg=Pos=0.

We draw the curves for MAP and error ratios in Figure 4 and we can easily observe the trade-offs, we found that using beam size of 5 can balance the burden of path-finder and path-reasoner optimally, therefore we keep to this beam size for the all the experiments.

4.4 Error Analysis

In order to investigate the bottleneck of DIVA, we take a subset from validation dataset to summarize the causes of different kinds of errors. Roughly, we classify errors into three categories, 1) KG noise: This error is caused by the KG itself, e.g some important relations are missing; some entities are duplicate; some nodes do not have valid outgoing edges. 2) Path-Finder error: This error is caused by the path finder, which fails to arrive destination. 3) Path-Reasoner error: This error

is caused by the path reasoner to assign a higher score to negative paths. Here we draw two pie charts to demonstrate the sources of reasoning errors in two reasoning tasks.

4.5 Failure Examples

We also show some failure samples in Table 5 to help understand where the errors are coming from. We can conclude that the "duplicate entity" and "missing entity" problems are mainly caused by the knowledge graph or the dataset, and the link prediction model has limited capability to resolve that. In contrast, the "wrong reasoning" problem is mainly caused by the reasoning model itself and can be improved with better algorithms.

5 Conclusion

In this paper, we propose a novel variational inference framework for knowledge graph reasoning. In contrast to prior studies that use a random walk with restarts (Lao et al., 2011) and explicit reinforcement learning path finding (Xiong et al., 2017), we situate our study in the context of variational inference in latent variable probabilistic graphical models. Our framework seamlessly integrates the path-finding and path-reasoning processes in a unified probabilistic framework, leveraging the strength of neural network based representation learning methods. Empirically, we show that our method has achieved the state-of-the-art performances on two popular datasets.

Abstract

Recognizing temporal relations among events and time expressions has been an essential but challenging task in natural language processing. Conventional annotation of judging temporal relations puts a heavy load on annotators. In reality, the existing annotated corpora include annotations on only "salient" event pairs, or on pairs in a fixed window of sentences. In this paper, we propose a new approach to obtain temporal relations from absolute time value (a.k.a. *time anchors*), which is suitable for texts containing rich temporal information such as news articles. We start from time anchors for events and time expressions, and temporal relation annotations are induced automatically by computing relative order of two time anchors. This proposal shows several advantages over the current methods for temporal relation annotation: it requires less annotation effort, can induce inter-sentence relations easily, and increases informativeness of temporal relations. We compare the empirical statistics and automatic recognition results with our data against a previous temporal relation corpus. We also reveal that our data contributes to a significant improvement of the downstream time anchor prediction task, demonstrating 14.1 point increase in overall accuracy.

1 Introduction

Temporal information extraction is becoming an active research field in natural language processing (NLP) due to the rapidly growing need for NLP applications such as timeline generation and question answering (Llorens et al., 2015; Meng et al., 2017). It has great potential to create many practical applications. For example, SemEval-2015 Task 4 (Minard et al., 2015) collects news articles about a target entity and the task required participants automatically ordering the events involving that entity in a timeline. The timeline representation of news can help people more easily comprehend a mass of information. This work aims to contribute to such timeline applications by extracting temporal information in specific domains like news articles.

TimeBank[1] (Pustejovsky et al., 2003) is the first widely used corpus with temporal information annotated in the NLP community. It contains 183 news articles that have been annotated with events, time expressions and temporal relations between events and time expressions. The annotation follows the TimeML[2] specification (Saurı et al., 2006). Along with the TimeBank and other temporal information corpora, a series of competitions on temporal information extraction (TempEval-1,2,3) (Verhagen et al., 2009, 2010; UzZaman et al., 2012) are attracting growing research efforts.

A majority of temporal information corpora adopt temporal links (TLINKs) to encode temporal information in documents. A TLINK denotes a temporal relation between mentions, i.e., events, time expressions and document creation time (DCT) (Setzer, 2002). However, annotating TLINKs is a painful work, because annotation candidates are quadratic to the number of mentions in a document. The original TimeBank only annotated those "salient" mention pairs judged by annotators, while the definition of "salient" is not necessarily clear. Annotators had to face a complicated task; identify "salient" mention pairs, and label temporal relations. For solving this, many dense annotation schemata are proposed to force annotators to annotate more or even complete graph pairs. However, dense annotation is time-consuming and unstable human judgments

on "salient" pairs are not improved at all. As a consequence, a high proportion of "vague" or "no-link" pairs appears in these dense corpora such as TimeBank-Dense (Cassidy et al., 2014).

In this work, we propose a new approach to obtain temporal relations from time anchors, i.e. absolute time value, of all mentions. We assume that a temporal relation can be induced by comparing the relative temporal order of two time anchors (e.g. *YYYY-MM-DD*) in a time axis. We use pre-defined rules (Section 3) to generate temporal order (TORDER) relations (e.g. BEFORE, AFTER, SAME_DAY, etc.) by taking two annotated time anchors as input. This proposal requires the annotation of time anchors, of which the annotation effort is linear with the number of mentions. This is the first work to obtain temporal relations shifted from the annotation of individual mentions, which is distinguished from most annotation work of manually annotating mention pairs.

This approach brings several advantages over the current temporal relation annotation. First, as long as time anchors of all mentions in a document are given, our pre-defined rules can induce the temporal relations for all the quadratic pairs. This skips the step of identifying "salient" pairs. Second, annotating the time anchors is relatively easy, as the annotation work is linear to the number of mentions. Third, the automatic generation rules can provide flexible relation types based on our definition and this increased informativeness might contribute positively to downstream tasks.

In our first evaluation (Section 4), we compare the correspondence and difference between the new TORDERs and conventional TLINKs. The comparison of empirical statistics shows the new data is label balanced, contains informative relations and reduces "vague" relations. Besides, the classification performance suggests the new data achieve reasonable accuracy, although accuracy numbers are not directly comparable.

Many text processing tasks are often requiring to know time anchors when events occurred in a timeline. In Section 5, we evaluate the data in a downstream time anchor prediction task (Reimers et al., 2016) by using the temporal relation recognizers separately trained with TORDERs or TLINKs. The main results show that the recognizer trained with our TORDERs significantly outperforms the recognizer trained with the TLINKs by 14.1 point *exact match* accuracy.

2 Background

2.1 Temporal Relation Annotation

TimeBank started a wave of data-driven temporal information extraction research in the NLP community. The original TimeBank only annotated relations judged to be *salient* by annotators and resulted in sparse annotations. Subsequent TempEval-1,2,3 competitions (Verhagen et al., 2009, 2010; UzZaman et al., 2012) mostly relied on TimeBank, but also aimed to improve coverage by annotating relations between all events and time expressions *in the same sentence*. However, most missing relations between mentions in different sentences are not considered.

In order to solve the sparsity issue, researchers started the work towards denser annotation schema. Bramsen et al. (2006) annotated multi-sentence segments of text to build directed acyclic graphs. Kolomiyets et al. (2012) annotated temporal dependency structures, though they only focused on relations between pairs of events. Do et al. (2012) produced the densest annotation and the annotator was required to annotate pairs "as many as possible". Cassidy et al. (2014) proposed a compulsory mechanism to force annotators to label every pair in a given sentence window. They performed the annotation (TimeBank-Dense) on a subset (36 documents) of TimeBank, which achieved a denser corpus with 6.3 TLINKs per event and time expression, comparing to 0.7 in the original TimeBank corpus. However, it raises the issue that hand-labeling all dense TLINKs is extremely time-consuming and the unclear definition of "salient" is not improved at all.

2.2 Temporal Relation Classification

The majority of the temporal relation classifiers focus on exploiting a variety of features to improve the performance in TimeBank. Laokulrat et al. (2013) extracted lexical and morphological features derived from WordNet synsets. Mani et al. (2006); D'Souza and Ng (2013) incorporated semantic relations between verbs from VerbOcean.

Recently, more researchers move on to diverse approaches on the TimeBank-Dense corpus. Chambers et al. (2014) proposed a multi-sieve classifier composed of several rule-based and machine learning based sieves ranked by their precision. Mirza and Tonelli (2016) started to mine the value of low-dimensional word embeddings by concatenating them with traditional sparse feature

vectors to improve their classifier.

Inspired by the success of the deep learning work in the similar task: relation extraction, Cheng and Miyao (2017) proposed the shortest dependency path based Bi-directional Long short-term memory (Hochreiter and Schmidhuber, 1997) (Bi-LSTM) to achieve state-of-the-art performance in the TimeBank-Dense corpus, which is adopted for the experiments in this paper. There are two reasons to use this classifier: 1) inter-sentence temporal relations are well treated. 2) only word, part-of-speech and dependency relation embeddings are required as input.

2.3 Time Anchor Annotation

A related task: Cross-Document Event Ordering (Minard et al., 2015) aims to order the events involving a target entity in a timeline given written news in English. Compared to traditional TLINKs, annotating time anchors of events is intuitively more straightforward in such tasks.

Reimers et al. (2016) proposed an annotation scheme, which requires annotators to infer the exact time of each individual event. They distinguished events that occur at a *Single-Day* from that span over *Multi-Day* by setting the granularity as one day. For *Single-Day* events, the event time is written in the format '*YYYY-MM-DD*' when the precise event time can be determined. Otherwise, they required annotators to narrow down the possible time as precisely as possible. An imprecise *Single-Day* event can be annotated as a tuple *(after, before)*, e.g. '*(after 1998-10-02,)*', '*(, before 2000-01-31)*' or '*(after 1998-10-02, before 2000-01-31)*'. In the case of *Multi-Day*, an event is annotated as a tuple *(begin, end)*, where *begin* and *end* are represented with *Single-Day*. For instance of a sentence:

> *The economy **created** jobs at a surprisingly robust pace in January, the government **reported** on Friday, evidence that America's economic stamina has withstood any **disruption** caused so far by the financial tumult in Asia.*

The *Multi-Day* event ***created*** is annotated as *(begin=1998-01-01, end=1998-01-31)*. The *Single-Day* event ***reported*** is annotated as the same day as DCT *(1998-02-06)*. The imprecise *Multi-Day* event ***disruption*** is annotated as *(begin=(, before1998-02-06), end=(, before1998-02-06))* as the event must have occurred before the time of this news, but the precise *begin* and *end* dates cannot be inferred from the text. Time anchors have the capability of anchoring all the events from a document into the same timeline as shown in Figure 1. They annotated the time anchors of total 1,498 events from 36 documents of TimeBank-Dense.

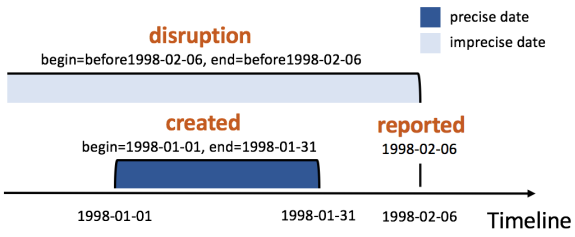

Figure 1: Anchoring events in a timeline

In temporal information retrieval, Berberich et al. (2010) proposed a four-tuple representation *('earliest begin', 'latest begin', 'earliest end', 'latest end')* for uncertain time expression (e.g. '1990s') in order to integrate such temporal information into language model. In the time anchor annotation, an event 'in 1990s' will be annotated as a *Multi-Day* event with imprecise *begin* and *end* points, i.e. *(begin=(after 1990-01-01, before1999-12-31), end=(after 1990-01-01, before1999-12-31))*, which is quite similar to their four-tuple representation.

3 Automatic generation of TORDERs

TimeML states that TLINKs present a temporal relation between event to event, event to time expression, and event to DCT. The sparse TLINK coverage in the majority of temporal information corpora is attributed to the unstable identification of "salient" pairs by human annotators. Denser annotation schemata somehow improved sparseness, but the annotation work became very time-consuming. These issues plague the development of temporal information extraction work.

Our temporal order (TORDER) proposal is designed with the goal of solving unstable recognition of "salient" pairs and reducing annotation effort. We hypothesize that a temporal relation can be automatically computed by comparing the relative temporal order between two time anchors (e.g. *YYYY-MM-DD*) in a time axis. We propose a set of pre-defined generation rules, which have the capability to rigorously induce a TORDER by taking the two annotated time anchors as input. Annotat-

TORDER	Condition
Two precise S_1 and S_2	
BEFORE	if $S_1 < S_2$
AFTER	if $S_1 > S_2$
SAME_DAY	if $S_1 = S_2$
A precise S_1 and an imprecise S_2 ($after_2, before_2$)	
BEFORE	if $S_1 \leq after_2$
AFTER	if $S_1 \geq before_2$
VAGUE	other cases
Two imprecise S_1 ($after_1, before_1$) and S_2 ($after_2, before_2$)	
BEFORE	if $before_1 \leq after_2$
AFTER	if $after_1 \geq before_2$
PVAGUE	if $before_1 = before_2$ and $after_1 = after_2$
VAGUE	other cases

IS_INCLUDED	if $begin_1$ **AFTER/SAME_DAY** $begin_2$ and end_1 **BEFORE/SAME_DAY** end_2 (*)
INCLUDES	if $begin_1$ **BEFORE/SAME_DAY** $begin_2$ and end_1 **AFTER/SAME_DAY** end_2 (*)
PVAGUE	if $begin_1$ **PVAGUE/SAME_DAY** $begin_2$ and end_1 **PVAGUE/SAME_DAY** end_2 (*)
VAGUE	other cases

Table 2: Definition of the temporal orders involving *Multi-Day* events M $(begin, end)$. '*' denotes excluding the **SAME_SPAN** case in the current condition.

ing time anchors of individual mentions extremely reduces annotation effort, as it is linear with mention numbers. As long as time anchors are given, our pre-defined rules can induce the temporal relations for all the quadratic pairs, which skips the step of identifying "salient" pairs.

TimeBank contains the normalized date '*YYYY-MM-DD*' of time expressions and DCT, but does not include events' time. Our proposal of inducing a TORDER by comparing two time anchors requires the time anchor annotation of events in the same granularity as time expressions and DCT. Therefore, annotating the events with '*YYYY-MM-DD*' is a reasonable setting and one day is used as the minimal granularity of annotation. We choose the annotation (Reimers et al., 2016) of the day-level time anchors of events as the source of our automatic TORDER generator. In the case that a corpus can provide more specific time information '*YYYY-MM-DD, hh-mm-ss*' (e.g. this morning, three o'clock in the afternoon), our TORDER generator can be flexible to handle this information as long as the time anchors of all mentions are annotated in the same granularity.

For the clear demonstration of the definition of the auto-generated temporal order, we separately describe the generation of the pairs with two *Single-Day* mentions, and the pairs involving *Multi-Day* mentions. In this paper, TORDER labels are written in the upper-case bold font to be distinguished from TLINK labels written in the lower-case italic font. Table 1 introduces the definition of temporal orders between two *Single-Day* pairs S_1 and S_2. **PVAGUE** (i.e. partially vague) denotes that two imprecise time anchors are equivalent. For instance, we cannot induce a clear temporal relation between two events both occurring on *(,before1998-02-06)*, but nevertheless both events provide partially equivalent date information *'1998-02-06'*. It can possibly provide useful information for the future processes of classification or time inference. **PVAGUE** in the *Multi-Day* definition takes the same consideration.

In order to introduce the temporal orders involving *Multi-Day* events, a *Multi-Day* event M is denoted as a tuple of two *Single-Day* dates $(begin, end)$. A temporal order between a *Single-Day* S_1 and *Multi-Day* M_2 $(begin_2, end_2)$ can be derived by computing the temporal order of two *Single-Day* S_1 and $begin_2$, or S_1 and end_2 first. All the types of temporal orders involving *Multi-Day* events are defined in Table 2. One additional INCLUDES relation that *Multi-Day* event includes a *Single-Day* event can be obtained by reversing the symmetric IS_INCLUDED.

The example of automatically computing temporal orders can be demonstrated by using the events in Figure 1. Both *Multi-Day* ***created*** and ***disruption*** are clearly BEFORE the *Single-Day* ***reported***, because ***reported*** is AFTER the *end* dates of ***created*** and ***disruption***. The relation between ***created*** and ***disruption*** is induced as VAGUE, as the imprecise *begin*, *end* of ***disruption*** cannot be determined with a relation to ***created***.

In this paper, the definition adopts a similar relation set to TLINK for the purpose that we can perform fair comparison and evaluation in the next two sections. However, our inducing proposal can be very scalable to introduce more temporal relations. For instance, Allen's interval algebra (Allen, 1990) defines 'starts', 'finish' relations, which are not included in our current defini-

tion. We can easily extend our definition by detecting whether two time anchors have the equivalent *begin* or *end* points.

Our inducing proposal takes human annotated time expressions and normalized values as inputs to generate TORDER relations as the training data of the next processes (e.g. classification). In the case of processing raw texts, we can perform detection and normalization of time expressions by using existing temporal taggers, e.g. HeidelTime (Strötgen and Gertz, 2015), SUTime (Chang and Manning, 2012), etc.

4 Comparison of TORDERs and TLINKs

Fairly evaluating the TORDER's capability of encoding temporal order information compared to the existing data is difficult but necessary work. This section provides empirical statistics of TORDER and TLINK annotations, and compare the performance of automatic recognition. Additionally, we evaluate these two frameworks in a downstream task performance in Section 5.

4.1 Correspondences and Differences

Our new TORDERs are formally similar to the conventional TLINKs, as both state a temporal relation between two mentions. BEFORE and AFTER represent that one mention occurs before or after in a timeline, which is close to *before* and *after*. INCLUDES and IS_INCLUDED are more clearly conditioned as a *Single-Day* or *Multi-Day* mention occurs during the other *Multi-Day* mention, compared to *includes* and *is_included*. SAME_DAY and SAME_SPAN are designed for the one-day minimal granularity. Ideally, these two relations will include *simultaneous* and other TLINKs with two mentions occurring in the same day. VAGUE and PVAGUE state that our generation rules cannot induce the relations, similar to *vague* (i.e. annotators cannot judge the relations).

The one-day minimal granularity is the main reason causing the difference between TORDER and TLINK types. For a sentence:

> *I went to **sleep** after taking a **bath**.*

According to the TimeML specification, ***sleep*** is obviously *after* ***bath***. But in the one-day granularity, the relation is shifted to SAME_DAY. This brings the obstacle that we cannot measure whether the temporal information encoded in TORDERs is more informative than TLINKs by directly comparing the classification results.

Our TORDER definition shows the capability of capturing some relations which cannot be encoded by TLINK. For instance:

> Stocks ***rose***, ***pushing*** the Dow Jones industrial average up 72.24 points, to 8,189.49, ***leaving*** the index within 70 points of its record.

These TLINKs among the three events are annotated as *vague* in TimeBank-Dense, as the annotators cannot state their temporal orders. However, we can easily obtain SAME_DAY relations, since their day-level time anchors are the same.

Imprecisely represented time anchors (e.g. *after YYYY-MM-DD*) are the major drawback of losing temporal order information. For instance:

> America's economic stamina has **withstood** any **disruption**...

The TLINK between ***withstood*** and ***disruption*** is annotated as *after*. While both of them were annotated as the same time anchor *(begin=before 1998-02-06, end= before 1998-02-06)*, our TORDER generator induced a PVAGUE relation and temporal order information is lost.

The hypothesis that our proposal skipping the unstable manual identification of "salient" pairs can reduce the VAGUE relations in the new data. This can be measured by comparing the numbers of the TORDER and TLINK relations on the same mention pairs. If the observation of a part of *vague* TLINKs induced as non-VAGUE TORDERs in the new data can be found, it will be the evidence.

Depending on the text domain, TLINKs or TORDERs can be advantageous in different scenarios. TLINKs can capture the temporal ordering information between events, when time expressions are often absent in the documents such as novels and narratives. But the annotation work is time consuming and a part of relations will be neglected by the unstable human identification of "salient" pairs. TORDERs have the capability of capturing more informative relations by skipping the "salient" pairs recognition and need less annotation effort. But they require that the events can be anchored in a timeline from a document (e.g. often the case of news articles) and imprecise time anchors cause some information loss.

4.2 Empirical Comparison

Investigating the quality of auto-generated TORDERs is important to demonstrate the value of this research. In this section, we empirically compare the statistics of the auto-generated TORDERs and human-annotated TLINKs. Theoretically, a TORDER between two mentions with any distance in a document can be automatically computed. However, it is important to make the new data in a comparable manner to the existing data. In this paper, we follow the process of TimeBank-Dense (Cassidy et al., 2014) to generate the complete graph of the 10,007 mention pairs in the same and adjacent sentences. The TORDER data used in this paper are publicly available[3] and our scalable generation method can be easily applied for inducing relations of longer distance pairs.

Table 3 shows the comparison between the numbers of the TimeBank-Dense TLINKs and the new TORDERs. One observation as we expected is that our approach captures new relations for a considerable part of the mention pairs that were judged as ***v*** (*vague*) in the human-annotated TLINKs. 542 *vague* relations are induced as AFTER in the new TORDERs, as well as other relation types. However, a part of non-*vague* TLINKs are shifted to VAGUE TORDERs. This matches our description of the imprecise time anchor issue. It is a trade-off between the part of mention pairs obtaining richer temporal information and the part of pairs losing information. That is the reason why we need a downstream task (i.e. Time Anchors Prediction in Section 5) to measure how much temporal order information is encoded in TORDERs and TLINKs. The shift of TLINK relations to SAME_DAY due to the one-day minimal granularity setting can also be clearly observed.

Figure 2 shows the label distributions of the auto-generated TORDERs and the TimeBank-Dense TLINKs. We investigate the statistics of Event-Event, Event-Time, and Event-DCT pairs. The TimeBank-Dense corpus is obviously sparser due to the high proportion of *vague* in all three types of pairs. Our TORDERs show a more balanced distribution of labels, which suggests that this method possibly encodes more informative temporal orders compared to the traditional TLINKs. In particular, TORDERs show extremely rare VAGUE labels in Event-DCT pairs. When given the precise *Single-Day* DCT of a document, our proposal to compare the temporal order between the time anchor of a event and the DCT manages to avoid the most unstable judgments made by the human annotators in the Event-DCT pairs. Although the different definition of TORDERs from TLINKs makes direct comparison difficult, the more balanced distribution of TORDERs can possibly provide more informative classification results to benefit the downstream tasks.

(b) TLINK

Table 4: The classification results of Event-Event, Event-DCT and Event-Time F1-measure on individual relation types and weighted overall F1. '**N**' denotes the number of the relations in the test split.

4.3 Classification Results

Although the classification results of TORDERs and TLINKs are not directly comparable, they can show some evidence whether TORDERs is functional to provide temporal order information. Table 4 shows the Bi-LSTM classification results with the data split[4](Chambers et al., 2014) (27 training/validation documents, 9 testing documents).

The classification system achieves fairly high F1 0.631 in Event-DCT and 0.485 in Event-Time on the SAME_DAY temporal orders, which are the main information source to predict the precise time of events. The performance on AFTER, BEFORE temporal orders are close to the TLINKs in number, but not meaningfully comparable. The high proportion of *vague* in the TLINKs results in biased predictions. When we use a more meaningful evaluation 'Non-*vague*' overall, the TLINKs performance drops sharply. Generally, the classification results suggest that our proposal of auto-generated TORDERs has sufficient capability to encode temporal information, which can be well classified from the textual inputs.

[4]https://github.com/nchambers/caevo/blob/master/src/main/java/caevo/Evaluate.java

5 Evaluation in Time Anchor Prediction

In this section, we describe a two-step system trained with the existing TLINKs and our data to challenge a downstream time anchor prediction task. The different performance can be seen as the evidence whether our auto-generated TORDERs can capture comparable temporal information to the human-annotated TLINKs.

5.1 Task Definition

Predicting the time of events from the news articles is an attractive goal, which is a necessary step towards automatic event timeline extraction. Reimers et al. (2016) bring the task of time anchor prediction, which aims to predict the time anchor of each *Single-Day* event given a document. They use a general two-step process to determine the event anchors as shown in Figure 3. Given a set of documents with events and time expressions already annotated, the system first obtains a list of possible times for each event. Then, the most precise time is selected for each event.

A serious issue is that their baseline system still depends on the TimeBank-Dense TLINK classifier and the time anchor annotation is only used for the final evaluation. That leaves the space to consider a new method without relying on the human-annotated TLINKs. Our auto-generated TORDERs are a natural alternative to TLINKs to provide the similar temporal order information of mention pairs, but with less annotation efforts. The second-step selection rules just need a slight modification to replace the previous TLINK types with the new TORDER types.

5.2 The Two-step System in Experiments

In this work, we adopt a similar two-step architecture. The first-step temporal order classifier is designed to provide the temporal relations of the mention pairs in a document.

The second-step selects the most precise time by taking all Event-Time and Event-DCT relations of a target event as input. For instance in Figure 3, the second-step received a set of relations e.g. $(is\_included, DCT)$, $(is\_included, Friday)$ and $(vague, January)$ of ***reported***. For the system trained with the TimeBank-Dense TLINKs, we adopt the same selection algorithm as described in (Reimers et al., 2016). When the system is trained

Event Type	Source	TORDER		Gold TORDER		TLINK		Gold TLINK

Table 5: The comparison of the cross-validation performance in the time anchor prediction task. 'Exact' and 'Partial' denote the two evaluation metrics: *exact match* and *partial match* accuracy. 'Gold' denotes the oracle performance of using the gold TORDERs or gold TLINKs as the input of the second-step.

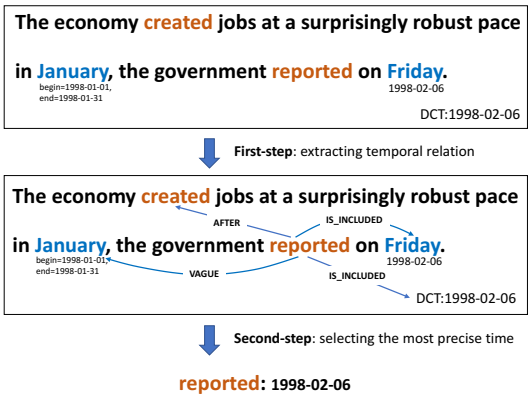

Figure 3: The two-step process to determine the event anchors proposed in (Reimers et al., 2016).

with the TORDERs, we slightly modified the algorithm by replacing the TLINK relations with similar TORDER relations. SAME_DAY replaces *simultaneous* to predict precise dates, although their definition is quite different.

5.3 Experiment Settings

We perform a 6-fold cross-validation strategy to predict all the TORDERs and TLINKs of the mention pairs in the 36 documents of the TimeBank-Dense corpus. In each run, we split 30 documents for training and validation to predict the other 6 test documents.

We define two evaluation metrics, i.e. *Exact Match* accuracy and *Partial Match* accuracy to measure the performance in this task as follows:

$$exact\ match = \frac{\#Number\ of\ the\ exact\ match\ predictions}{\#Total\ number\ of\ the\ test\ samples}$$

$$partial\ match = \frac{\#Number\ of\ the\ partial\ match\ predictions}{\#Total\ number\ of\ the\ test\ samples}$$

We define two *partial match* cases: 1) a precise *(1998-02-06)* is *partial match* with an imprecise *(after 1998-02-06)*, if the date values are the same. 2) *(after 1998-02-06)* is *partial match* with *(after 1998-02-06, before 1998-02-21)*, if one is a part of the other.

5.4 Main Results

Table 5 summarizes the main results of the two-step time anchor prediction system trained with TORDER and TLINK data. 'Precise', 'Imprecise' and 'Overall' denote the results of predicting time anchors of precise events, imprecise events, and overall performance. 'Event-DCT' or 'Event-Time' denotes the second-step selection takes only Event-DCT or Event-Time pairs as input, which helps us to investigate how much information is provided by the different types of pairs for predicting the final time anchors. The new TORDERs show significantly superior out-performance in all three settings (i.e. only Event-DCT pairs, only Event-Time pairs, or Event-DCT + Event-Time), compared to the TLINKs. With both Event-DCT and Event-Time temporal order information, the system achieves the highest overall *exact match* and *partial match* accuracy.

The Event-DCT, Event-Time pairs are the source of temporal information for predicting *time anchors*. The system only using the Event-DCT achieves surprisingly high accuracy, particularly on the TORDER *partial match* accuracy of the

	Exact	Partial
CAEVO	0.442	0.553
Bi-LSTM TLINK	0.437	0.550
Bi-LSTM TORDER	0.586	0.811

Table 6: The comparison to the state-of-the-art dense TLINK classifier

precise events. The reason is that most events reported in news articles usually occur in precisely the same day as DCT. Therefore, the TORDER Event-DCT is benefited from the low proportion of vague relations, which sharply outperforms the TLINK Event-DCT by 16.3% overall *exact match*. However, the contribution of the Event-Time to the overall might be underestimated in this task somehow. The TORDER Event-Time still beats the TLINKs by 11% overall *exact match* and 16.4% overall partial match. Furthermore, the Event-Time encoding the temporal information within 1-sentence window in our experiments can be easily strengthen by our TORDER proposal to introduce more inter-sentence pairs.

5.5 Comparison to a state-of-the-art dense TLINK classifier

In this section, we perform an additional experiment to make a comparison to a system with the first-step replaced by a state-of-the-art dense TLINK classifier CAEVO (Chambers et al., 2014). We adopt the data split setting in Section 4.3 for three classifiers: CAEVO, Bi-LSTM classifier trained with TLINKs and Bi-LSTM classifier trained with TORDERs.

The results are summarized in Table 6. CAEVO achieves the *exact match* accuracy slightly better than the Bi-LSTM model trained with the TLINKs. The Bi-LSTM model trained with the TORDERs sharply outperforms the other two systems by approximate 14% *exact match* accuracy and approximate 26% in *partial match* accuracy.

6 Conclusion

In this paper, we propose a new approach to obtain temporal relations based on time anchors (i.e. absolute time value) of mentions in news articles. Our pre-defined generation rules can automatically induce TORDER relations by comparing the temporal order of two time anchors in a timeline. The requirement of our proposal for annotating time anchors is much easier compared to conventional methods, as the annotation effort is linear with the number of mentions. The TORDER data used in this paper are publicly available. The analysis, empirical comparison and classification results of the new TORDERs and the TimeBank-Dense TLINKs show our new data achieve the low VAGUE proportion, the informative relation types and the balanced label distribution. We perform the second evaluation of using the temporal relation classifier to complete the downstream task of time anchor prediction in news articles. The main results show our TORDERs significantly outperform the TLINKs in this task, which suggests our proposal has the capability to encode informative temporal order information with less annotation effort.

The main limitation of TORDER is that events are required to be anchored in a timeline. Strötgen and Gertz (2016) introduce the highly different characteristics of time expressions in four domains of text. It suggests that our proposal is difficult to be applied in some domains. One possible solution is to adopt a hybrid annotation method to annotate a target event towards the most relevant event (TLINK-style), when temporal information is absent in its context. Although this work is motivated for contributing to timeline applications, evaluating this proposal in the temporal question answering is also valuable. **SAME_DAY** could be harmful because this task possibly requires to know the exact order between two events occurring on the same day. It is worth conceiving a more general solution to improve the limitations of TORDER in the future work.

Abstract

Entity Linking (EL) systems aim to automatically map mentions of an entity in text to the corresponding entity in a Knowledge Graph (KG). Degree of connectivity of an entity in the KG directly affects an EL system's ability to correctly link mentions in text to the entity in KG. This causes many EL systems to perform well for entities well connected to other entities in KG, bringing into focus the role of KG density in EL. In this paper, we propose Entity Linking using Densified Knowledge Graphs (ELDEN). ELDEN is an EL system which first densifies the KG with co-occurrence statistics from a large text corpus, and then uses the densified KG to train entity embeddings. Entity similarity measured using these trained entity embeddings result in improved EL. ELDEN outperforms state-of-the-art EL system on benchmark datasets. Due to such densification, ELDEN performs well for sparsely connected entities in the KG too. ELDEN's approach is simple, yet effective. We have made ELDEN's code and data publicly available.

1 Introduction

Entity Linking (EL) is the task of mapping *mentions* of an *entity* in text to the corresponding entity in Knowledge Graph (KG) (Hoffart et al., 2011; Dong et al., 2014; Chisholm and Hachey, 2015). EL systems primarily exploit two types of information: (1) similarity of the mention to the candidate entity string, and (2) coherence between the candidate entity and other entities mentioned in the vicinity of the mention in text. Coherence essentially measures how well the candidate entity is connected, either directly or indirectly, with other KG entities mentioned in the vicinity (Milne and Witten, 2008; Globerson et al., 2016). In the state-of-the-art EL system by (Yamada et al., 2016), coherence is measured as distance between embeddings of entities. This system performs well on entities which are densely-connected in KG, but not so well on sparsely-connected entities in the KG.

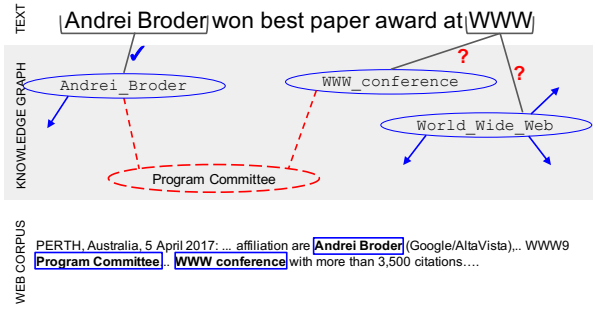

Figure 1: Improving entity disambiguation performance using KG densification: edges to `WWW_conference`, a sparsely-connected entity in the KG, is increased by adding edges from *pseudo entity* `Program Committee` whose mention co-occurs with it in web corpus. ELDEN, the system proposed in this paper, uses such densified KG to successfully link ambiguous mention *WWW* to the correct entity `WWW_conference`, instead of the more popular entity `World Wide Web`.

We demonstrate this problem using the example sentence in Figure 1. This sentence has two mentions: *Andrei Broder* and *WWW*. The figure also shows mention-entity linkages, i.e., mentions and their candidate entities in KG. Using a conventional EL system, the first mention *Andrei Broder*[1] can be easily linked to `Andrei_Broder` using string similarity between the mention and candidate entity strings. String similarity works well in this case as this mention is unambiguous in the given setting. However, the second mention

[1]We use *italics* to denote textual mentions and `typewriter` to indicate an entity in KG.

Proceedings of NAACL-HLT 2018, pages 1844–1853
New Orleans, Louisiana, June 1 - 6, 2018.

WWW has two candidates, World_Wide_Web and WWW_conference, and hence is ambiguous. In such cases, coherence measure between the candidate entity and other unambiguously linked entity(ies) is used for disambiguation.

State-of-the-art EL systems measure coherence as similarity between embeddings of entities. The entity embeddings are trained based on the number of common edges in KG[2]. In our example, common edges are edges World_Wide_Web shares with Andrei_Broder and edges WWW_conference shares with Andrei_Broder. But WWW_conference has less number of edges (it is a sparsely-connected entity) compared to World_Wide_Web. This leads to poor performance[3] whereby *WWW* is erroneously linked to World_Wide_Web instead of linking to WWW_conference.

In this paper, we propose ELDEN, an EL system which increases nodes and edges of the KG by using information available on the web about entities and *pseudo entities*. Pseudo Entities are words and phrases that frequently occur in Wikipedia, and co-occur with mentions of KG entities in the web corpus. Thus ELDEN uses a web corpus to find pseudo entities and refines the co-occurrences with Pointwise Mutual Information (PMI) (Church and Hanks, 1989) measure. ELDEN then adds edges to the entity from pseudo entities. In Figure 1, pseudo entity *Program Committee* co-occurs with mentions of Andrei_Broder and WWW_conference in web corpus and has a positive PMI value with both. So ELDEN adds edges from *Program Committee* to Andrei_Broder and WWW_conference, densifying neighborhood of the entities. Coherence, now measured as similarity between entity embeddings where embeddings are trained on densified KG, leads to improved EL performance.

Density (number of KG edges) of candidate entity affects EL performance. In our analysis of density and number of entities having that density in the Wikipedia KG, we find that entities with 500 edges or less make up more than 90%. Thus, creating an EL system that performs well on densely as well as sparsely-connected entities is a challenging, yet unavoidable problem.

We make the following contributions:

- ELDEN presents a simple yet effective graph densification method which may be applied to improve EL involving any KG.
- By using pseudo entities and unambiguous mentions of entity in a corpus, we demonstrate how non-entity-linked corpus can be used to improve EL performance.
- We have made ELDEN's code and data publicly available[4].

2 Related Work

Entity linking: Most EL systems use coherence among entities (Cheng and Roth, 2013) to link mentions. We studied coherence measures and datasets used in six recent[5] EL systems (He et al., 2013; Huang et al., 2015; Sun et al., 2015; Yamada et al., 2016; Globerson et al., 2016; Barrena et al., 2016). We see that the two popular datasets used for evaluating EL (Chisholm and Hachey, 2015) on documents are CoNLL (Hoffart et al., 2011) and TAC2010 (Ji et al., 2010), here after TAC. The popular coherence measures used are (1) WLM, (2) Entity Embedding Similarity and (3) Jaccard Similarity (Chisholm and Hachey, 2015; Guo et al., 2013). WLM is widely acknowledged as most popular (Hoffart et al., 2012) with almost all the six approaches analyzed above using WLM or its variants. Entity embedding similarity (Yamada et al., 2016) is reported to give highest EL[6] performance and is the baseline of ELDEN.

Enhancing entity disambiguation: Among methods proposed in literature to enhance entity disambiguation utilizing KG (Bhattacharya and Getoor) uses additional relational information between database references; (Han and Zhao, 2010) uses semantic relatedness between entities in other KGs; and (Shen et al., 2018) uses paths consisting of defined relations between entities in the KG (IMDB and DBLP). All these methods utilize structured information, while our method shows how unstructured data (web corpus about the entity to be linked) can be effectively used for entity disambiguation.

Entity Embeddings: ELDEN presents a method to enhance embedding of entities and words in a

[2]Wikipedia Link based Measure (WLM) (Milne and Witten, 2008) used in Yamada et al.'s system is based on number of common edges in KG.

[3]This paper focuses on mention disambiguation. We assume mention and candidate entities are detected already.

[4]https://github.com/priyaradhakrishnan0/ELDEN

[5] (Shen et al., 2015) presents a survey of EL systems.

[6]Named Entity Disambiguation (NED) and EL are synonymous terms in research (Hoffart et al., 2011)

common vector space. Word embedding methods like word2vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014) have been extended to entities in EL (Yamada et al., 2016; Fang et al., 2016; Zwicklbauer et al., 2016; Huang et al., 2015). These methods use data about entity-entity co-occurrences to improve the entity embeddings. In ELDEN, we improve it with web corpus co-occurrence statistics. Ganea and Hofmann (2017) present a very interesting neural model for jointly learning entity embedding along with mentions and contexts.

KG densification with pseudo entities: KG densification using external corpus has been studied by Kotnis *et al.* (2015) and Hegde and Talukdar (2015). Densifying edge graph is also studied as 'link prediction' in literature (Martínez et al., 2016). Kotnis *et al.* augment paths between KG nodes using 'bridging entities' which are noun phrases mined from an external corpus. ELDEN has a similar approach as it proposes densifying the KG edges of entities by adding edges from pseudo entities. However, densification is used for relation inference in the former methods whereas it is used for entity coherence measurement in ELDEN.

Word co-occurrence measures: Chaudhari *et al.* (2011) survey several co-occurrence measures for word association including PMI, Jaccard (Dice, 1945) and Co-occurrence Significance Ratio (CSR). Damani (2013) proves that considering corpus level significant co-occurrences, PMI is better than others. Budiu *et al.* (2007) compare Latent Semantic Analysis (LSA), PMI and Generalized Latent Semantic Analysis (GLSA) and conclude that for large corpora like web corpus, PMI works best on word similarity tests. Hence, we chose PMI to refine co-occurring mentions of entities in web corpus.

3 Definitions and Problem Formulation

In this section, we present a few definitions and formulate the EL problem.

Knowledge Graph (KG): A Knowledge Graph is defined as $G = (E, F)$ with entities E as nodes and F as edges. In allegiance to EL literature and baselines (Milne and Witten, 2008; Globerson et al., 2016), we use the Wikipedia hyperlink graph as the KG in this paper, where nodes correspond to Wikipedia articles and edges are incoming links from one Wikipedia article to another. ELDEN ultimately uses a densified version of this Wikipedia KG, as described in Section 4.

Sparsely connected entities: Following Hoffart *et al.* (2012), we define an entity to be a sparsely connected entity, if the number of edges incident on the entity node in the KG is less than threshold η[7]. Otherwise, the entity is called a densely-connected entity.

Entity Linking (EL): *Given a set of mentions $M_D = \{m_1, ..., m_n\}$ in a document D, and a knowledge graph $G = (E, F)$, the problem of entity linking is to find the assignment $\Lambda : M_D \rightarrow E_D$, where E_D is the set of entities linked to mentions in document D such that $E_D \subseteq E$.*

For mention $m_i \in M_D$, let the set of possible entities it can link to (candidate entities) be $\mathbb{C}_i$. Then, the solution to the EL problem is an assignment Λ where,

$$\Lambda(m_i) = \arg\max_{e \in \mathbb{C}_i} [\phi(m_i, e) + \beta \cdot \psi(e, E_D)] \quad (1)$$

Here, $\phi(m_i, e) \in [0, 1]$ measures the contextual compatibility of mention m_i and entity e. $\phi(m_i, e)$ is obtained by combining prior probability and context similarity. $\psi(e, E_D)$ measures the coherence of e with entities in E_D. β is a variable controlling inclusion of ψ in the assignment Λ.

Problem Formulation : (Yamada et al., 2016) is a recently proposed state-of-the-art EL system. We consider it as a representative EL system and use it as the main baseline for the experiments in this paper. In this section, we briefly describe Yamada *et al.* (2016)'s two-step approach that solves the EL problem presented above.

Step 1: A mention $m_i \in M_D$ is defined to be *unambiguous* if $\exists e \in \mathbb{C}_i$ such that $\phi(m_i, e) \geq \gamma$. Let $M_D^{(u)} \subseteq M_D$ be the set of such unambiguous mentions in document D. For all unambiguous mentions $m \in M_D^{(u)}$, Yamada *et al.* freeze the assignment by solving Equation 1 after setting $\beta = 0$. In other words, $\psi(e, E_D)$ is not used while assigning entities to unambiguous mentions. Assigning entities first to unambiguous mentions has also been found to be helpful in prior research (Milne and Witten, 2008; Guo and Barbosa, 2014). Let A_D be the set of entities linked to in this step. In Figure 1, mention *Andrei Broder* is unambiguous[8].

[7] Like (Hoffart et al., 2012) we set $\eta = 500$ for the experiments in this paper.

[8] Between mention *Andrei Broder* and entity `Andrei_Broder`, string similarity and prior probability are 1.0. In the experiments we use a γ value of 0.95.

Notation	Definition
v_e	entity embedding of entity e with dimension $1 * d$
E	set of all titles in Wikipedia
S	set of all pseudo entities considered in ELDEN
E_+	set of all entities considered in ELDEN
$\mathbf{V}$	word vectors of E_+ where $\mathbf{V} \in \mathbb{R}^{k*d}$
ψ_{ELDEN}	Embedding similarity measured using $\mathbf{V}$ trained on G_{dense}
ψ_{Yamada}	Embedding similarity measured using $\mathbf{V}$ trained on input KG G

Table 1: Notation used in KG densification and learning entity embeddings (Please see Sec 4 for more details).

Step 2: In this step, Yamada *et al.* links all ambiguous mentions by solving Equation 2.

$$\Lambda(m_i) = \arg\max_{e \in \mathbb{C}_i} \left(\phi(m_i, e) + \frac{1}{|A_D|} \sum_{e_j \in A_D} v_e \cdot v_{e_j} \right) \quad \forall m_i \in M_D \setminus M_D^{(u)} \quad (2)$$

where $v_e, v_{e_j} \in \mathbb{R}^d$ are d-dimensional embeddings of entities e and e_j respectively. Please note that the equation above is a reformulation of Equation 1 with $\beta = 1$ and $\psi(e, E_D) = \frac{1}{|A_D|} \sum_{e_j \in A_D} v_e \cdot v_{e_j}$, where A_D is derived from E_D as described in Step 1. As coherence $\psi(e, E_D)$ is applied only in disambiguation of ambiguous mentions, we apply densification to only selective nodes of KG.

Embeddings of entities are generated using word2vec model and trained using WLM (Details in Section 5). Given a graph $G = (E, F)$, the WLM coherence measure $\psi_{wlm}(e_i, e_j)$ between two entities e_i and e_j is defined in Equation 3 where C_e is the set of entities with edge to entity e.

$$\psi_{\text{wlm}}(e_i, e_j) = 1 - \frac{log(max(|C_{e_i}|, |C_{e_j}|)) - log(|C_{e_i} \cap C_{e_j}|)|}{log(|E|) - log(min(|C_{e_i}|, |C_{e_j}|))} \quad (3)$$

4 Our Approach: ELDEN

In this section, we present ELDEN, our proposed approach. ELDEN extends (Yamada et al., 2016), with one important difference: rather than working with the input KG directly, ELDEN works with the densified KG, created by selective densification of the KG with co-occurrence statistics extracted from a large corpus. Even though this is a simple change, this results in improved EL performance. The method performs well even for sparsely connected entities.

Overview : Overview of the ELDEN system is shown in Figure 2. ELDEN starts off with densification of the input KG, using statistics from web corpus. Embeddings of entities are then learned utilizing the densified KG in the next step. Embedding similarity estimated using the learned entity embeddings is used in calculating coherence measure in subsequent EL. Notation used is summarized in Table 1.

***(i)*KG Densification** Figure 2 depicts densification of KG in 'Input KG' and 'Densified KG'. It shows two Wikipedia titles `Andrei_Broder` and `WWW_conference` from our running example (Figure 1). There are no edges common between `Andrei_Broder` and `WWW_conference`. In a web corpus, mentions of `Andrei_Broder` and `WWW_conference` co-occur with *Program committee* and it has a positive PMI value with both the entities. So ELDEN adds an edge from *Program committee* to both the entities. Here *Program committee* is a pseudo entity. Thus, ELDEN densifies the KG by adding edges from pseudo entities when the mentions of Wikipedia entity and pseudo entity co-occur in a web corpus and the pseudo entity has a positive PMI value with given entity.

Taking a closer look, KG densification process starts from 'input KG' which is Wikipedia hyperlink graph $G = (E, F)$, where the nodes are Wikipedia titles (E) and edges are hyperlinks (F). ELDEN processes Wikipedia text corpus and identifies phrases (unigrams and bi-grams) that occur frequently, i.e. more than 10 times in it. We denote these phrases as *pseudo entities* (S) and add them as nodes to the KG. Let $E_+ = E \cup S$ be the resulting set of nodes.

ELDEN then adds edges connecting entities in E_+ to entities in E. This is done by processing a web text corpus looking for mentions of entities in E_+, and linking the mentions to entities in KG $G' = (E_+, F)$. ELDEN uses Equation 1 with $\beta = 0$ for this entity linking, i.e. only mention-entity similarity $\phi(m, e)$ is used during this linking[9]. Based on this entity linked corpus, a co-occurrence matrix M of size $|E_+| \times |E_+|$ is constructed. Each cell $M_{i,j}$ is set to the PMI between

[9]Since prior probabilities of pseudo entities are not available, only mention-entity similarity component of $\phi(m, s)$ is used while linking a mention m to a pseudo entity $s \in S$.

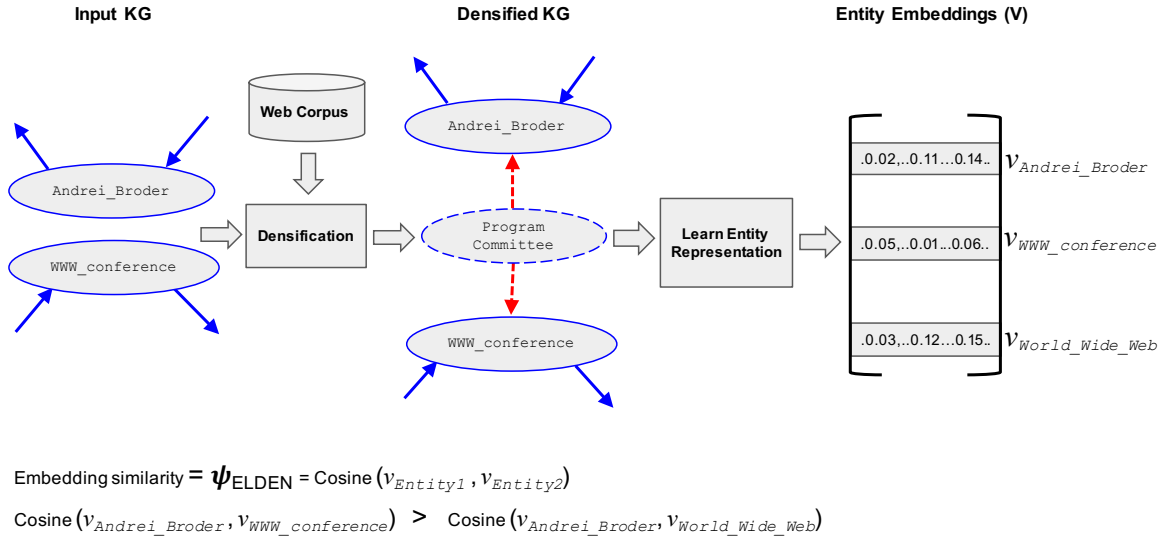

Figure 2: ELDEN consists of KG densification, training entity embeddings on densified KG and building EL system that uses similarity between the trained embeddings as coherence measure. ELDEN's difference from baseline method is that while baseline method uses input KG for training v_e, ELDEN uses densified KG for training v_e. Hence, the improved performance of ELDEN is solely attributed to densification.

Objective function component	Feature Group	Feature	Explanation
Contextual compatibility $\phi(m_i, e_i)$	Base	Entity Prior	Fraction of edges that links to the entity
		Prior Probability	Of all possible pages a mention can link to, the probability that it links to a given page
		Max Prior Probability	Maximum value of prior probabilities for a mention
		Max Prior Probability in document	Maximum value of prior probabilities for a document
		Num of candidates	Candidate count of the mention
	String Similarity	Exact match	Whether mention is an exact match of candidate
		Partial match	Whether mention is part of candidate
Coherence $\psi(e_i, e_j)$	Coherence measures	ψ_{wlm}	WLM (Please see Equation 3)
		ψ_{Yamada}	Similarity between entity embeddings that are learned using ψ_{wlm}
		ψ_{dense}	ψ_{wlm} calculated on densified KB
		ψ_{ELDEN}	Similarity between entity embeddings that are trained using ψ_{dense}
		$\psi_{\text{ELDEN++}}$	Combination of ψ_{wlm}, ψ_{Yamada}, ψ_{dense}, and ψ_{ELDEN}. ELDEN uses this coherence feature.

Table 2: Features used by various EL systems. Context compatibility $\phi(m_i, e_i)$ and coherence $\psi(e_i, e_j)$ of Equation 1 are parameterized using features as shown above. Context compatibility features are used by all systems. Coherence features used by Yamada16 are ψ_{wlm} and ψ_{Yamada}. ELDEN uses $\psi_{\text{ELDEN++}}$ as coherence feature.

the entities e and e'.

$$M_{e,e'} = \text{PMI}(e, e') = \log \frac{f(e, e') \times N}{f(e) \times f(e')}$$

where $f(e)$ is the frequency of entity e in web corpus, $f(e, e')$ is the sentence-constrained pair frequency of the entity pair (e, e') in web corpus, and $N = \sum_{e,e' \in E_+} f(e, e')$. Please note that PMI, and there by M, are symmetric. The expanded set of edges, F_+, is now defined as

$$F_+ = F \cup \{(e, e'), (e', e) \mid e' \in E_+, e \in E, M_{e,e'} > 0\}$$

In other words, we augment the set of initial edges F with additional edges connecting entities in E_+ with entities in E such that PMI between the entities is positive.

ELDEN now constructs the KG $G_{\text{dense}} = (E_+, F_+)$, which is a densified version of the input KG $G = (E, F)$. ELDEN uses this densified KG G_{dense} for subsequent processing and entity linking.

***(ii)*Learning Embeddings of Densified KG Entities** ELDEN derives entity embeddings using the same setup, corpus and Word2vec skip-gram with negative sampling model as in Yamada *et al.*, However, instead of training embeddings over the input KG, ELDEN trains embeddings of entities in the densified KG G_{dense}. Let $\mathbf{V}$ be the word2vec matrix containing embeddings of entities in E_+ where $\mathbf{V} \in \mathbb{R}^{k*d}$. v_e is the embedding of entity e in E_+ with dimension $1 * d$.

In word2vec model, entities in context are used

to predict the target entity. ELDEN maximizes the objective function (Goldberg and Levy, 2014) of word2vec skip-gram model with negative sampling, $L = \sum_{(t,c)\in\mathbb{P}} L_{t,c}$ where

$$L_{t,c} = log\ \theta(v_c \cdot v_t) + \sum_{n\in\mathbb{N}_{(t,c)}} log\ \theta(-v_n \cdot v_t)$$

Here v_t and v_c are the entity embeddings of target entity t and context entity c. $\mathbb{P}$ is the set of target-context entity pairs considered by the model. $\mathbb{N}_{(t,c)}$ is a set of randomly sampled entities used as negative samples with pair (t, c). This objective is maximized with respect to variables v_t's and v_c's, where $\theta(x) = \frac{1}{1+e^{-x}}$.

$\mathbb{P}$ and $\mathbb{N}$ are derived using G_{dense}. t and c are entities in E_+ such that c shares a common edge with t. v_n is randomly sampled from $\mathbf{V}$, for entities that do not share a common edge with t. Entity embedding similarity measured using $\mathbf{V}$ trained this way on G_{dense} is ψ_{ELDEN}. Embedding similarity is measured as cosine distance between v_es. Embeddings of S are trained using positive and negative word contexts derived using context length.

***(iii)* Bringing it All Together: ELDEN**

ELDEN is a supervised EL system which uses two sets of features: (1) contextual compatibility $\phi(m, e)$; and (2) coherence $\psi(e_i, e_j)$. These features are summarized in Table 2. Similarity between entity embeddings is measured as cosine similarity between v_es.

5 Experiments

In this section, we evaluate the following:

- Is ELDEN's corpus co-occurrence statistics-based densification helpful in disambiguating entities better? (Sec. 6.1)
- Where does ELDEN's selective densification of KG nodes link entities better? (Sec. 6.3)

Setup : ELDEN is implemented using Random Forest ensemble [10] (Breiman, 1998). Parameter values were set using CoNLL development set. Feature limit of 3 with number of estimators as 100 yielded best performance.

Knowledge Graph: Wikipedia Following prior EL literature, we use Wikipedia hypergraph as our KG (Milne and Witten, 2008; Globerson et al., 2016). This KG is enhanced with pseudo entities as explained in Section 4. We process the Wikipedia corpus following the same procedure as in Yamada *et al.* (2016). We cleaned [11] Wikipedia dump dated Nov 2015. We then parsed the Wikipedia article text to identify pseudo entities. More details on KG and parameters used for training embeddings are in Table 3. Training took 4 days on gpu with 2 cores.

Specifics	Value
Number of titles after cleaning ($\|E\|$)	4.6 M
Number of pseudo entities ($\|S\|$)	1.3 M
Total number of entities ($\|E_+\|$)	5.9 M
Number of epochs	3
Learning rate	0.25 linearly reducing to 0.01
Number of negative samples ($\|\mathbb{N}\|$)	5
Context window size	3
Dimensions of embedding (d)	100

Table 3: Parameters used in Wikipedia processing and training KG.

Preprocessing: Web corpus and Densified KG For our experiments, we created a web corpus by querying Google[12]. Candidate entities of all mentions in the dataset are queried in Google and top ten search results are considered for unigram and bigram frequencies. This corpus occupied 6.8GB for candidate entities of TAC and CoNLL dataset mentions (54336 entities). Even for sparsely connected entities, an average corpus size of 670 lines or more[13] was collected. We note that though some of the entities mentioned in this dataset are ten or more years old, we are able to collect, on an average more than 670 lines of web content. Thus corpus proves to be a good source of additional links for densification, for both common and rare entities. As Taneva and Weikum (2013) also note, it is not hard to find content about sparsely connected entities on the web.

The web corpus is analyzed for mentions and pseudo entities. Co-occurrence matrix M is created[14] for mention and pseudo entities occurring within window of size 10 for PMI calculation[15]. Edges are added from pseudo entities with positive PMI to mention of given entity. In experiments we add edges from top 10 pseudo entities ordered by

[10] http://scikit-learn.org

[11] by removing disambiguation, navigation, maintenance and discussion pages.

[12] https://www.google.com/

[13] A detailed analysis of knowledge gained from crawling for common versus less common entities is present in Figure 1 of supplementary material.

[14] This co-occurrence matrix is downloadable with source code.

[15] We experimented with window sizes 10, 25 and 50. We chose 10 that gave best results

PMI values[16].

Evaluation Dataset: In line with prior work on EL, we test the performance of ELDEN on CoNLL and TAC datasets. As this paper focuses on entity disambiguation, we tested ELDEN against datasets and baseline methods for disambiguation. We note that the entity disambiguation evaluation part of other recent datasets like ERD 2014 and TAC 2015 is exactly same as the TAC 2010 evaluation (Ellis et al., 2014) [17].

Training: ELDEN's parameters were tuned using training (development) sets of CoNLL and TAC datasets. CoNLL and TAC datasets consist of documents where mentions are marked and entity to which the mention links to, is specified. We use only mentions that link to a valid Wikipedia title (non NIL entities) and report performance on test set. Some aspects of these datasets relevant to our experiments are provided below.

CoNLL: In CoNLL test set (5267 mentions), we report Precision of topmost candidate entity, aggregated over all mentions (P-micro) and aggregated over all documents (P-macro), i.e., if tp, fp and p are the individual true positives, false positives and precision for each document in a dataset of δ documents, then

$$P_{\text{micro}} = \frac{\sum_{i=1}^{\delta} \text{tp}_i}{\sum_{i=1}^{\delta} \text{tp}_i + \sum_{i=1}^{\delta} \text{fp}_i} \text{ and } P_{\text{macro}} = \frac{\sum_{i=1}^{\delta} \text{p}_i}{\delta}.$$

For CoNLL candidate entities, we use (Pershina et al., 2015) dataset[18].

TAC: In TAC dataset, we report P-micro of top-ranked candidate entity on 1,020 mentions. P-macro is not applicable to TAC as most documents have only one mention as query mention (or 'mention to be linked'). For TAC candidate entities, we index the Wikipedia word tokens and titles using solr[19]. We index terms in (1) title of the entity, (2) title of another entity redirecting to the entity, and (3) names of anchors that point to the entity, in line with baselines. We are making this TAC candidate set publicly available.

Baseline: Yamada16 Our baseline is the Yamada *et al.* system explained in Section 3. Entity embedding distance measured using v_e trained on the input KG G is ψ_{Yamada}.

[16]This is a tunable parameter.

[17]These recent datasets consist of other evaluations, e.g., mention detection, multilinguality etc. which is beyond the scope of the paper and hence we didnt focus on them in the paper.

Method	CONLL (P-micro)	CONLL (P-macro)	TAC (P-micro)
(Hoffart et al., 2011)	82.5	81.7	-
(He et al., 2013)	85.6	84.0	81.0
(Ling et al., 2015)	67.5	-	86.8
(Barrena et al., 2016)	88.32	-	-
(Chisholm and Hachey, 2015)	88.7	-	80.7
(Pershina et al., 2015)	91.8	89.9	-
(Globerson et al., 2016)	91.7	-	87.2
(Yamada et al., 2016)	**93.1**	92.6	85.2
ELDEN	93.0	**93.7**	**89.6**

Table 4: Performance comparison with other recent EL approaches. ELDEN matches best results in CoNLL and outperforms the state-of-the-art in TAC dataset. (Please see Section 6.1 for details and $\psi_{\text{ELDEN++}}$ row of Table 5 for ELDEN results.)

6 Results

6.1 Does ELDEN's selective densification help in disambiguation in EL?

In Table 4, we compare ELDEN's EL performance with results of other recently proposed state-of-the-art EL methods that use coherence models. We see that ELDEN results matches best results on CoNLL and outperforms state-of-the-art in TAC dataset. In the table, the last four rows uses the Pershina *et al.* (2015) candidate set and hence, we provide a comparison of their disambiguation performance. Improved results of ELDEN over baseline is attributed to the improved disambiguation due to KG densification.

6.2 Why does ELDEN's selective densification work?

We conduct ablation analysis using various feature and feature combinations and present performance of ELDEN and baseline in Table 5. Starting with base features, we add various features to ELDEN incrementally and report their impact on performance. The results when using base feature group alone, and base and string similarity groups together (ϕ) are presented in first and second rows for each dataset. We compare ψ_{ELDEN} to three coherence measures: ψ_{wlm}, ψ_{Yamada} and ψ_{dense}, details of which are provided in Table 2. The performance improvement from each of the four coherence measures are in the next four rows. Performance of ELDEN from using all four coherence features is given in $\psi_{\text{ELDEN++}}$ row.

On CoNLL dataset, ψ_{dense} combined with ϕ,

Dataset	Features	P-micro	P-macro
CoNLL	Base	87.0	88.3
	ϕ	90.0	91.2
	$\phi + \psi_{\text{wlm}}$	91.0*	91.8
	$\phi + \psi_{\text{Yamada}}$	90.0*	91.1
	$\phi + \psi_{\text{dense}}$	92.0*	93.0
	$\phi + \psi_{\text{ELDEN}}$	91.0*	91.2
	$\phi + \psi_{\text{wlm}} + \psi_{\text{Yamada}}$	91.0	91.8
	$\phi + \psi_{\text{dense}} + \psi_{\text{ELDEN}}$	91.0	92.6
	$\phi + \psi_{\text{ELDEN++}}$	**93.0**	**93.7**
TAC	Base	78.2	
	ϕ	80.2	
	$\phi + \psi_{\text{wlm}}$	82.5*	
	$\phi + \psi_{\text{Yamada}}$	83.1*	
	$\phi + \psi_{\text{dense}}$	85.5*	
	$\phi + \psi_{\text{ELDEN}}$	87.3*	
	$\phi + \psi_{\text{wlm}} + \psi_{\text{Yamada}}$	84.4	
	$\phi + \psi_{\text{dense}} + \psi_{\text{ELDEN}}$	88.7	
	$\phi + \psi_{\text{ELDEN++}}$	**89.6**	

Table 5: Ablation analysis involving various coherence measures (see Table 2 for definitions of these measures). Statistically significant improvements over ϕ are marked with an asterisk. ELDEN's coherence measure, $\psi_{\text{ELDEN++}}$, achieves the best overall performance. P-macro is not applicable to TAC as most documents have only one mention marked as query. (Please see Section 6.2).

gave an improvement of 2.0 and 1.9 (P-micro and P-macro) over Yamada16 results. We note that Yamada16 results are from our re-implementation of (Yamada et al., 2016) system [20] and we are able to almost reproduce the baseline results. We also present the results combining baseline's ψ_{Yamada} and ψ_{wlm} versus ELDEN's ψ_{ELDEN} and ψ_{dense} in next two rows. We find the ELDEN's KG densification features perform better than baselines.

On TAC dataset also, combined with ϕ, ψ_{dense} is found to do better than ψ_{wlm} and ψ_{ELDEN} gives a significant P-micro improvement of 4.2 over ψ_{Yamada}. The $\psi_{\text{ELDEN++}}$ P-micro in TAC dataset is statistically significant[21]. In short, we find the KG densification features, ψ_{dense} and ψ_{ELDEN}, as the features causing better performance of ELDEN on both datasets.

6.3 Where does ELDEN's selective densification work better?

While most EL systems give higher precision on CoNLL dataset than TAC dataset, ELDEN performs with high precision on TAC dataset too.

[20]We have re-implemented the Yamada *et al* system using hyper-parameters specified in the paper and these are our best-effort results.

[21]We performed two tailed t-test, with 2-tail 95% value of 1.96.

	% sparsely connected Entities	
Dataset	**Train**	**Test**
TAC	78.8	63.6
CoNLL	48.4	48.2

Table 6: Percentage of sparsely connected entities in evaluation datasets. TAC has higher composition of sparsely connected entities than CoNLL. Hence, ELDEN results are better in TAC over CoNLL (Please see Table 4).

This is explained by analyzing distribution of densely-connected and sparsely connected entities in TAC and CoNLL datasets as presented in Table 6. We see that CoNLL test set has almost half as densely-connected and half as sparsely connected entities, whereas in TAC test set, 63.6% are sparsely connected entities. This higher constitution of sparsely connected entities in TAC, explains ELDEN's better results in TAC relative to CoNLL dataset. As the number of sparsely connected entities is more than the number of densely-connected entities in most KGs (Reinanda et al., 2016), our method is expected to be of significance for most KGs.

6.4 What type of EL errors are best fixed with ELDEN's selective densification ?

We analyzed errors fixed by ELDEN on TAC dataset. We categorize the errors into four classes in line with error classes of Ling *et al.* (2015). We

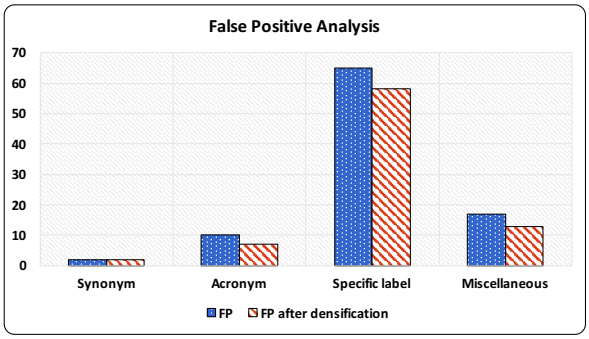

Figure 3: False positives of ELDEN before and after KG densification. Errors reduce with use of ψ_{dense} and ψ_{ELDEN} measures. (Please see Sec 6.4)

manually analyzed 240 wrong predictions of Yamada16 and compared it with that of ELDEN, and the results are presented in Figure 3. We found errors to reduce with use of KG densification features and most of the errors eliminated were in "Specific label" class. Errors in this class called for better modeling of mention's context and link-based similarity (Ling et al., 2015).(More details of this analysis in the supplementary document.)

7 Conclusion

We started this study by analyzing the performance of a state-of-the-art Entity Linking (EL) system and found that its performance was low when linking entities sparsely-connected in the KG. We saw that this can be addressed by densifying the KG with respect to the given entity. We proposed ELDEN, which densifies edge graph of entities using pseudo entities and mentions of entities in a large web corpus. Through our experiments, we find that ELDEN outperforms state-of-the-art baseline on benchmark datasets.

We believe that ELDENs combination of KG densification and entity embeddings is novel. Poor performance of EL systems on sparsely connected entities has been recognized as one of the open challenges by prior research. ELDEN performs well on sparsely connected entities too, as a validation of our method of combining KG densification followed by embedding. Our approach may be applied to any KG as the densification is performed with the help of *unstructured data*, and not any specific KG. We hope the simple graph densification method utilized in ELDEN will be of much interest to the research community.

Pseudo entities can be looked at as entity candidates for KG expansion, as also noted by Farid *et al.* (2016). In future, we plan to enhance ELDEN using EL of pseudo entities to estimate *entity prior* of entities not present in KG. We also plan to explore entity embeddings obtained using other graph densifying methods.

Abstract

In this paper, we propose to study the problem of COURT VIEW GENeration from the fact description in a criminal case. The task aims to improve the interpretability of charge prediction systems and help automatic legal document generation. We formulate this task as a text-to-text natural language generation (NLG) problem. Sequence-to-sequence model has achieved cutting-edge performances in many NLG tasks. However, due to the non-distinctions of fact descriptions, it is hard for Seq2Seq model to generate charge-discriminative court views. In this work, we explore charge labels to tackle this issue. We propose a label-conditioned Seq2Seq model with attention for this problem, to decode court views conditioned on encoded charge labels. Experimental results show the effectiveness of our method.[1]

1 Introduction

Previous work has brought up multiple legal assistant systems with various functions, such as finding relevant cases given the query (Chen et al., 2013), providing applicable law articles for a given case (Liu and Liao, 2005) and etc., which have substantially improved the working efficiency. As legal assistant systems, charge prediction systems aim to determine appropriate charges such as *homicide* and *assault* for varied criminal cases by analyzing textual fact descriptions from cases (Luo et al., 2017), but ignore to give out the interpretations for the charge determination.

Court view is the written explanation from judges to interprete the charge decision for certain criminal case and is also the core part in a legal document, which consists of *rationales* and a *charge* where the charge is supported by the rationales as shown in Fig. 1. In this work, we propose to study the problem of COURT VIEW GENeration from fact descriptions in cases, and we formulate it as a text-to-text natural language generation (NLG) problem (Gatt and Krahmer, 2017). The input is the fact description in a case and the output is the corresponding court view. We only focus on generating rationales because charges can be decided by judges or charge prediction systems by also analyzing the fact descriptions (Luo et al., 2017; Lin et al., 2012). COURT-VIEW-GEN has beneficial functions, in that: (1) improve the interpretability of charge prediction systems by generating rationales in court views to support the predicted charges. The justification for charge decision is as important as deciding the charge itself (Hendricks et al., 2016; Lei et al., 2016). (2) benefit the automatic legal document generation as legal assistant systems, by automatically generating court views from fact descriptions, to release much human labor especially for simple cases but in large amount, where fact descriptions can be obtained from legal professionals or techniques such as information extraction (Cowie and Lehnert, 1996).

COURT-VIEW-GEN is not a trivial task. High-quality rationales in court views should contain the important fact details such as the degree of injury for charge of *intentional injury*, as they are important basis for charge determination. Fact details are like the summary for the fact description similar to the task of DOCument SUMmarization (Yao et al., 2017). However, rationales are not the simple summary with only fact details, to support charges, they should be charge-discriminative with *deduced information* which does not appear in fact descriptions. The fact descriptions for charge of *negligent homicide* usually only describe someone being killed without direct statement about

* indicates equal contribution.

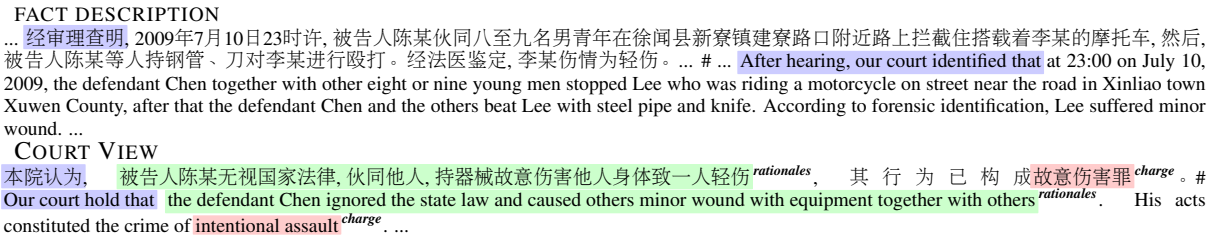

Figure 1: An example of fact description and court view from a legal document in a case.

the motive for killing, DOC-SUM will only summarize the fact of someone being killed, but rationales have to further contain the killing intention, aiming to be discriminative from those rationales for other charges like *intentional homicide*. However, it is hard to generate charge-discriminative rationales when input fact descriptions are not distinct among other facts with different charges. The fact descriptions for charge of *intentional homicide* are similar to those for charge of *negligent homicide* and also describe someone being killed but without clear motive, making it hard to generate charge-discriminative court views with accurate killing motives among the two charges.

Recently, sequence-to-sequence model with encoder-decoder paradigm (Sutskever et al., 2014) has achieved cutting-edge results in many NLG tasks, such as paraphrase (Mallinson et al., 2017), code generation (Ling et al., 2016) and question generation (Du et al., 2017). Seq2Seq model has also exhibited state-of-the-art performances on task of DOC-SUM (Chopra et al., 2016; Tan et al., 2017). However, non-distinctions of fact descriptions render Seq2Seq model hard to generate charge-discriminative rationales. In this paper, we explore charge labels of the corresponding fact descriptions, to benefit generating charge-discriminative rationales, where charge labels can be easily decided by human or charge prediction systems. Charge labels will provide with extra information to classify the non-discriminative fact descriptions. We propose a *label-conditioned* Seq2Seq model with attention for our task, in which fact descriptions are encoded into context vectors by an encoder and a decoder generates rationales with these vectors. We further encode charges as the labels and decode the rationales conditioned on the labels, to entail the decoder to learn to select gold-charge-related words to decode. Widely used attention mechanism (Luong et al., 2015) is fused into the Seq2Seq model, to learn to align target words to fact details in fact descriptions. Similar to Luo et al. (2017), we evaluate our model on Chinese criminal cases by constructing dataset from Chinese government website.

Our contributions in this paper can be summarized as follows:

- We propose the task of *court view generation* and release a real-world dataset for this task.
- We formulate the task as a text-to-text NLG problem. We utilize charge labels to benefit charge-discriminative court views generation, and propose a label-conditioned sequence-to-sequence model with attention for this task.
- Extensive experiments are conducted on a real-world dataset. The results show the efficiency of our model and exploiting charge labels for charge-discriminations improvement.

2 Related Work

Our work is firstly related to previous studies on legal assistant systems. Previous work considers the task of charge prediction as a text classification problem (Luo et al., 2017; Liu et al., 2004; Liu and Hsieh, 2006; Lin et al., 2012). Recently, Luo et al. (2017) investigate deep learning methods for this task. Besides, there are also works on identifying applicable articles for a given case (Liu and Liao, 2005; Liu and Hsieh, 2006; Liu et al., 2015), answering legal questions as a consulting system (Kim et al., 2014; Carvalho et al., 2015) and searching relevant cases for a given query (Raghav et al., 2016; Chen et al., 2013). As a legal assistant system, COURT-VIEW-GEN can benefit automatic legal document generation by generating court views from fact descriptions obtained from the last phase, through legal professionals or other technics like information extraction (Cowie and Lehnert, 1996) from raw documents in a case, if we generate legal documents step by step.

Our work is also related to recent studies on model interpretation (Ribeiro et al., 2016; Lipton, 2016; Ling et al., 2017). Recently, much work has

paid attention to giving textual explanations for classifications. Hendricks et al. (2016) generate visual explanations for image classification. Lei et al. (2016) propose to learn to select most supportive snippets from raw texts for text classification. COURT-VIEW-GEN can improve the interpretability of charge prediction systems by generating textual court views when predict the charges.

Our label-conditioned Seq2Seq model steams from widely used encoder-decoder paradigm (Sutskever et al., 2014) which has been widely used in machine translation (Bahdanau et al., 2014; Luong et al., 2015), summarization (Tan et al., 2017; Nallapati et al., 2016; Chopra et al., 2016; Cheng and Lapata, 2016), semantic parsing (Dong and Lapata, 2016) and paraphrase (Mallinson et al., 2017) or other NLG problems such as product review generation (Dong et al., 2017) and code generation (Yin and Neubig, 2017; Ling et al., 2016). Hendricks et al. (2016) propose to encode image labels for visual-language models to generate justification texts for image classification. We also introduce charge labels into Seq2Seq model to improve the charge-discriminations of generated rationales. Widely used attention mechanism (Luong et al., 2015; Xu et al., 2015) is applied to generate fact details more accurately.

3 COURT-VIEW-GEN Problem

Court View is the judicial explanation to interpret the reasons for the court making such charge for a case, consisting of the rationales and the charge supported by the rationales as shown in Fig. 1. In this work, we only focus on generating the part of rationales in court views. Charge prediction can be achieved by human or charge prediction systems (Luo et al., 2017). Final court views can be easily constructed by combining the generated rationales and the pre-decided charges.

Fact Description is the identified facts in a case (relevant events that have happened) such as the criminal acts (e.g. *degree of injury*).

The input of our model is the word sequential fact description in a case and the output is a word sequential court view (rationales part). We define the fact description as $\mathrm{x} = (x_1, x_2, \cdots, x_{|\mathrm{x}|})$ and the corresponding rationales as $\mathrm{y} = (y_1, y_2, \cdots, y_{|\mathrm{y}|})$. The charge for the case is denoted as v and will be exploited for COURT-VIEW-GEN. The task of COURT-VIEW-GEN is to find $\hat{\mathrm{y}}$ given x conditioned on the charge label v:

$$\hat{\mathrm{y}} = \arg\max_{\mathrm{y}} P(\mathrm{y}|\mathrm{x}, \mathrm{v}) \tag{1}$$

where $P(\mathrm{y}|\mathrm{x}, \mathrm{v})$ is the likelihood of the predicted rationales in the court view.

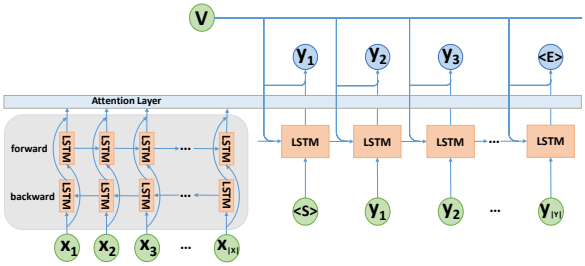

Figure 2: Label-conditioned Seq2Seq model with attention.

4 Our Model

4.1 Sequence-to-Sequence Model with Attention

Similar to Luong et al. (2015), our Seq2Seq model consists of an encoder and a decoder as shown in Fig. 2. Given the pair of fact description and rationales in court view (x, y), the encoder reads the word sequence of x and then the decoder will learn to predict the rationales in court view y. The probability of predicted y is given as follows:

$$P(\mathrm{y}) = \prod_{i=1}^{|\mathrm{y}|} P(y_i|y_{<i}, \mathrm{x}) \tag{2}$$

where $y_{<i} = y_1, y_2, \cdots, y_{i-1}$. We use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) as encoder and use another LSTM as decoder similar to Du et al. (2017).

Decoder. From the decoder side, at time t, the probability to predict y_t is computed as follows:

$$P(y_t|y_{<t}, \mathbf{c}_t) = \mathrm{softmax}(\mathbf{W}_1 \tanh(\mathbf{W}_0[\mathbf{s}_t; \mathbf{c}_t]))$$

where $\mathbf{W}_0$ and $\mathbf{W}_1$ are learnable parameters; $\mathbf{s}_t$ is the hidden state of decoder at time t; $\mathbf{c}_t$ is the context vector generated from the encoder side containing the information of x at time t; here the bias of model is omitted for simplification. The hidden state of $\mathbf{s}_t$ is computed as follows:

$$\mathbf{s}_t = \mathrm{LSTM}_d(y_{t-1}, \mathbf{s}_{t-1})$$

where y_{t-1} is the word embedding vector for pre-state target word at time $t-1$. The initial state for decoder is initialized by the last state of encoder.

Context vector of $\mathbf{c}_t$ is computed by summing up the hidden states of $\{\mathbf{h}_k\}_{k=1}^{|\mathrm{x}|}$ generated by the encoder with attention mechanism and we adopt global attention (Luong et al., 2015) in our work.

Encoder with Attention. We adopt a one-layer bidirectional LSTM to encoder the fact descriptions. The hidden state $\mathbf{h}_j$ at time j is computed as follows:

$$\mathbf{h}_j = [\overrightarrow{\mathbf{h}_j}; \overleftarrow{\mathbf{h}_j}]$$

where $\mathbf{h}_j$ is the concatenation of forward hidden state $\overrightarrow{\mathbf{h}_j}$ and backward hidden state $\overleftarrow{\mathbf{h}_j}$, specifically:

$$\overrightarrow{\mathbf{h}_j} = \overrightarrow{\mathrm{LSTM}}_e(x_j, \overrightarrow{\mathbf{h}}_{j-1})$$
$$\overleftarrow{\mathbf{h}_j} = \overleftarrow{\mathrm{LSTM}}_e(x_j, \overleftarrow{\mathbf{h}}_{j+1})$$

The hidden outputs $\{\mathbf{h}_k\}_{k=1}^{|\mathrm{x}|}$ will be used to compute the context vectors for decoder.

From the decoder side, by applying attention mechanism at time i, the context vector of $\mathbf{c}_i$ is generated as follows:

$$\mathbf{c}_i = \sum_{j=1}^{|\mathrm{x}|} \alpha_{ij} \mathbf{h}_j \tag{3}$$

where α_{ij} is the attention weight and is computed as follows:

$$\alpha_{ij} = \frac{\exp(\mathbf{s}_i^T \mathbf{W}_2 \mathbf{h}_j)}{\sum_{k=1}^{|\mathrm{x}|} \exp(\mathbf{s}_i^T \mathbf{W}_2 \mathbf{h}_k)} \tag{4}$$

where $\mathbf{s}_i$ is the hidden output state at time i in the decoder side.

4.2 Label-conditioned Sequence-to-Sequence Model with Attention

Given the tuple of fact description, rationales in court view and charge label $(\mathrm{x}, \mathrm{y}, \mathrm{v})$, the probability to predict y is computed as follows:

$$P(\mathrm{y}) = \prod_{i=1}^{|\mathrm{y}|} P(y_i | y_{<i}, \mathrm{x}, \mathrm{v}) \tag{5}$$

From this formula, encoding charge labels provides extra constrains comparing to Eq. (2), and restricts the target word searching space from the whole space to only gold-charge-related space for rationales generation, so model can generate more charge-distinct rationales. Charge labels are trainable parameters denoted by $\mathbf{E}^v$ where every charge will have a trainable vector from $\mathbf{E}^v$, which will be updated in the model training process.

As shown in Fig. 2, in the decoder side, at time t, y_t is predicted with the probability as follows:

$$P(y_t | y_{<t}, \mathbf{c}_t, \mathrm{v}) = \mathrm{softmax}(\mathbf{W}_1 \tanh(\mathbf{W}_0[\mathbf{s}_t; \mathbf{c}_t; \mathbf{E}^v_{[\mathrm{v}]}])) \tag{6}$$

where $\mathbf{E}^v_{[\mathrm{v}]}$ is the embedding vector of v obtained from $\mathbf{E}^v$. In this formula, we connect charge label v to $\mathbf{s}_t$ and $\mathbf{c}_t$ aiming to influence the word selection process. We hope that our model can learn the latent connections between the charge label v and the words of rationales in court views through this way, to decode out charge-discriminative words.

As shown in Fig. 2, we further embed the charge label v to highlight the computing of hidden state $\mathbf{s}_t$ at time t and $\mathbf{s}_t$ is merged as follows:

$$\begin{aligned} \mathbf{s}_t &= \mathrm{LSTM}_d(y_{t-1}, \mathbf{s}^v_{t-1}) \\ \mathbf{s}^v_{t-1} &= f_v(\mathbf{s}_{t-1}, \mathrm{v}) \\ f_v &= \tanh(\mathbf{W}^v[\mathbf{s}_{t-1}; \mathbf{E}^v_{[\mathrm{v}]}] + \mathbf{b}^v) \end{aligned} \tag{7}$$

where $\mathbf{W}^v$ and $\mathbf{b}^v$ are learnable parameters. In this way, the information of charge label can be embedded into $\mathbf{s}_t$. From Eq. (3) and Eq. (4), attention weights $\mathbf{c}_t$ are computed from $\mathbf{s}_t$, so encoding the charge label v to hidden states will make the model concentrate more on charge-related information from fact descriptions to help generate more accurate fact details.

4.3 Model Training and Inference

Suppose we are given the training data: $\{\mathrm{x}^{(i)}, \mathrm{y}^{(i)}, \mathrm{v}^{(i)}\}_{i=1}^N$, we aim to maximize the log-likelihood of generated rationales in court views given the fact descriptions and charge labels, so the loss function is computed as follows:

$$\begin{aligned} \mathcal{L}(\theta) &= -\sum_{i=1}^{N} \log P(\mathrm{y}^{(i)} | \mathrm{x}^{(i)}, \mathrm{v}^{(i)}; \theta) \\ &= -\sum_{i=1}^{N} \sum_{j=1}^{|\mathrm{y}^{(i)}|} \log P(y_j^{(i)} | y_{<j}^{(i)}, \mathrm{x}^{(i)}, \mathrm{v}^{(i)}; \theta) \end{aligned}$$

We split the training data into multiple batches with size of 64 and adopt adam learning (Kingma and Ba, 2014) to update the parameters in every batch data. At the inference time, we encode the fact descriptions and charge labels into vectors and use the decoder to generate rationales in

# Training set	153706
# Dev set	9152
# Test set	9123
Avg. # tokens in fact desc.	219.9
Avg. # tokens in rationales	30.6
Num. of # charge labels	51
# Dict. size in fact desc.	222482
# Dict. size in rationales	21305

Table 1: Statistics of our dataset.

court views based on Eq. (1). We adopt the algorithm of beam search to generate rationales. Beam search size is set to 5. To make generation process stoppable, an indicator tag "</s>" is added to the end of the rationales sequences, and when "</s>" is generated the inference process will be terminated. The generated word sequential paths will be ranked and the one with largest value is selected as the final rationales in court view.

5 Experiments

5.1 Data Preparation

Following Luo et al. (2017), we construct dataset from the published legal documents in China Judgements Online[2]. We extract the fact descriptions, rationales in court views and charge labels using regular expressions. The paragraph started with "经审理查明" ("our court identified that") is regarded as the fact description and the part between "本院认为" ("our court hold that") and the charge are regarded as the rationales. Nearly all the samples in dataset match this extraction pattern. Length threshold of 256 is set up, and fact description longer than that will be stripped, leaving too long facts for future study. We use the tokens of "<name>", "<num>" and "<date>" to replace the names, numbers and dates appearing in the corpus. We tokenize the Chinese texts with the open source tool of HanLP[3]. For charge labels, we select the top 50 charge labels ranked by occurrences and leave the left charges as others. Details about our dataset are shown in Table 1.

For cases with multiple charges and multiple defendants, we can separate the fact descriptions and the court views according to the charges or the defendants. In this work, we only focus on the cases with one defendant and one charge, leaving the complex cases for future study, so we can collect large enough data from the published legal documents without human to annotate the data.

5.2 Experimental Settings

Word embeddings are randomly initialized and updated in the training process, with the size of 512 tuned from $\{256, 512, 1024\}$. Charge label vectors are initialized randomly with size of 512. Maximal vocabulary size of encoder is set to 100K words and decoder is 50K by stripping words exceeding the bounds. Maximal source length is 256 and target is 50. The hidden size of LSTM is 1024 tuned from $\{256, 512, 1024\}$. We choose perplexity as the update metric. Early stopping mechanism is applied to train the model. The initial learning rate is set to 0.0003 and the reduce factor is 0.5. Model performance will be checked on the validation set after every 1000 batches training and keep the parameters with lowest perplexity. Training process will be terminated if model performance is not improved for successive 8 times.

5.3 Comparisons with Baselines

Evaluation Metrics. We adopt both automatic evaluation and human judgement for model evaluation. BLEU-4 score (Papineni et al., 2002) and variant Rouge scores (Lin, 2004) are adopted for automatic evaluation which have been widely used in many NLG tasks. We set up two evaluation dimensions for human judgement: 1) how *fluent* of the rationales in court view is; 2) how *accurate* of the rationales is, aiming to evaluate how many fact details have been accurately expressed in the generated rationales. We adopt 5 scales for both *fluent* and *accurate* evaluation (5 is for the best). We ask three annotators who knows well about our task to conduct the human judgement. We randomly select 100 generated rationales in court views for every evaluated method. The three raters are also asked to judge whether rationales can be adopted for use in comprehensive evaluation (*adoptable*) and record the number of adoptable rationales for every evaluated method.

Baselines.

• **Rand** is to randomly select rationales in court views from the training set (method of $\textbf{Rand}_{\textbf{all}}$). We also randomly choose rationales from pools with same charge labels ($\textbf{Rand}_{\textbf{charge}}$). Adopting Rand method is to indicate the low bound performance of COURT-VIEW-GEN.

• **BM25** is a retrieval baseline to index the fact description match to the input fact description with highest BM25 score (Robertson and Walker,

[2]http://wenshu.court.gov.cn

[3]https://github.com/hankcs/HanLP

$\text{BM25}_{\text{f2f+charge}}$	4.94	3.90**	0.50**
MOSES+	1.39**	1.31**	0**
NN-S2S	4.97	4.07**	0.62*
RAS†	4.96	4.25*	0.64*
Ours	4.93	**4.54**	**0.72**

Table 2: Results of automatic evaluation and human judgement with BLEU-4 and full length of F1 scores of variant Rouges. Best results are labeled as boldface. Statistical significance is indicated with $**(p < 0.01)$ and $*$ $(p < 0.05)$ comparing to our full model.

1994) from the training set, and use its rationales as the result (**BM25_{f2f}**). Similar fact descriptions may have the similar rationales. Fact descriptions from pools with same charges are also retrieved (**$\text{BM25}_{\text{f2f+charge}}$**), to see how much improvement that adding charge labels can gender.

• **MOSES+** (Koehn et al., 2007) is a phrase-based statistical machine translation system mapping fact descriptions to rationales. KenLM (Heafield et al., 2013) is adopted to train a trigram language model on the target corpus of training set which is tuned on the validation set with MERT.

• **NN-S2S** is the basic Seq2Seq model without attention from Sutskever et al. (2014) for machine translation. We set one LSTM layer for encoding and another one LSTM layer for decoding. We adopt perplexity for training metric and select the model with lowest perplexity on validation set.

• **RAS†** is an attention based abstract summarization model from Chopra et al. (2016). To deal with the much longer fact descriptions, we exploit the more advanced bidirectional LSTM model for the encoder instead of the simple convolutional model. Another LSTM model is set as the decoder coherent to Chopra et al. (2016).

Experimental Results. In automatic evaluation from Table 2, the evaluation scores are relatively high even for method of $\text{Rand}_{\text{charge}}$, which indicates that the expressions of the rationales with same charge labels are similar with many overlapped n-grams, such that the rationales for *crime of theft* usually begin with "以非法占有为目的" ("in intention of illegal possession"). Accurately generating fact details like degree of injury or time of theft is more difficult. Retrieval method by adding charge labels is the strong baseline even better than basic Seq2Seq model. Adding attention mechanism will improve the performance indicated by the method of RAS† which is superior to retrieval methods. By exploiting charge labels, our full model achieves the best performance. The performances of statistical machine translation model are really poor, for it requiring the lengths of parallel corpus to be similar.

In human evaluation, we can see that retrieval methods can not accurately express fact details, for that it is hard to retrieve rationales containing details all matching the fact descriptions. However, our system can learn to generate fact details by analyzing fact descriptions. Dropping attention mechanism will have negative effects on model performance. RAS† has worse performance in ACC. whose main reason may lie in that RAS† can not generate charge-discriminative rationales with *deduced information*, which demonstrates that our task is not the simple DOC-SUM task. For the *fluent* evaluation, generation models are highly close to retrieval methods whose rationales are written by humans, which reflects that the generation models can generate highly natural rationales.

5.4 Further Analysis

Impact of Exploiting Charge Labels.

• **Charge2Charge Analysis.** We first analyze the effects of exploiting charge labels on model performance charge to charge, by dropping to encode charges based on our full model. From the results shown in Fig. 3, we can find that the results can be improved much by exploiting charge labels among nearly all charges. This result also indicates that the non-distinct fact descriptions are common among nearly all charges and reflects the difficulty of this task, but utilizing charge labels can release the seriousness of the problem.

• **Charge-discriminations Analysis.** We further evaluate the effects of charge labels for charge-discriminations improvement on specific charges with non-distinct fact descriptions: *intentional homicide*, *negligent homicide*, *duty embezzlement* and *corruption*. For every charge, two participants are asked to count the number of ra-

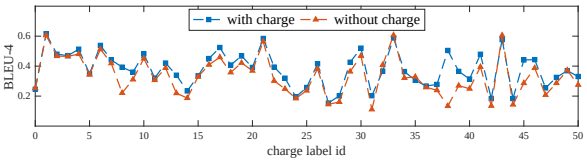

Figure 3: Results of impact of exploiting charge labels evaluated charge to charge in the metric of BLEU-4 (similar results can gender in other three metrics but are omitted for space saving).

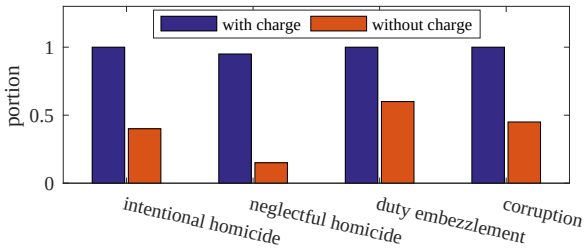

Figure 4: Portions of charge-discriminative rationales in court views for every charge with 20 candidates.

tionales that are relevant to the charge on 20 randomly selected candidates.

From Fig. 4, the number of charge discriminative rationales can be much improved among every charge by utilizing charge information, which demonstrates that charge labels can provide with much extra charge-related information to deal with latent information in fact descriptions. For crimes of *homicide*, the motives for killing are latent in the descriptions of killing without direct statement, but our system can learn to align the motives in rationales to the charge labels which are the strong distinct indicator for the two motives.

Ablation Study. We also ablate our full model to reveal different components of encoding charge labels for performance improvement. As shown in Table 3, " / softmax comp." is to remove the part in Eq. (6) and yields worse performance than our full model, but better than " / charge comp." that ignores to encode charge labels, which is same to the situation of " / hidden comp." that removes the part in Eq. (7). Our full model is still better than the ablated models. This finding shows that both of the methods of exploiting charge labels can improve model performance and stacking them will achieve better results.

Attention Mechanism Analysis. Heat map in Fig. 5 is used to illustrate the attention mechanism. The "slight injury" is aligned between the source and target. "responsibility" and "run" are well aligned to "away", which demonstrate the

	Ablation Study			
Model (%)	B-4	R-1	R-2	R-L
Our System	45.8**	70.9**	52.5**	67.7**
/ softmax comp.	45.7**	70.8**	52.3**	67.5**
/ hidden comp.	45.7**	70.2*	51.9*	67.0*
/ charge comp.	43.7	68.6	49.7	65.5

Table 3: Results of ablation study. Statistical significance is indicated with $**$ ($p < 0.01$) and $*$ ($p < 0.05$) comparing to the ablation of " / charge comp.".

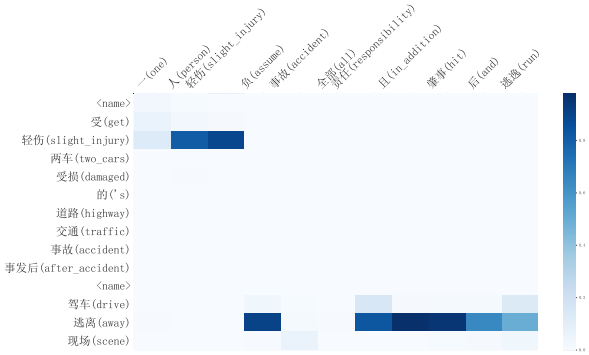

Figure 5: Heat map for attention mechanism analysis. The column is the source and the raw is the target.

efficiency of attention mechanism for generating fact details by forcing context vectors to focus more on fact details.

Performance by Reference Size. We further investigate the model performance by rationales length in court views. As shown in Fig. 6, not surprisingly the model performance drops when the length of reference rationales increases. Within the size of 30, BLEU-4 score can maintain around 0.4 and F1 score keeps around 0.5. Exceeding the length of 30, model performance decreases dramatically.

Human eval. vs. Automatic eval. *Are BLEU and Rouge suitable for* Court-View-Gen *evaluation*? Following the work of (Papineni et al., 2002; Liu et al., 2016), for the models evaluated in human judgemnet, we draw the linear regressions of their BLEU-4 and variant Rouge scores, as the function of Acc. and Adopt. from human judgement respectively as shown in Fig. 7. From

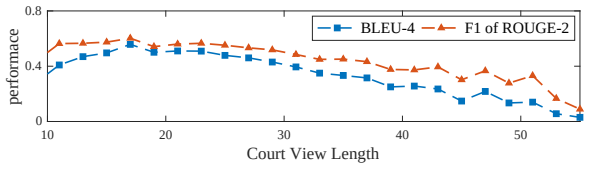

Figure 6: Model performance by rationales length with BLEU-4 and full length of F1 of Rouge-2.

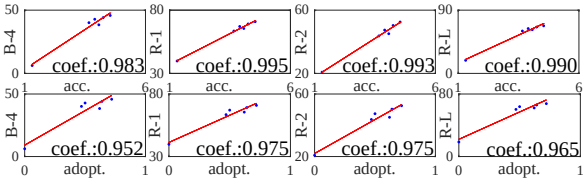

Figure 7: ACC. and ADOPT. of human judgement predict automatic evaluation scores.

the results, we can find that automatic evaluations track well with the human judgement with high correlation coefficients. This finding demonstrates that BLEU-4 and variant Rouges are adoptable for COURT-VIEW-GEN evaluation and provides the basis for future studies on this task.

Error Analysis. Our model has the drawback of *generating latent fact details*, which appear in rationales but are not clearly expressed in fact descriptions. For example, for the time of theft in charge of *larceny*, the term of "多次" ("several times") appears in rationales but may not be expressed in fact descriptions directly, only with descriptions of larceny but without exact term for this detail, so it will be hard for attention mechanism to learn to align "多次" in rationales to latent information in fact descriptions. In the generated rationales on test set, we find that only 42.4% samples can accurately extract out the term of "多次". It may need designed rules to deal with such details, like that count the time of theft from the descriptions, and if the time exceeds 1 then the term of "多次" can be generated in rationales.

5.5 Analysis through Cases

Fake Charge Label Conditioned Study. What generated rationales in court views will be if they are conditioned on fake charge labels? We select one fact description with gold charge of *intentional injury*, then generate rationales conditioned on fake charges of *defiance and affray crime*, *intentional homicide* and *neglectful homicide*.

From Fig. 8, the rationales conditioned on fake charges will be partly relevant to fake charge labels and also maintain fact details from the input fact description of gold charge. For the fake charge of *intentional homicide*, its fact details should be "caused someone dead", but instead express "causing someone slight injury" which is relevant to charge of *intentional injury*. For charge prediction systems, the discriminations between fact details and charges will help to remind people that the prediction results may be unreliable.

Case Study. Examples of generated rationales in court views are shown in Fig. 8. Generally speaking, our full label-conditioned model has high accuracy on generating fact details better than baseline models. For charges of *traffic accident crime* and *negligent homicide*, all fact details are generated. The extra information from charge labels helps the model to capture more important fact details, by forcing model to pay more attention to charge-related information in fact descriptions.

As for the charge-discrimination analysis, from the rationales of *negligent homicide*, we can infer that its fact description may relate to a traffic accident, which is non-distinct from that for *traffic accident crime*. Without encoding charge labels, Ours $_{/c}$ wrongly generates the rationales coherent to *traffic accident crime*, because traffic accidents are the strong indicator for traffic crimes, but the charge label will provide extra bias towards the *homicide crime*, so our full model can generate highly discriminative rationales. Utilizing charge labels, retrieval method can easily retrieve charge-related rationales, but hard to index rationales with accurate fact details. For charge of *larceny*, our full model extracts nearly all fact details but misses the fact of "多次"("several times"), reflecting the shortcoming of dealing with latent details.

6 Conclusion and Future Work

In this paper, we propose a novel task of court view generation and formulate it as a text-to-text NLG problem. We utilize charge labels to benefit the generation of charge-discriminative rationales in court views and propose a label-conditioned Seq2Seq model with attention for this task. Extensive experiments show the efficiency of our model and exploiting charge labels.

In the future: 1) More advanced technologies like reinforcement learning (Sutton and Barto, 1998) can be introduced to generate latent fact details such as the time of theft more accurately; 2) In this work, we only generate rationales in court views omitting charge prediction, it is interesting to see whether jointly generating the two parts will benefit both of the tasks; 3) Studying verification mechanism is meaningful to judge whether generated court views can really be adopted which is important for COURT-VIEW-GEN in practice; 4) More complex cases with multiple charges and multiple defendants will be considered in the future.

Delete, Retrieve, Generate: A Simple Approach to Sentiment and Style Transfer

Abstract

We consider the task of text attribute transfer: transforming a sentence to alter a specific attribute (e.g., sentiment) while preserving its attribute-independent content (e.g., changing *"screen is just the right size"* to *"screen is too small"*). Our training data includes only sentences labeled with their attribute (e.g., positive or negative), but not pairs of sentences that differ only in their attributes, so we must learn to disentangle attributes from attribute-independent content in an unsupervised way. Previous work using adversarial methods has struggled to produce high-quality outputs. In this paper, we propose simpler methods motivated by the observation that text attributes are often marked by distinctive phrases (e.g., *"too small"*). Our strongest method extracts content words by deleting phrases associated with the sentence's original attribute value, retrieves new phrases associated with the target attribute, and uses a neural model to fluently combine these into a final output. On human evaluation, our best method generates grammatical and appropriate responses on 22% more inputs than the best previous system, averaged over three attribute transfer datasets: altering sentiment of reviews on Yelp, altering sentiment of reviews on Amazon, and altering image captions to be more romantic or humorous.

1 Introduction

The success of natural language generation (NLG) systems depends on their ability to carefully control not only the topic of produced utterances, but also attributes such as sentiment and style. The desire for more sophisticated, controllable NLG has led to increased interest in text attribute transfer—the task of editing a sentence to alter specific attributes, such as style, sentiment, and tense (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018). In each of these cases, the goal is to convert a sentence with one attribute (e.g., negative sentiment) to one with a different attribute (e.g., positive sentiment), while preserving all attribute-independent content[1] (e.g., what properties of a restaurant are being discussed). Typically, aligned sentences with the same content but different attributes are not available; systems must learn to disentangle attributes and content given only unaligned sentences labeled with attributes.

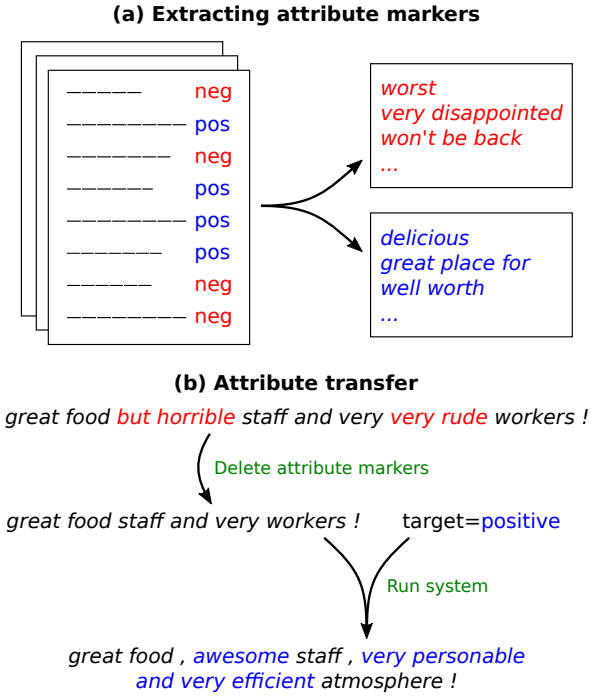

Figure 1: An overview of our approach. (a) We identify attribute markers from an unaligned corpus. (b) We transfer attributes by removing markers of the original attribute, then generating a new sentence conditioned on the remaining words and the target attribute.

Previous work has attempted to use adversarial

[*] Work done while the author was a visiting researcher at Stanford University.

[1] Henceforth, we refer to attribute-independent content as simply *content*, for simplicity.

Proceedings of NAACL-HLT 2018, pages 1865–1874
New Orleans, Louisiana, June 1 - 6, 2018.

networks (Shen et al., 2017; Fu et al., 2018) for this task, but—as we demonstrate—their outputs tend to be low-quality, as judged by human raters. These models are also difficult to train (Salimans et al., 2016; Arjovsky and Bottou, 2017; Bousmalis et al., 2017).

In this work, we propose a set of simpler, easier-to-train systems that leverage an important observation: attribute transfer can often be accomplished by changing a few *attribute markers*—words or phrases in the sentence that are indicative of a particular attribute—while leaving the rest of the sentence largely unchanged. Figure 1 shows an example in which the sentiment of a sentence can be altered by changing a few sentiment-specific phrases but keeping other words fixed.

With this intuition, we first propose a simple baseline that already outperforms prior adversarial approaches. Consider a sentiment transfer (negative to positive) task. First, from unaligned corpora of positive and negative sentences, we identify attribute markers by finding phrases that occur much more often within sentences of one attribute than the other (e.g., *"worst"* and *"very disppointed"* are negative markers). Second, given a sentence, we delete any negative markers in it, and regard the remaining words as its content. Third, we retrieve a sentence with similar content from the positive corpus.

We further improve upon this baseline by incorporating a neural generative model, as shown in Figure 1. Our neural system extracts content words in the same way as our baseline, then generates the final output with an RNN decoder that conditions on the extracted content and the target attribute. This approach has significant benefits at training time, compared to adversarial networks: having already separated content and attribute, we simply train our neural model to reconstruct sentences in the training data as an auto-encoder.

We test our methods on three text attribute transfer datasets: altering sentiment of Yelp reviews, altering sentiment of Amazon reviews, and altering image captions to be more romantic or humorous. Averaged across these three datasets, our simple baseline generated grammatical sentences with appropriate content and attribute 23% of the time, according to human raters; in contrast, the best adversarial method achieved only 12%. Our best neural system in turn outperformed our baseline, achieving an average success rate of 34%. Our code and data, including newly collected human reference outputs for the Yelp and Amazon domains, can be found at https://github.com/lijuncen/Sentiment-and-Style-Transfer.

2 Problem Statement

We assume access to a corpus of labeled sentences $\mathcal{D} = \{(x_1, v_1), \ldots, (x_m, v_m)\}$, where x_i is a sentence and $v_i \in \mathcal{V}$, the set of possible attributes (e.g., for sentiment, $\mathcal{V} = \{\text{"positive"}, \text{"negative"}\}$). We define $\mathcal{D}_v = \{x : (x, v) \in \mathcal{D}\}$, the set of sentences in the corpus with attribute v. Crucially, we do not assume access to a parallel corpus that pairs sentences with different attributes and the same content.

Our goal is to learn a model that takes as input (x, v^{tgt}) where x is a sentence exhibiting source (original) attribute v^{src}, and v^{tgt} is the target attribute, and outputs a sentence y that retains the content of x while exhibiting v^{tgt}.

3 Approach

As a motivating example, suppose we wanted to change the sentiment of *"The chicken was delicious."* from positive to negative. Here the word *"delicious"* is the only sentiment-bearing word, so we just need to replace it with an appropriate negative sentiment word. More generally, we find that the attribute is often *localized* to a small fraction of the words, an inductive bias not captured by previous work.

How do we know which negative sentiment word to insert? The key observation is that the remaining content words provide strong cues: given *"The chicken was ..."*, one can infer that a taste-related word like *"bland"* fits, but a word like *"rude"* does not, even though both have negative sentiment. In other words, while the deleted sentiment words do contain non-sentiment information too, this information can often be recovered using the other content words.

In the rest of this section, we describe our four systems: two baselines (RETRIEVEONLY and TEMPLATEBASED) and two neural models (DELETEONLY and DELETEANDRETRIEVE). An overview of all four systems is shown in Figure 2. Formally, the main components of these systems are as follows:

1. **Delete**: All 4 systems use the same procedure to separate the words in x into a set of

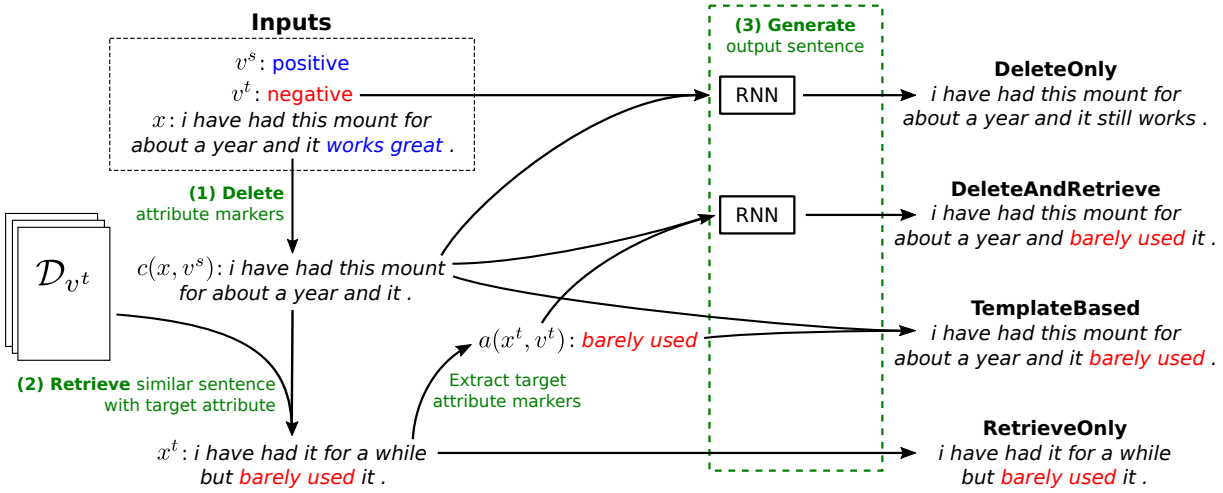

Figure 2: Our four proposed methods on the same sentence, taken from the AMAZON dataset. Every method uses the same procedure (1) to separate attribute and content by deleting attribute markers; they differ in the construction of the target sentence. RETRIEVEONLY directly returns the sentence retrieved in (2). TEMPLATEBASED combines the content with the target attribute markers in the retrieved sentence by slot filling. DELETEANDRETRIEVE generates the output from the content and the retrieved target attribute markers with an RNN. DELETEONLY generates the output from the content and the target attribute with an RNN.

attribute markers $a(x, v^{\text{src}})$ and a sequence of content words $c(x, v^{\text{src}})$.

2. **Retrieve**: 3 of the 4 systems look through the corpus and retrieve a sentence x^{tgt} that has the target attribute v^{tgt} and whose content is similar to that of x.
3. **Generate**: Given the content $c(x, v^{\text{src}})$, target attribute v^{tgt}, and (optionally) the retrieved sentence x^{tgt}, each system generates y, either in a rule-based fashion or with a neural sequence-to-sequence model.

We describe each component in detail below.

3.1 Delete

We propose a simple method to delete attribute markers (n-grams) that have the most discriminative power. Formally, for any $v \in \mathcal{V}$, we define the *salience* of an n-gram u with respect to v by its (smoothed) relative frequency in $\mathcal{D}_v$:

$$s(u, v) = \frac{\text{count}(u, \mathcal{D}_v) + \lambda}{\left(\sum_{v' \in \mathcal{V}, v' \neq v} \text{count}(u, \mathcal{D}_{v'})\right) + \lambda}, \quad (1)$$

where $\text{count}(u, \mathcal{D}_v)$ denotes the number of times an n-gram u appears in $\mathcal{D}_v$, and λ is the smoothing parameter. We declare u to be an attribute marker for v if $s(u, v)$ is larger than a specified threshold γ. The attributed markers can be viewed as discriminative features for a Naive Bayes classifier.

We define $a(x, v^{\text{src}})$ to be the set of all source attribute markers in x, and define $c(x, v^{\text{src}})$ as the sequence of words after deleting all markers in $a(x, v^{\text{src}})$ from x. For example, for *"The chicken was delicious,"* we would delete *"delicious"* and consider *"The chicken was..."* to be the content (Figure 2, Step 1).

3.2 Retrieve

To decide what words to insert into $c(x, v^{\text{src}})$, one useful strategy is to look at similar sentences with the target attribute. For example, negative sentences that use phrases similar to *"The chicken was..."* are more likely to contain *"bland"* than *"rude."* Therefore, we retrieve sentences of similar content and use target attribute markers in them for insertion.

Formally, we retrieve x^{tgt} according to:

$$x^{\text{tgt}} = \underset{x' \in \mathcal{D}_{v^{\text{tgt}}}}{\text{argmin}}\, d(c(x, v^{\text{src}}), c(x', v^{\text{tgt}})), \quad (2)$$

where d may be any distance metric comparing two sequences of words. We experiment with two options: (i) TF-IDF weighted word overlap and (ii) Euclidean distance using the content embeddings in Section 3.3 (Figure 2, Step 2).

3.3 Generate

Finally, we describe how each system generates y (Figure 2, Step 3).

RETRIEVEONLY returns the retrieved sentence x^{tgt} verbatim. This is guaranteed to produce a grammatical sentence with the target attribute, but its content might not be similar to x.

TEMPLATEBASED replaces the attribute markers deleted from the source sentence $a(x, v^{\text{src}})$ with those of the target sentence $a(x^{\text{tgt}}, v^{\text{tgt}})$.[2] This strategy relies on the assumption that if two attribute markers appear in similar contexts , they are roughly syntactically exchangeable. For example, *"love"* and *"don't like"* appear in similar contexts (e.g., *"i **love** this place."* and *"i **don't like** this place."*), and exchanging them is syntactically valid. However, this naive swapping of attribute markers can result in ungrammatical outputs.

DELETEONLY first embeds the content $c(x, v^{\text{src}})$ into a vector using an RNN. It then concatenates the final hidden state with a learned embedding for v^{tgt}, and feeds this into an RNN decoder to generate y. The decoder attempts to produce words indicative of the source content and target attribute, while remaining fluent.

DELETEANDRETRIEVE is similar to DELETEONLY, but uses the attribute markers of the retrieved sentence x^{tgt} rather than the target attribute v^{tgt}. Like DELETEONLY, it encodes $c(x, v^{\text{src}})$ with an RNN. It then encodes the sequence of attribute markers $a(x^{\text{tgt}}, v^{\text{tgt}})$ with another RNN. The RNN decoder uses the concatenation of this vector and the content embedding to generate y.

DELETEANDRETRIEVE combines the advantages of TEMPLATEBASED and DELETEONLY. Unlike TEMPLATEBASED, DELETEANDRETRIEVE can pick a better place to insert the given attribute markers, and can add or remove function words to ensure grammaticality. Compared to DELETEONLY, DELETEANDRETRIEVE has a stronger inductive bias towards using target attribute markers that are likely to fit in the current context. Guu et al. (2018) showed that retrieval strategies like ours can help neural generative models. Finally, DELETEANDRETRIEVE gives us finer control over the output; for example, we can control the degree of sentiment by deciding whether to add *"good"* or *"fantastic"* based on the retrieved sentence x^{tgt}.

[2] Markers are replaced from left to right, in order. If there are not enough markers in x^{tgt}, we use an empty string.

3.4 Training

We now describe how to train DELETEANDRETRIEVE and DELETEONLY. Recall that at training time, we do not have access to ground truth outputs that express the target attribute. Instead, we train DELETEONLY to reconstruct the sentences in the training corpus given their content and *original* attribute value by maximizing:

$$L(\theta) = \sum_{(x, v^{\text{src}}) \in \mathcal{D}} \log p(x \mid c(x, v^{\text{src}}), v^{\text{src}}); \theta). \tag{3}$$

For DELETEANDRETRIEVE, we could similarly learn an auto-encoder that reconstructs x from $c(x, v^{\text{src}})$ and $a(x, v^{\text{src}})$. However, this results in a trivial solution: because $a(x, v^{\text{src}})$ and $c(x, v^{\text{src}})$ were known to come from the same sentence, the model merely learns to stitch the two sequences together without any smoothing. Such a model would fare poorly at test time, when we may need to alter some words to fluently combine $a(x^{\text{tgt}}, v^{\text{tgt}})$ with $c(x, v^{\text{src}})$. To address this train/test mismatch, we adopt a denoising method similar to the denoising auto-encoder (Vincent et al., 2008). During training, we apply some noise to $a(x, v^{\text{src}})$ by randomly altering each attribute marker in it independently with probability 0.1. Specifically, we replace an attribute marker with another randomly selected attribute marker of the same attribute and word-level edit distance 1 if such a noising marker exists, e.g., *"was very rude"* to *"very rude"*, which produces $a'(x, v^{\text{src}})$.

Therefore, the training objective for DELETEANDRETRIEVE is to maximize:

$$L(\theta) = \sum_{(x, v^{\text{src}}) \in \mathcal{D}} \log p(x \mid c(x, v^{\text{src}}), a'(x, v^{\text{src}}); \theta). \tag{4}$$

4 Experiments

We evaluated our approach on three domains: flipping sentiment of Yelp reviews (YELP) and Amazon reviews (AMAZON), and changing image captions to be romantic or humorous (CAPTIONS). We compared our four systems to human references and three previously published adversarial approaches. As judged by human raters, both of our two baselines outperform all three adversarial methods. Moreover, DELETEANDRETRIEVE outperforms all other automatic approaches.

Dataset	Attributes	Train	Dev	Test
YELP	Positive	270K	2000	500
	Negative	180K	2000	500
CAPTIONS	Romantic	6000	300	0
	Humorous	6000	300	0
	Factual	0	0	300
AMAZON	Positive	277K	985	500
	Negative	278K	1015	500

Table 1: Dataset statistics.

4.1 Datasets

First, we describe the three datasets we use, which are commonly used in prior works too. All datasets are randomly split into train, development, and test sets (Table 1).

YELP Each example is a sentence from a business review on Yelp, and is labeled as having either positive or negative sentiment.

AMAZON Similar to YELP, each example is a sentence from a product review on Amazon, and is labeled as having either positive or negative sentiment (He and McAuley, 2016).

CAPTIONS In the CAPTIONS dataset (Gan et al., 2017), each example is a sentence that describes an image, and is labeled as either factual, romantic, or humorous. We focus on the task of converting factual sentences into romantic and humorous ones. Unlike YELP and AMAZON, CAPTIONS is actually an aligned corpus—it contains captions for the same image in different styles. Our systems do not use these alignments, but we use them as gold references for evaluation.

CAPTIONS is also unique in that we reconstruct romantic and humorous sentences during training, whereas at test time we are given factual captions. We assume these factual captions carry only content, and therefore do not look for and delete factual attribute markers; The model essentially only inserts romantic or humorous attribute markers as appropriate.

4.2 Human References

To supply human reference outputs to which we could compare the system outputs for YELP and AMAZON, we hired crowdworkers on Amazon Mechanical Turk to write gold outputs for all test sentences. Workers were instructed to edit a sentence to flip its sentiment while preserving its content.

Our delete-retrieve-generate approach relies on the prior knowledge that to accomplish attribute transfer, a small number of attribute markers should be changed, and most other words should be kept the same. We analyzed our human reference data to understand the extent to which humans follow this pattern. We measured whether humans preserved words our system marks as content, and changed words our system marks as attribute-related (Section 3.1). We define the *content word preservation rate* S_c as the average fraction of words our system marks as content that were preserved by humans, and the *attribute-related word change rate* S_a as the average fraction of words our system marks as attribute-related that were changed by humans:

$$S_c = \frac{1}{|\mathcal{D}_{\text{test}}|} \sum_{(x, v^{\text{src}}, y^*) \in \mathcal{D}_{\text{test}}} \frac{|c(x, v^{\text{src}}) \cap y^*|}{|c(x, v^{\text{src}})|}$$
$$S_a = 1 - \frac{1}{|\mathcal{D}_{\text{test}}|} \sum_{(x, v^{\text{src}}, y^*) \in \mathcal{D}_{\text{test}}} \frac{|a(x, v^{\text{src}}) \cap y^*|}{|a(x, v^{\text{src}})|}, \quad (5)$$

where $\mathcal{D}_{\text{test}}$ is the test set, y^* is the human reference sentence, and $|\cdot|$ denotes the number of non-stopwords. Higher values of S_c and S_a indicate that humans preserve content words and change attribute-related words, in line with the inductive bias of our model. S_c is 0.61, 0.71, and 0.50 on YELP, AMAZON, and CAPTIONS, respectively; S_a is 0.72 on YELP and 0.54 on AMAZON (not applicable on CAPTIONS).

To understand why humans sometimes deviated from the inductive bias of our model, we randomly sampled 50 cases from YELP where humans changed a content word or preserved an attribute-related word. 70% of changed content words were unimportant words (e.g., *"whole"* was deleted from *"whole experience"*), and another 18% were paraphrases (e.g., *"charge"* became *"price"*); the remaining 12% were errors where the system mislabeled an attribute-related word as a content word (e.g., *"old"* became *"new"*). 84% of preserved attribute-related words did pertain to sentiment but remained fixed due to changes in the surrounding context (e.g., *"don't **like**"* became *"**like**"*, and *"below **average**"* became *"above **average**"*); the remaining 16% were mistagged by our system as being attribute-related (e.g., *"walked out"*).

4.3 Previous Methods

We compare with three previous models, all of which use adversarial training. **STYLEEMBED-**

	Yelp				Amazon				Captions			
	Gra	Con	Att	Suc	Gra	Con	Att	Suc	Gra	Con	Att	Suc
CrossAligned	2.8	2.9	3.5	14%	3.2	2.5	2.9	7%	3.9	2.0	3.2	16%
StyleEmbedding	3.5	3.7	2.1	9%	3.2	2.9	2.8	11%	3.3	2.9	3.0	17%
MultiDecoder	2.8	3.1	3.0	8%	3.0	2.6	2.8	7%	3.4	2.8	3.2	18%
RetrieveOnly	**4.2**	2.7	**4.2**	25%	3.8	2.8	3.1	17%	**4.2**	2.6	3.8	27%
TemplateBased	3.0	**3.9**	3.9	21%	3.4	3.6	3.1	19%	3.3	**4.1**	3.5	33%
DeleteOnly	3.0	3.7	3.9	24%	3.7	**3.8**	3.2	24%	3.6	3.5	3.5	32%
DeleteAndRetrieve	3.3	3.7	4.0	**29%**	**3.9**	3.7	**3.4**	**29%**	3.8	3.5	**3.9**	**43%**
Human	4.6	4.5	4.5	75%	4.2	4.0	3.7	44%	4.3	3.9	4.0	56%

Table 2: Human evaluation results on all three datasets. We show average human ratings for grammaticality (Gra), content preservation (Con), and target attribute match (Att) on a 1 to 5 Likert scale, as well as overall success rate (Suc). On all three datasets, DeleteAndRetrieve is the best overall system, and all four of our methods outperform previous work.

ding (Fu et al., 2018) learns an vector encoding of the source sentence such that a decoder can use it to reconstruct the sentence, but a discriminator, which tries to identify the source attribute using this encoding, fails. They use a basic MLP discriminator and an LSTM decoder. **MultiDecoder** (Fu et al., 2018) is similar to StyleEmbedding, except that it uses a different decoder for each attribute value. **CrossAligned** (Shen et al., 2017) also encodes the source sentence into a vector, but the discriminator looks at the hidden states of the RNN decoder instead. The system is trained so that the discriminator cannot distinguish these hidden states from those obtained by forcing the decoder to output real sentences from the target domain; this objective encourages the real and generated target sentences to look similar at a population level.

4.4 Experimental Details

For our methods, we use 128-dimensional word vectors and a single-layer GRU with 512 hidden units for both encoders and the decoder. We use the maxout activation function (Goodfellow et al., 2013). All parameters are initialized by sampling from a uniform distribution between -0.1 and 0.1. For optimization, we use Adadelta (Zeiler, 2012) with a minibatch size of 256.

For attribute marker extraction, we consider spans up to 4 words, and the smoothing parameter λ is set to 1. We set the attribute marker threshold γ, which controls the precision and recall of our attribute markers, to 15, 5.5 and 5 for Yelp, Amazon, and Captions. These values were set by manual inspection of the resulting markers and tuning slightly on the dev set. For retrieval, we used the TF-IDF weighted word overlap score for DeleteAndRetrieve and TemplateBased, and the Euclidean distance of content embeddings for RetrieveOnly. We find the two scoring functions give similar results.

For all neural models, we do beam search with a beam size of 10. For DeleteAndRetrieve, similar to Guu et al. (2018), we retrieve the top-10 sentences and generate results using markers from each sentence. We then select the output with the lowest perplexity given by a separately-trained neural language model on the target-domain training data.

4.5 Human Evaluation

We hired workers on Amazon Mechanical Turk to rate the outputs of all systems. For each source sentence and target attribute, the same worker was shown the output of each tested system. Workers were asked to rate each output on three criteria on a Likert scale from 1 to 5: grammaticality, similarity to the target attribute, and preservation of the source content. Finally, we consider a generated output "successful" if it is rated 4 or 5 on all three criteria. For each dataset, we evaluated 400 randomly sampled examples (200 for each target attribute).

Table 2 shows the human evaluation results. On all three datasets, both of our baselines have a higher success rate than the previously published models, and DeleteAndRetrieve achieves the best performance among all systems. Additionally, we see that human raters strongly preferred the human references to all systems, suggesting there is still significant room for improvement on this task.

We find that a human evaluator's judgment of a sentence is largely relative to other sentences being evaluated together and examples given in the instruction (different for each dataset/task). There-

fore, evaluating all system outputs in one batch is important and results on different datasets are not directly comparable.

4.6 Analysis

We analyze the strengths and weaknesses of the different systems. Table 3 show typical outputs of each system on the YELP and CAPTIONS dataset.

We first analyze the adversarial methods. CROSSALIGNED and MULTIDECODER tend to lose the content of the source sentence, as seen in both the example outputs and the overall human ratings. The decoder tends to generate a frequent but only weakly related sentence with the target attribute. On the other hand, STYLEEMBEDDING almost always generates a paraphrase of the input sentence, implying that the encoder preserves some attribute information. We conclude that there is a delicate balance between preserving the original content and dropping the original attribute, and existing adversarial models tend to sacrifice one or the other.

Next, we analyze our baselines. RETRIEVEONLY scores well on grammaticality and having the target attribute, since it retrieves sentences with the desired attribute directly from the corpus. However, it is likely to change the content when there is no perfectly aligned sentence in the target domain. In contrast, TEMPLATEBASED is good at preserving the content because the content words are guaranteed to be kept. However, it makes grammatical mistakes due to the unsmoothed combination of content and attribute words.

DELETEANDRETRIEVE and DELETEONLY achieve a good balance among grammaticality, preserving content, and changing the attribute. Both have strong inductive bias on what words should be changed, but still have the flexibility to smooth out the sentence. The main difference is that DELETEONLY fills in attribute words based on only the target attribute, whereas DELETEANDRETRIEVE conditions on retrieved attribute words. When there is a diverse set of phrases to fill in—for example in CAPTIONS— conditioning on retrieved attribute words helps generate longer sentences with more specific attribute descriptions.

4.7 Automatic Evaluation

Following previous work (Hu et al., 2017; Shen et al., 2017), we also compute automatic evaluation metrics, and compare these numbers to our human evaluation results.

We use an attribute classifier to assess whether outputs have the desired attribute (Hu et al., 2017; Shen et al., 2017). We define the *classifier score* as the fraction of outputs classified as having the target attribute. For each dataset, we train an attribute classifier on the same training data. Specifically, we encode the sentence into a vector by a bidirectional LSTM with an average pooling layer over the outputs, and train the classifier by minimizing the logistic loss.

We also compute BLEU between the output and the human references, similar to Gan et al. (2017). A high BLEU score primarily indicates that the system can correctly preserve content by retaining the same words from the source sentence as the reference. One might also hope that it has some correlation with fluency, though we expect this correlation to be much weaker.

Table 4 shows the classifier and BLEU scores. In Table 5, we compute the system-level correlation between classifier score and human judgments of attribute transfer, and between BLEU and human judgments of content preservation and grammaticality. We also plot scores given by the automatic metrics and humans in Figure 4. While the scores are sometimes well-correlated, the results vary significantly between datasets; on AMAZON, there is no correlation between the classifier score and the human evaluation. Manual inspection shows that on AMAZON, some product genres are associated with either mostly positive or mostly negative reviews. However, our systems produce, for example, negative reviews about products that are mostly discussed positively in the training set. Therefore, the classifier often gives unreliable predictions on system outputs. As expected, BLEU does not correlate well with human grammaticality ratings. The lack of automatic fluency evaluation artificially favors systems like TEMPLATEBASED, which make more grammatical mistakes. We conclude that while these automatic evaluation methods are useful for model development, they cannot replace human evaluation.

4.8 Trading off Content versus Attribute

One advantage of our methods is that we can control the trade-off between matching the target attribute and preserving the source content. To achieve different points along this trade-off curve,

From negative to positive (YELP)	
SOURCE	we sit down and we got some really slow and lazy service .
CROSSALIGNED	we *went* down and we *were a good , friendly food* .
STYLEEMBEDDING	we sit down and we got some really *slow* and *prices suck* .
MULTIDECODER	we sit down and we got some really and *fast food* .
TEMPLATEBASED	we sit down and we got some *the service is always great* and *even better* service .
RETRIEVEONLY	*i* got *a veggie hoagie that was massive* and some *grade a customer* service .
DELETEONLY	we sit down and we got some *great* and *quick* service .
DELETEANDRETRIEVE	we got *very nice place to* sit down and we got some service .
From factual to romantic (CAPTIONS)	
SOURCE	two dogs play by a tree .
CROSSALIGNED	*a dog is running through the grass* .
STYLEEMBEDDING	two dogs play *against* a tree .
MULTIDECODER	two dogs play by a tree .
TEMPLATEBASED	two dogs play by a tree *loving* .
RETRIEVEONLY	two dogs *are playing in a pool as best friends* .
DELETEANDRETRIEVE	two dogs play by a tree , *enjoying the happiness of childhood* .
DELETEONLY	two dogs *in love* play *happily* by a tree .
From negative to positive (AMAZON)	
SOURCE	this is the worst game i have come across in a long time .
CROSSALIGNED	this is the *best thing* i *ve had for a few years* .
STYLEEMBEDDING	this is the worst game i have come across in a long time .
MULTIDECODER	this is the *best knife* i have *no room with* a long time .
TEMPLATEBASED	this is the *best* come across in a long time .
RETRIEVEONLY	*the customer support is some of the best* i have come across in a long time .
DELETEONLY	this is the *best* game i have come across in a long time .
DELETEANDRETRIEVE	this is the *best* game i have come across in a long time .

Table 3: Example outputs on YELP, CAPTIONS, and AMAZON. Additional examples for transfer from opposite directions are given in Table 6. Added or changed words are in *italic*. Attribute markers are colored.

	YELP		CAPTIONS		AMAZON	
	Classifier	BLEU	Classifier	BLEU	Classifier	BLEU
CROSSALIGNED	73.7%	3.1	74.3%	0.1	**74.1%**	0.4
STYLEEMBEDDING	8.7%	**11.8**	54.7%	6.7	43.3%	10.0
MULTIDECODER	47.6%	7.1	68.5%	4.6	68.3%	5.0
TEMPLATEBASED	81.7%	**11.8**	92.5%	**17.1**	68.7%	**27.1**
RETRIEVEONLY	**95.4%**	0.4	**95.5%**	0.7	**70.3%**	0.9
DELETEONLY	85.7%	7.5	83.0%	9.0	45.6%	24.6
DELETEANDRETRIEVE	88.7%	8.4	**96.8%**	7.3	48.0%	22.8

Table 4: Automatic evaluation results. "Classifier" shows the percentage of sentences labeled as the target attribute by the classifier. BLEU measures content similarity between the output and the human reference.

we simply vary the threshold γ (Section 3.1) *at test time* to control how many attribute markers we delete from the source sentence. In contrast, other methods (Shen et al., 2017; Fu et al., 2018) would require retraining the model with different hyperparameters to achieve this effect.

Figure 3 shows this trade-off curve for DELETEANDRETRIEVE, DELETEONLY, and TEMPLATEBASED on YELP, where target attribute match is measured by the classifier score and content preservation is measured by BLEU.[3] We see a clear trade-off between changing the attribute and retaining the content.

[3] RETRIEVEONLY is less affected by what content words are preserved, especially when no good output sentence exists in the target corpus. Therefore, we found that it did not exhibit a clear content-attribute trade-off.

5 Related Work and Discussion

Our work is closely related to the recent body of work on text attribute transfer with *unaligned* data, where the key challenge to disentangle attribute and content in an unsupervised way. Most existing work (Shen et al., 2017; Zhao et al., 2018; Fu et al., 2018; Melnyk et al., 2017) uses adversarial training to separate attribute and content: the content encoder aims to fool the attribute discriminator by removing attribute information from the content embedding. However, we find that empirically it is often easy to fool the discriminator without actually removing the attribute information. Therefore, we explicitly separate attribute and content by taking advantage of the prior knowledge that the attribute is localized to parts of the sentence.

To address the problem of unaligned data, Hu

	Classifier	BLEU	
	Attribute	Content	Grammaticality
All data	0.810 ($p < 0.01$)	0.876 ($p < 0.01$)	−0.127 ($p = 0.58$)
YELP	0.991 ($p < 0.01$)	0.935 ($p < 0.01$)	0.119 ($p = 0.80$)
CAPTIONS	0.982 ($p < 0.01$)	0.991 ($p < 0.01$)	−0.631 ($p = 0.13$)
AMAZON	−0.036 ($p = 0.94$)	0.857 ($p < 0.01$)	0.306 ($p = 0.50$)

Table 5: Spearman correlation between two automatic evaluation metrics and related human evaluation scores. While some correlations are strong, the classifier exhibits poor correlation on AMAZON, and BLEU only measures content, not grammaticality.

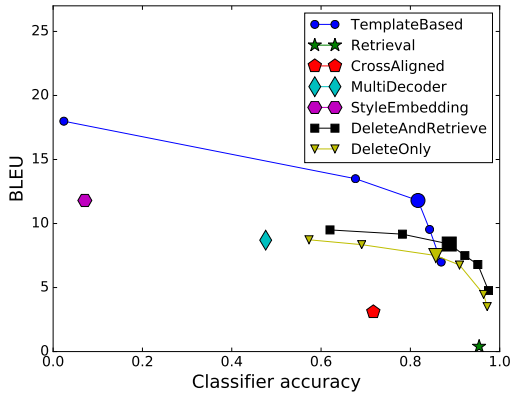

Figure 3: Trade-off curves between matching the target attribute (measured by classifier scores) and preserving the content (measured by BLEU). Bigger points on the curve correspond to settings used for both training and our official evaluation.

et al. (2017) relies on an attribute classifier to guide the generator to produce sentences with a desired attribute (e.g. sentiment, tense) in the Variational Autoencoder (VAE) framework. Similarly, Zhao et al. (2018) used a regularized autoencoder in the adversarial training framework; however, they also find that these models require extensive hyperparameter tuning and the content tends to be changed during the transfer. Shen et al. (2017) used a discriminator to align target sentences and sentences transfered to the target domain from the source domain. More recently, unsupervised machine translation models (Artetxe et al., 2017; Lample et al., 2017) used a cycle loss similar to Jun-Yan et al. (2017) to ensure that the content is preserved during the transformation. These methods often rely on bilinguial word vectors to provide word-for-word translations, which are then finetune by back-translation. Thus they can be used to further improve our results.

Our method of detecting attribute markers is reminiscent of Naive Bayes, which is a strong baseline for tasks like sentiment classification (Wang and Manning, 2012). Deleting these attribute markers can be viewed as attacking a Naive Bayes classifier by deleting the most informative features (Globerson and Roweis, 2006), similarly to how adversarial methods are trained to fool an attribute classifier. One difference is that our classifier is fixed, not jointly trained with the model.

To conclude, we have described a simple method for text attribute transfer that outperforms previous models based on adversarial training. The main leverage comes from the inductive bias that attributes are usually manifested in localized discriminative phrases. While many prior works on linguistic style analysis confirm our observation that attributes often manifest in idiosyncratic phrases (Recasens et al., 2013; Schwartz et al., 2017; Newman et al., 2003), we recognize the fact that in some problems (e.g., Pavlick and Tetreault (2017)), content and attribute cannot be so cleanly separated along phrase boundaries. Looking forward, a fruitful direction is to develop a notion of attributes more general than n-grams, but with more inductive bias than arbitrary latent vectors.

Reproducibility. All code, data, and experiments for this paper are available on the CodaLab platform at `https://worksheets.codalab.org/worksheets/0xe3eb416773ed4883bb737662b31b4948/`.

Abstract

We propose *syntactically controlled paraphrase networks* (SCPNs) and use them to generate adversarial examples. Given a sentence and a target syntactic form (e.g., a constituency parse), SCPNs are trained to produce a paraphrase of the sentence with the desired syntax. We show it is possible to create training data for this task by first doing back-translation at a very large scale, and then using a parser to label the syntactic transformations that naturally occur during this process. Such data allows us to train a neural encoder-decoder model with extra inputs to specify the target syntax. A combination of automated and human evaluations show that SCPNs generate paraphrases that follow their target specifications without decreasing paraphrase quality when compared to baseline (uncontrolled) paraphrase systems. Furthermore, they are more capable of generating syntactically adversarial examples that both (1) "fool" pretrained models and (2) improve the robustness of these models to syntactic variation when used to augment their training data.

1 Introduction

Natural language processing datasets often suffer from a dearth of linguistic variation, which can hurt the generalization of models trained on them. Recent work has shown it is possible to easily "break" many learned models by evaluating them on *adversarial examples* (Goodfellow et al., 2015), which are generated by manually introducing lexical, pragmatic, and syntactic variation not seen in the training set (Ettinger et al., 2017). Robustness to such adversarial examples can potentially be improved by augmenting the training data, as shown by prior work that introduces rule-based lexical substitutions (Jia and Liang, 2017; Liang et al., 2017). However, more complex transformations, such as generating syntactically adversarial examples, remain an open challenge, as input semantics must be preserved in the face of potentially substantial structural modifications. In this paper, we introduce a new approach for learning to do *syntactically controlled paraphrase generation*: given a sentence and a target syntactic form (e.g., a constituency parse), a system must produce a paraphrase of the sentence whose syntax conforms to the target.

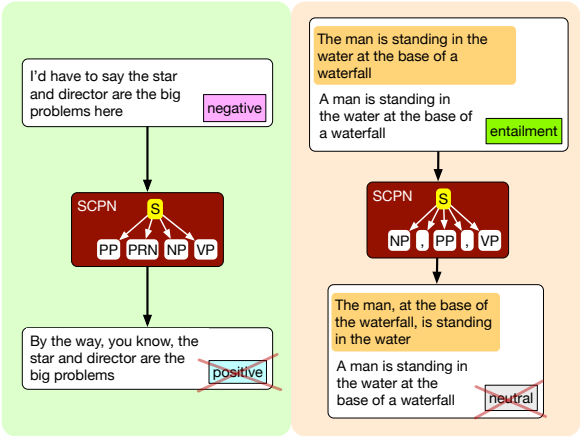

Figure 1: Adversarial examples for sentiment analysis (left) and textual entailment (right) generated by our syntactically controlled paraphrase network (SCPN) according to provided parse templates. In both cases, a pretrained classifier correctly predicts the label of the original sentence but not the corresponding paraphrase.

General purpose syntactically controlled paraphrase generation is a challenging task. Approaches that rely on handcrafted rules and grammars, such as the question generation system of McKeown (1983), support only a limited number of syntactic targets. We introduce the first learning approach for this problem, building on the generality of neural encoder-decoder models to support a wide range of transformations. In doing

so, we face two new challenges: (1) obtaining a large amount of paraphrase pairs for training, and (2) defining syntactic transformations with which to label these pairs.

Since no large-scale dataset of sentential paraphrases exists publicly, we follow Wieting et al. (2017) and automatically generate millions of paraphrase pairs using neural *backtranslation*. Backtranslation naturally injects linguistic variation between the original sentence and its backtranslated counterpart. By running the process at a very large scale and testing for the specific variations we want to produce, we can gather ample input-output pairs for a wide range of phenomena. Our focus is on syntactic transformations, which we define using templates derived from linearized constituency parses (§2). Given such parallel data, we can easily train an encoder-decoder model that takes a sentence and target syntactic template as input, and produces the desired paraphrase.[1]

A combination of automated and human evaluations show that the generated paraphrases almost always follow their target specifications, while paraphrase quality does not significantly deteriorate compared to vanilla neural backtranslation (§4). Our model, the syntactically controlled paraphrase network (SCPN), is capable of generating adversarial examples for sentiment analysis and textual entailment datasets that significantly impact the performance of pretrained models (Figure 1). We also show that augmenting training sets with such examples improves robustness without harming accuracy on the original test sets (§5). Together these results not only establish the first general purpose syntactically controlled paraphrase approach, but also suggest that this general paradigm could be used for controlling many other aspects of the target text.

2 Collecting labeled paraphrase pairs

In this section, we describe a general purpose process for gathering and labeling training data for controlled paraphrase generation.

2.1 Paraphrase data via backtranslation

Inducing paraphrases from bilingual data has long been an effective method to overcome data limitations. In particular, bilingual pivoting (Bannard and Callison-Burch, 2005) finds quality paraphrases by pivoting through a different language. Mallinson et al. (2017) show that neural machine translation (NMT) systems outperform phrase-based MT on several paraphrase evaluation metrics.

In this paper, we use the PARANMT-50M corpus from Wieting and Gimpel (2017). This corpus consists of over 50 million paraphrases obtained by backtranslating the Czech side of the CzEng (Bojar et al., 2016) parallel corpus. The pretrained Czech-English model used for translation came from the Nematus NMT system (Sennrich et al., 2017). The training data of this system includes four sources: Common Crawl, CzEng 1.6, Europarl, and News Commentary. The CzEng corpus is the largest of these four and was found to have significantly more syntactic diversity than the other data sources (Wieting and Gimpel, 2017).[2]

2.2 Automatically labeling paraphrases with syntactic transformations

We need labeled transformations in addition to paraphrase pairs to train a controlled paraphrase model. Manually annotating each of the millions of paraphrase pairs is clearly infeasible. Our key insight is that target transformations can be detected (with some noise) simply by parsing these pairs.[3]

Specifically, we parse the backtranslated paraphrases using the Stanford parser (Manning et al., 2014),[4] which yields a pair of constituency parses $\langle p_1, p_2 \rangle$ for each sentence pair $\langle s_1, s_2 \rangle$, where s_1 is the reference English sentence in the CzEng corpus and s_2 is its backtranslated counterpart. For syntactically controlled paraphrasing, we assume s_1 and p_2 are inputs, and the model is trained to produce s_2. To overcome learned biases of the NMT system, we also include reversed pairs $\langle s_2, s_1 \rangle$ during training.

2.2.1 Syntactic templates

To provide syntactic control, we linearize the bracketed parse structure without leaf nodes (i.e., tokens). For example, the corresponding linearized parse

[1] Code, labeled data, and pretrained models available at https://github.com/miyyer/scpn.

[2] Syntactic diversity was measured by the entropy of the top two levels of parse trees in the corpora.

[3] Similar automated filtering could be used to produce data for many other transformations, such as tense changes, point-of-view shifts, and even stylometric pattern differences (Feng et al., 2012). This is an interesting area for future work.

[4] Because of the large dataset size, we use the faster but less accurate shift-reduce parser written by John Bauer.

tree for the sentence "*She drove home.*" is `(S(NP(PRP))(VP(VBD)(NP(NN)))(.))`. A system that requires a complete linearized target parse at test-time is unwieldy; how do we go about choosing the target parse? To simplify test-time usage, we relax the target syntactic form to a parse *template*, which we define as the top two levels of the linearized parse tree (the level immediately below the root along with the root); the prior example's template is $\texttt{S} \rightarrow \texttt{NP VP}$. In the next section, we design models such that users can feed in either parse templates or full parses depending on their desired level of control.

3 Syntactically Controlled Paraphrase Networks

The SCPN encoder-decoder architecture is built from standard neural modules, as we describe in this section.

3.1 Neural controlled paraphrase generation

Given a sentential paraphrase pair $\langle s_1, s_2 \rangle$ and a corresponding target syntax tree p_2 for s_2, we encode s_1 using a bidirectional LSTM (Hochreiter and Schmidhuber, 1997), and our decoder is a two-layer LSTM augmented with soft attention over the encoded states (Bahdanau et al., 2014) as well as a copy mechanism (See et al., 2017). Following existing work in NMT (Sennrich et al., 2015), we preprocess s_1 and s_2 into subword units using byte pair encoding, and we perform decoding using beam search. For all attention computations, we use a bilinear product with a learned parameter matrix $\mathbf{W}$: given vectors $\boldsymbol{u}$ and $\boldsymbol{v}$, we score them by $\boldsymbol{u}^T \mathbf{W} \boldsymbol{v}$.

We incorporate the target syntax p_2 into the generation process by modifying the inputs to the decoder. In particular, a standard decoder LSTM receives two inputs at every time step: (1) the embedding $\boldsymbol{w}_{t-1}$ of the ground-truth previous word in s_2, and (2) an attention-weighted average $\boldsymbol{a}_t$ of the encoder's hidden states. We additionally provide a representation $\boldsymbol{z}_t$ of the target p_2, so at every time step the decoder computes

$$\boldsymbol{h}_t = \text{LSTM}([\boldsymbol{w}_{t-1}; \boldsymbol{a}_t; \boldsymbol{z}_t]). \quad (1)$$

Since we preserve bracketed parse structure, our linearized parses can have hundreds of tokens. Forcing all of the relevant information contained by the parse tree into a single fixed representation (i.e., the last hidden state of an LSTM) is difficult with such large sequences. Intuitively, we want the decoder to focus on portions of the target parse tree that correspond with the current time step. As such, we encode p_2 using a (unidirectional) LSTM and compute $\boldsymbol{z}_t$ with an attention-weighted average of the LSTM's encoded states at every time step. This attention mechanism is conditioned on the decoder's previous hidden state $\boldsymbol{h}_{t-1}$.

3.2 From parse templates to full parses

As mentioned in Section 2.2.1, user-friendly systems should be able to accept high-level parse templates as input rather than full parses. Preliminary experiments show that SCPN struggles to maintain the semantics of the input sentence when we replace the full target parse with templates, and frequently generates short, formulaic sentences. The paraphrase generation model seems to rely heavily on the full syntactic parse to determine output length and clausal ordering, making it difficult to see how to modify the SCPN architecture for template-only target specification.

Instead, we train another model with exactly the same architecture as SCPN to generate complete parses from parse templates. This allows us to do the prediction in two steps: first predict the full syntactic tree and then use that tree to produce the paraphrase. Concretely, for the first step, assume t_2 is the parse template formed from the top two levels of the target parse p_2. The input to this *parse generator* is the input parse p_1 and t_2, and it is trained to produce p_2. We train the parse generator separately from SCPN (i.e., no joint optimization) for efficiency purposes. At test time, a user only has to specify an input sentence and target template; the template is fed through the parse generator, and its predicted target parse is in turn sent to SCPN for paraphrase generation (see Figure 2).

3.3 Template selection and post-processing

By switching from full parses to templates, we have reduced but not completely removed the burden of coming up with a target syntactic form. Certain templates may be not be appropriate for particular input sentences (e.g., turning a long sentence with multiple clauses into a noun phrase). However, others may be too similar to the input syntax, resulting in very little change. Since template selection is not a major focus of this paper, we use a relatively simple procedure, selecting the twenty most frequent templates in PARANMT-

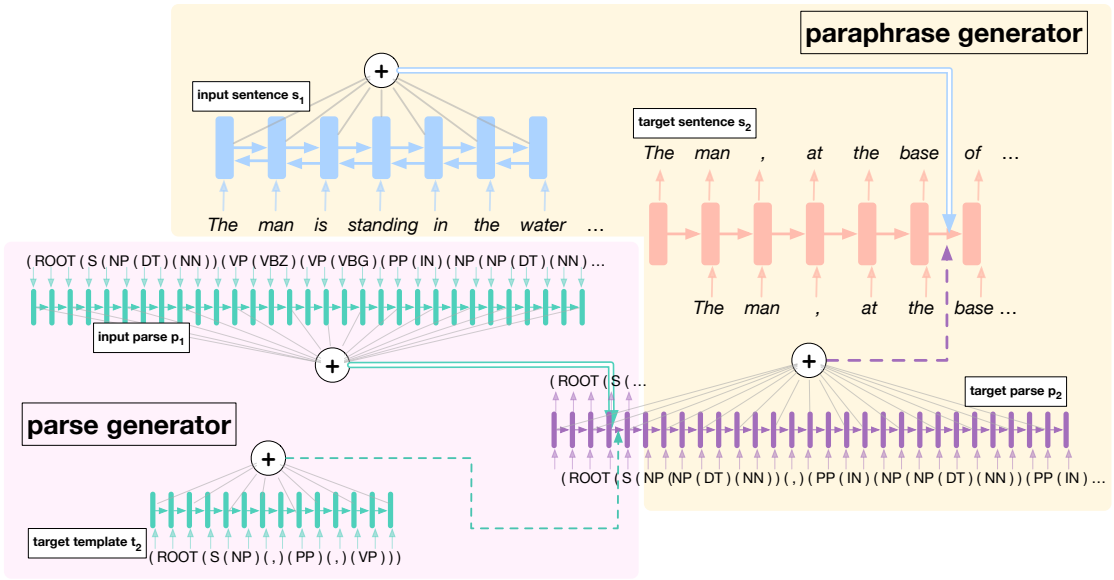

Figure 2: SCPN implements parse generation from templates as well as paraphrase generation from full parses as encoder-decoder architectures (attention depicted with dotted lines, copy mechanism with double stroked lines). While both components are trained separately, at test-time they form a pipelined approach to produce a controlled paraphrase from an input sentence s_1, its corresponding parse p_1, and a target template t_2.

50M.[5]

Since we cannot generate a valid paraphrase for every template, we postprocess to remove nonsensical outputs. In particular, we filter generated paraphrases using n-gram overlap and paraphrastic similarity, the latter of which is computed using the pretrained WORD,TRIAVG sentence embedding model from Wieting and Gimpel (2017).[6] These paraphrastic sentence embeddings significantly outperform prior work due to the PARANMT-50M data.

4 Intrinsic Experiments

Before using SCPN to generate adversarial examples on downstream datasets, we need to make sure that its output paraphrases are valid and grammatical and that its outputs follow the specified target syntax. In this section, we compare SCPN to a neural backtranslation baseline (NMT-BT) on the development set of our PARANMT-50M split using both human and automated experiments. NMT-BT is the same pretrained Czech-English model used to create PARANMT-50M; however, here we use it to generate in both directions (i.e., English-Czech and Czech-English).

[5]However, we do provide some qualitative examples of rare and medium-frequency templates in Table 3.

[6]After qualitatively analyzing the impact of different filtering choices, we set minimum n-gram overlap to 0.5 and minimum paraphrastic similarity to 0.7.

Model	**2**	**1**	**0**
SCPN w/ full parses	63.7	14.0	22.3
SCPN w/ templates	62.3	19.3	18.3
NMT-BT	65.0	17.3	17.7

Table 1: A crowdsourced paraphrase evaluation on a three-point scale (**0** = no paraphrase, **1** = ungrammatical paraphrase, **2** = grammatical paraphrase) shows both that NMT-BT and SCPN produce mostly grammatical paraphrases. Feeding parse templates to SCPN instead of full parses does not impact its quality.

4.1 Paraphrase quality & grammaticality

To measure paraphrase quality and grammaticality, we perform a crowdsourced experiment in which workers are asked to rate a paraphrase pair $\langle s, g \rangle$ on the three-point scale of Kok and Brockett (2010), where s is the source sentence and g is the generated sentence. A **0** on this scale indicates no paraphrase relationship, while **1** means that g is an ungrammatical paraphrase of s and **2** means that g is a grammatical paraphrase of s. We select 100 paraphrase pairs from the development set of our PARANMT-50M split (after the postprocessing steps detailed in Section 3.3) and have three workers rate each pair.[7] To focus the evaluation on the effect of syntactic manipulation on quality, we

[7]We use the Crowdflower platform for our experiments.

only select sentences whose top-level parse templates differ (i.e., $t_s \neq t_g$), ensuring that the output of both systems varies syntactically from the source sentences.

The results (Table 1) show that the uncontrolled NMT-BT model's outputs are comparable in quality and grammaticality to those of SCPN; neither system has a significant edge. More interestingly, we observe no quality drop when feeding templates to SCPN (via the parse generator as described in Section 3.2) instead of complete parse trees, which suggests that the parse generator is doing a good job of generating plausible parse trees; thus, for all of the adversarial evaluations that follow, we only use the templated variant of SCPN.

4.2 Do the paraphrases follow the target specification?

We next determine how often SCPN's generated paraphrases conform to the target syntax: if g is a generated paraphrase and p_g is its parse, how often does p_g match the ground-truth target parse p_2? We evaluate on our development set using *exact template match*: g is deemed a syntactic match to s_2 only if the top two levels of its parse p_g matches those of p_2. We evaluate two SCPN configurations, where one is given the full target parse p_2 and the other is given the result of running our parse generator on the target template t_2. As a sanity check, we also evaluate our parse generator using the same metric.

The results (Table 2) show that SCPN does indeed achieve syntactic control over the majority of its inputs. Our parse generator produces full parses that almost always match the target template; however, paraphrases generated using these parses are less syntactically accurate.[8] A qualitative inspection of the generated parses reveals that they can differ from the ground-truth target parse in terms of ordering or existence of lower-level constituents (Table 6); we theorize that these differences may throw off SCPN's decoder.

The NMT-BT system produces paraphrases that tend to be syntactically very similar to the input sentences: 28.7% of these paraphrases have the same template as that of the input sentence s_1, while only 11.1% have the same template as the ground-truth target s_2. Even though we train SCPN on data generated by NMT backtranslation, we avoid this issue by incorporating syntax into our learning process.

Model	Parse Acc.
SCPN w/ gold parse	64.5
SCPN w/ generated parse	51.6
Parse generator	99.9

Table 2: The majority of paraphrases generated by SCPN conform to the target syntax, but the level of syntactic control decreases when using generated target parses instead of gold parses. Accuracy is measured by exact template match (i.e., how often do the top two levels of the parses match).

5 Adversarial example generation

The intrinsic evaluations show that SCPN produces paraphrases of comparable quality to the uncontrolled NMT-BT system while also adhering to the specified target specifications. Next, we examine the utility of controlled paraphrases for adversarial example generation. To formalize the problem, assume a pretrained model for some downstream task produces prediction y_x given test-time instance x. An *adversarial* example x' can be formed by making label-preserving modifications to x such that $y_x \neq y_{x'}$. Our results demonstrate that controlled paraphrase generation with appropriate template selection produces far more valid adversarial examples than backtranslation on sentiment analysis and entailment tasks.

5.1 Experimental setup

We evaluate our syntactically adversarial paraphrases on the Stanford Sentiment Treebank (Socher et al., 2013, SST) and SICK entailment detection (Marelli et al., 2014). While both are relatively small datasets, we select them because they offer different experimental conditions: SST contains complicated sentences with high syntactic variance, while SICK almost exclusively consists of short, simple sentences. As a baseline, we compare the ten most probable beams from NMT-BT to controlled paraphrases generated by SCPN using ten templates randomly sampled from the template set described in Section 3.3.[9] We also need pretrained models

[8] With that said, exact match is a harsh metric; these paraphrases are more accurate than the table suggests, as often they differ by only a single constituent.

[9] We also experimented with the diverse beam search modification proposed by Li et al. (2016b) for NMT-BT but found that it dramatically warped the semantics of many beams; crowdsourced workers rated 49% of its outputs as **0**

template	paraphrase

(SQ(MD)(SBARQ))	can i get a good burglar when the time comes ?
(S(NP)(IN)(NP)(NP)(VP)	look at the time the thief comes .

Table 3: Syntactically controlled paraphrases generated by SCPN for two examples from the PARANMT-50M development set. For each input sentence, we show the outputs of four different templates; the fourth template is a failure case (highlighted in green) exhibiting semantic divergence and/or ungrammaticality, which occurs when the target template is unsuited for the input.

for which to generate adversarial examples; we use the bidirectional LSTM baseline for both SST and SICK outlined in Tai et al. (2015) since it is a relatively simple architecture that has proven to work well for a variety of problems.[10] Since the SICK task involves characterizing the relationship between two sentences, for simplicity we only generate adversarial examples for the first sentence and keep the second sentence fixed to the ground truth.

5.2 Breaking pretrained models

For each dataset, we generate paraphrases for held-out examples and then run a pretrained model over them.[11] We consider a development example x *broken* if the original prediction y_x is correct, but the prediction $y_{x'}$ for at least one paraphrase x' is incorrect. For SST, we evaluate on the binary sentiment classification task and ignore all phrase-level labels (because our paraphrase models are trained on only sentences). Table 4 shows that for both datasets, SCPN breaks many more examples than NMT-BT. Moreover, as shown in Table 5, NMT-BT's paraphrases differ from the original example mainly by lexical substitutions, while SCPN often produces dramatically different syntactic structures.

5.3 Are the adversarial examples valid?

We have shown that we can break pretrained models with controlled paraphrases, but are these paraphrases actually valid adversarial examples? After all, it is possible that the syntactic modifications cause informative clauses or words (e.g., negations) to go missing. To measure the validity of our adversarial examples, we turn again to crowdsourced experiments. We ask workers to choose the appropriate label for a given sentence or sentence pair (e.g., positive or negative for SST), and then we compare the worker's judgment to the original development example's label. For both models, we randomly select 100 adversarial examples and have three workers annotate each one. The results (Table 4) show that on the more complex SST data, a higher percentage of SCPN's paraphrases are valid adversarial examples than those of NMT-BT, which is especially encouraging given our model also generates significantly *more* adversarial examples.

5.4 Increasing robustness to adversarial examples

If we additionally augment the *training* data of both tasks with controlled paraphrases, we can increase a downstream model's robustness to adversarial examples in the development set. To quantify this effect, we generate controlled paraphrases for the training sets of SST and SICK using the same templates as in the previous experiments. Then, we include these paraphrases as additional training examples and retrain our biLSTM task models.[12] As shown by Table 4, training on SCPN's paraphrases significantly improves robustness to syntactic adversaries without affecting accuracy on the original test sets. One im-

on the three-point scale.

[10] We initialize both models using pretrained GloVe embeddings (Pennington et al., 2014) and set the LSTM hidden dimensionality to 300.

[11] Since the SICK development dataset is tiny, we additionally generate adversarial examples on its test set.

[12] We did not experiment with more complex augmentation methods (e.g., downweighting the contribution of paraphrased training examples to the loss).

			No augmentation		With augmentation	
Model	Task	Validity	Test Acc	Dev Broken	Test Acc	Dev Broken
SCPN	SST	77.1	83.1	41.8	83.0	31.4
NMT-BT	SST	68.1	83.1	20.2	82.3	20.0
SCPN	SICK	77.7	82.1	33.8	82.7	19.8
NMT-BT	SICK	81.0	82.1	20.4	82.0	11.2

Table 4: SCPN generates more legitimate adversarial examples than NMT-BT, shown by the results of a crowd-sourced validity experiment and the percentage of held-out examples that are broken through paraphrasing. Furthermore, we show that by augmenting the training dataset with syntactically-diverse paraphrases, we can improve the robustness of downstream models to syntactic adversaries (see "Dev Broken" before and after augmentation) without harming accuracy on the original test set.

portant caveat is that this experiment only shows robustness to the set of templates used by SCPN; in real-world applications, careful template selection based on the downstream task, along with using a larger set of templates, is likely to increase robustness to less constrained syntactic adversaries. Augmentation with NMT-BT's paraphrases increases robustness on SICK, but on SST, it degrades test accuracy without any significant gain in robustness; this is likely due to its lack of syntactic variation compared to SCPN.

6 Qualitative Analysis

In the previous section, we quantitatively evaluated the SCPN's ability to produce valid paraphrases and adversarial examples. Here, we take a look at actual sentences generated by the model. In addition to analyzing SCPN's strengths and weaknesses compared to NMT-BT, we examine the differences between paraphrases generated by various configurations of the model to determine the impact of each major design decision (e.g., templates instead of full parses).

Syntactic manipulation: Table 3 demonstrates SCPN's ability to perform syntactic manipulation, showing paraphrases for two sentences generated using different templates. Many of the examples exhibit complex transformations while preserving both the input semantics and grammaticality, even when the target syntax is very different from that of the source (e.g., when converting a declarative to question). However, the failure cases demonstrate that not every template results in a valid paraphrase, as nonsensical outputs are sometimes generated when trying to squeeze the input semantics into an unsuitable target form.

Adversarial examples: Table 5 shows that SCPN and NMT-BT differ fundamentally in the type of adversaries they generate. While SCPN mostly avoids lexical substitution in favor of making syntactic changes, NMT-BT does the opposite. These examples reinforce the results of the experiment in Section 4.2, which demonstrates NMT-BT's tendency to stick to the input syntax. While SCPN is able to break more validation examples than NMT-BT, it is alarming that even simple lexical substitution can break such a high percentage of both datasets we tested.

Ebrahimi et al. (2017) observe a similar phenomenon with HotFlip, their gradient-based substitution method for generating adversarial examples. While NMT-BT does not receive signal from the downstream task like HotFlip, it also does not require external constraints to maintain grammaticality and limit semantic divergence. As future work, it would be interesting to provide this downstream signal to both NMT-BT and SCPN; for the latter, perhaps this signal could guide the template selection process, which is currently fixed to a small, finite set.

Templates vs. gold parses: Why does the level of syntactic control decrease when we feed SCPN parses generated from templates instead of gold parses (Table 2)? The first two examples in Table 6 demonstrate issues with the templated approach. In the first example, the template is not expressive enough for the parse generator to produce slots for the highlighted clause. A potential way to combat this type of issue is to dynamically define templates based on factors such as the length of the input sentence. In the second example, a parsing error results in an inaccurate template which in turn causes SCPN to generate a semantically-divergent paraphrase. The final two examples

template	original	paraphrase

Table 5: Adversarial sentiment examples generated by SCPN (top) and NMT-BT (bottom). The predictions of a pretrained model on the original sentences are correct (red is negative, blue is positive), while the predictions on the paraphrases are incorrect. The syntactically controlled paraphrases of SCPN feature more syntactic modification and less lexical substitution than NMT-BT's backtranslated outputs.

show instances where the templated model performs equally as well as the model with gold parses, displaying the capabilities of our parse generator.

Removing syntactic control: To examine the differences between syntactically controlled and uncontrolled paraphrase generation systems, we train an SCPN without including $\boldsymbol{z}_t$, the attention-weighted average of the encoded parse, in the decoder input. This uncontrolled configuration produces outputs that are very similar to its inputs, often identical syntactically with minor lexical substitution. Concretely, the uncontrolled SCPN produces a paraphrase with the same template as its input 38.6% of the time, compared to NMT-BT's 28.7% (Section 4.2).[13]

7 Related Work

Paraphrase generation (Androutsopoulos and Malakasiotis, 2010; Madnani and Dorr, 2010) has been tackled using many different methods, including those based on hand-crafted rules (McKeown, 1983), synonym substitution (Bolshakov and Gelbukh, 2004), machine translation (Quirk et al., 2004), and, most recently, deep learning (Prakash et al., 2016; Mallinson et al., 2017; Dong et al., 2017). Our syntactically controlled setting also relates to controlled language generation tasks in which one desires to generate or rewrite a sentence with particular characteristics. We review related work in both paraphrase generation and controlled language generation below.

7.1 Data-driven paraphrase generation

Madnani and Dorr (2010) review data-driven methods for paraphrase generation, noting two primary families: template-based and translation-based. The first family includes approaches that use hand-crafted rules (McKeown, 1983), thesaurus-based substitution (Bolshakov and Gelbukh, 2004; Zhang and LeCun, 2015), lattice matching (Barzilay and Lee, 2003), and template-based "shake & bake" paraphrasing (Carl et al., 2005). These methods often yield grammatical outputs but they can be limited in diversity.

The second family includes methods that rewrite the input using methods based on parallel text (Bannard and Callison-Burch, 2005), machine translation (Quirk et al., 2004; Napoles et al., 2016; Suzuki et al., 2017), or related statistical techniques (Zhao et al., 2009). Of particular relevance to our work are methods that incorporate syntax to improve fluency of paraphrase output. Callison-Burch (2008) constrains paraphrases to be the same syntactic type as the input, though he was focused on phrase-level, not sentential, paraphrasing. Pang et al. (2003) learn finite-state automata from translation pairs that generate syntactic paraphrases, though this requires multiple translations into the same language and cannot be used to generate paraphrases outside this dataset. Shen et al. (2006) extend this to deeper syntactic analysis. All of these approaches use syntax to

[13] A configuration without the copy mechanism copies input syntax even more, with a 47.7% exact template match.

template	(S(CC)(S)(,)(NP)(ADVP)(VP))
original	damian encouraged me , criticized , he ... he always made me go a little deeper .
SCPN parse	but damian , he supported me , he told me , he always made me go a little deeper .
SCPN template	but damian supported me , he always made me go a little deeper .
template	(S(S)(,)(NP)(VP))
original	zacharias did n't deserve to die , grishanov thought , and he was aware of the huge irony of his situation
SCPN parse	zacharias did not deserve to die , grishanov told himself , realizing the greatest irony of all .
SCPN template	zacharias did not deserve to die , he was aware of the great irony of his situation .
template	S(S)(,)(S))
original	give me some water , my lips are dry , and i shall try to tell you .
SCPN parse	give me some water , i have just a dry mouth .
SCPN template	give me some water , my lips are dry .
template	(S(NP)(,)(ADVP)(,)(VP))
original	in the meantime , the house is weakened , and all its old alliances and deals are thrown into doubt .
SCPN parse	the house , meanwhile , is weakening , which will be all of its old alliances and business .
SCPN template	the house , meanwhile , is weakened , and its old alliances and deals are thrown into doubt .

Table 6: Examples from PARANMT-50M comparing the output of two SCPN configurations, one with gold target parses (SCPN parse) and one with parses generated from templates (SCPN template), where templates are the top two levels of the gold parses. The first two examples demonstrate issues with missing information caused by inexpressive templates and parsing errors, respectively. The remaining examples, in which both configurations produce syntactically similar paraphrases, showcase the ability of the parse generator to produce viable full parses.

improve grammaticality, which is handled by our decoder language model.

Recent efforts involve neural methods. Iyyer et al. (2014) generate paraphrases with dependency tree recursive autoencoders by randomly selecting parse trees at test time. Li et al. (2017) generate paraphrases using deep reinforcement learning. Gupta et al. (2017) use variational autoencoders to generate multiple paraphrases. These methods differ from our approach in that none offer fine-grained control over the syntactic form of the paraphrase.

7.2 Controlled language generation

There is growing interest in generating language with the ability to influence the topic, style, or other properties of the output.

Most related to our methods are those based on syntactic transformations, like the tree-to-tree sentence simplification method of Woodsend and Lapata (2011) based on quasi-synchronous grammar (Smith and Eisner, 2006). Our method is more general since we do not require a grammar and there are only soft constraints. Perhaps the closest to the proposed method is the conditioned recurrent language model of Ficler and Goldberg (2017), which produces language with user-selected properties such as sentence length and formality but is incapable of generating paraphrases.

For machine translation output, Niu et al. (2017) control the level of formality while Sennrich et al. (2016) control the level of politeness. For dialogue, Li et al. (2016a) affect the output using speaker identity, while Wang et al. (2017) develop models to influence topic and style of the output. Shen et al. (2017) perform style transfer on non-parallel texts, while Guu et al. (2017) generate novel sentences from prototypes; again, these methods are not necessarily seeking to generate meaning-preserving paraphrases, merely transformed sentences that have an altered style.

8 Conclusion

We propose SCPN, an encoder-decoder model for syntactically controlled paraphrase generation, and show that it is an effective way of generating adversarial examples. Using a parser, we label syntactic variation in large backtranslated data, which provides training data for SCPN. The model exhibits far less lexical variation than existing uncontrolled paraphrase generation systems, instead preferring purely syntactic modifications. It is capable of generating adversarial examples that fool pretrained NLP models. Furthermore, by training on such examples, we increase the robustness of these models to syntactic variation.

Acknowledgments

We thank the reviewers for their insightful comments. We would also like to thank Mark Yatskar for many useful suggestions on our experiments.

Abstract

Sentiment analysis is used as a proxy to measure human emotion, where the objective is to categorize text according to some predefined notion of sentiment. Sentiment analysis datasets are typically constructed with gold-standard sentiment labels, assigned based on the results of manual annotations. When working with such annotations, it is common for dataset constructors to discard "noisy" or "controversial" data where there is significant disagreement on the proper label. In datasets constructed for the purpose of Twitter sentiment analysis (TSA), these controversial examples can compose over 30% of the originally annotated data. We argue that the removal of such data is a problematic trend because, when performing real-time sentiment classification of short-text, an automated system cannot know *a priori* which samples would fall into this category of disputed sentiment. We therefore propose the notion of a "complicated" class of sentiment to categorize such text, and argue that its inclusion in the short-text sentiment analysis framework will improve the quality of automated sentiment analysis systems as they are implemented in real-world settings. We motivate this argument by building and analyzing a new publicly available TSA dataset of over 7,000 tweets annotated with 5x coverage, named MTSA. Our analysis of classifier performance over our dataset offers insights into sentiment analysis dataset and model design, how current techniques would perform in the real world, and how researchers should handle difficult data.

1 Introduction

The goal of sentiment analysis is to determine the attitude or emotional state held by the author of a piece of text. Automatic sentiment classification that can quickly garner user sentiment is useful for applications ranging from product marketing to measuring public opinion. The volume and availability of short-text user content makes automated sentiment analysis systems highly attractive for companies and organizations, despite potential complications arising from their short length and specialized use of language. The popularity of Twitter as a social media platform on which people can readily express their thoughts, feelings, and opinions, coupled with the openness of the platform, provides a large amount of publicly accessible data ripe for analysis, being a well established domain for sentiment analysis as reflecting real-world attitudes (Pak and Paroubek, 2010; Bollen et al., 2011). In this paper, we look into Twitter sentiment analysis (TSA) as a suitable, core instance of general short-text sentiment analysis (Thelwall et al., 2010, 2012; Kiritchenko et al., 2014; Dos Santos and Gatti, 2014), and encourage the methods and practices presented to be applied across other domains.

determine the sentiment of a tweet has received significant attention over the past several years. However, since most state-of-the-art TSA models use machine learning to tune their parameters, their performance – and relevance to a real-world implementation setting – is highly dependent on the dataset on which they are trained.

TSA dataset construction has, unfortunately, received less attention than TSA model design. Many commonly used TSA datasets make assumptions that do not hold in a real-world implementation setting. For example, it is a common practice for studies to discard tweets on which there is high annotator disagreement. While some argue that this is done to remove noise resulting from poor annotator quality, this argument does not hold when considering that these datasets present high rates of unanimous annotator agreement[1]. This suggests that the problem is not poor annotators, but, rather, difficult data that does not fall into the established categories of sentiment.

Consider the sample tweets in Table 1 drawn from our dataset, one with unanimous agreement on an OBJECTIVE label, one with 60% agreement, and one with complete disagreement. We observe that, as the amount of disagreement across annotations increases, so too does the clarity of what the tweet's gold standard label really should be. Though the issues we raise may seem obvious, the absence of their proper treatment in the existing literature suggests the need to systematically consider their implications in sentiment analysis.

In this paper, we propose the inclusion of a COMPLICATED class of sentiment to indicate that the text does not fall into the established categories of sentiment. We offer insights into the differences between tweets that receive different levels of inter-annotator-agreement, providing empirical evidence that tweets with differing levels of agreement are qualitatively different from each other.

Our claims are supported by empirical analysis of a new TSA dataset, the McGill Twitter Sentiment Analysis dataset (MTSA), which we release publicly with this work[2]. The dataset contains 7,026 tweets across five different topic-domains, annotated with 5x coverage. We release this dataset with the raw annotation results, and hope that researchers and organizations will be able to analyze our dataset and build models that can be applied in real-world sentiment analysis settings.

2 Current Problems in TSA

The field of Twitter Sentiment Analysis (TSA) has seen a considerable productive work over the past several years, and several large reviews and surveys have been written to highlight the trends and progress of the field, its datasets, and the methods used for building automatic TSA systems (Saif et al., 2013; Medhat et al., 2014; Martínez-Cámara et al., 2014; Giachanou and Crestani, 2016).

There are a variety of methods for constructing TSA datasets along a variety of domains, ranging from very specific (e.g., OMD (Shamma et al., 2009)) to general (e.g., SemEval 2013-2014 (Nakov et al., 2016)). While there is the popular Stanford Twitter corpus, constructed with noisy labellings (Go et al., 2009), the more common method of constructing TSA datasets relies on manual annotation (usually crowd-sourced) of tweet sentiment to establish gold-standard labellings according to a pre-defined set of possible label categories (often POSITIVE, NEGATIVE, and NEUTRAL) (Shamma et al., 2009; Speriosu et al., 2011; Thelwall et al., 2012; Saif et al., 2013; Nakov et al., 2016; Rosenthal et al., 2017).

One of the earliest manually annotated TSA datasets, the Obama-McCain Debate (OMD) (Shamma et al., 2009) was released with the specific annotator votes for each tweet, rather than a final specific label assignment. Nonetheless, most work on this dataset filters out tweets with less than two-thirds agreement (Speriosu et al., 2011; Saif et al., 2013) (Table 2). Unfortunately, many later dataset releases have not followed the example of the OMD; the designers of such datasets have opted instead to release only the resultant labelling according to a motivated (but constraining) label-assignment schema, often removing tweets with high inter-annotator disagreement from the final dataset release (Saif et al., 2013; Nakov et al., 2016; Rosenthal et al., 2017).

The assumptions and implications resulting from such design choices should be carefully considered by researchers before deciding on how to construct or analyze sentiment analysis datasets. Indeed, a current limitation in the field is the lack of attention paid to label-assignment schemes, which ultimately determine the gold-standard labellings of samples. We argue that researchers

[1] Annotator disagreement information has proven useful in other areas of sentiment analysis (Wilson et al., 2005).

Name	# Annotated	Discarded	Coverage	Labels	Ref.
OMD	3,238	1,087 (33.6%)[3]	3x	**+**, **-**, MIXED, OTHER	(Shamma et al., 2009)
STS-Gold	3,000	794 (26.5%)	3x	**+**, **-**, **0**, MIXED, OTHER	(Saif et al., 2013)
SemEval 2013-14 (B)	17,048	Unknown	5x	**+**, **-**, **0**	(Nakov et al., 2016)
SemEval 2017	12,379	None (0%)	5x	**s+**, **w+**, **w-**, **s-**, **0**	(Rosenthal et al., 2017)

Table 2: Summary of some of the major TSA datasets used in recent work. Symbols **+**, **-**, **0** stand for POSITIVE, NEGATIVE, and NEUTRAL, respectively; prefixes **s**, **w** stand for STRONGLY and WEAKLY.

should consider whether or not the choices made during dataset construction adequately reflect a situation in which automatic sentiment analysis systems would be used in real-world settings.

2.1 General Trends in TSA Datasets

In the SemEval 2017 Task 4 (Rosenthal et al., 2017), a thorough 5x coverage annotation scheme is used (each tweet is annotated by at least five people). Annotations were made on a five-point scale, with categories STRONGLYNEGATIVE, WEAKLYNEGATIVE, NEUTRAL, WEAKLYPOSITIVE, and STRONGLYPOSITIVE. If at least three out of five of the annotators gave the same labelling, that was accepted as the final annotation. Otherwise, the authors used an averaging scheme (mapping the labels to integers $-2, -1, 0, 1, 2$) to determine the final label, taking the average of the labellings and rounding according to a specific criterion. This is highly problematic. For example, if a controversial tweet receives two STRONGLYNEGATIVE, two STRONGLYPOSITIVE, and one NEUTRAL labelling, it will have a resultant label of NEUTRAL. Yet, the tweet would certainly not be "neutral", it would be qualitatively different from a tweet with unanimous agreement on a NEUTRAL labelling. In Section 5, we provide empirical results supporting this claim, discovering that high-disagreement data is qualitatively different from high-agreement data.

Nakov et al. (2016) provide a thorough exploration into the specific design decisions and considerations made during the construction of the 2013-2014 SemEval shared task for short-text sentiment analysis. In Subtask B, annotators determined the overall polarity of a piece of text, according to a ternary labelling scheme between POSITIVE, NEGATIVE, or NEUTRAL. The final label of the sentence was "determined based on the majority of the labels" according to 5x coverage. The designers thus discarded sentences where there was no majority annotator agreement, since such sentences "are likely to be controversial cases" (p. 40); they do not report how much data was discarded.

Saif et al. (2013) constructed a new dataset, the STS-Gold, by taking into account several limitations of the TSA datasets they reviewed. In their study, 3,000 tweets were labelled with 3x coverage. Any tweet without unanimous agreement on the label was discarded; this decision was justified by the argument that they did not want "noisy data" in their dataset. Thus, they discarded 794 tweets, or 26.5% of their originally annotated data. While we argue that this is a problematic design decision, we note that discarding data in this way successfully isolated unanimous-agreement from majority-agreement data, thus avoiding conflating tweets with different levels of agreement, unlike in the 2013-14 and 2017 SemEval tasks.

The annotation scheme for the STS-Gold resolves one of the problems in the SemEval 2017 Task, as it provides an option for labelling a MIXED category, capturing tweets bearing multiple conflicting sentiments. It also provides the OTHER category for tweets where it is "difficult to decide on a proper label". Interestingly, the dichotomy between the high frequency of high-disagreement tweets (794 total) compared to the low frequency of tweets unanimously labelled as OTHER (4 total) is consistent with our findings on the COMPLICATED label (Section 3.3).

[3]Note that the entire OMD dataset was released with annotator votes, but most studies remove that proportion tweets where there was not at least two-thirds agreement on label.

The challenges and possible approaches to manual sentiment annotation have been previously discussed by Mohammad (2016), who offers important insights into how questions and problem descriptions should be posed to annotators.

2.2 Summary of TSA Problems

Based on analysis of the design choices of the three datasets described above, and on the thorough overview of other datasets found in (Saif et al., 2013), we conclude that there are two primary limitations in the standard TSA datasets.

First, the lack of distinction between data with majority- vs. unanimous-agreement on the annotated label (Nakov et al., 2016; Rosenthal et al., 2017). In the analysis (Sections 3.3 and 6) of our TSA dataset, we observe a clear qualitative difference between majority-agreement and unanimous-agreement data, suggesting that these sets of data should not necessarily be treated in the same way.

Second, the systematic removal of controversial (or, high-disagreement) data (Saif et al., 2013; Nakov et al., 2016). We argue that this tendency is problematic because any automatic sentiment analysis system to be implemented in a real-world setting cannot know *a priori* which tweets will be "noisy" or "controversial". An automatic sentiment analysis system trained on such a dataset will inevitably mislabel such tweets as they appear in a real-world implementation setting.

We therefore suggest that the following paradigm become the norm in the field: in releasing sentiment analysis datasets, *researchers should provide the specific annotations obtained for each sample* (as was done by Shamma et al. (2009)), in addition to the resultant labelling based on the label-assignment scheme they decide upon. Additionally, *data with high levels of annotator disagreement should not be discarded*, rather, it should be included in dataset releases.

3 Building the MTSA Dataset

The absence of a TSA dataset containing raw annotations and sufficient coverage to identify sources of annotator disagreement necessitated the creation of a new annotated dataset. Here, we provide an overview of the development of a new McGill TSA (MTSA) dataset composed of 7,026 tweets annotated with 5x coverage.

Topic	Count	% of Total
Sports	1752	24.9
Food	1729	24.6
Media	1697	24.2
Commercial Tech.	1353	19.3
General	495	7.0
Total	**7026**	100

Table 3: Distribution of annotated tweets by topic.

3.1 Data Collection

Tweets were collected from Twitter's streaming API, filtered for English tweets that contained at least one English token, that were posted by users in North American time-zones. Each tweet had to contain at least one keyword from a topic cloud relating to *Food* (example keywords: "weight", "breakfast", "protein"), *Media* ("cinema", "gameofthrones", "reggae"), *Commercial Technology* ("microsoft", "laptop", "iphone"), or *Sports* ("spurs", "hockey", "habs"). Using this topic cloud and a diverse set of keywords per topic (average of 38 hand-selected keywords per topic), we collected tweets with the intent to represent the general sentiment surrounding a specific topic, while reducing the bias that would result by relying on a single topic or keyword. A further subset of tweets (categorized as *General*) was collected from the stream, without any keyword filters, in order to further broaden the representative scope of our dataset.

We additionally filtered out tweets containing external links or images, arguing that analysis of these multimodal tweets is a separate problem, belonging to the domain of Multimodal Sentiment Analysis (Poria et al., 2016; Soleymani et al., 2017). After the entire filtering process[4] was complete, we obtained 7,026 tweets across the different topics, which would be annotated with 5x coverage. The distribution of these tweets is seen below in Table 3.

3.2 Data Annotation

Data annotation was crowd-sourced using the CrowdFlower platform[5]. All qualified CrowdFlower contributors had the opportunity to complete the task, which was presented as: carefully

[4]See supplemental material for full enumeration of the specific filters used and the keywords used for each topic.

[5]Website: https://www.crowdflower.com

read the tweet, determine whether or not it expresses sentiment (e.g., OBJECTIVE or not), if it does, categorize the sentiment as being either POSITIVE, NEGATIVE, or COMPLICATED. In the instructions, COMPLICATED was presented as the preferable option when the sentiment expressed in the tweet was ambiguous, mixed or could be interpreted as both positive and/or negative. After a one-line description of the meaning of each category, the contributor was presented with examples of tweets belonging in each category before starting the task.

In order to be considered qualified to complete the task, the contributor had to correctly answer at least 8 of 10 test questions, which we manually selected and labelled. When a user failed a test question, they were presented with the correct answer and a corresponding justification to ensure that they understood the task.

We experimented with the inclusion of test questions from the COMPLICATED category during screening, and found that this was a major source of protest among high-quality annotators. Indeed, it may be paradoxical to expect annotators to agree on tweets that cause significant disagreement. Furthermore, due to the heterogeneous nature of this class, such test questions would risk biasing the annotators' notion of the category. As such, we limited our test questions to OBJECTIVE, POSITIVE, and NEGATIVE tweets.

Users who successfully passed the initial test questions annotated a maximum of 400 tweets. Of those tweets, 10% were additional hidden test questions to continuously assess the quality of the annotators; an accuracy of at least 80% on these test questions was the threshold for including their annotations in the dataset. In the end, a total of 35,926 tasks were completed by 181 trusted contributors, resulting in 7,026 annotated tweets.

3.3 Dataset Analysis

The annotated tweets are categorized by four agreement levels: *Unanimous* (5 out of 5 agreed on the label), *Consensus* (exactly 4 out of 5 agreed), *Majority* (exactly 3 out of 5 agreed), or *Disputed* (maximum 2 out of 5 agreed). The distribution of agreement rates was consistent across topics (see supplemental material), thus the entire dataset is merged for the remainder of the analysis.

Annotator agreement distribution. Tweets with at least *Consensus* agreement compose 64% of the dataset (4505 tweets), and tweets with at least *Majority* agreement compose 92% of the dataset (6473 tweets; see Table 4). The decision to discard tweets with significant annotator disagreement, as previously done in TSA research, would result in the loss of 8% to 34% of the annotated tweets in our dataset, depending on whether to filter to a minimum *Majority* or *Consensus* agreement, respectively. Interestingly, these numbers are consistent with the proportion of discarded tweets in previous literature (Table 2).

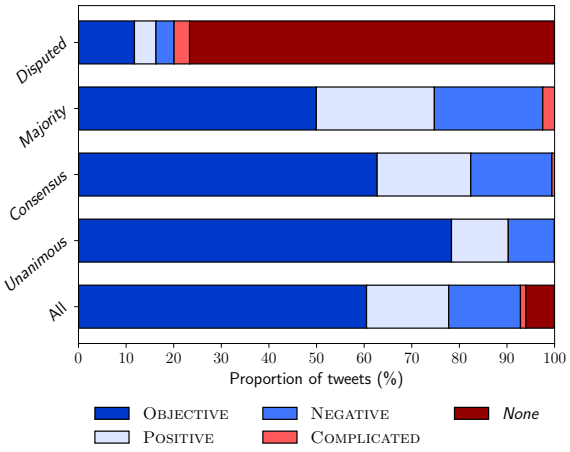

Figure 1: Most frequent annotation by annotator agreement rates. Of the 553 *Disputed* tweets, only 129 had a single most frequent annotation.

Sentiment and annotator agreement. Tweets that caused more disagreement among the human annotators were found to be more sentiment-laden (majority label of POSITIVE, NEGATIVE, or COMPLICATED; Figure 1). Objective tweets composed 78% (1892 tweets), 63% (1311), and 50% (983) of the *Unanimous*, *Consensus*, and *Majority* subsets of annotated tweets, respectively.

COMPLICATED label usage. Use of the COMPLICATED label by annotators was infrequent, and of those tweets with high inter-annotator agreement, almost exclusively limited to tweets that expressed clear, mixed sentiment. For example, the single tweet that received a unanimous COMPLICATED annotation had clear mixed sentiment: "the iPhone 6s is so big and hard to use but I still like it". There were a total of 13 tweets with at least *Consensus* agreement for the COMPLICATED label (see supplemental material). These specific tweets largely corresponded to the MIXED label used in previous TSA datasets (Shamma et al., 2009; Saif et al., 2013). Other types of ambiguous

Agreement	Count	% of Total
Unanimous	2415	34.4
Consensus	2090	29.7
Majority	1968	28.0
Disputed	553	7.9
Total	7026	100

Table 4: Annotator agreement rates. *Unanimous* stands for 100% annotator agreement, *Consensus* 80%, *Majority* 60%, and *Disputed* <60%.

Label	Count	% of Total
OBJECTIVE	4186	59.6
POSITIVE	1187	16.9
NEGATIVE	1038	14.8
COMPLICATED	62	0.9
Disputed	553	7.9
Total	7026	100

Table 5: Distribution of tweets across classes, where the label given is the result of majority vote.

tweets that did not clearly fall clearly within OBJECTIVE, POSITIVE, and NEGATIVE categories were not consistently identified as COMPLICATED by annotators. Rather, those tweets were a source of significant disagreement.

4 Classifying Tweet Sentiment

Here, we present the construction of shallow classifier and the experiments performed to study the phenomenon of annotator disagreement. Our objective was not to build a state-of-the-art classifier with optimal accuracy rates, rather, we sought to understand how the inclusion or exclusion of tweet subsets based on annotator disagreement impacts classification accuracy.

4.1 Preprocessing and Feature Extraction

To use machine learning methods with textual data, it is necessary to represent the data in a vector space such that each sample has the same dimensionality, despite varying sequence lengths. We concatenated three different standard feature extraction methods to build vector representations of tweets: N-Grams (unigrams and bigrams), mean word embedding (GLoVE embeddings built from twitter data (Pennington et al., 2014)[6]), and SentiWordNet scores (Baccianella et al., 2010).[7]

4.2 Experimental Design

As described in Section 2, most recent work in TSA has agglomerated tweets together based on the majority labelling. For example, a tweet annotated with a *Majority* agreement labelling (e.g., 3 OBJECTIVE and 2 NEGATIVE) would be given the label OBJECTIVE, just as one with *Unanimous* agreement on an OBJECTIVE labelling. In our experiments with our collected dataset (Section 3) we seek to determine whether or not there is a qualitative difference between high- versus low-agreement data.

Experiment I. In the first experiment setting, we agglomerate tweets according to the traditional practice for assigning labels based on annotations (Section 2); e.g., we remove tweets with at least a *Majority* voted label as COMPLICATED, and remove the *Disputed* tweets (that is, we remove 8.75% of our annotated data for these experiments), creating a 3-class classification problem. We experiment over four different sets of our data in this scenario: the full dataset (minus the COMPLICATED 8.75%); tweets with exactly *Majority* agreement; tweets with exactly *Consensus* agreement; and tweets with exactly *Unanimous* agreement on the label (see Figure 1 for the label distributions over each of these subsets). Additionally, when making predictions on a specific subset, we present results from training solely on the subset versus training on all of the data in this setting.

Experiment II. In the second experiment setting, we sought to determine the impact of including controversial samples, making a 4-class classification problem. Samples that were labelled with at least *Majority* agreement on a COMPLICATED label, and samples with *Disputed* agreement, were all assigned the label COMPLICATED. We thus used the entirety of our dataset for this experiment, where the COMPLICATED class accounted for 8.75% (615) of the samples, with the rest of the samples being given the majority-vote labelling.

Methods. For both experiments, we use a logistic regression classifier with balanced training set class weights, using the feature set described in Section 4.1. Preliminary experiments with fea-

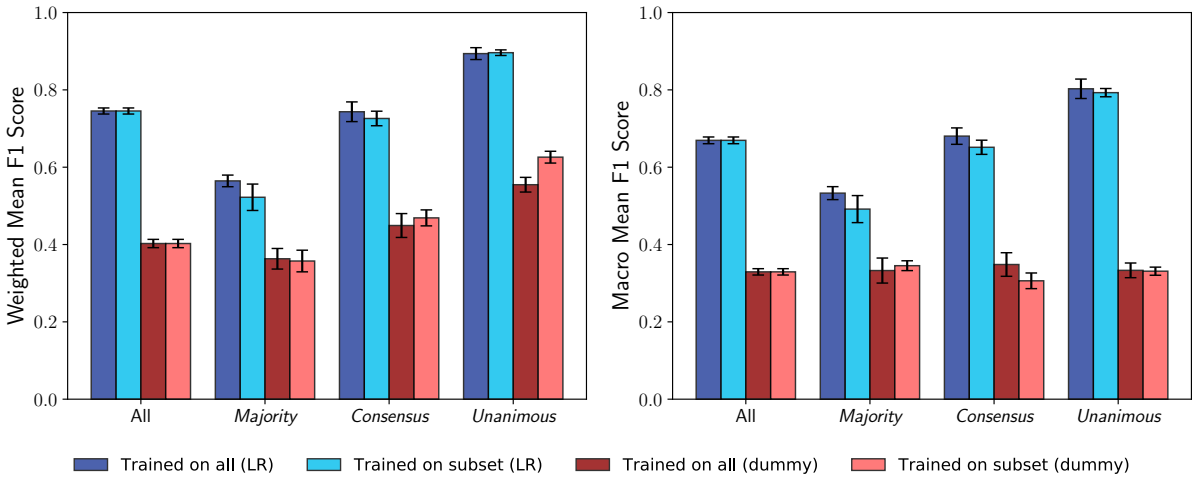

Figure 2: *Experiment I.* Weighted- and macro-F1-scores, obtained by testing logistic regression (LR) and a stratified random guesser (dummy) on the different agreement-level subsets, as described in Section 4.2. Black bars indicate plus/minus one standard deviation from the mean, as computed from the accuracies obtained across each of the 5 cross-validated folds.

ture ablation, whether or not to balance the train set classes, and different models (SVM with linear or RBF kernel, Random Forests, Naive Bayes, and K-Nearest-Neighbors), proved that this model variant was the best. We compare to a stratified random guesser, which predicts according to the distribution of classes in the training set (e.g., if 50% of the training set has samples labelled as OBJECTIVE, it will guess OBJECTIVE 50% of the time). To account for possible variance in the results, we use 5-fold cross validation over the full dataset, where the accuracy reported is the average over the specific scores obtained on each fold.

4.3 Evaluation

We evaluate with weighted- and macro-F1-scores to assess classifier performance. F1-score is a common way to measure classifier performance in sentiment analysis as it computes the harmonic mean between precision and recall. In multi-class classification, we obtain a one-versus-all F-score, F_c, for each class c in our set of possible classes, $\mathcal{C}$. Weighted F-score weights each F-score by its support in the test set; if there are n_c samples in the test set belonging to class c, then the weighted F-score is expressed by $\mathbf{F}_{weighted}$ in Equation 1.

$$\mathbf{F}_{weighted} = \frac{1}{(\sum n_c)} \sum_{c \in \mathcal{C}} n_c F_c \qquad (1)$$

Naturally, the weighted F-score is influenced by the frequency of samples in a class; so, in our case, it is biased toward the OBJECTIVE class due to its large frequency compared to the other classes (Table 5; Figure 1). Thus, we also report the macro F-score, which averages the F-scores for each class without considering their support, expressed by $\mathbf{F}_{macro}$ in Equation 2. This score evaluates model performance isolated from the class distribution, allowing us to determine if a change in accuracy is the result of simply a change in distribution of classes or a change in model generalization ability.

$$\mathbf{F}_{macro} = \frac{1}{|C|} \sum_{c \in \mathcal{C}} F_c \qquad (2)$$

5 Results

In Figure 2, we present the results for Experiment I (Section 4.2). We note that the presented accuracy is higher when evaluated with weighted F-score versus macro F-score. Since both weighted- and macro-F1-score increase as we move along to higher agreement subsets, we conclude that the accuracy improvement is not solely due to a change in distribution of classes. Rather, there must be a qualitative difference between high- vs. low-agreement tweets, otherwise the accuracy would have been the same across agreement levels.

In Figure 3, we present the normalized confusion matrix obtained from Experiment II. We observe that the model poorly classifies COMPLICATED tweets. Although the model uses balanced class weights for training, it predicts OBJECTIVE the majority of the time, where each other class is most frequently mistaken as OBJEC-

Test subset	Trained on all			Trained on subset		
	Precision	*Recall*	*F1-Score*	*Precision*	*Recall*	*F1-Score*
All	0.681	0.660	0.669	–	–	–
Majority	0.552	0.524	**0.533**	0.502	0.488	0.491
Consensus	0.689	0.674	**0.680**	0.680	0.633	0.652
Unanimous	0.789	0.821	**0.803**	0.843	0.761	0.793

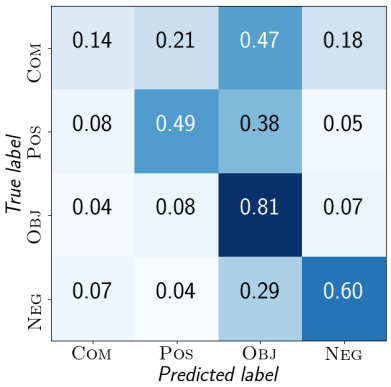

Figure 3: *Experiment II.* Normalized confusion matrix from using logistic regression.

Label	*Precision*	*Recall*	*F1*
COMPLICATED	0.199	0.138	0.163
POSITIVE	0.599	0.605	0.602
OBJECTIVE	0.766	0.806	0.786
NEGATIVE	0.510	0.487	0.498
Total – *weighted*	0.650	0.667	0.658
Total – *macro*	0.518	0.509	0.512

Table 7: *Experiment II.* Results across evaluation metrics, as shown visually in Figure 3. Results are computed by agglomerating all predictions made across each of the 5 cross-validated folds.

TIVE. The final weighted-F1-score and macro-F1-scores, were, respectively: 65.8% and 51.2% with logistic regression, and 41.1% and 24.7% with the stratified random guesser. This large difference between weighted and macro is largely due to the poor classifier performance on the COMPLICATED class.

6 Discussion

The interpretation of expressed sentiment is an inherently subjective exercise, the gold-standard of which is the sentiment perceived by other humans. Thus, it is crucial to better understand sentiment annotation itself to inform future classifier design.

Annotator disagreement is not human error. Our results show that annotator disagreements cannot simply be attributed to human error. There is a clear decrease in classifier performance when testing on subsets of tweets with lower annotator agreement (Figure 2), suggesting that tweets across these subsets are qualitatively different from each other. From a probabilistic perspective, this means that samples that obtain high annotator agreement are generated by a different real-world function than those that obtain low annotator agreement. This perspective is further justified by the fact that classifier performance is roughly the same when training on the full dataset versus when training just on the specific agreement level subsets. Future work should explore how to handle this data, and we recommend reporting results on the different subsets by agreement-level.

On defaulting to the majority label. When each tweet is assigned a gold-standard label according to the majority annotation, we demonstrated that there are qualitative differences between tweets with *Majority*, *Consensus*, and *Unanimous* agreement. As exemplified by the sample tweets in Table 1, the differences between the two tweets with a majority OBJECTIVE annotation is reflected in the inter-annotator disagreement. We have shown that the subtleties in sentiment expression are masked by simply taking the majority label, and future work would involve factoring in these varying levels of agreement on labels during the model design process.

Standards for sentiment analysis datasets. To advance the field of short-text sentiment analysis, it is necessary to change common practices

in dataset design and development. First, future datasets should be released with the raw annotator label assignments without discarding any annotated data. This would allow other researchers to experiment with different means of handling annotation-disagreement during the model design process. Secondly, we argue that sufficient resolution of short-text sentiment annotations requires at least 5x coverage. Our dataset, MTSA, of 7,026 tweets was constructed with 5x annotation coverage, a resolution at which we can just begin to distinguish these subsets of tweets. Higher coverage may be needed still to identify and understand these annotator disagreements. In contrast, the differences between these two subsets would be masked using the 3x coverage commonly found in other datasets.

Identifying ambiguous data. Results from Experiment II, and analysis of our COMPLICATED tweets, reveal that detecting high-disagreement tweets is a difficult task for both classifiers and humans. The poor performance of human annotators on identifying ambiguous tweets in our study, and the fact that high disagreement affected up to one third of the samples across TSA datasets, suggests that "complicatedness" is a real phenomenon. The optimal way to handle and identify this data requires further research. It is, however, an essential problem to solve, as real-world implementations of automated sentiment analysis systems will inevitably be confronted with such data. Such a system may be able to leverage the raw annotations during training, which is why we release the MTSA dataset with the raw annotation results included, and suggest all others do this as well.

7 Conclusion

In this paper, we highlight the need to better engage with how humans actually annotate data in short-text sentiment analysis dataset construction by constructing the new McGill Twitter Sentiment Analysis (MTSA) dataset. Future work involves leveraging raw human annotations to improve sentiment analysis classifiers, and finding ways to better detect and understand the "complicated" property in these samples that cause high annotator disagreement. Additionally, we encourage researchers to use MTSA in the development of other methods for short text sentiment analysis, including unsupervised, lexicon-based, and rule-based methods.

Multi-task Learning of Pairwise Sequence Classification Tasks Over Disparate Label Spaces

Abstract

We combine multi-task learning and semi-supervised learning by inducing a joint embedding space between disparate label spaces and learning transfer functions between label embeddings, enabling us to jointly leverage unlabelled data and auxiliary, annotated datasets. We evaluate our approach on a variety of sequence classification tasks with disparate label spaces. We outperform strong single and multi-task baselines and achieve a new state-of-the-art for topic-based sentiment analysis.

1 Introduction

Multi-task learning (MTL) and semi-supervised learning are both successful paradigms for learning in scenarios with limited labelled data and have in recent years been applied to almost all areas of NLP. Applications of MTL in NLP, for example, include partial parsing (Søgaard and Goldberg, 2016), text normalisation (Bollman et al., 2017), neural machine translation (Luong et al., 2016), and keyphrase boundary classification (Augenstein and Søgaard, 2017).

Contemporary work in MTL for NLP typically focuses on learning representations that are useful across tasks, often through hard parameter sharing of hidden layers of neural networks (Collobert et al., 2011; Søgaard and Goldberg, 2016). If tasks share optimal hypothesis classes at the level of these representations, MTL leads to improvements (Baxter, 2000). However, while sharing hidden layers of neural networks is an effective regulariser (Søgaard and Goldberg, 2016), we potentially *loose synergies between the classification functions* trained to associate these representations with class labels. This paper sets out to build an architecture in which such synergies are exploited, with an application to pairwise sequence classification tasks. Doing so, we achieve a new state of the art on topic-based sentiment analysis.

For many NLP tasks, disparate label sets are weakly correlated, e.g. part-of-speech tags correlate with dependencies (Hashimoto et al., 2017), sentiment correlates with emotion (Felbo et al., 2017; Eisner et al., 2016), etc. We thus propose to induce a joint label embedding space (visualised in Figure 2) using a Label Embedding Layer that allows us to model these relationships, which we show helps with learning.

In addition, for tasks where labels are closely related, we should be able to not only model their relationship, but also to directly estimate the corresponding label of the target task based on auxiliary predictions. To this end, we propose to train a Label Transfer Network (LTN) jointly with the model to produce pseudo-labels across tasks.

The LTN can be used to label unlabelled and auxiliary task data by utilising the 'dark knowledge' (Hinton et al., 2015) contained in auxiliary model predictions. This pseudo-labelled data is then incorporated into the model via semi-supervised learning, leading to a natural combination of multi-task learning and semi-supervised learning. We additionally augment the LTN with data-specific diversity features (Ruder and Plank, 2017) that aid in learning.

Contributions Our contributions are: a) We model the relationships between labels by inducing a joint label space for multi-task learning. b) We propose a Label Transfer Network that learns to transfer labels between tasks and propose to use semi-supervised learning to leverage them for training. c) We evaluate MTL approaches on a variety of classification tasks and shed new light on settings where multi-task learning works. d) We perform an extensive ablation study of our model.

*The first two authors contributed equally.

e) We report state-of-the-art performance on topic-based sentiment analysis.

2 Related work

Learning task similarities Existing approaches for learning similarities between tasks enforce a clustering of tasks (Evgeniou et al., 2005; Jacob et al., 2009), induce a shared prior (Yu et al., 2005; Xue et al., 2007; Daumé III, 2009), or learn a grouping (Kang et al., 2011; Kumar and Daumé III, 2012). These approaches focus on homogeneous tasks and employ linear or Bayesian models. They can thus not be directly applied to our setting with tasks using disparate label sets.

Multi-task learning with neural networks Recent work in multi-task learning goes beyond hard parameter sharing (Caruana, 1993) and considers different sharing structures, e.g. only sharing at lower layers (Søgaard and Goldberg, 2016) and induces private and shared subspaces (Liu et al., 2017; Ruder et al., 2017). These approaches, however, are not able to take into account relationships between labels that may aid in learning. Another related direction is to train on disparate annotations of the same task (Chen et al., 2016; Peng et al., 2017). In contrast, the different nature of our tasks requires a modelling of their label spaces.

Semi-supervised learning There exists a wide range of semi-supervised learning algorithms, e.g., self-training, co-training, tri-training, EM, and combinations thereof, several of which have also been used in NLP. Our approach is probably most closely related to an algorithm called *co-forest* (Li and Zhou, 2007). In co-forest, like here, each learner is improved with unlabeled instances labeled by the ensemble consisting of all the other learners. Note also that several researchers have proposed using auxiliary tasks that are unsupervised (Plank et al., 2016; Rei, 2017), which also leads to a form of semi-supervised models.

Label transformations The idea of manually mapping between label sets or learning such a mapping to facilitate transfer is not new. Zhang et al. (2012) use distributional information to map from a language-specific tagset to a tagset used for other languages, in order to facilitate cross-lingual transfer. More related to this work, Kim et al. (2015) use canonical correlation analysis to transfer between tasks with disparate label spaces. There has also been work on label transformations in the context of multi-label classification problems (Yeh et al., 2017).

3 Multi-task learning with disparate label spaces

3.1 Problem definition

In our multi-task learning scenario, we have access to labelled datasets for T tasks $\mathcal{T}_1, \ldots, \mathcal{T}_T$ at training time with a target task $\mathcal{T}_T$ that we particularly care about. The training dataset for task $\mathcal{T}_i$ consists of N_k examples $X_{\mathcal{T}_i} = \{x_1^{\mathcal{T}_i}, \ldots, x_{N_k}^{\mathcal{T}_i}\}$ and their labels $Y_{\mathcal{T}_i} = \{\mathbf{y}_1^{\mathcal{T}_i}, \ldots, \mathbf{y}_{N_k}^{\mathcal{T}_i}\}$. Our base model is a deep neural network that performs classic hard parameter sharing (Caruana, 1993): It shares its parameters across tasks and has task-specific softmax output layers, which output a probability distribution $\mathbf{p}^{\mathcal{T}_i}$ for task $\mathcal{T}_i$ according to the following equation:

$$\mathbf{p}^{\mathcal{T}_i} = \mathrm{softmax}(\mathbf{W}^{\mathcal{T}_i}\mathbf{h} + \mathbf{b}^{\mathcal{T}_i}) \quad (1)$$

where $\mathrm{softmax}(\mathbf{x}) = e^{\mathbf{x}} / \sum_{i=1}^{\|\mathbf{x}\|} e^{\mathbf{x}_i}$, $\mathbf{W}^{\mathcal{T}_i} \in \mathbb{R}^{L_i \times h}$, $\mathbf{b}^{\mathcal{T}_i} \in \mathbb{R}^{L_i}$ is the weight matrix and bias term of the output layer of task $\mathcal{T}_i$ respectively, $\mathbf{h} \in \mathbb{R}^h$ is the jointly learned hidden representation, L_i is the number of labels for task $\mathcal{T}_i$, and h is the dimensionality of $\mathbf{h}$.

The MTL model is then trained to minimise the sum of the individual task losses:

$$\mathcal{L} = \lambda_1 \mathcal{L}_1 + \ldots + \lambda_T \mathcal{L}_T \quad (2)$$

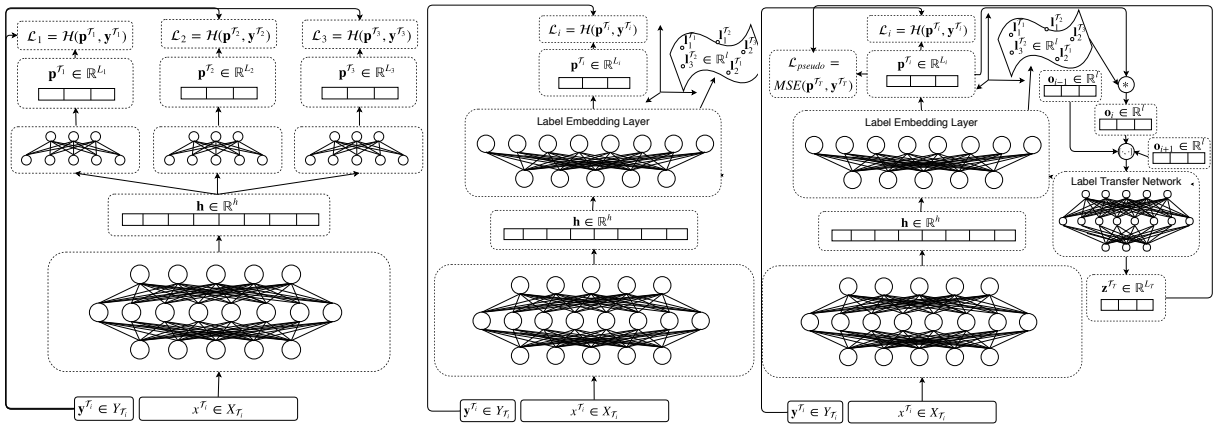
where $\mathcal{L}_i$ is the negative log-likelihood objective $\mathcal{L}_i = \mathcal{H}(\mathbf{p}^{\mathcal{T}_i}, \mathbf{y}^{\mathcal{T}_i}) = -\frac{1}{N} \sum_n \sum_j \log \mathbf{p}_j^{\mathcal{T}_i} \mathbf{y}_j^{\mathcal{T}_i}$ and λ_i is a parameter that determines the weight of task $\mathcal{T}_i$. In practice, we apply the same weight to all tasks. We show the full set-up in Figure 1a.

3.2 Label Embedding Layer

In order to learn the relationships between labels, we propose a Label Embedding Layer (LEL) that embeds the labels of all tasks in a joint space. Instead of training separate softmax output layers as above, we introduce a label compatibility function $c(\cdot, \cdot)$ that measures how similar a label with embedding $\mathbf{l}$ is to the hidden representation $\mathbf{h}$:

$$c(\mathbf{l}, \mathbf{h}) = \mathbf{l} \cdot \mathbf{h} \quad (3)$$

where $\cdot$ is the dot product. This is similar to the Universal Schema Latent Feature Model introduced by Riedel et al. (2013). In contrast to



(a) Multi-task learning (b) MTL with LEL (c) Semi-supervised MTL with LTN

Figure 1: a) Multi-task learning (MTL) with hard parameter sharing and 3 tasks $\mathcal{T}_{1-3}$ and L_{1-3} labels per task. A shared representation $\mathbf{h}$ is used as input to task-specific softmax layers, which optimise cross-entropy losses $\mathcal{L}_{1-3}$. b) MTL with the Label Embedding Layer (LEL) embeds task labels $\mathbf{l}_{1-L_i}^{\mathcal{T}_{1-3}}$ in a joint embedding space and uses these for prediction with a label compatibility function. c) Semi-supervised MTL with the Label Transfer Network (LTN) in addition optimises an unsupervised loss $\mathcal{L}_{pseudo}$ over pseudo-labels $\mathbf{z}^{\mathcal{T}_T}$ on auxiliary/unlabelled data. The pseudo-labels $\mathbf{z}^{\mathcal{T}_T}$ are produced by the LTN for the main task $\mathcal{T}_T$ using the concatenation of auxiliary task label output embeddings $[\mathbf{o}_{i-1}, \mathbf{o}_i, \mathbf{o}_{i+1}]$ as input.

other models that use the dot product in the objective function, we do not have to rely on negative sampling and a hinge loss (Collobert and Weston, 2008) as negative instances (labels) are known. For efficiency purposes, we use matrix multiplication instead of a single dot product and softmax instead of sigmoid activations:

$$\mathbf{p} = \text{softmax}(\mathbf{L}\mathbf{h}) \tag{4}$$

where $\mathbf{L} \in \mathbb{R}^{(\sum_i L_i) \times l}$ is the label embedding matrix for all tasks and l is the dimensionality of the label embeddings. In practice, we set l to the hidden dimensionality h. We use padding if $l < h$. We apply a task-specific mask to $\mathbf{L}$ in order to obtain a task-specific probability distribution $\mathbf{p}^{\mathcal{T}_i}$. The LEL is shared across all tasks, which allows us to learn the relationships between the labels in the joint embedding space. We show MTL with the LEL in Figure 1b.

3.3 Label Transfer Network

The LEL allows us to learn the relationships between labels. In order to make use of these relationships, we would like to leverage the predictions of our auxiliary tasks to estimate a label for the target task. To this end, we introduce the Label Transfer Network (LTN). This network takes the auxiliary task outputs as input. In particular, we define the output label embedding $\mathbf{o}_i$ of task $\mathcal{T}_i$ as the sum of the task's label embeddings $\mathbf{l}_j$ weighted with their probability $\mathbf{p}_j^{\mathcal{T}_i}$:

$$\mathbf{o}_i = \sum_{j=1}^{L_i} \mathbf{p}_j^{\mathcal{T}_i} \mathbf{l}_j \tag{5}$$

The label embeddings $\mathbf{l}$ encode general relationship between labels, while the model's probability distribution $\mathbf{p}^{\mathcal{T}_i}$ over its predictions encodes fine-grained information useful for learning (Hinton et al., 2015). The LTN is trained on labelled target task data. For each example, the corresponding label output embeddings of the auxiliary tasks are fed into a multi-layer perceptron (MLP), which is trained with a negative log-likelihood objective $\mathcal{L}_{\text{LTN}}$ to produce a pseudo-label $\mathbf{z}^{\mathcal{T}_T}$ for the target task $\mathcal{T}_T$:

$$\text{LTN}_T = \text{MLP}([\mathbf{o}_1, \ldots, \mathbf{o}_{T-1}]) \tag{6}$$

where $[\cdot, \cdot]$ designates concatenation. The mapping of the tasks in the LTN yields another signal that can be useful for optimisation and act as a regulariser. The LTN can also be seen as a mixture-of-experts layer (Jacobs et al., 1991) where the experts are the auxiliary task models. As the label embeddings are learned jointly with the main model, the LTN is more sensitive to the relationships between labels than a separately learned mixture-of-experts model that only relies on the experts' output distributions. As such, the LTN

can be directly used to produce predictions on unseen data.

3.4 Semi-supervised MTL

The downside of the LTN is that it requires additional parameters and relies on the predictions of the auxiliary models, which impacts the runtime during testing. Instead, of using the LTN for prediction directly, we can use it to provide pseudo-labels for unlabelled or auxiliary task data by utilising auxiliary predictions for semi-supervised learning.

We train the target task model on the pseudo-labelled data to minimise the squared error between the model predictions $\mathbf{p}^{\mathcal{T}_i}$ and the pseudo labels $\mathbf{z}^{\mathcal{T}_i}$ produced by the LTN:

$$\mathcal{L}_{pseudo} = MSE(\mathbf{p}^{\mathcal{T}_T}, \mathbf{z}^{\mathcal{T}_T}) = ||\mathbf{p}^{\mathcal{T}_T} - \mathbf{z}^{\mathcal{T}_T}||^2 \tag{7}$$

We add this loss term to the MTL loss in Equation 2. As the LTN is learned together with the MTL model, pseudo-labels produced early during training will likely not be helpful as they are based on unreliable auxiliary predictions. For this reason, we first train the base MTL model until convergence and then augment it with the LTN. We show the full semi-supervised learning procedure in Figure 1c.

3.5 Data-specific features

When there is a domain shift between the datasets of different tasks as is common for instance when learning NER models with different label sets, the output label embeddings might not contain sufficient information to bridge the domain gap.

To mitigate this discrepancy, we augment the LTN's input with features that have been found useful for transfer learning (Ruder and Plank, 2017). In particular, we use the number of word types, type-token ratio, entropy, Simpson's index, and Rényi entropy as diversity features. We calculate each feature for each example.[1] The features are then concatenated with the input of the LTN.

3.6 Other multi-task improvements

Hard parameter sharing can be overly restrictive and provide a regularisation that is too heavy when jointly learning many tasks. For this reason, we propose several additional improvements that seek to alleviate this burden: We use skip-connections, which have been shown to be useful for multi-task learning in recent work (Ruder et al., 2017). Furthermore, we add a task-specific layer before the output layer, which is useful for learning task-specific transformations of the shared representations (Søgaard and Goldberg, 2016; Ruder et al., 2017).

[1]For more information regarding the feature calculation, refer to Ruder and Plank (2017).

Table 1: Training set statistics and evaluation metrics of every task. N: # of examples. L: # of labels.

4 Experiments

For our experiments, we evaluate on a wide range of text classification tasks. In particular, we choose pairwise classification tasks—i.e. those that condition the reading of one sequence on another sequence—as we are interested in understanding if knowledge can be transferred even for these more complex interactions. To the best of our knowledge, this is the first work on transfer learning between such pairwise sequence classification tasks. We implement all our models in Tensorflow (Abadi et al., 2016) and release the code at `https://github.com/coastalcph/mtl-disparate`.

4.1 Tasks and datasets

We use the following tasks and datasets for our experiments, show task statistics in Table 1, and summarise examples in Table 2:

Topic-based sentiment analysis Topic-based sentiment analysis aims to estimate the sentiment of a tweet known to be about a given topic. We use the data from SemEval-2016 Task 4 Subtask B and C (Nakov et al., 2016) for predicting on a two-point scale of positive and negative (`Topic-2`) and five-point scale ranging from highly negative to highly positive (`Topic-5`) respectively. An example from this dataset would be to classify the

Topic-based sentiment analysis: *Tweet*: No power at home, sat in the dark listening to AC/DC in the hope it'll make the electricity come back again *Topic*: AC/DC *Label*: positive
Target-dependent sentiment analysis: *Text*: how do you like settlers of catan for the wii? *Target*: wii *Label*: neutral
Aspect-based sentiment analysis: *Text*: For the price, you cannot eat this well in Manhattan *Aspects*: restaurant prices, food quality *Label*: positive
Stance detection: *Tweet*: Be prepared - if we continue the policies of the liberal left, we will be #Greece *Target*: Donald Trump *Label*: favor
Fake news detection: *Document*: Dino Ferrari hooked the whopper wels catfish, (...), which could be the biggest in the world. *Headline*: Fisherman lands 19 STONE catfish which could be the biggest in the world to be hooked *Label*: agree
Natural language inference: *Premise*: Fun for only children *Hypothesis*: Fun for adults and children *Label*: contradiction

Table 2: Example instances from the datasets described in Section 4.1.

tweet "No power at home, sat in the dark listening to AC/DC in the hope it'll make the electricity come back again" known to be about the topic "AC/DC", which is labelled as a positive sentiment. The evaluation metrics for `Topic-2` and `Topic-5` are macro-averaged recall (ρ^{PN}) and macro-averaged mean absolute error (MAE^M) respectively, which are both averaged across topics.

Target-dependent sentiment analysis Target-dependent sentiment analysis (`Target`) seeks to classify the sentiment of a text's author towards an entity that occurs in the text as positive, negative, or neutral. We use the data from Dong et al. (2014). An example instance is the expression "how do you like settlers of catan for the wii?" which is labelled as neutral towards the target "wii'.' The evaluation metric is macro-averaged F_1 (F_1^M).

Aspect-based sentiment analysis Aspect-based sentiment analysis is the task of identifying whether an aspect, i.e. a particular property of an item is associated with a positive, negative, or neutral sentiment (Ruder et al., 2016). We use the data of SemEval-2016 Task 5 Subtask 1 Slot 3 (Pontiki et al., 2016) for the laptops (`ABSA-L`) and restaurants (`ABSA-R`) domains. An example is the sentence "For the price, you cannot eat this well in Manhattan", labelled as positive towards both the aspects "restaurant prices" and "food quality". The evaluation metric for both domains is accuracy (Acc).

Stance detection Stance detection (`Stance`) requires a model, given a text and a target entity, which might not appear in the text, to predict whether the author of the text is in favour or against the target or whether neither inference is likely (Augenstein et al., 2016). We use the data of SemEval-2016 Task 6 Subtask B (Mohammad et al., 2016). An example from this dataset would be to predict the stance of the tweet "Be prepared - if we continue the policies of the liberal left, we will be #Greece" towards the topic "Donald Trump", labelled as "favor". The evaluation metric is the macro-averaged F_1 score of the "favour" and "against" classes (F_1^{FA}).

Fake news detection The goal of fake news detection in the context of the Fake News Challenge[2] is to estimate whether the body of a news article agrees, disagrees, discusses, or is unrelated towards a headline. We use the data from the first stage of the Fake News Challenge (`FNC-1`). An example for this dataset is the document "Dino Ferrari hooked the whopper wels catfish, (...), which could be the biggest in the world." with the headline "Fisherman lands 19 STONE catfish which could be the biggest in the world to be hooked" labelled as "agree". The evaluation metric is accuracy (Acc)[3].

Natural language inference Natural language inference is the task of predicting whether one sentences entails, contradicts, or is neutral towards another one. We use the Multi-Genre NLI corpus (`MultiNLI`) from the RepEval 2017 shared task (Nangia et al., 2017). An example for an instance would be the sentence pair "Fun for only children", "Fun for adults and children", which are in a "contradiction" relationship. The evaluation metric is accuracy (Acc).

Table 3: Comparison of our best performing models on the test set against a single task baseline and the state of the art, with task specific metrics. *: lower is better. Bold: best. Underlined: second-best.

4.2 Base model

Our base model is the Bidirectional Encoding model (Augenstein et al., 2016), a state-of-the-art model for stance detection that conditions a bidirectional LSTM (BiLSTM) encoding of a text on the BiLSTM encoding of the target. Unlike Augenstein et al. (2016), we do not pre-train word embeddings on a larger set of unlabelled in-domain text for each task as we are mainly interested in exploring the benefit of multi-task learning for generalisation.

4.3 Training settings

We use BiLSTMs with one hidden layer of 100 dimensions, 100-dimensional randomly initialised word embeddings, a label embedding size of 100. We train our models with RMSProp, a learning rate of 0.001, a batch size of 128, and early stopping on the validation set of the main task with a patience of 3.

5 Results

Our main results are shown in Table 3, with a comparison against the state of the art. We present the results of our multi-task learning network with label embeddings (MTL + LEL), multi-task learning with label transfer (MTL + LEL + LTN), and the semi-supervised extension of this model. On 7/8 tasks, at least one of our architectures is better than single-task learning; and in 4/8, all our architectures are much better than single-task learning.

The state-of-the-art systems we compare against are often highly specialised, task-dependent architectures. Our architectures, in contrast, have not been optimised to compare favourably against the state of the art, as our main objective is to develop a novel approach to multi-task learning leveraging synergies between label sets and knowledge of marginal distributions from unlabeled data. For example, we do not use pre-trained word embeddings (Augenstein et al., 2016; Palogiannidi et al., 2016; Vo and Zhang, 2015), class weighting to deal with label imbalance (Balikas and Amini, 2016), or domain-specific sentiment lexicons (Brun et al., 2016; Kumar et al., 2016). Nevertheless, our approach outperforms the state-of-the-art on two-way topic-based sentiment analysis (Topic-2).

The poor performance compared to the state-of-the-art on FNC and MultiNLI is expected; as we alternate among the tasks during training, our model only sees a comparatively small number of examples of both corpora, which are one and two orders of magnitude larger than the other datasets. For this reason, we do not achieve good performance on these tasks as main tasks, but they are still useful as auxiliary tasks as seen in Table 4.

6 Analysis

6.1 Label Embeddings

Our results above show that, indeed, modelling the similarity between tasks using label embeddings sometimes leads to much better performance. Figure 2 shows why. In Figure 2, we visualise the label embeddings of an MTL+LEL model trained on all tasks, using PCA. As we can see, similar labels are clustered together across tasks, e.g. there are two positive clusters (middle-right and top-right), two negative clusters (middle-left and bottom-left), and two neutral clusters (middle-top
