Figure 2: Label embeddings of all tasks. Positive, negative, and neutral labels are clustered together.

and middle-bottom).

Our visualisation also provides us with a picture of what auxilary tasks are beneficial, and to what extent we can expect synergies from multi-task learning. For instance, the notion of positive sentiment appears to be very similar across the topic-based and aspect-based tasks, while the conceptions of negative and neutral sentiment differ. In addition, we can see that the model has failed to learn a relationship between `MultiNLI` labels and those of other tasks, possibly accounting for its poor performance on the inference task. We did not evaluate the correlation between label embeddings and task performance, but Bjerva (2017) recently suggested that mutual information of target and auxiliary task label sets is a good predictor of gains from multi-task learning.

6.2 Auxilary Tasks

For each task, we show the auxiliary tasks that achieved the best performance on the development data in Table 4. In contrast to most existing work, we did not restrict ourselves to performing multi-task learning with only one auxiliary task (Søgaard and Goldberg, 2016; Bingel and Søgaard, 2017). Indeed we find that most often a combination of auxiliary tasks achieves the best performance. In-domain tasks are less used than we assumed; only `Target` is consistently used by all Twitter main tasks. In addition, tasks with a higher number of labels, e.g. `Topic-5` are used more often. Such tasks provide a more fine-grained reward signal, which may help in learning representations that generalise better. Finally, tasks with large amounts of training data such as `FNC-1` and `MultiNLI` are also used more often. Even if not directly related, the larger amount of training data that can be indirectly leveraged via multi-task learning may help the model focus on relevant parts of the representation space (Caruana, 1993). These observations shed additional light on when multi-task learning may be useful that go beyond existing studies (Bingel and Søgaard, 2017).

Main task	Auxiliary tasks
`Topic-2`	`FNC-1`, `MultiNLI`, `Target`
`Topic-5`	`FNC-1`, `MultiNLI`, `ABSA-L`, `Target`
`Target`	`FNC-1`, `MultiNLI`, `Topic-5`
`Stance`	`FNC-1`, `MultiNLI`, `Target`
`ABSA-L`	`Topic-5`
`ABSA-R`	`Topic-5`, `ABSA-L`, `Target`
`FNC-1`	`Stance`, `MultiNLI`, `Topic-5`, `ABSA-R`, `Target`
`MultiNLI`	`Topic-5`

Table 4: Best-performing auxiliary tasks for different main tasks.

6.3 Ablation analysis

We now perform a detailed ablation analysis of our model, the results of which are shown in Table 5. We ablate whether to use the LEL (+ *LEL*), whether to use the LTN (+ *LTN*), whether to use the LEL output or the main model output for prediction (main model output is indicated by , *main model*), and whether to use the LTN as a regulariser or for semi-supervised learning (semi-supervised learning is indicated by + *semi*). We further test whether to use diversity features (– *diversity feats*) and whether to use main model predictions for the LTN (+ *main model feats*).

Overall, the addition of the Label Embedding Layer improves the performance over regular MTL in almost all cases.

6.4 Label transfer network

To understand the performance of the LTN, we analyse learning curves of the relabelling function vs. the main model. Examples for all tasks without semi-supervised learning are shown in Figure 3. One can observe that the relabelling model does not take long to converge as it has fewer parameters than the main model. Once the relabelling model is learned alongside the main

	Stance	FNC	MultiNLI	Topic-2	Topic-5*	ABSA-L	ABSA-R	Target
MTL	44.12	72.75	49.39	**80.74**	0.859	74.94	82.25	65.73
MTL + LEL	**46.26**	72.71	**49.94**	80.52	0.814	74.94	79.90	**66.42**
MTL + LTN	40.95	72.72	44.14	78.31	0.851	73.98	82.37	63.71
MTL + LTN, main model	41.60	72.72	47.62	79.98	0.814	75.54	81.70	65.61
MTL + LEL + LTN	44.48	**72.76**	43.72	74.07	0.821	**75.66**	81.92	65.00
MTL + LEL + LTN, main model	43.16	72.73	48.75	73.90	0.810	75.06	**83.71**	66.10
MTL + LEL + LTN + main preds feats	42.78	72.72	45.41	66.30	0.835	73.86	81.81	65.08
MTL + LEL + LTN + main preds feats, main model	42.65	72.73	48.81	67.53	**0.803**	75.18	82.59	63.95
MTL + LEL + LTN + main preds feats – diversity feats	42.78	72.72	43.13	66.3	0.835	73.5	81.7	63.95
MTL + LEL + LTN + main preds feats – diversity feats, main model	42.47	72.74	47.84	67.53	0.807	74.82	82.14	65.11
MTL + LEL + LTN + semi	42.65	72.75	44.28	77.81	0.841	74.10	81.36	64.45
MTL + LEL + LTN + semi, main model	43.56	72.72	48.00	72.35	0.821	75.42	83.26	63.00

Table 5: Ablation results with task-specific evaluation metrics on test set with early stopping on dev set. *LTN* means the output of the relabelling function is shown, which does not use the task predictions, only predictions from other tasks. *LTN + main preds feats* means main model predictions are used as features for the relabelling function. *LTN, main model* means that the main model predictions of the model that trains a relabelling function are used. Note that for MultiNLI, we down-sample the training data. *: lower is better. Bold: best. Underlined: second-best.

Task	Main	LTN	Main (Semi)	LTN (Semi)
Stance	2.12	2.62	1.94	1.28
FNC	4.28	2.49	6.92	4.84
MultiNLI	1.5	1.95	1.94	1.28
Topic-2	6.45	4.44	5.87	5.59
Topic-5*	9.22	9.71	11.3	5.90
ABSA-L	3.79	2.52	9.06	6.63
ABSA-R	10.6	6.70	9.06	6.63
Target	26.3	14.6	20.1	15.7

Table 6: Error analysis of LTN with and without semi-supervised learning for all tasks. Metric shown: percentage of correct predictions only made by either the relabelling function or the main model, respectively, relative to the the number of all correct predictions.

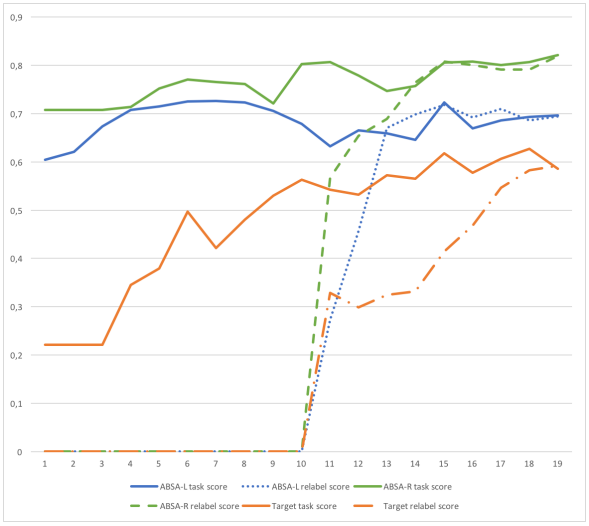

Figure 3: Learning curves with LTN for selected tasks, dev performances shown. The main model is pre-trained for 10 epochs, after which the relabelling function is trained.

model, the main model performance first stagnates, then starts to increase again. For some of the tasks, the main model ends up with a higher task score than the relabelling model. We hypothesise that the softmax predictions of other, even highly related tasks are less helpful for predicting main labels than the output layer of the main task model. At best, learning the relabelling model alongside the main model might act as a regulariser to the main model and thus improve the main model's performance over a baseline MTL model, as it is the case for TOPIC-5 (see Table 5).

To further analyse the performance of the LTN, we look into to what degree predictions of the main model and the relabelling model for individual instances are complementary to one another. Or, said differently, we measure the percentage of correct predictions made only by the relabelling model or made only by the main model, relative to the number of correct predictions overall. Results of this for each task are shown in Table 6 for the LTN with and without semi-supervised learning. One can observe that, even though the relabelling function overall contributes to the score to a lesser degree than the main model, a substantial number of correct predictions are made by the relabelling function that are missed by the main model. This is most prominently pronounced for ABSA-R, where the proportion is 14.6.

7 Conclusion

We have presented a multi-task learning architecture that (i) leverages potential synergies between classifier functions relating shared representations with disparate label spaces and (ii) enables learning from mixtures of labeled and unlabeled data. We have presented experiments with combinations of eight pairwise sequence classification tasks. Our results show that leveraging synergies between label spaces sometimes leads to big improvements, and we have presented a new state of the art for topic-based sentiment analysis. Our analysis further showed that (a) the learned label embeddings were indicative of gains from multi-task learning, (b) auxiliary tasks were often beneficial across domains, and (c) label embeddings almost always led to better performance. We also investigated the dynamics of the label transfer network we use for exploiting the synergies between disparate label spaces.

Word Emotion Induction for Multiple Languages as a Deep Multi-Task Learning Problem

Sven Buechel & Udo Hahn
{sven.buechel|udo.hahn}@uni-jena.de
Jena University Language & Information Engineering (JULIE) Lab
Friedrich-Schiller-Universität Jena, Jena, Germany
http://www.julielab.de

Abstract

Predicting the emotional value of lexical items is a well-known problem in sentiment analysis. While research has focused on polarity for quite a long time, meanwhile this early focus has been shifted to more expressive emotion representation models (such as Basic Emotions or Valence-Arousal-Dominance). This change resulted in a proliferation of heterogeneous formats and, in parallel, often small-sized, non-interoperable resources (lexicons and corpus annotations). In particular, the limitations in size hampered the application of deep learning methods in this area because they typically require large amounts of input data. We here present a solution to get around this language data bottleneck by rephrasing word emotion induction as a multi-task learning problem. In this approach, the prediction of each independent emotion dimension is considered as an individual task and hidden layers are *shared* between these dimensions. We investigate whether multi-task learning is more advantageous than single-task learning for emotion prediction by comparing our model against a wide range of alternative emotion and polarity induction methods featuring 9 typologically diverse languages and a total of 15 conditions. Our model turns out to outperform each one of them. Against all odds, the proposed deep learning approach yields *the largest gain* on *the smallest* data sets, merely composed of one thousand samples.

1 Introduction

Deep Learning (DL) has radically changed the rules of the game in NLP by dramatically boosting performance figures in almost all applications areas. Yet, one of the major premises of high-performance DL engines is their dependence on huge amounts of training data. As such, DL seems ill-suited for areas where training data are scarce, such as in the field of word emotion induction.

We will use the terms *polarity* and *emotion* here to distinguish between research focusing on "semantic orientation" (Hatzivassiloglou and McKeown, 1997) (the positiveness or negativeness) of affective states, on the one hand, and approaches which provide predictions based on some of the many more elaborated representational systems for affective states, on the other hand.

Originally, research activities focused on polarity alone. In the meantime, a shift towards more expressive representation models for emotion can be observed that heavily draws inspirations from psychological theory, e.g., Basic Emotions (Ekman, 1992) or the Valence-Arousal-Dominance model (Bradley and Lang, 1994).

Though this change turned out to be really beneficial for sentiment analysis in NLP, a large variety of mutually incompatible encodings schemes for emotion and, consequently, annotation formats for emotion metadata in corpora have emerged that hinder the interoperability of these resources and their subsequent reuse, e.g., on the basis of alignments or mergers (Buechel and Hahn, 2017).

As an alternative way of dealing with thus unwarranted heterogeneity, we here examine the potential of multi-task learning (MTL; Caruana (1997)) for word-level emotion prediction. In MTL for neural networks, a single model is fitted to solve multiple, independent tasks (in our case, to predict different emotional dimensions) which typically results in learning more robust and meaningful intermediate representations. MTL has been shown to greatly decrease the risk of overfitting (Baxter, 1997), work well for various NLP tasks (Setiawan et al., 2015; Liu et al., 2015; Søgaard and Goldberg, 2016; Cummins et al., 2016; Liu et al., 2017; Peng et al., 2017), and practically increases sample size, thus making it a natural choice for small-sized data sets typically found in the area of word emotion induction.

Proceedings of NAACL-HLT 2018, pages 1907–1918
New Orleans, Louisiana, June 1 - 6, 2018.

After a discussion of related work in Section 2, we will introduce several reference methods and describe our proposed deep MTL model in Section 3. In our experiments (Section 4), we will first validate our claim that MTL is superior to single-task learning for word emotion induction. After that, we will provide a large-scale evaluation of our model featuring 9 typologically diverse languages and multiple publicly available embedding models for a total of 15 conditions. Our MTL model surpasses the current state-of-the-art for each of them, and even performs competitive relative to human reliability. Most notably however, our approach yields the largest benefit on the smallest data sets, comprising merely one thousand samples. This finding, counterintuitive as it may be, strongly suggests that MTL is particularly beneficial for solving the word emotion induction problem. Our code base as well as the resulting experimental data is freely available.[1]

2 Related Work

This section introduces the emotion representation format underlying our study and describes external resources we will use for evaluation before we discuss previous methodological work.

Emotion Representation and Data Sets. Psychological models of emotion can typically be subdivided into *discrete* (or *categorical*) and *dimensional* ones (Stevenson et al., 2007; Calvo and Mac Kim, 2013). Discrete models are centered around particular sets of emotional categories considered to be fundamental. Ekman (1992), for instance, identifies six *Basic Emotions* (Joy, Anger, Sadness, Fear, Disgust and Surprise).

In contrast, dimensional models consider emotions to be composed of several influencing factors (mainly two or three). These are often referred to as *Valence* (a positive–negative scale), *Arousal* (a calm–excited scale), and *Dominance* (perceived degree of control over a (social) situation)—the VAD model (Bradley and Lang (1994); see Figure 1 for an illustration). Many contributions though omit Dominance (the VA model) (Russell, 1980). For convenience, we will still use the term "VAD" to jointly refer to both variants (with and without Dominance).

VAD is the most common framework to acquire empirical emotion values for words in psychology.

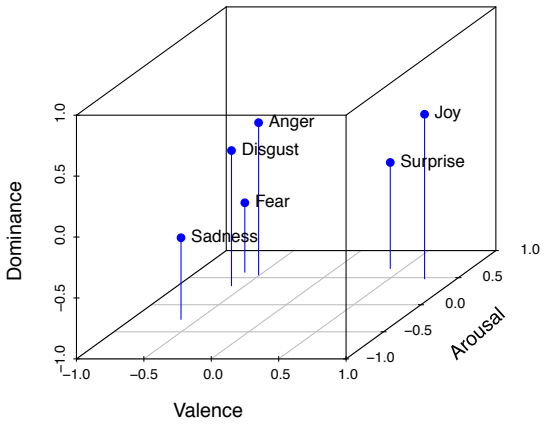

Figure 1: Affective space spanned by the Valence-Arousal-Dominance (VAD) model, together with the position of six Basic Emotions; as determined by Russell and Mehrabian (1977).

Over the years, a considerable number of such resources (also called "emotion lexicons") have emerged from psychological research labs (as well as some NLP labs) for diverse languages. The emotion lexicons we use in our experiments are listed in Table 1. An even more extensive list of such data sets is presented by Buechel and Hahn (2018). For illustration, we also provide three sample entries from one of those lexicons in Table 2. As can be seen, the three affective dimensions behave complementary to each other, e.g., "terrorism" and "orgasm" display similar Arousal but opposing Valence.

The task we address in this paper is to predict the values for Valence, Arousal and Dominance, given a lexical item. As is obvious from these examples, we consider emotion prediction as a regression, not as a classification problem (see arguments discussed in Buechel and Hahn (2016)).

In this paper, we focus on the VAD format for the following reasons: First, note that the Valence dimension exactly corresponds to polarity (Turney and Littman, 2003). Hence, with the VAD model, emotion prediction can be seen as a generalization over classical polarity prediction. Second, to the best of our knowledge, the amount and diversity of available emotion lexicons with VAD encodings is larger than for any other format (see Table 1).

Word Embeddings. Word embeddings are dense, low-dimensional vector representations of words trained on large volumes of raw text in an unsupervised manner. The following are among today's most popular embedding algorithms:

[1] https://github.com/JULIELab/wordEmotions

Source	ID	Language	Format	# Entries

Word	Valence	Arousal	Dominance
sunshine	8.1	5.3	5.4
terrorism	1.6	7.4	2.7
orgasm	8.0	7.2	5.8

Table 2: Three sample entries from Warriner et al. (2013). They use 9-point scales ranging from 1 (most negative/calm/submissive) to 9 (most positive/excited/dominant).

WORD2VEC (with its variants SGNS and CBOW) features an extremely trimmed down neural network (Mikolov et al., 2013). FASTTEXT is a derivative of WORD2VEC, also incorporating sub-word character n-grams (Bojanowski et al., 2017). Unlike the former two algorithms which fit word embeddings in a streaming fashion, GLOVE trains word vectors directly on a word co-occurrence matrix under the assumption to make more efficient use of word statistics (Pennington et al., 2014). Somewhat similar, SVD_{PPMI} performs singular value decomposition on top of a point-wise mutual information co-occurrence matrix (Levy et al., 2015).

In order to increase the reproducibility of our experiments, we rely on the following widely used, publicly available embedding models trained on very large corpora (summarized in Table 3): the SGNS model trained on the Google News corpus[2] (GOOGLE), the FASTTEXT model trained on Common Crawl[3] (COMMON), as well as the FASTTEXT models for a wide range of languages trained on the respective Wikipedias[4] (WIKI). Note that WIKI denotes multiple embedding models with different training and vocabulary sizes (see Grave et al. (2018) for further details). Additionally, we were given the opportunity to reuse the English embedding model from Sedoc et al. (2017) (GIGA), a strongly related contribution (see below). Their embeddings were trained on the English Gigaword corpus (Parker et al., 2011).

Word-Level Prediction. One of the early approaches to word *polarity* induction which is still popular today (Köper and Schulte im Walde, 2016) was introduced by Turney and Littman (2003). They compute the polarity of an unseen word based on its point-wise mutual information (PMI) to a set of positive and negative seed words, respectively.

SemEval-2015 Task 10E featured polarity induction on Twitter (Rosenthal et al., 2015). The best system relied on support vector regression (SVR) using a radial base function kernel (Amir et al., 2015). They employ the embedding vector of the target word as features. The results of their SVR-based system were beaten by the DENSIFIER algorithm (Rothe et al., 2016). DENSIFIER learns an orthogonal transformation of an embedding space into a subspace of strongly reduced dimensionality.

Hamilton et al. (2016) developed SENTPROP, a graph-based, semi-supervised learning algorithm which builds up a word graph, where vertices correspond to words (of known as well as unknown polarity) and edge weights correspond to the similarity between them. The polarity information is then propagated through the graph, thus computing scores for unlabeled nodes. According to their evaluation, DENSIFIER seems to be superior overall, yet SENTPROP produces competitive results

only when the seed lexicon or the corpus the word embeddings are trained on is very small.[5]

For word *emotion* induction, a very similar approach to SENTPROP has been proposed by Wang et al. (2016a). They also propagate affective information (Valence and Arousal, in this case) through a word graph with similarity weighted edges.

Sedoc et al. (2017) recently proposed an approach based on signed spectral clustering where a word graph is constructed not only based on word similarity but also on the considered affective information (again, Valence and Arousal). The emotion value of a target word is then computed based on the seed words in its cluster. They report to outperform the results from Wang et al. (2016a).

Contrary to the trend to graph-based methods, the best system of the IALP 2016 Shared Task on Chinese word emotion induction (Yu et al., 2016b) employed a simple feed-forward neural network (FFNN) with one hidden layer in combination with boosting (Du and Zhang, 2016).

Another very recent contribution which advocates a supervised set-up was published by Li et al. (2017). They propose ridge regression, again using word embeddings as features. Even with this simple approach, they report to outperform many of the above methods in the VAD prediction task.[6]

Sentence-Level and Text-Level Prediction. Different from the word-level prediction task (the one we focus on in this contribution), the determination of emotion values for higher-level linguistic units (especially sentences and texts) is also heavily investigated. For this problem, DL approaches are meanwhile fully established as the method of choice (Wang et al., 2016b; Abdul-Mageed and Ungar, 2017; Felbo et al., 2017; Mohammad and Bravo-Marquez, 2017).

[5]Personal correspondence with William L. Hamilton; See also README at https://github.com/williamleif/socialsent

[6]However, they also report extremely weak performance figures for some of their reference methods.

It is important to note, however, that the methods discussed for these higher-level units cannot easily be transferred to solve the word emotion induction problem. Sentence-level and text-level architectures are either adapted to *sequential* input data (typical for RNN, LSTM, GRNN and related architectures) or *spatially arranged* input data (as with CNN architectures). However, for word embeddings (the default input for word emotion induction) there does not seem to be any meaningful order of their components. Therefore, these more sophisticated DL methods are, for the time being, not applicable for the study at hand.

3 Methods

In this section, we will first introduce various reference methods (two originally polarity-based for which we offer adaptations for VAD prediction) before defining our own neural MTL model and discussing its difference from previous work.

Let $V := \{w_1, w_2, ..., w_m\}$ be our word vocabulary and let $E := \{e_1, e_2, ..., e_m\}$ be a set of embedding vectors such that $e_i \in \mathbb{R}^n$ denotes the n-dimensional vector representation of word w_i. Let $D := \{d_1, d_2, ..., d_l\}$ be a set of emotional dimensions. Our task is to predict the empirically determined emotion vector $emo(w) \in \mathbb{R}^l$ given a word w and the embedding space E.

3.1 Reference Methods

Linear Regression Baseline (LinReg). We propose (multi-variate) linear regression as an obvious baseline for the problem:

$$emo_{LR}(w_k) := We_k + b \quad (1)$$

where W is a matrix, W_{i*} contains the regression coefficients for the i-th affective dimension and b is the vector of bias terms. The model parameters are fitted using ordinary least squares. Technically, we use the `scikit-learn.org` implementation with default parameters.

Ridge Regression (RidgReg). Li et al. (2017) propose ridge regression for word emotion induction. Ridge regression works identically to linear regression during prediction, but introduces L_2 regularization during training. Following the authors, for our implementation, we again use the `scikit-learn` implementation with default parameters.

Turney-Littman Algorithm (TL). As one of the earliest contributions in the field, Turney and Littman (2003) defined a simple PMI-based approach to determine the semantic polarity SP_{TL} of a word w:

$$SP_{TL}(w) := \sum_{s \in seeds^+} pmi(w,s) - \sum_{s \in seeds^-} pmi(w,s) \quad (2)$$

where $seeds^+$ and $seeds^-$ are sets of positive and negative seed words, respectively. Since this algorithm is still popular today (Köper and Schulte im Walde, 2016), we here provide a novel modification for adapting this originally polarity-based approach to word emotion induction with vectorial seed and output values.

First, we replace PMI-based association of seed and target word w and s by their similarity sim based on their word embeddings e_w and e_s:

$$sim(w,s) := max(0, \frac{e_w \cdot e_s}{||e_w|| \times ||e_s||}) \quad (3)$$

$$emo(w) := \sum_{s \in seeds^+} sim(w,s) - \sum_{s \in seeds^-} sim(w,s) \quad (4)$$

Although this step is technically not required for the adaptation, it renders the TL algorithm more comparable to the other approaches evaluated in Section 4 besides from most likely increasing performance. Equation (4) can be rewritten as

$$emo(w) := \sum_{s \in seeds} sim(w,s) \times emo(s) \quad (5)$$

where $seeds := seeds^+ \cup seeds^-$ and $emo(s)$ maps to 1, if $s \in seeds^+$, and -1, if $s \in seeds^-$.

Equation (5) can be trivially adapted to an n-dimensional emotion format by redefining $emo(s)$ such that it maps to a vector from $\mathbb{R}^n$ instead of $\{-1, 1\}$. Our last step is to introduce a normalization term such that $emo(w)_{TL}$ lies within the range of the seed lexicon.

$$emo_{TL}(w) := \frac{\sum_{s \in seeds} sim(w,s) \times emo(s)}{\sum_{s \in seeds} sim(w,s)} \quad (6)$$

As can be seen from Equation (6), for the more general case of n-dimensional emotion prediction, the Turney-Littman algorithm naturally translates into a weighted average where the seed emotion values are weighted according to the similarity to the target item.

Densifier. Rothe et al. (2016) train an orthogonal matrix $Q \in \mathbb{R}^{n \times n}$ (n being the dimensionality of the word embeddings) such that applying Q to an embedding vector e_i concentrates all the polarity information in its first dimension such that the polarity of a word w_i can be computed as

$$SP_{\text{DENSIFIER}}(w_i) := pQe_i \quad (7)$$

where $p = (1, 0, 0, ..., 0)^T \in \mathbb{R}^{1 \times n}$.

For fitting Q, the seeds are arranged into pairs of equal polarity (the set $pairs^=$) and those of opposing polarity ($pairs^\neq$). A good fit for Q will minimize the distance within the former and maximize the distance within the latter which can be expressed by the following two training objectives:

$$\underset{Q}{\text{argmin}} \sum_{(w_i,w_j) \in pairs^=} |pQ(e_i - e_j)| \quad (8)$$

$$\underset{Q}{\text{argmax}} \sum_{(w_i,w_j) \in pairs^\neq} |pQ(e_i - e_j)| \quad (9)$$

The objectives described in the expressions (8) and (9) are combined into a single loss function (using a weighting factor $\alpha \in [0, 1]$) which is then minimized using stochastic gradient descent (SGD).

To adapt this algorithm to dimensional emotion formats, we construct a positive seed set, $seeds_v^+$, and a negative seed set, $seeds_v^-$, for each emotion dimension $v \in D$. Let M_v be the mean value of all the entries of the training lexicon for the affective dimension v. Let SD_v be the respective standard deviation and $\beta \in \mathbb{R}$, $\beta \geq 0$. Then all entries greater than $M_v + \beta SD_v$ are assigned to $seeds_v^+$ and those less than $M_v - \beta SD_v$ are assigned to $seeds_v^-$. Q is fitted individually for each emotion dimension v.

Training was performed according to the original paper with the exception that (following Hamilton et al. (2016)) we did not apply the proposed re-orthogonalization after each training

step, since we did not find any evidence that this procedure actually results in improved performance. The hyperparameters α and β were set to .7 and .5 (respectively) for all experiments based on a pilot study. Since the original implementation is not accessible, we devised our own using `tensorflow.org`.

Boosted Neural Networks (ensembleNN). Du and Zhang (2016) propose simple FFNNs in combination with a boosting algorithm. An FFNN consists of an *input* or *embedding layer* with activation $a^{(0)} \in \mathbb{R}^n$ which is equal to the embedding vector e_k when predicting the emotion of a word w_k. The input layer is followed by multiple hidden layers with activation

$$a^{(l+1)} := \sigma(W^{(l+1)}a^{(l)} + b^{(l+1)}) \qquad (10)$$

where $W^{(l+1)}$ and $b^{(l+1)}$ are the weights and biases for layer $l+1$ and σ is a nonlinear activation function. Since we treat emotion prediction as a regression problem, the activation on the output layer a^{out} (where out is the number of non-input layers in the network) is computed as the affine transformation

$$a^{(out)} := W^{(out)}a^{(out-1)} + b^{(out)} \qquad (11)$$

Boosting is a general machine learning technique where several weak estimators are combined to form a strong estimator. The authors used FFNNs with a single hidden layer of 100 units and rectified linear unit (ReLU) activation. The boosting algorithm AdaBoost.R2 (Drucker, 1997) was used to train the ensemble (one per affective dimension). Our re-implementation copies their technical set-up[7] exactly using `scikit-learn`.

3.2 Multi-Task Learning Neural Network

The approaches introduced in Section 3.1 and Section 2 vary largely in their methodological foundations, i.e., they comprise semi-supervised and supervised machine learning techniques—both statistical and neural ones. Yet, they all have in common that they treat the prediction of the different emotional dimensions *as separate* tasks. That is, they fit one individual model per VAD dimension without sharing parameters between them.

In contradistinction, the key feature of our approach is that we fit a single FFNN model to predict *all VAD dimensions jointly*, thus applying multi-task learning to word emotion induction. Hence, we treat the prediction of Valence, Arousal and Dominance as three independent tasks. Our multi-task learning neural network (MTLNN) (depicted in Figure 2) has an output layer of three units such that each output unit represents one of the VAD dimensions. However, the activation in our two hidden layers (of 256 and 128 units, respectively) is *shared* across all VAD dimensions, and so are the associated weights and biases.

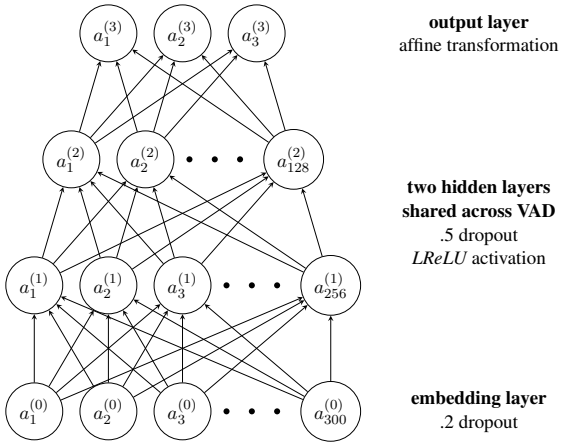

Figure 2: MTL architecture for VAD prediction.

Thus, while we train our MTLNN model it is forced to learn intermediate representations of the input which are generally informative for all VAD dimensions. This serves as a form of regularization, since it becomes less likely for our model to fit the noise in the training set as noise patterns may vary across emotional dimensions. Simultaneously, this has an effect similar to an increase of the training size, since each sample now leads to additional error signals during backpropagation. Intuitively, both properties seem extremely useful for relatively small-sized emotion lexicons (see Section 4 for empirical evidence).

The remaining specifications of our model are as follows. We use *leaky* ReLU activation (LReLU) as nonlinearity (Maas et al., 2013).

$$LReLU(z_i) := max(\gamma z_i, z_i) \qquad (12)$$

with $\gamma := .01$ for our experiments. For regularization, dropout (Srivastava et al., 2014) is applied during training with a probability of .2 on the embedding layer and .5 on the hidden layers. We train for $15,000$ iterations (well beyond convergence on each data set we use) with the ADAM optimizer (Kingma and Ba, 2015) of .001 base learning rate,

[7] Original settings available at `https://github.com/StevenLOL/ialp2016_Shared_Task`

batch size of 128 and Mean-Squared-Error loss. The weights are randomly initialized (drawn from a normal distribution with a standard deviation .001) and biases are uniformly initialized as .01. `Tensorflow` is used for implementation.

4 Results

In this section, we first validate our assumption that MTL is superior to single-task learning for word emotion induction. Next, we compare our proposed MTLNN model in a large-scale evaluation experiment.

Performance figures will be measured as Pearson correlation (r) between our automatically predicted values and human gold ratings. The Pearson correlation between two data series $X = x_1, x_2, ..., x_n$ and $Y = y_1, y_2, ..., y_n$ takes values between $+1$ (perfect positive correlation) and -1 (perfect negative correlation) and is computed as

$$r_{xy} := \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}} \quad (13)$$

where $\bar{x}$ and $\bar{y}$ denote the mean values for X and Y, respectively.

4.1 Single-Task vs. Multi-Task Learning

The main hypothesis of this contribution is that an MTL set-up is superior to single-task learning for word emotion induction. Before proceeding to the large-scale evaluation of our proposed model, we will first examine this aspect of our work.

For this, we use the following experimental set-up: We will compare the MTLNN model against its single-task learning counterpart (SepNN). SepNN simultaneously trains three separate neural networks where only the input layer, yet no parameters of the intermediate layers are shared across the models. Each of the separate networks is identical to MTLNN (same layers, dropout, initialization, etc.), yet has only one output neuron, thus modeling only one of the three affective VAD dimensions. SepNN is equivalent to fitting our proposed model (but with only one output unit) to the different VAD dimensions individually, one after the other. Yet, training these separate networks simultaneously (not jointly!) makes both approaches, MTLNN and SepNN, easier to compare.

We will run MTLNN against SepNN on the EN and the EN+ data set (the former is very small, the latter relatively large; see Table 1) using the following set-up: for each gold lexicon and model, we randomly split the data $9/1$ and train for $15,000$ iterations on the larger split (the same number of steps is used for the main experiment). After each one-thousand iterations step, model performance is tested on the held-out data. This process will be repeated 20 times and the performance figures at each one-thousand iterations step will be averaged. In a final step, we will average the results for each of the three emotional dimensions and only plot this average value. The results of this experiment are depicted in Figure 3.

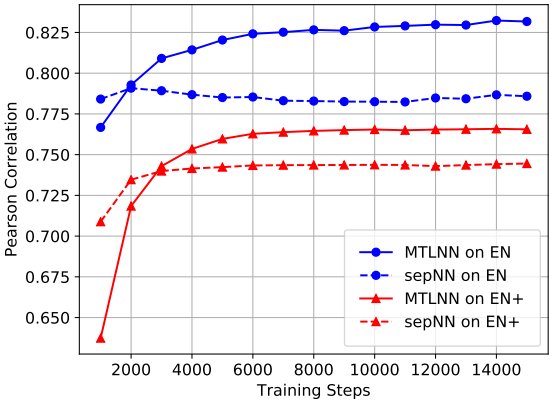

Figure 3: Performance of our proposed MTLNN model vs. its single-task learning counterpart SepNN against training steps.

First of all, each combination of model and data set displays a satisfactory performance of at least $r \approx .75$ after 15,000 steps compared to previous work (see below). Overall, performance is higher for the smaller EN lexicon. Although counterintuitive (since smaller lexicons lead to fewer training samples), this finding is consistent with prior work (Sedoc et al., 2017; Li et al., 2017) and is probably related to the fact that smaller lexicons usually comprise a larger portion of strongly emotion-bearing words. In contrast, larger lexicons add more neutral words which tend to be harder to predict in terms of correlation.

As hypothesized, the MTLNN model does indeed outperform the single task model on both data sets. Our data also suggest that the gain from the MTL approach is larger on smaller data sets (again in concordance with our expectations). Figure 3 reveals that this might be due to the regularizing effect of MTL, since the SepNN model shows signs of overfitting on the EN data set. Yet, even

Table 4: Results of our main experiment in averaged Pearson correlation; best result per condition (in rows) in bold, second best result underlined; significant difference (paired two-tailed t-test) over the second best system marked with "*", "**", or "***" for $p < .05$, .01, or .001, respectively.

when the separate model does not overfit (as on the EN+ lexicon), MTLNN reveals better results.

Although SepNN needs fewer *training steps* before convergence, the MTLNN model trains much faster, thus still converging faster in terms of *runtime* (about a minute on a middle-class GPU). This is because MTLNN has only about a third as many parameters as the separate model SepNN.

4.2 Comparison against Reference Methods

We combined each of the selected lexicon data sets (Table 1) with each of the applicable publicly available embedding models (Section 2; the embedding model provided by Sedoc et al. (2017) will be used separately) for a total of 15 conditions, i.e, the rows in Table 4.

For each of these conditions, we performed a 10-fold cross-validation (CV) for each of the 6 methods presented in Section 3 such that each method is presented with the identical data splits.[8] For each condition, algorithm, and VA(D) dimension, we compute the Pearson correlation r between gold ratings and predictions. For conciseness, we present only the average correlation over the respective affective dimensions in Table 4 (Valence and Arousal for ES+ and ZH, VAD for the others). Note that the methods we compare ourselves against comprise the current state-of-the art in both polarity and emotion induction (as described in Section 2).

[8]This procedure constitutes a more direct comparison than using different splits for each method and allows using *paired* t-tests.

As can be seen, our proposed MTLNN model outperforms all other approaches in each of the 15 conditions. Regarding the average over all affective dimensions and conditions, it outperforms the second best system, ensembleNN, by more than 5%-points. In line with our results from Section 4.1, those improvements are especially pronounced on smaller data sets containing one up to two thousand entries (EN, ES, IT, PT, ID) with close to 10%-points improvement over the respective second-best system.

Concerning the relative ordering of the affective dimensions, in line with former studies (Sedoc et al., 2017; Li et al., 2017), the performance figures for the Valence dimension are usually much higher than for Arousal and Dominance. Using MTLNN, for many conditions, we see the pattern that Valence is about 10%-points above the VAD average, Arousal being 10%-points below and Dominance being roughly equal to the average over VAD (this applies, e.g., to EN, EN+ and IT). On other data sets (e.g., PL, NL and ID), the ordering between Arousal and Dominance is less clear though Valence still stands out with the best results. We observe the same general pattern for the reference methods, as well.

Concerning the comparison to Sedoc et al. (2017), arguably one of most related contributions, they report a performance of $r = .768$ for Valence and .582 for Arousal on the EN+ data set in a 10-fold CV using their own embeddings. In contrast, MTLNN using the COMMON model achieves $r = .870$ and .674 in the same set-up—about 10%-

	Valence	Arousal	Dominance
MTLNN EN	.918	.730	.825
MTLNN EN+	.870	.674	.758
ISR EN $\sim$ EN+	.953	.759	.795
SHR EN+	.914	.689	.770

Table 5: Comparison of the MTLNN model against inter-study reliability (ISR) between the EN and the EN+ data set and split-half reliability (SHR) of the EN+ data set (in Pearson correlation).

points better on both dimensions. However, the COMMON model was trained on much more data than the embeddings Sedoc et al. (2017) use. For the most direct comparison, we also repeated this experiment using *their* embedding model (GIGA). We find that MTLNN still clearly outperforms their results with $r = .814$ for Valence and .607 for Arousal.[9]

MTLNN achieves also very strong results in direct comparison to human performance (see Table 5). Warriner et al. (2013) (who created EN+) report an inter-study reliability (ISR; i.e., the correlation of the aggregated ratings from two different studies) between the EN and the EN+ lexicon of $r = .953$, .759 and .795 for VAD, respectively. Since EN is a subset of EN+, we can compare these performance figures against our own results on the EN data set where we achieved $r = .918$, .730 and .825, respectively. Thus, our proposed method did actually outperform human reliability for Dominance and is competitive for Valence and Arousal, as well.

This general observation is also backed up by split-half reliability data (SHR; i.e., when randomly splitting all individual ratings in two groups and averaging the ratings within each group, how strong is the correlation between these averaged ratings?). For the EN+ data set, Warriner et al. (2013) report an SHR of $r = .914$, .689 and .770 for VAD, respectively. Again, our MTLNN model performs very competitive with $r = .870$, .674 and .758, respectively using the COMMON embeddings.

5 Conclusion

In this paper, we propose multi-task learning (MTL) as a simple, yet surprisingly efficient method to improve the performance and, at the same time, to deal with existing data limitations in word emotion induction—the task to predict a complex emotion score for an individual word. We validated our claim that MTL is superior to single-task learning by achieving better results with our proposed method in performance as well as training time compared to its single-task counterpart. We performed an extensive evaluation of our model on 9 typologically diverse languages, using different kinds of word embedding models for a total 15 conditions. Comparing our approach to state-of-the-art methods from word polarity and word emotion induction, our model turns out to be superior in each condition, thus setting a novel state-of-the-art performance for both polarity *and* emotion induction. Moreover, our results are even competitive to human annotation reliability in terms of inter-study as well as split-half reliability. Since this contribution was restricted to the VAD format of emotion representation, in future work we will examine whether MTL yields similar gains for other representational schemes, as well.

[9]We also clearly outperform their results for the NL and ES+ data sets. For these cases, our embedding models were similar in training size.

Acknowledgments

We would like to thank the Positive Psychology Center, University of Pennsylvania for providing us with the embedding model used in Sedoc et al. (2017), Johannes Hellrich, JULIE Lab, for insightful discussions, and the reviewers for their valuable comments.

Abstract

We often talk about events that impact us positively or negatively. For example *"I got a job"* is good news, but *"I lost my job"* is bad news. When we discuss an event, we not only understand its affective polarity but also the reason *why* the event is beneficial or detrimental. For example, getting or losing a job has affective polarity primarily because it impacts us financially. Our work aims to categorize affective events based upon *human need* categories that often explain people's motivations and desires: PHYSIOLOGICAL, HEALTH, LEISURE, SOCIAL, FINANCIAL, COGNITION, and FREEDOM. We create classification models based on event expressions as well as models that use contexts surrounding event mentions. We also design a co-training model that learns from unlabeled data by simultaneously training event expression and event context classifiers in an iterative learning process. Our results show that co-training performs well, producing substantially better results than the individual classifiers.

1 Introduction

Recent research has focused on identifying *affective events* in text, which are activities or states that positively or negatively affect the people who experience them. Recognizing affective events in text is challenging because they appear as factual expressions and their affective polarity is often implicit. For example, *"I broke my arm"* and *"I got fired"* are usually negative experiences, while *"I broke a record"* and *"I went to a concert"* are typically positive experiences. Several NLP techniques have been developed to recognize affective events, including patient polarity verb bootstrapping (Goyal et al., 2010, 2013), implicature rules (Deng and Wiebe, 2014), label propagation (Ding and Riloff, 2016), pattern-based learning (Vu et al., 2014; Reed et al., 2017), and semantic consistency optimization (Ding and Riloff, 2018).

Our research aims to probe deeper and understand not just the polarity of affective events, but *the reason for* the polarity. Events can impact people in many ways, and understanding *why* an event is beneficial or detrimental is a fundamental aspect of language understanding and narrative text comprehension. Additionally, many applications could benefit from understanding the nature of affective events, including text summarization, conversational dialogue processing, and mental health therapy or counseling systems. As an illustration, a mental health therapy system can benefit from understanding why someone is in a negative state. If the triggering event for depression is *"I broke my leg"* then the reason is about the person's Health, but if the triggering event is *"I broke up with my girlfriend"* then the reason is based on Social relationships.

We hypothesize that the polarity of affective events can often be attributed to a relatively small set of *human need* categories. Our work is motivated by theories in psychology that explain people's motivations, desires, and overall well-being in terms of categories associated with basic human needs, such as Maslow's Hierarchy of Needs (Maslow et al., 1970) and Fundamental Human Needs (Max-Neef et al., 1991). Drawing upon these works, we propose that the polarity of affective events often arises from 7 types of human needs: PHYSIOLOGICAL, HEALTH, LEISURE, SOCIAL, FINANCIAL, COGNITION, and FREEDOM. For example, *"I broke my arm"* has negative polarity because it negatively impacts one's Health, *"I got fired"* is negative because it negatively impacts one's Finances, and *"I am confused"* is negative because it reflects a problem related to Cognition.

We explore this hypothesis and tackle the chal-

Proceedings of NAACL-HLT 2018, pages 1919–1929
New Orleans, Louisiana, June 1 - 6, 2018.

lenge of categorizing affective events in text with respect to these 7 human need categories. As our evaluation data, we use events extracted from personal blog posts and manually labeled with affective polarity in previous work (Ding and Riloff, 2018). These affective events were then subsequently annotated for the human need categories.

In this paper, we design several types of classification models that learn from both labeled and unlabeled data. First, we present supervised learning models that use lexical and embedding features for the words in event expressions, as well as models that learn from the sentence contexts surrounding mentions of event expressions. Next, we explore self-training and co-training models that exploit both labeled and unlabeled data for training. The most effective system is a co-training model that uses two classifiers with two different views in an iterative learning process: one classifier only uses the words in an event expression, and the other classifier only uses the contexts surrounding instances of an event expression. Our results show that this co-training model effectively uses unlabeled data to substantially improve results compared to classifiers trained only with labeled data, yielding gains in both precision and recall.

2 Related Work

Recently, there has been growing interest in recognizing the affective polarity of events. For example, Goyal et al. (2013) developed a bootstrapped learning method to learn *patient polarity verbs*, which impart affective polarities to their patients. Li et al. (2015) designed methods to extract verb expressions that imply negative opinions from reviews. Rashkin et al. (2016) recently proposed connotation frames to incorporate the connotative polarities for a verb's arguments from the writer's and other event entities' perspectives. Li et al. (2014) proposed a bootstrapping approach to extract major life events from tweets using congratulation and condolence speech acts. Most of these major life events are affective although their work did not identify polarity. Another group of researchers have studied +/- effect events (Deng et al., 2013; Choi and Wiebe, 2014) which they previously called benefactive/malefactive events. Their work mainly focused on inferring implicit opinions through implicature rules (Deng and Wiebe, 2014, 2015).

Ding and Riloff (2016) designed an event context graph model to identify affective events using label propagation. Reed et al. (2017) demonstrated that automatically acquired patterns could benefit the recognition of first-person related affective sentences. Most recently, Ding and Riloff (2018) developed a semantic consistency model to induce a large set of affective events using three types of semantic relations in an optimization framework. (We use their annotated affective event data set in our work.) All of this previous work only identifies affective events and their polarities. In contrast, our work aims to identify the reason for the affective polarity of an event.

The human need categories are inspired by two prior theories. The first one is Maslow's Hierarchy of Needs (Maslow et al., 1970) which was developed to study people's motivations and personalities. The second one is Fundamental Human Needs (Max-Neef et al., 1991) which was developed to help communities identify their strengths and weaknesses. The human need categories are also related to the concept of "goals", which has been proposed by (Schank and Abelson, 1977) to understand narrative stories. Goals could be very specific to a character in a particular narrative story. However, but many types of goals originate from universal needs and desires shared by most people (Max-Neef et al., 1991). In addition, our work is also related to research on wish detection (Goldberg et al., 2009), desire fulfillment (Chaturvedi et al., 2016), and modelling protagonist goals and desires (Rahimtoroghi et al., 2017).

Self-training is a semi-supervised learning method to improve performance by exploiting unlabeled data. Self-training has been successfully used in many NLP applications such as information extraction (Ding and Riloff, 2015) and syntactic parsing (McClosky et al., 2006). Co-training (Blum and Mitchell, 1998) uses both labeled and unlabeled data to train models that have two different views of the data. Co-training has been previously used for many NLP tasks including spectral clustering (Kumar and Daumé, 2011), word sense disambiguation (Mihalcea, 2004), coreference resolution (Phillips and Riloff, 2002), and sentiment analysis (Wan, 2009; Xia et al., 2015).

3 Affective Event Data

The goal of our research is to categorize affective events based on 7 categories of human needs. To facilitate this work, we build upon a large data set

Physiological	Health	Leisure	Social	Finance	Cognition	Freedom	Emotion	None
19 (4%)	52 (10%)	75 (14%)	108 (20%)	29 (5%)	26 (5%)	7 (1%)	128 (24%)	98 (18%)

Table 1: Distribution of Human Need Categories (each cell shows the frequency and percentage).

created for prior research (Ding and Riloff, 2018) which aims to identify affective events. We will refer to this data as the AffectEvent dataset. We will briefly describe this data and the human need category annotations that we added on top of it.

The AffectEvent dataset contains events extracted from a personal story corpus that was created by applying a personal story classifier (Gordon and Swanson, 2009) to 177 million blog posts. The personal story corpus contains 1,383,425 personal story blogs. StanfordCoreNLP (Manning et al., 2014) was used for POS and NER tagging and SyntaxNet (Andor et al., 2016) for parsing. Each event is represented using a frame-like structure to capture the meanings of different types of events. Each event representation contains four components: ⟨**Agent**, **Predicate**, **Theme**, **PP**⟩. The Predicate is a simple verb phrase corresponding to an action or state. The Agent is a named entity, nominal, or pronoun, and is extracted using syntactic heuristics rather than semantic role labeling. We use "Theme" loosely to allow a NP or adjective to fill this role. The PP component is composed of a preposition and a NP. All words in the event are lemmatized, and active and passive voices are normalized to have the same representation. See (Ding and Riloff, 2018) for more details of the event representation. Table 2 shows some examples of extracted events.

Positive Events	**Human Need**
⟨ our pizza; arrive, -, -⟩	Physiological
⟨ ear, be, better, - ⟩	Health
⟨ I, watch, Hellboy II, -⟩	Leisure
⟨ we, get, marry, -⟩	Social
⟨ I, get, my new laptop, -⟩	Finance
⟨ my memory, be, vivid, -⟩	Cognition
⟨ my heart, feel, happy, -⟩	Emotion
⟨ we, be, legal, -⟩	None
Negative Events	**Human Need**
⟨ I, grow, hungry, - ⟩	Physiological
⟨ my face, look, pale, - ⟩	Health
⟨ -, rain out, game, -⟩	Leisure
⟨ you, confront, me, -⟩	Social
⟨ I, be, unemployed, at time ⟩	Finance
⟨ my memory, not serve, me, -⟩	Cognition
⟨ I, be, scared, -⟩	Emotion
⟨ it, not work, -, for me⟩	None

Table 2: Examples of Affective Events with Human Need Category Labels

3.1 Human Need Category Annotations

Affective events impact people in a positive or negative way for a variety of reasons. We hypothesized that the polarity of most affective events arises from the satisfaction or violation of basic human needs. Psychologists have developed theories that explain people's motivations, desires, and overall well-being in terms of categories associated with basic human needs, such as Maslow's Hierarchy of Needs (Maslow et al., 1970) and Fundamental Human Needs (Max-Neef et al., 1991). Based upon this work, we defined 7 human need categories, which are briefly described below.

Physiological Needs maintain our body's basic functions (e.g., air, food, water, sleep). *Health Needs* are to be physically healthy and safe. *Leisure Needs* are to have fun, to be relaxed, to have leisure time, to appreciate and enjoy beauty. *Social Needs* are to have good social relations (e.g., family, friendship), to have good self-worth and self-esteem, and to be respected by others. *Financial Needs* are to obtain and protect financial income, to acquire and maintain valuable possessions, to have a job and satisfying work. *Cognition Needs* are to obtain skills, information, and knowledge, to receive education, to improve one's intelligence, and to mentally process information correctly. *Freedom Needs* are the ability to move or change positions freely, and to access things or services in a timely manner. We also defined two categories for event expressions that represent explicit emotions and opinions (*Emotions/Sentiments/Opinions*) and events that do not fall into any other categories (*None of the Above*).

We added manual annotations for human need categories on top of the manually annotated positive and negative affective events in the AffectEvent dataset. Three people were asked to assign a human need category label to each of the 559 affective events in the AffectEvent test set. Annotators achieved good pairwise inter-annotator agreement ($\kappa \geq .65$) on this task. The Cohen's kappa scores were κ=.69, κ=.66 and κ=.65. We assigned a single category to each event because most of the affective events fell into just one category in our preliminary study, even though some cases could legitimately be argued

for multiple categories. We discuss this issue further in Section 5.4

The distribution of human need categories is shown in Table 1. Since very few affective events were found to belong to the *Freedom* category, this category was merged into None. Additionally, 17 events received three different labels from the annotators, so they were discarded. The majority label was then assigned to the remaining events, yielding a gold standard data set of 542 affective events with human need category labels. Some of the annotated examples are shown in Table 2. A more detailed description of the human need category definitions, data set, and manual annotation effort is described in (Ding et al., 2018). This data set is freely available for other researchers to use.

In the next section, we present classification models designed to tackle this human needs categorization task.

4 Categorizing Human Needs with Labeled and Unlabeled Data

Automatically categorizing affective events in text based on human needs is a new task, so we investigated several types of approaches. First, we designed supervised classifiers to categorize affective events based upon the words in the event expressions, which we will refer to as *Event Expression Classifiers*. We explored lexical features, word embedding features, and semantic category features, along with several types of machine learning algorithms.

Our task is to determine the human need category of an affective event based on the meaning of the event itself, independent of any specific context.[1] But we hypothesized that collecting the contexts around instances of the events could also provide valuable information to infer human need categories. So we also designed *Event Context Classifiers* to use the sentence contexts around event mentions as features.

Our gold standard data set is relatively small, so supervised learning that relies entirely on manually labeled data may not have sufficient coverage to perform well across the human need categories. However, the AffectEvent dataset contains a very large set of events that were extracted from the same blog corpus, but not manually labeled with affective polarity. Consequently, we explored two weakly supervised learning methods to exploit this large set of unlabeled events. First, we tried self-training to iteratively improve the event expression classifier. Second, we designed a co-training model that takes advantage of both an event expression classifier and an event context classifier to learn from the unlabeled events. These two types of classifiers provide complementary views of an event, so new instances labeled by one classifier can be used as valuable new data to benefit the other classifier, in an iterative learning cycle.

4.1 Event Expression Classifiers

The most obvious approach is to use the words in event expressions as features for recognizing human need categories (e.g., {ear, be, better} for the event <ear, be, better>). We experimented with both lexical (string) features and pre-trained word embedding features. For the latter, we used GloVe (Pennington et al., 2014) vectors (200d) pretrained on 27B tweets. For each event expression, we compute its embedding as the average of its words' embeddings.

We also designed semantic features using the lexical categories in the LIWC lexicon (Pennebaker et al., 2007) to capture a more general meaning for each word. LIWC is a dictionary of words associated with "psychologically meaningful" lexical categories, some of which are directly relevant to our task, such as AFFECTIVE, SOCIAL, COGNITIVE, and BIOLOGICAL PROCESS. We identify the LIWC category of the head word of each phrase in the event representation and use them as *Semantic Category* features.

We experimented with three types of supervised classification models: logistic regression (LR), support vector machines (SVM), and recurrent neural network classifiers (RNN). One advantage of the RNN is that it considers the word order in the event expression, which can be important. In our experiments, we used the Scikit-learn implementation (Pedregosa et al., 2011) for the LR classifier, and LIBSVM (Chang and Lin, 2011) with a linear kernel for the SVM classifier. For the RNN, we used the example LSTM implementation from Keras (Chollet et al., 2015) github, which was developed to build a sentiment classifier. We used the default parameters in our experiments[2].

[1] We view this as assuming the most common interpretation of an event, which would be the default in the absence of context.

[2] LR and SVM use the one-vs-rest (ovr) scheme, while RNN is a single multi-class classifier.

4.2 Event Context Classifiers

The event dataset was originally extracted from a large collection of blog posts, which contain many instances of the events in different sentences. We hypothesized that the contexts surrounding instances of an event can also provide strong clues about the human need category associated with the event. Therefore, we also created *Event Context Classifiers* to exploit the sentence contexts around event mentions. We explored several designs for event context classifiers, which are explained below.

Context$^{\text{SentBOW}}$: For each event in the training set, we first collect all sentences mentioning this event and assign the event's human need category as the label for each sentence. Each sentence is then used as a training instance for the event context classifier. We use a bag-of-words representation for each sentence.

Context$^{\text{SentEmbed}}$: This variation labels sentences exactly the same way as the previous model. But each sentence is represented as a dense embedding vector, which is computed as the average of the embeddings for each word in the sentence. We used GloVe (Pennington et al., 2014) vectors (200d) pretrained on 27B tweets.

Context$^{\text{AllBOW}}$: Instead of treating each sentence as a training instance, for this model we aggregate all of the sentences that mention the same event to create one giant context for the event. Each event corresponds to one training instance in this model, which is represented using bag-of-word features.

Context$^{\text{AllEmbed}}$: This variation aggregates the sentences that mention an event exactly like the previous model. But each sentence is represented as a dense embedding vector. First, we compute an embedding vector for each sentence as the average of the embeddings of its words. Then we compute a single context embedding by averaging all of the sentence embeddings.

In the data, some events appear in many sentences, while others appear in just a few sentences. To maintain balance, we randomly sample 10 sentences for each event to use as its contexts.

To predict the human need category of an event, we first apply the event context classifier to contexts that mention the event, which produces a probability distribution over the human need categories. For each category, we compute its mean probability. Finally, we assign the event with the human need category that has the highest mean probability (i.e. argmax).

4.3 Self-Training the Event Expression Classifier

Our labeled data set is relatively small, but as mentioned previously, the AffectEvent dataset contains a large set of unlabeled events as well. So we designed a self-training model to try to iteratively improve the event expression classifier by exploiting the unlabeled event data.

The self-training process works as follows. Initially, the event expression classifier is trained using the manually labeled events. Then the classifier is applied to the unlabeled events and assigns a human need category to each event with a confidence value. For each human need category, we select the unlabeled event that has been assigned to that category with the highest confidence. Therefore, each category will have one additional labeled event at each iteration. The newly labeled events are added to the labeled data set, and the classifier is re-trained for the next iteration.

4.4 Co-Training with Event Expression and Event Context Classifiers

The sentence contexts in which an event appears contain complementary information to the event expression itself. So we designed co-training models to exploit these complementary types of classifiers to iteratively learn from unlabeled data.

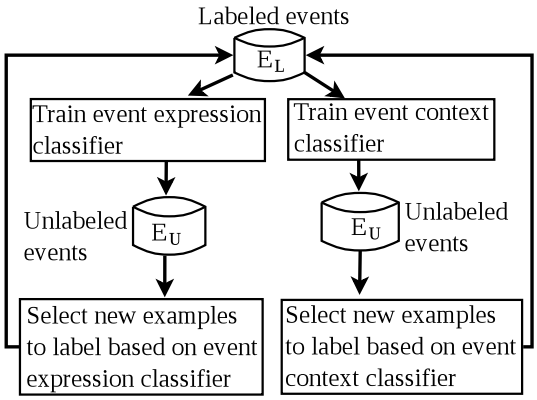

Figure 1: The Co-Training Model

Figure 1 shows the architecture of our co-training model. Initially, an event expression classifier and an event context classifier are independently trained on the manually labeled training data. Each classifier is then applied to the large collection of unlabeled events E_U. For each hu-

man need category, we then select the event that has been assigned to the category with the highest confidence value as a new instance to label. Consequently, each category will receive two additional labeled events at each iteration, one from the event expression classifier and another one from the event context classifier.[3] Both sets of newly labeled events are then added to the labeled set E_L, and each of the classifiers is re-trained on the expanded set of labeled data. Because the classifiers have different views of the events, the new instances labeled by one classifier serve as fresh training instances for the other, unlike self-training with a single classifier where it is learning entirely from its own predictions. The following section describes the co-training algorithm in more detail.

4.4.1 The Co-Training Algorithm

Our co-training algorithm is shown in Algorithm 1. The input to the algorithm are the sets of labeled events E_L and unlabeled events E_U. Each event is associated with both an event expression and the set of sentences in which it occurs in the blogs corpus.

For each iteration, the event expression classifier is first trained using the labeled events E_L with the event expression view. Then, we construct an event context view X_{con} for each event in the labeled set E_L. The context sentences are used differently depending on the type of context model (described in Section 4.2). An event context classifier is then trained using the context view X_{con}. Both classifiers are then independently applied to the unlabeled events E_U. For each human need category, each classifier selects one event to label based on its most confident prediction. All of the newly labeled events are then added to the labeled training set E_L, and the process repeats.

4.4.2 Prediction with Co-Trained Classifiers

The co-training process simultaneously trains two classifiers, so here we explain how we use the resulting classifiers after the co-training process has finished. For each event e in the test set, we apply both the event expression classifier and the event context classifier, which each produce a probability distribution over the human need categories. Then we explore two different methods to combine the two probability distributions for each test event: (1) **sum**, we compute the final probability vector $\boldsymbol{p}(e)$ by applying the element-wise summarization operation to the two predicted probability vectors; (2) **product**, we compute the final $\boldsymbol{p}(e)$ as the element-wise product of the two vectors. Then, the final probability vector is normalized to make sure the sum of probabilities over all classes is 1. Finally, we predict an event's human need category as the one with the highest probability.

[3]The event expression classifier first selects from unlabeled events, then the event context classifier does the selection. This ensures that there are 16 new events in total at each iteration.

Algorithm 1 Co-Training Algorithm

Input: Labeled E_L, unlabeled E_U events
while Not maximum iteration **do**
  Train the event expression classifier on E_L
  Construct context view (X_{con}) of E_L
  Train the event context classifier on X_{con}
  Apply the event expression classifier to E_U and select new labeled events (E_{exp})
  Apply the event context classifier to E_U and select new labeled events (E_{con})
  Update labeled events:
$$E_L = E_L \cup E_{exp} \cup E_{con}$$
end while

5 Evaluation

We conducted experiments to evaluate the methods described in Section 4. For all of our experiments, the results are reported based on 3-fold cross-validation on the 542 affective events manually labeled with human need categories. We show the average results over 3-folds in the following sections. For development, we used a distinct set of events labeled during preliminary studies. We did not tune any of the models, using only their default parameter settings. We present experimental results in terms of precision, recall, and F1 score, macro-averaged over the human need categories.

5.1 Performance of Event Expression Classifiers

Table 4 shows the results[4] for the event expression classifiers. We also evaluated the ability of the LIWC lexicon (Pennebaker et al., 2007) to label the event expressions. We manually aligned the relevant LIWC categories with our human need categories, as shown in Table 3. Then we labeled each event by identifying the human need category of each word in the event phrase and assign-

[4]Since we report the average precision, recall, F1 score over 3-folds, the F1 score can be smaller than both precision and recall in some cases.

ing the most frequent category to the event.[5] If no words were assigned to our categories, we labeled the event as None. The top row of Table 4 shows that LIWC achieved 39% recall but only 47.7% precision. The reason is that some categories in LIWC are more generalized compared with the definitions of our corresponding categories. For example, the words "abandon" and "damage" belong to the Affect category (corresponding to our Emotion category) in LIWC. However, based on our definition the event "my house was damaged" actually belongs to the Finance category. In this way, the Emotion category is overly generalized which leads to low precision for this class.

LIWC Category		**Human Need Category**
Ingest	→	Physiological
Health, Body, Death	→	Health
Leisure	→	Leisure
Social	→	Social
Money, Work	→	Finance
Inhib, Insight	→	Cognition
Affect	→	Emotion

Table 3: LIWC Mapping to Human Need Categories.

The LR and SVM rows in Table 4 show the performance of the logistic regression (LR) and support vector machine (SVM) classifiers, respectively. We evaluated classifiers with bag-of-words features (BOW) and classifiers with event embedding features (Embed), computed as the average of the embeddings for all words in the event expression. We also tried adding semantic category features from LIWC to each feature set, denoted as +SemCat. The results show that the Embed features performed best for both the LR and SVM classifiers. Adding the SemCat features improved upon the bag-of-word representations, but not the embeddings.

The last two rows of Table 4 show the performance of two RNN classifiers, one using lexical words as input ($\text{RNN}^{\text{Words}}$) and one using pre-trained word embeddings as input ($\text{RNN}^{\text{EmbedSeq}}$). The $\text{RNN}^{\text{EmbedSeq}}$ system takes the sequence of word embeddings as input rather than the average embeddings. As with the other classifiers, the word embedding feature representations performed best, achieving an F1 score 54.4%, which is comparable to the F1 score of the LR^{Embed} system. However, the RNN's precision was only 58%, compared to 64.2% for the logistic regression model, with only 2% higher recall that does not fully compensate for the lower precision. Neural net models often need large training sets, so the relatively small size of our training data may not be ideal for an RNN.

[5]For ties, we remove a component one by one in the order of Agent, PP, Theme until we obtain a majority label.

Method	Precision	Recall	F1
LIWC	47.7	39.0	38.6
LR^{BOW}	33.6	28.7	27.3
$\text{LR}^{\text{BOW+SemCat}}$	55.2	39.6	41.9
$\text{LR}^{\text{Embed+SemCat}}$	60.1	49.3	51.9
LR^{Embed}	**64.2**	51.7	**54.8**
SVM^{BOW}	52.3	43.1	44.8
$\text{SVM}^{\text{BOW+SemCat}}$	51.0	45.9	46.8
$\text{SVM}^{\text{Embed+SemCat}}$	50.4	48.4	48.6
$\text{SVM}^{\text{Embed}}$	51.3	50.7	50.5
$\text{RNN}^{\text{Words}}$	45.2	39.6	40.1
$\text{RNN}^{\text{EmbedSeq}}$	58.0	**53.7**	54.4

Table 4: Performance of Event Expression Classifiers

Overall, we concluded that the logistic regression classifier with event embedding features (LR^{Embed}) achieved the best performance because of its F1 score (54.8%) and higher precision (64.2%).

5.2 Performance of Event Context Classifiers

Table 5 shows the performance[4] of the event context classifiers described in Section 4.2. Since logistic regression worked best in the previous experiments, we only evaluated logistic regression classifiers in our remaining experiments. The results show that using each context sentence as an individual training instance ($\text{Context}^{\text{SentBOW}}$ and $\text{Context}^{\text{SentEmbed}}$) substantially outperformed the classifiers that merged all the context sentences as a single training instance ($\text{Context}^{\text{AllBOW}}$ and $\text{Context}^{\text{AllEmbed}}$). Overall, the best performing system $\text{Context}^{\text{SentEmbed}}$ achieved an F1 score of 44.3% with 59.1% Precision.

Method	Precision	Recall	F1
$\text{Context}^{\text{AllBOW}}$	20.6	18.0	17.8
$\text{Context}^{\text{AllEmbed}}$	38.2	29.9	29.1
$\text{Context}^{\text{SentBOW}}$	48.2	31.4	32.8
$\text{Context}^{\text{SentEmbed}}$	**59.1**	**41.9**	**44.3**

Table 5: Performance of Event Context Classifiers

It is worth noting that the precision of the best contextual classifier was only 5% below that of the best event expression classifier, while there was a 10% difference in their recall. Since they achieved (roughly) similar levels of precision and represent complementary views of events, a co-training

framework seemed like a logical way to use them together to gain additional benefits from unlabeled event data.

We also created a classifier that combined event expression features and event context features together. But combining them did not improve performance.

5.3 Performance of Self-Training and Co-Training Models

In this section, we evaluate the weakly supervised self-training and co-training methods that additionally use unlabeled data. To keep the number of unlabeled events manageable, we only used events in the AffectEvent dataset that had frequency ≥ 100, which produced an unlabeled data set of 23,866 events.

We used the best performing event expression classifier (LR^{Embed}) in these models, and the co-training framework includes the best performing event context classifier ($Context^{SentEmbed}$) as well. We also experimented with the **sum** and **product** variants for co-training (described in Section 4.4.2), which are denoted as $CoTrain^{sum}$ and $CoTrain^{prod}$. We ran both the self-training and co-training methods for 20 iterations.

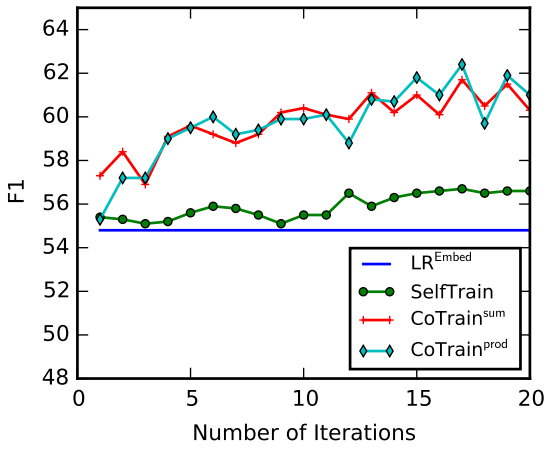

Figure 2: Learning Curves

Figure 2 tracks the performance of the self-training and co-training models after each iteration, in terms of F1 score. The flat line shows the F1 score for the best classifier that uses only labeled data (LR^{Embed}). Both types of models yield performance gains from iteratively learning with the unlabeled data, but the co-training models perform substantially better than the self-training model. Even after just 5 iterations, co-training achieves an F1 score over 58%, and by 20 iterations performance improves to $> 60\%$.

Table 6 shows the results for these models after 20 iterations, which was an arbitrary stopping criterion, and after 17 iterations, which happened to produce the best results for all three systems. The first two rows show the results of the best performing event context classifier ($Context^{SentEmbed}$) and best performing event expression classifier (LR^{Embed}) from the previous experiments, for the sake of comparison.

Table 6 shows that after 20 iterations, the $CoTrain^{prod}$ model performed best, yielding an F1 score of 61% compared to 54.8% for the LR^{Embed} model. Furthermore, we see gains in both recall and precision.

All three systems performed best after 17 iterations, so we show those results as well to give an idea of additional gains that would be possible if we could find an optimal stopping criterion. Our data set was small so we did not feel that we had enough data to fine-tune parameters, but we see the potential to further improve performance given additional tuning data.

Method	Precision	Recall	F1
Supervised Models			
$Context^{SentEmbed}$	59.1	41.9	44.3
LR^{Embed}	64.2	51.7	54.8
After 20 Iterations			
SelfTrain	63.2	54.2	56.6
$CoTrain^{sum}$	66.2	58.2	60.3
$CoTrain^{prod}$	**67.1**	**58.7**	**61.0**
Best Results, After 17 Iterations			
SelfTrain	63.5	54.1	56.7
$CoTrain^{sum}$	68.6	59.0	61.7
$CoTrain^{prod}$	**69.7**	**59.5**	**62.4**

Table 6: Performance of Self-Training and Co-Training

Table 7 shows a breakdown of the performance across the individual human need categories for two models: the best event expression classifier and the best co-training model ($CoTrain^{prod}$ after 17 iterations). We see that the co-training model outperformed the LR^{Embed} model on every category. Co-training improved performance the most for the Finance and Cognition categories, yielding F1 score gains of +12% and +16%, respectively, and notably improving both recall and precision.

5.4 Analysis

We manually examined our system's predictions to better understand its behavior. We found that most of the correctly classified Physiological

Category	LR^{Embed} Pre	Rec	F1	CoTrain^{Prod} Pre	Rec	F1
Physiological	82	57	67	81	68	**74**
Health	65	40	49	68	50	**57**
Leisure	62	59	60	69	63	**66**
Social	61	72	66	68	79	**73**
Finance	61	31	40	67	44	**52**
Cognition	75	31	42	92	46	**58**
Emotion	60	75	66	64	74	**69**
None	47	49	48	48	52	**50**

Table 7: Breakdown of results across Human Need categories. Each cell shows Precision, Recall, and F1.

events were related to food, while the correctly classified Cognition events were primarily about learning and understanding. Our method missed many events for the Health, Finance, and Cognition classes. For Health, many medical symptoms were not recognized, such as *"my face looks pale"* and *"I puked"*. For Finance, the system missed events related to possessions (e.g., *"engine stopped running"* and *"my clock is wrong"*) and jobs (e.g., *"I went to resign"*).

We also took a closer took at which categories were confused with other categories. Figure 3 shows the confusion matrix between CoTrain^{Prod} and the gold annotations. Each cell shows the total number of confusions across the 3-folds of cross-validation. The category names are abbreviated as Physiological (Phy), Health (Hlth), Leisure (Leis), Social (Socl), Finance (Fnc), Cognition (Cog), and Emotion (Emo). #Tot denotes the total number of events in each row or column.

Pred. \ Gold	Phy	Hlth	Leis	Socl	Fnc	Cog	Emo	None	#Tot
Phy	13	1	0	0	1	0	0	2	17
Hlth	1	26	1	0	1	1	4	8	42
Leis	1	1	48	4	0	1	4	10	69
Socl	0	6	4	84	2	3	10	11	120
Fnc	1	0	2	0	13	0	1	5	22
Cog	0	0	0	0	0	12	1	2	15
Emo	1	5	12	12	3	1	91	16	141
None	2	13	8	8	9	8	17	51	116
#Tot	19	52	75	108	29	26	128	105	542

Figure 3: Confusion between Predictions and Gold.

The co-training model had difficulty distinguishing the None category from other classes, presumably because None does not have its own semantics but is used for affective events that do not belong to any of the other categories. We also see that the system often confuses Emotion with Leisure and Social. This happens because many event expressions contain words that refer to emotions. Our guidelines instructed annotators to focus on the event and assign the Emotion label only when no event is described beyond an emotion (e.g., *"I was thrilled"*). Consequently, the gold label of *"I love journey"* is Leisure and *"I'm worried about my mom"* is Social, but both were classified by the system as Emotion. In future work, it may be advantageous to allow event expressions to be labeled as both an explicit Emotion and a Human Need category based on the target of the emotion.

6 Conclusions

In this work, we introduced a new challenge to recognize the reason for the affective polarity of events in terms of basic human needs. We designed four types of classification methods to categorize affective events according to human need categories, exploiting both labeled and unlabeled data. We first evaluated event expression and event context classifiers, trained using only labeled data. Then we designed self-training and co-training methods to additionally exploit unlabeled data. A co-training model that simultaneously trains event expression and event context classifiers produced substantial performance gains over the individual models. However, performance on the human need categories still has substantial room for improvement. In future work, obtaining more human annotations will be useful to build a better human needs categorization system. In addition, applying and analyzing the human needs of affective events in narrative stories and conversations is a fruitful and interesting direction for future research.

The Argument Reasoning Comprehension Task: Identification and Reconstruction of Implicit Warrants

Abstract

Reasoning is a crucial part of natural language argumentation. To comprehend an argument, one must analyze its *warrant*, which explains why its claim follows from its premises. As arguments are highly contextualized, warrants are usually presupposed and left implicit. Thus, the comprehension does not only require language understanding and logic skills, but also depends on common sense. In this paper we develop a methodology for reconstructing warrants systematically. We operationalize it in a scalable crowdsourcing process, resulting in a freely licensed dataset with warrants for 2k authentic arguments from news comments.[1] On this basis, we present a new challenging task, the *argument reasoning comprehension task*. Given an argument with a claim and a premise, the goal is to choose the correct implicit warrant from two options. Both warrants are plausible and lexically close, but lead to contradicting claims. A solution to this task will define a substantial step towards automatic warrant reconstruction. However, experiments with several neural attention and language models reveal that current approaches do not suffice.

1 Introduction

Most house cats face enemies. Russia has the opposite objectives of the US. There is much innovation in 3-d printing and it is sustainable.

What do the three propositions have in common? They were never uttered but solely presupposed in arguments made by the participants of online discussions. Presuppositions are a fundamental pragmatic instrument of natural language argumentation in which parts of arguments are left unstated. This phenomenon is also referred to as common knowledge (Macagno and Walton, 2014, p. 218), enthymemes (Walton, 2007b, p. 12), tacit major premises (Amossy, 2009, p. 319), or implicit *warrants* (Newman and Marshall, 1991, p. 8). Wilson and Sperber (2004) suggest that, when we comprehend arguments, we reconstruct their warrants driven by the cognitive principle of relevance. In other words, we go straight for the interpretation that seems most relevant and logical within the given context (Hobbs et al., 1993). Although any incomplete argument can be completed in different ways (Plumer, 2016), it is assumed that certain knowledge is shared between the arguing parties (Macagno and Walton, 2014, p. 180).

Filling the gap between the claim and premises (aka reasons) of a natural language argument empirically remains an open issue, due to the inherent difficulty of reconstructing the world knowledge and reasoning patterns in arguments. In a direct fashion, Boltužić and Šnajder (2016) let annotators write down implicit warrants, but they concluded only with a preliminary analysis due to large variance in the responses. In an indirect fashion, implicit warrants correspond to major premises in argumentation schemes; a concept heavily referenced in argumentation theory (Walton, 2012). However, mapping schemes to real-world arguments has turned out difficult even for the author himself.

Our main hypothesis is that, even if there is no limit to the tacit length of the reasoning chain between claims and premises, it is possible to systematically reconstruct a meaningful warrant, depending only on what we take as granted and what needs to be explicit. As warrants encode our current presupposed world knowledge and connect the reason with the claim in a given argument, we expect that other warrants can be found which connect the reason with a different claim. In the ex-

Title: Is Marijuana a Gateway Drug? **Description:** Does using marijuana lead to the use of more dangerous drugs, making it too dangerous to legalize?

Reason: Milk isn't a gateway drug even though most people drink it as children. And since {*Warrant 1* | *Warrant 2*}, **Claim:** Marijuana is not a gateway drug.

✔ **Warrant 1:** milk is similar to marijuana

✗ **Warrant 2:** milk is not marijuana

Figure 1: Instance of the argument reasoning comprehension task. The correct warrant has to be identified. Notice the fallacious presupposed false analogy used by the author to make the argument.

treme case, there may exist an *alternative warrant* in which the same reason is connected to the opposite claim.

The intuition of alternative warrants is key to the systematic methodology that we develop in this paper for reconstructing a warrant for the original claim of an argument. In particular, we first 'twist' the stance of a given argument, trying to plausibly explain its reasoning towards the opposite claim. Then, we twist the stance back and use a similar reasoning chain to come up with a warrant for the original argument. As we discuss further below, this works for real-world arguments with a missing piece of information that is taken for granted and considered as common knowledge, yet, would lead to the opposite stance if twisted.

We demonstrate the applicability of our methodology in a large crowdsourcing study. The study results in 1,970 high-quality instances for a new task that we call *argument reasoning comprehension*: Given a reason and a claim, identify the correct warrant from two opposing options. An example is given in Figure 1. A solution to this task will represent a substantial step towards automatic warrant reconstruction. However, we present experiments with several neural attention and language models which reveal that current approaches based on the words and phrases in arguments and warrants do not suffice to solve the task.

The main contributions of this paper are (1) a *methodology* for obtaining implicit warrants realized by means of scalable crowdsourcing and (2) a new *task* along with a high-quality dataset. In addition, we provide (a) 2,884 user-generated arguments annotated for their stance, covering 50+ controversial topics, (b) 2,026 arguments with annotated reasons supporting the stance, (c) 4,235 rephrased reason gists, useful for argument summarization and sentence compression, and (d) a method for checking the reliability of crowdworkers in document and span labeling using traditional inter-annotator agreement measures.

2 Related Work

It is widely accepted that an argument consists of a *claim* and one or more *premises* (reasons) (Damer, 2013). Toulmin (1958) elaborated on a model of argument in which the reason supports the claim on behalf of a *warrant*. The abstract structure of an argument then is *Reason* → (since) *Warrant* → (therefore) *Claim*. The warrant takes the role of an inference rule, similar to the *major premise* in Walton's terminology (Walton, 2007a).

In principle, the chain *Reason* → *Warrant* → *Claim* is applicable to deductive arguments and syllogisms, which allows us to validate arguments properly formalized in propositional logic. However, most natural language arguments are in fact inductive (Govier, 2010, p. 255) or defeasible (Walton, 2007b, p. 29).[2] Accordingly, the unsuitability of formal logic for natural language arguments has been discussed by argumentation scholars since the 1950's (Toulmin, 1958). To be clear, we do not claim that arguments cannot be represented logically (e.g., in predicate logic), however the drift to *informal logic* in the 20th century makes a strong case that natural language argumentation is more than modus ponens (van Eemeren et al., 2014).

In argumentation theory, the notion of a *warrant* has also been contentious. Some argue that the distinction of warrants from premises is clear only in Toulmin's examples but fails in practice, i.e., it is hard to tell whether the reason of a given argument is a premise or a warrant (van Eemeren et al., 1987, p. 205). However, Freeman (2011) provides alternative views on modeling an argument. Given a claim and two or more premises, the argument structure is *linked* if the reasoning step involves the logical conjunction of the premises. If we treat a warrant as a simple premise, then the linked structure fits the intuition behind Toulmin's model, such that premise and warrant combined give support to the claim. For details, see (Freeman, 2011, Chap. 4).

[2] A recent empirical example is provided by Walker et al. (2014) who propose possible approaches to identify patterns of inference from premises to claims in vaccine court cases. The authors conclude that it is extremely rare that a reasoning is explicitly laid out in a deductively valid format.

What makes comprehending and analyzing arguments hard is that claims and warrants are usually implicit (Freeman, 2011, p. 82). As they are 'taken for granted' by the arguer, the reader has to infer the contextually most relevant content that she believes the arguer intended to use. To this end, the reader relies on common sense knowledge (Oswald, 2016; Wilson and Sperber, 2004).

The reconstruction of implicit premises has already been faced in computational approaches. In light of the design of their argument diagramming tool, Reed and Rowe (2004) pointed out that the automatic reconstruction is a task that skilled analysts find both taxing and hard to explain. More recently, Feng and Hirst (2011) as well as Green (2014) outlined the reconstruction of missing enthymemes or warrants as future work, but they never approached it since. To date, the most advanced attempt in this regard is from Boltužić and Šnajder (2016). The authors let annotators 'reconstruct' several propositions between premises and claims and investigated whether the number of propositions correlates with the semantic distance between the claim and the premises. However, they conclude that the written warrants heavily vary both in depth and in content. By contrast, we explore cases with a missing single piece of information that is considered as common knowledge, yet leading to the opposite conclusion if twisted. Recently, Becker et al. (2017) also experimented with reconstructing implicit knowledge in short German argumentative essays. In contrast to our work, they used expert annotators who iteratively converged to a single proposition.

As the task we propose involves natural language comprehension, we also review relevant work outside argumentation here. In particular, the goal of the semantic inference task *textual entailment* is to classify whether a proposition entails or contradicts a hypothesis (Dagan et al., 2009). A similar task, *natural language inference*, was boosted by releasing the large SNLI dataset (Bowman et al., 2015) containing 0.5M entailment pairs crowdsourced by describing pictures. While the understanding of semantic inference is crucial in language comprehension, argumentation also requires coping with phenomena beyond semantics. Rajpurkar et al. (2016) presented a large dataset for reading comprehension by answering questions over Wikipedia articles (SQuAD). In an analysis of this dataset Sugawara and Aizawa (2016) found, though, that only 6.2% of the questions require causal reasoning, 1.2% logical reasoning, and 0% analogy. In contrast, these reasoning types often make up the core of argumentation (Walton, 2007a). Mostafazadeh et al. (2016) introduced the *cloze story test*, in which the appropriate ending of a narrative has to be selected automatically. The overall context of this task is completely different to ours. Moreover, the narratives were written from scratch by explicitly instructing crowd workers, whereas our data come from genuine argumentative comments. Common-sense reasoning was also approached by Angeli and Manning (2014) who targeted the inference of commonsense facts from a large knowledge base. Since their logical formalism builds upon an enhanced version of Aristotle's syllogisms, its applicability to natural language argumentation remains limited (see our discussion above). In contrast to our data source, a few synthetic datasets for general natural language reasoning have been recently introduced, such as answers to questions over a described physical world (Weston et al., 2016) or an evaluation set of 100 questions in the Winograd Schema Challenge (Levesque et al., 2012).

Finally, we note that, although being related, research on argument mining, argumentation quality, and stance classification is not in the immediate scope of this paper. For details on these, we therefore refer to recent papers from Lippi and Torroni (2016); Habernal and Gurevych (2017) or Mohammad et al. (2016).

3 Argument Reasoning Comprehension

Let R be a reason for a claim C, both of which being propositions extracted from a natural language argument. Then there is a warrant W that justifies the use of R as support for C, but W is left implicit.

For example, in a discussion about whether declawing a cat should be illegal, an author takes the following position (which is her claim C): 'It should be illegal to declaw your cat'. She gives the following reason (R): 'They need to use their claws for defense and instinct'.[3] The warrant W could then be 'If cat needs claws for instincts, declawing would be against nature' or similar. W remains implicit, because R already implies C quite obviously and so, according to common sense, any further explanation seems superfluous.

[3]The example is taken from our dataset introduced below.

Now, the question is how to find the warrant W for a given reason R and claim C. Our key hypothesis in the definition of the argument reasoning comprehension task is the existence of an *alternative warrant* AW that justifies the use of R as support for the opposite $\neg C$ of the claim C (regardless of the question of how strong this justification is).

For the example above, assume that we 'twist' C to 'It should be *legal* to declaw your cat' ($\neg C$) but use the same reason R. Is it possible to come up with an alternative warrant AW that justifies R? In the given case, 'most house cats don't face enemies' would bridge R to $\neg C$ quite plausibly. If we now use a reasoning based on AW but twist AW again such that it leads to the claim C, we get 'most house cats face enemies', which is a plausible warrant W for the original argument containing R and C. [4]

Constructing an alternative warrant is not possible for all reason/claim pairs; in some reasons the arguer's position is deeply embedded. As a result, trying to give a plausible reasoning for the opposite claim $\neg C$ either leads to nonsense or to a proposition that resembles a rebuttal rather than a warrant (Toulmin, 1958). However, if both W and AW are available, they usually capture the core of a reason's relevance and reveal the implicit presuppositions (examples follow further below).

Based on our key hypothesis, we define the argument reasoning comprehension task as:

Given a reason R and a claim C along with the title and a short description of the debate they occur in, identify the correct warrant W from two candidates: the correct warrant W and an incorrect alternative warrant AW.

An instance of the task is thus basically given by a tuple (R, C, W, AW). The debate title and description serve as the context of R and C. As it is binary, we propose to evaluate the task using accuracy.

4 Reconstruction of Implicit Warrants

We now describe our methodology to systematically reconstruct implicit warrants, along with the scalable crowdsourcing process that operationalizes the methodology. The result of the process is a dataset with authentic instances (R, C, W, AW) of the argument reasoning comprehension task.

4.1 Source Data

Instead of extending an existing dataset, we decided to create a new one from scratch, because we aimed to study a variety of controversial issues in user-generated web comments and because we sought for a dataset with a permissive license.

As a source, we opted for the *Room for Debate* section of the New York Times.[5] It provides authentic argumentation on contemporary issues with good editorial work and moderation — as opposed to debate portals such as *createdebate.com*, where classroom assignments, silly topics, and bad writing prevail. We manually selected 188 debates with polar questions in the title. These questions are controversial and provoking, giving a stimulus for stance-taking and argumentation.[6] For each debate we created two explicit opposing claims, e.g., 'It should be illegal to declaw your cat' and 'It should be legal to declaw your cat'. We crawled all comments from each debate and sampled about 11k high-ranked, root-level comments.[7]

4.2 Methodology and Crowdsourcing Process

The methodology we propose consists of eight consecutive steps that are illustrated in Figure 2 and detailed below. Each step can be operationalized with crowdsourcing. For our dataset, we performed crowdsourcing on 5,000 randomly sampled comments using Amazon Mechanical Turk (AMT) from December 2016 to April 2017. Before, each comment was split into elementary discourse units (EDUs) using SistaNLP (Surdeanu et al., 2015).

1. Stance Annotation For each comment, we first classify what stance it is taking (recall that we always have two explicit claims with opposing stance). Alternatively, it may be neutral (consider-

[4] This way, we also reveal the weakness of the original argument that was hidden in the implicit premise. It can be challenged by asking the arguer whether house cats really face enemies.

[5] https://www.nytimes.com/roomfordebate

[6] Detailed theoretical research on polar and alternative questions can be found in (van Rooy and Šafářová, 2003); Asher and Reese (2005) analyze bias and presupposition in polar questions.

[7] To remove 'noisy' candidates, we applied several criteria, such as the absence of quotations or URLs and certain lengths. For details, see the source code we provide. We did not check any quality criteria of arguments, as this was not our focus; see, e.g., (Wachsmuth et al., 2017) for argumentation quality.

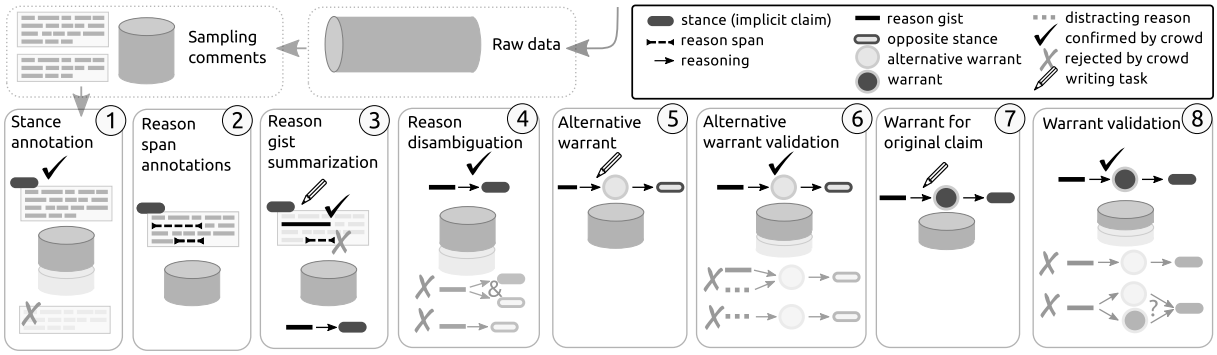

Figure 2: Overview of the methodology of reconstructing implicit warrants for argument reasoning comprehension.

ing both sides) or may not take any stance.[8]

All 2,884 comments in our dataset classified as stance-taking by the crowdworkers were then also annotated as to whether being sarcastic or ironic; both pose challenges in analyzing argumentation not solved so far (Habernal and Gurevych, 2017).

2. Reason Span Annotation For all comments taking a stance, the next step is to select those spans that give a reason for the claim (with a single EDU as the minimal unit).

In our dataset, the workers found 5,119 reason spans, of which 2,026 lay within arguments. About 40 comments lacked any explicit reason.

3. Reason Gist Summarization This new task is, in our view, crucial for downstream annotations. Each reason from the previous step is rewritten, such that the reason's gist in the argument remains the same but the clutter is removed (examples are given in the supplementary material which is available both in the ACL Anthology and the project GitHub site). Besides, wrongly annotated reasons are removed in this step. The result is pairs of reason R and claim C.

All 4,294 gists in our dataset were summarized under Creative Commons Zero license (CC-0).

4. Reason Disambiguation Within our methodology, we need to be able to identify to what extent a reason itself implies a stance: While 'C because R' allows for many plausible interpretations (as discussed above), whether $R \rightarrow C$ or $R \rightarrow \neg C$ depends on how much presupposition is encoded in R. In this step, we decide which claim (C or $\neg C$) is most plausible for R, or whether both are similarly plausible (in the given data, respective reasons turned out to be rather irrelevant though).

We used only those 1,955 instances where R indeed implied C according to the workers, as this suggests at least some implicit presupposition in R.

5. Alternative Warrant This step is the trickiest, since it requires both creativity and 'brain twisting'. As exemplified in Section 3, a plausible explanation needs to be given why R supports $\neg C$ (i.e., the alternative warrant AW). Alternatively, this may be classified as being impossible.

Exact instructions for our workers can be found in the provided sources. All 5,342 alternative warrants in our dataset are written under CC-0 license.

6. Alternative Warrant Validation As the previous step produces largely uncontrolled writings, we validate each fabricated alternative warrant AW as to whether it actually relates to the reason R. To this end, we show AW and $\neg C$ together with two alternatives: R itself and a distracting reason. Only instances with correctly validated R are kept.

For our dataset, we sampled the distracting reason from the same debate topic, using the most dissimilar to R in terms of skip-thought vectors (Kiros et al., 2015) and cosine similarity. We kept 3,791 instances, for which the workers also rated how 'logical' the explanation of AW was (0–2 scale).

7. Warrant For Original Claim This step refers to the second task in the example from Section 3: Given R and C, make minimal modifications to the alternative warrant AW, such that it becomes an actual warrant W (i.e., such that $R \rightarrow W \rightarrow C$).

For our dataset, we restricted this step to those 2,613 instances that had a 'logic score' of at least 0.68 (obtained from the annotations mentioned

[8] We also experimented with approaching the annotations top-down starting by annotating explicit claims, but the results were unsatisfying. This is in line with empirical observations made by Habernal and Gurevych (2017) who showed that the majority of claims in user-generated arguments are implicit.

above), in order to filter out nonsense alternative warrants. All resulting 2,447 warrants were written by the workers again under CC0 license.

8. Warrant Validation To ensure that each tuple (R,C,W,AW) allows only one logical explanation (i.e., either $R \rightarrow W \rightarrow C$ or $R \rightarrow AW \rightarrow C$ is correct, not both), all instances are validated again.

Disputed cases in the dataset (according to our workers) were fixed by an expert to ensure quality. We ended up with 1,970 instances to be used for the argument reasoning comprehension task.

4.3 Agreement and Dataset Statistics

To strictly assess quality in the entire crowdsourcing process, we propose an evaluation method that enables 'classic' inter-annotator agreement measures for crowdsourcing, such as Fleiss' κ or Krippendorff's α. Applying κ and α directly to crowdsourced data has been disputed (Passonneau and Carpenter, 2014). For estimating gold labels from the crowd, several models have been proposed; we rely on MACE (Hovy et al., 2013). Given a number of noisy workers, MACE outputs best estimates, outperforming simple majority votes. At least five workers are recommended for a crowdsourcing task, but how reliable is the output really?

We hence collected 18 assignments per item and split them into two groups (9+9) based on their submission time. We then considered each group as an independent crowdsourcing experiment and estimated gold labels using MACE for each group, thus yielding two 'experts from the crowd.' Having two independent 'experts' from the crowd allowed us to compute standard agreement scores. We also varied the size of the sub-sample from each group from 1 to 9 by repeated random sampling of assignments. This revealed how the score varies with respect to the crowd size per 'expert'.

Figure 3 shows the Cohen's κ agreement for stance annotation with respect to the crowd size computed by our method. As MACE also includes a threshold for keeping only the most confident predictions in order to benefit precision, we tuned this parameter, too. Deciding on the number of workers per task is a trade-off between the desired quality and the budget. For example, reason span annotation is a harder task; however, the results for six workers are comparable to those for the expert annotations of Habernal and Gurevych (2017).[9]

[9]The supplementary material contains a detailed figure; not to be confused with Figure 3 which refers to stance annotation.

Figure 3: Cohen's κ agreement for stance annotation on 98 comments. As a trade-off between reducing costs (i.e., discarding fewer instances) and increasing reliability, we chose 5 annotators and a threshold of 0.95 for this task, which resulted in $\kappa = 0.58$ (moderate to substantial agreement).

Table 1 lists statistics of the entire crowdsourcing process carried out for our dataset, including tasks for which we created data as a by-product.

4.4 Examples

Below, we show three examples in which implicit common-sense presuppositions were revealed during the construction of the alternative warrant *AW* and the original warrant *W*. For brevity, we omit the debate title and description here. A full walkthrough example is found in the supplementary material.

R: Cooperating with Russia on terrorism ignores Russia's overall objectives.
C: Russia cannot be a partner.
AW: Russia has the same objectives of the US.
W: Russia has the opposite objectives of the US.

R: Economic growth needs innovation.
C: 3-D printing will change the world.
AW: There is no innovation in 3-d printing since it's unsustainable.
W: There is much innovation in 3-d printing and it is sustainable.

R: College students have the best chance of knowing history.
C: College students' votes do matter in an election.
AW: Knowing history doesn't mean that we will repeat it.
W: Knowing history means that we won't repeat it.

5 Experiments

Given the dataset, we performed first experiments to assess the complexity of argument reasoning comprehension. To this end, we split the 1,970 instances into three sets based on the year of the de-

#	Methodology Step	Input Sata	Size	Output Data	Size	Quality Assurance	Use of Data
1	Stance annotation	Comment, topic	5,000	Stance-taking arguments	2,884	Cohen's κ 0.58	Argument stance detection; sarcastic argument detection
2	Reason span annotation	Stance-taking argument	2,884	Reason spans (in arguments)	5,119 (2,026)	Krippendorff's α_u 0.51	Argument component detection; argumentative text segmentation
3	Reason gist summarization	Claim, reason span	5,119	Summarized reason gists (in arguments)	4,294 (1,927)	Qualified workers, manual inspection	Abstractive argument summarization; reason clustering; empirical analysis of controversies
4	Reason disambiguation	Reason gist, both claims	4,235	Reasons implying original stance	1,955	Cohen's κ 0.42 (task-important categories)	Argument component stance detection
5	Writing alternative warrant	Reason gist, opposing claim	1,955	Fabricated warrant for reason and opposing claim	5,342	Qualified workers, manual inspection	–
6	Alternative warrant validation	Opposing claim, alternative warrant, reason, distracting reason	5,342	Plausible triple of reason, alternative warrant, and opposing claim	3,791	–	Reason/Warrant relevance detection
7	Writing warrant for original claim	Claim, reason, alternative warrant	2,613*	Warrant similar to alternative warrant for reason and claim	2,447	Qualified workers, manual inspection	–
8	Warrant validation	Claim, reason, warrant, alternative warrant	2,447	Validated triple of reason, warrant, and claim	1,970	Qualified workers, experts for hard cases	Argument reasoning comprehension (our main task)

Table 1: Details and statistics of the datasets resulting from the eight steps of our methodology implemented in a crowdsourcing process. *Input instances were filtered by their 'logic score' assigned in Step 6, such that the weakest 30% were discarded. A more detailed description is available in the readme file of the source code.

bate they were taken from: 2011–2015 became the training set (1,210 instances), 2016 the development set (316 instances), and 2017 the test set (444 instances). This follows the paradigm of learning on past data and predicting on new ones. In addition, it removes much lexical and topical overlap.

5.1 Human Upper Bounds

To evaluate human upper bounds for the task, we sampled 100 random questions (such as those presented in Section 4.4) from the test set and distributed them among 173 participants of an AMT survey. Every participant had to answer 10 questions. We also asked the participants about their highest completed education (six categories) and the amount of formal training they have in reasoning, logic, or argumentation (no training, some, or extensive). In addition, they specified for each question how familiar they were with the topic (3-point scale).

How Hard is the Task for Humans? It depends, as shown in Figure 4. Whereas education had almost negligible influence on the performance, the more extensive formal training in reasoning the participants had, the higher their score was. Overall, 30 of the 173 participants scored 100%. The mean score for those with extensive

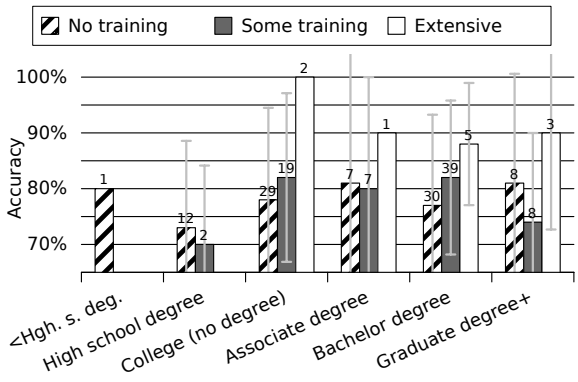

Figure 4: Human upper bounds on the argument reasoning comprehension task with respect to education and formal training in reasoning, logic, or argumentation. For each configuration, the mean values are displayed together with the number of participants (above the bar) and with their standard deviations (error bars).

formal training was 90.9%. For all participants, the mean was 79.8%. However, we have to note that some of the questions are more difficult than others, for which we could not control explicitly.

Does Topic Familiarity Affect Human Performance? Not really, i.e., we found no significant (Spearman) correlation between the mean score and familiarity of a participant in almost all education/training configurations. This suggests that ar-

gument reasoning comprehension skills are likely to be independent of topic-specific knowledge.

5.2 Computational Models

To assess the complexity of computationally approaching argument reasoning comprehension, we carried out first experiments with systems based on the following models.

The simplest considered model was the *random baseline*, which chooses either of the candidate warrants of an instance by chance. As another baseline, we used a 4-gram Modified Kneser-Ney *language model* trained on 500M tokens (100k vocabulary) from the C4Corpus (Habernal et al., 2016). The effectiveness of language models was demonstrated by Rudinger et al. (2015) for the narrative cloze test where they achieved state-of-the-art results. We computed log-likelihood of the candidate warrants and picked the one with lower score.[10]

To specifically appoach the given task, we implemented two neural models based on a bidirectional LSTM. In the standard *attention* version, we encoded the reason and claim using a BiLSTM and provided it as an attention vector after max-pooling to LSTM layers from the two available warrants W_0 and W_1 (corresponding to W and AW, see below). Our more elaborated version used *intra-warrant attention*, as shown in Figure 5. Both versions were also extended with the debate title and description added as context to the attention layer (*w/ context*). We trained the resulting four models using the ADAM optimizer, with heavy dropout (0.9) and early stopping (5 epochs), tuned on the development set. Input embeddings were pre-trained word2vec's (Mikolov et al., 2013). We ran each model three times with random initializations.

To evaluate all systems, each instance in our dataset is represented as a tuple (R, C, W_0, W_1) with a label (0 or 1). If the label is 0, W_0 is the correct warrant, otherwise W_1. Recall that we have two warrants W and AW whose correctness depends on the claim: W is correct for R and the original claim C, whereas AW would be correct for R and the opposite claim $\neg C$. We thus doubled the training data by adding a permuted instance (R, C, W_1, W_0) with the respective correct label; this led to increased performance. The overall

[10] This might seem counterintuitive, but since W is created by rewriting AW, it may suffer from some dis-coherency, which is then caught by the language model.

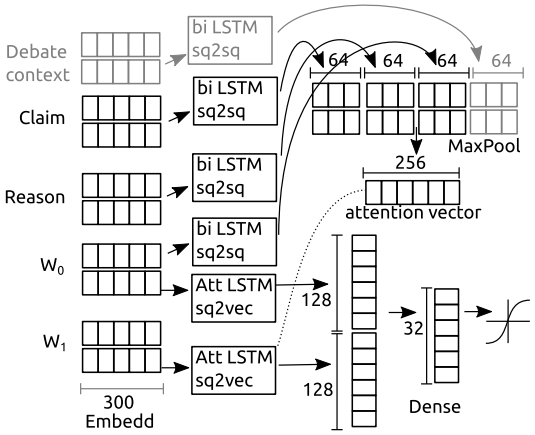

Figure 5: Intra-warrant attention. Only the attention vector for the warrant W_1 is shown; the attention vector for W_0 is constructed analogously. Grey areas represent a modification with additional context.

results of all approaches (humans and systems) are shown in Table 2. Intra-warrant attention with rich context outperforms standard neural models with a simple attention, but it only slightly beats the language model on the dev set. The language model is basically random on the test set.

A manual error analysis of 50 random wrong predictions (a single run of the best-performing system on the dev set) revealed no explicit pattern of encountered errors. Drawing any conclusions is hard given the diversity of included topics and the variety of reasoning patterns. A possible approach would be to categorize warrants using, e.g., argumentation schemes (Walton et al., 2008) and break down errors accordingly. However, this is beyond the scope here and thus left for future work.

Can We Benefit from Alternative Warrants and Opposite Claims? Since the reasoning chain $R \rightarrow AW \rightarrow \neg C$ is correct, too, we also tried adding respective instances to the training set (thus doubling the size). In this configuration, however, the neural models failed to learn anything better than a random guess. The reason behind is probably that the opposing claims are lexically very close, usually negated, and the models cannot pick this up. This underlines that argument reasoning comprehension cannot be solved by simply looking at the occurring words or phrases.

6 Conclusion and Outlook

We presented a new task called *argument reasoning comprehension* that tackles the core of reasoning in natural language argumentation — im-

Approach	Dev	(±)	Test	(±)
Human average			.798	.162
Human w/ training in reasoning			.909	.114
Random baseline	.473	.039	.491	.031
Language model	.617		.500	
Attention	.488	.006	.513	.012
Attention w/ context	.502	.031	.512	.014
Intra-warrant attention	**.638**	.024	.556	.016
Intra-warrant attent. w/ context	.637	.040	**.560**	.055

Table 2: Accuracy of each approach (humans and systems) on the development set and test set, respectively.

plicit warrants. Moreover, we proposed a methodology to systematically reconstruct implicit warrants in eight consecutive steps. So far, we implemented the methodology in a manual crowdsourcing process, along with a strategy that enables standard inter-annotator agreement measures in crowdsourcing.

Following the process, we constructed a new dataset with 1,970 instances for the task. This number might not seem large (e.g., compared to 0.5M from SNLI), but tasks with hand-crafted data are of a similar size (e.g., 3,744 Story Cloze Test instances). Also, the crowdsourcing process is scalable and is limited only by the budget.[11] Moreover, we created several data 'by-products' that are valuable for argumentation research: 5,000 comments annotated with stance, which outnumbers the 4,163 tweets for stance detection of Mohammad et al. (2016); 2,026 arguments with 4,235 annotated reasons, which is six times larger than the 340 documents of Habernal and Gurevych (2017); and 4,235 summarized reason gists — we are not aware of any other hand-crafted dataset for abstractive argument summarization built upon authentic arguments.

Based on the dataset, we evaluated human performance in argument reasoning comprehension. Our findings suggest that the task is harder for people without formal argumentation training, while being solvable without knowing the topic. We also found that neural attention models outperform language models on the task.

In the short run, we plan to draw more attention to this topic by running a SemEval 2018 shared task.[12] A deep qualitative analysis of the warrants from the theoretical perspective of reasoning patterns or argumentation schemes is also necessary. In the long run, an automatic generation and validation warrants can be understood as the ultimate goal in argument evaluation. It has been claimed that for reconstructing and evaluating natural language arguments, one has to fully 'roll out' their implicit premises (van Eemeren et al., 2014, Chap. 3.2) and leverage knowledge bases (Wyner et al., 2016). We believe that a system that can distinguish between the wrong and the right warrant given its context will be helpful in filtering out good candidates in argument reconstruction.

For the moment, we just made a first empirical step towards exploring how much common-sense reasoning is necessary in argumentation and how much common sense there might be at all.

[11] In our case, the total costs were about $6,000 including bonuses and experiments with the workflow set-up.

Linguistic Cues to Deception and Perceived Deception in Interview Dialogues

Abstract

We explore deception detection in interview dialogues. We analyze a set of linguistic features in both truthful and deceptive responses to interview questions. We also study the perception of deception, identifying characteristics of statements that are perceived as truthful or deceptive by interviewers. Our analysis show significant differences between truthful and deceptive question responses, as well as variations in deception patterns across gender and native language. This analysis motivated our selection of features for machine learning experiments aimed at classifying globally deceptive speech. Our best classification performance is 72.74 F1-Score (about 27% better than human performance), which is achieved using a combination of linguistic features and individual traits.

1 Introduction

Deception detection is a critical problem studied by psychologists, criminologists, and computer scientists. In recent years the NLP and speech communities have increased their interest in deception detection. Language cues are inexpensive and easy to collect, and research examining text-based and speech-based cues to deception has been quite promising. Prior work has examined deceptive language in several domains, including fake reviews, mock crime scenes, and opinions about topics such as abortion or the death penalty. In this work we explore the domain of interview dialogues, which are similar to many real-world deception conditions.

Previous work has presented the results of classification experiments using linguistic features, attempting to identify which features contribute most to classification accuracy. However, studies often do not include an empirical analysis of features. We might know that a particular feature set (e.g. LIWC categories) is useful for deception classification, but we lack insight about the nature of the deceptive and truthful language that makes the feature set useful, and whether the differences in language use are statistically significant. In this work we conduct an empirical analysis of feature sets and report on the different characteristics of truthful and deceptive language. In addition, previous work has focused on the characteristics of deceptive language, and not on the characteristics of *perceived* deceptive language. We are also interested in human perception of deception; that is, what are the characteristics of language that listeners perceive as truthful or deceptive? We examine a unique dataset that includes information about both the deceiver and the interviewer, along with interviewer judgments of deception. Along with an analysis of deceptive and truthful speech, we analyze the believed and disbelieved speech, according to reported interviewer judgments. Finally, previous work has focused on general inferences about deception; here we include analysis of gender and native language, to study their effect on deceptive behavior, and also their effect on perception of deception. This work contributes to the critical problem of automatic deception detection, and increases our scientific understanding of deception, deception perception, and speaker differences in deceptive behavior.

The paper is organized as follows: In Section 2 we review related work in language-based cues to deception. Section 3 describes the dataset used for this work, and Section 4 details the different feature sets we employ. In Section 5, we report on the results of our empirical study of indicators of deception and perceived deception, as well as gender and native language differences. Section 6 presents our machine learning classification results using the deception indicator feature sets. We conclude in Section 7 with a discussion and ideas

for future work.

2 Related Work

Language-based cues to deception have been analyzed in many genres. Ott et al. (2011) compared approaches to automatically detecting deceptive opinion spam, using a crowdsourced dataset of fake hotel reviews. Several studies use a fake opinion paradigm for collecting data, instructing subjects to write or record deceptive and truthful opinions about controversial topics such as the death penalty or abortion, or about a person that they like/dislike (Newman et al., 2003; Mihalcea and Strapparava, 2009). Other research has focused on real-world data obtained from court testimonies and depositions (Fornaciari and Poesio, 2013; Bachenko et al., 2008; Pérez-Rosas et al., 2015). Real-world deceptive situations are high-stakes, where there is much to be gained or lost if deception succeeds or fails; it is hypothesized that these conditions are more likely to elicit strong cues to deception. However, working with such data requires extensive research to annotate each utterance for veracity, so such datasets are often quite small and not always reliable.

Linguistic features such as n-grams and language complexity have been analyzed as cues to deception (Pérez-Rosas and Mihalcea, 2015; Yancheva and Rudzicz, 2013). Syntactic features such as part of speech tags have also been found to be useful for structured data (Ott et al., 2011; Feng et al., 2012). Statement Analysis (Adams, 1996) is a text-based deception detection approach that combines lexical and syntactic features. An especially useful resource for text-based deception detection is the Linguistic Inquiry and Word Count (LIWC) (Pennebaker and King, 1999), which groups words into psychologically motivated categories. In addition to lexical features, some studies have examined acoustic-prosodic cues to deception (Rockwell et al., 1997; Enos, 2009; Mendels et al., 2017). (Benus et al., 2006) studied pause behavior in deceptive speech. This work is very promising, but it is more difficult to obtain large, cleanly recorded speech corpora with deception annotations than to obtain text corpora. An excellent meta-study of verbal cues to deception can be found in (DePaulo et al., 2003).

3 Data

3.1 Corpus

For this work, we examined the Columbia X-Cultural Deception (CXD) Corpus (Levitan et al., 2015a) a collection of within-subject deceptive and non-deceptive speech from native speakers of Standard American English (SAE) and Mandarin Chinese (MC), all speaking in English. The corpus contains dialogues between 340 subjects. A variation of a fake resume paradigm was used to collect the data. Previously unacquainted pairs of subjects played a ”lying game” with each other. Each subject filled out a 24-item biographical questionnaire and were instructed to create false answers for a random half of the questions. They also reported demographic information including gender and native language, and completed the NEO-FFI personality inventory (Costa and McCrae, 1989).

The lying game was recorded in a sound booth. For the first half of the game, one subject assumed the role of the interviewer, while the other answered the biographical questions, lying for half and telling the truth for the other; questions chosen in each category were balanced across the corpus. For the second half of the game, the subjects roles were reversed, and the interviewer became the interviewee. During the game, the interviewer was allowed to ask the 24 questions in any order s/he chose; the interviewer was also encouraged to ask follow-up questions to aid them in determining the truth of the interviewees answers. Interviewers recorded their judgments for each of the 24 questions, providing information about human perception of deception. The entire corpus was orthographically transcribed using the Amazon Mechanical Turk (AMT)[1] crowd-sourcing platform, and the speech was segmented into *inter-pausal units* (IPUs), defined as pause-free segments of speech separated by a minimum pause length of 50 ms. The speech was also segmented into turn units, where a turn is defined as a maximal sequence of IPUs from a single speaker without any interlocutor speech that is not a *backchannel*. There are two forms of deception annotations in the corpus: local and global. Interviewees labeled their responses with local annotations by pressing a ”T” or ”F” key for each utterance as they spoke. These keypresses were automatically aligned with speaker IPUs and turns. Global la-

[1] https://www.mturk.com/mturk/

bels were provided by the biographical questionnaire, where each of the 24 questions was labeled as truthful or deceptive.

Consider the following dialogue:
Interviewer: What is your mother's job?
Interviewee: My mother is a doctor (F). She has always worked very late hours and I felt neglected as a child (T).

Is the interviewee response true or false? We differentiate between global and local deception. Globally, the response to the question is deceptive. However, it contains local instances of both truth and deception. In this work we focus on dialogue-based deception, using global deception labels.

3.2 Global Segmentation

Previous work with the CXD corpus has focused on IPU-level and turn-level analysis and classification of local deception, mostly with acoustic-prosodic features (Levitan et al., 2015b; Mendels et al., 2017). Here we are interested in exploring global deception at the dialogue-level for the first time in this corpus. We define response-segments as sets of turns that are related to a single question (of the 24 interview questions). In order to annotate these segments, we first used a question detection and identification system (Maredia et al., 2017) that uses word embeddings to match semantically similar variations of questions to a target question list. This was necessary because interviewers asked the 24 questions using different wording from the original list of questions. On this corpus, (Maredia et al., 2017) obtained an F1-score of .95%.

After tagging interviewer turns with this system, we labeled the set of interviewee turns between two interviewer questions q1 and q2 as corresponding to question q1. The intuition behind this was that those turns were responses to follow up questions related to q1, and while the question detection and identification system discussed above did not identify follow up questions, we found that most of the follow up questions after an interviewer question q1 would be related to q1 in our hand annotation. We evaluated this global segmentation on a hand-annotated test set of 17 interviews (about 10% of the corpus) consisting of 2,671 interviewee turns, 408 interviewer questions, and 977 follow up questions. Our global segmentation approach resulted in 77.8% accuracy on our hand-labeled test set (errors were mostly due to turns that were unrelated to any question).

We performed our analysis and classification on two segmentations of the data using this tagging method: (1) **first turn:** we analyzed only the single interviewee turn directly following the original question, and (2) **multiple turns** we analyzed the entire segment of interviewee turns that were responding to the original interviewer question and subsequent follow-up questions. In our classification experiments, we explore whether a deceptive answer is be better classified by the interviewee's initial response or by all of the follow-up conversation between interviewer and interviewee.

4 Features

LIWC Previous work has found that deceivers tend to use different word usage patterns when they are lying (Newman et al., 2003). We used LIWC (Pennebaker et al., 2001) to extract semantic features from each utterance. LIWC is a text analysis program that computes features consisting of normalized word counts for 93 semantic classes. LIWC dimensions have been used in many studies to predict outcomes including personality (Pennebaker and King, 1999), deception (Newman et al., 2003), and health (Pennebaker et al., 1997). We extracted a total of 93 features using LIWC 2015 [2], including standard linguistic dimensions (e.g. percentage of words that are pronouns, articles), markers of psychological processes (e.g. affect, social, cognitive), punctuation categories (e.g periods, commas), and formality measures (e.g. fillers, swear words).

Linguistic We extracted 23 linguistic features [3] which we adopted from previous deception studies such as (Enos, 2009; Bachenko et al., 2008). Included in this list are binary and numeric features capturing hedge words, filled pauses, laughter, complexity, contractions, and denials. We include Dictionary of Affect Language (DAL) (Whissell et al., 1986) scores that measure the emotional meaning of texts, and a specificity score which measures level of detail (Li and Nenkova, 2015). The full list of features is: 'hasAbsolutelyReally', 'hasContraction', 'hasI', 'hasWe', 'hasYes', 'hasNAposT' (turns

[2] A full description of the features is found here: https://s3-us-west-2.amazonaws.com/downloads.liwc.net/LIWC2015_OperatorManual.pdf

[3] A detailed explanation of these linguistic features and how they were computed is found here: http://www.cs.columbia.edu/speech/cxd/features.html

that contain words with the contraction "n't"), 'hasNo', 'hasNot', 'isJustYes', 'isJustNo', 'noYesOrNo', 'specificDenial', 'thirdPersonPronouns', 'hasFalseStart', 'hasFilledPause', 'numFilledPauses', 'hasCuePhrase', 'numCuePhrases', 'hasHedgePhrase', 'numHedgePhrases', 'hasLaugh', 'complexity', 'numLaugh', 'DAL-wc', 'DAL-pleasant', 'DAL-activate', 'DAL-imagery', 'specScores' (specificity score).

Response Length Previous work has found that response length, in seconds, is shorter in deceptive speech, and that the difference in number of words in a segment of speech is insignificant between deceptive and truthful speech (DePaulo et al., 2003). For our question-level analysis, we used four different measures for response length: the total number of seconds of an interviewee response-segment, the total number of words in an interviewee response-segment, the average response time of a turn in an interviewee response-segment, and the average number of words per turn in an interviewee response-segment.

Individual Traits We analyzed gender and native language of the speakers to determine if these traits were related to ability to deceive and to detect deception. We also analyzed linguistic cues to deception across gender and native language, and used gender and native language information in our classification experiments. All speakers were either male or female, and their native language was either Standard American English or Mandarin Chinese. In addition, we used the NEO-FFI (5 factor) personality inventory scores as features in classification experiments, but not for the statistical analysis in this paper.

Follow-up Questions Follow-up questions are questions that an interviewer asks after they ask a question from the original prescribed set of questions. We hypothesized that if an interviewer asked more follow-up questions, they were more likely to identify deceptive responses, because asking follow-up questions indicated interviewer doubt of the interviewee's truthfulness. For each interviewee response-segment, we counted the number of follow-up questions interviewees were asked by the interviewer.

5 Analysis

In order to analyze the differences between deceptive and truthful speech, we extracted the above features from each question response-segment, and calculated a series of paired t-tests between the features of truthful speech and deceptive speech. All tests for significance correct for family-wise Type I error by controlling the false discovery rate (FDR) at $\alpha = 0.05$. The k^{th} smallest p value is considered significant if it is less than $\frac{k*\alpha}{n}$.

5.1 Interviewee Responses

Table 1 shows the features that were statistically significant indicators of truth and deception in interviewee response-segments consisting of multiple turns. Below, we highlight some interesting findings.

In contrast to (DePaulo et al., 2003), we found that the total duration of an interviewee response-segment was longer for deceptive speech than for truthful speech. Additionally, while (DePaulo et al., 2003) showed that the number of words in a segment of speech was not significantly different between deceptive and truthful speech, we found that deceptive response-segments had more words than truthful response-segments. Furthermore, we found that longer average response time per turn and more words per sentence were significant indicators of deception. These results show that when interviewees are trying to deceive, not only is their aggregate response longer in duration and number of words, but their individual responses to each follow-up question are also longer. Consistent with (DePaulo et al., 2003), we found that more filled pauses in an interviewee response-segment was a significant indicator of deception. Deceivers are hypothesized to experience an increase in cognitive load (Vrij et al., 1996), and this can result in difficulties in speech planning, which can be signaled by filled pauses. Although (Benus et al., 2006) found that, in general, the use of pauses correlates more with truthful than with deceptive speech, we found that filled pauses such as "um" were correlated with deceptive speech. The LIWC *cogproc* (cognitive processes) dimension, which includes words such as "cause", "know", "ought" was significantly more frequent in truthful speech, also supporting the theory that cognitive load is increased while practicing deception.

We found that increased $DALimagery$ scores, which compute words often used in speech to create vivid descriptions, were indicators of deception. We also found that the LIWC language summary variables of $authenticity$ and $adjectives$

Table 2: Statistically significant indicators of perceived truth and deception in interviewer judgments of interviewee responses.

were indicators of deception: in an effort to sound more truthful and authentic, interviewees may have provided a level of detail that is uncharacteristic of truthful speech. Similarly, the $specificity$ metric was indicative of deception: deceptive responses contained more detailed language. Words in the LIWC $clout$ category - a category describing words that indicate power of influence - were more prevalent in deceptive responses, suggesting that subjects sounded more confident while lying. $Interrogatives$ were an indicator of deception. In the context of the interviewer-interviewee paradigm, these are interviewee questions to the interviewer. Perhaps this was a technique used to stall so that they had more time to develop an answer (e.g. "Can you repeat the question?"), or to deflect the interviewer's attention from their deception and put the interviewer on the spot. We observed that $hedge$ words and phrases, which speakers use to distance themselves from a proposition, were more frequent in deceptive speech. This is consistent with Statement Analysis (Adams, 1996), which posits that hedge words are used in deceptive statements to intentionally create vagueness that obscures facts. Consistent with this finding, $certainty$ in language (words such as "always" or "never") was a strong indicator of truthfulness.

It is also interesting to note the features that were not significant indicators of truth or decep-

tion. For example, there was no significant difference in laughter frequency or apostrophes (used for contractions in this corpus) between truthful and deceptive responses.

When we compared indicators of truth vs. deception across multiple turns to indicators of truth vs. deception in just the first turns of interviewee response-segments, we found that, generally, indicators in first turns are a subset of indicators across multiple turns. In some cases there were interesting differences. For example, although $tone$ (emotional tone - higher numbers indicate more positive, and lower indicate negative) was not a significant indicator of deception for the entire interviewee response-segment, negative tone was a moderate indicator of deception in first turns. This suggests that the tone of interviewees, when they have just started their lie, is different from when they are given the opportunity to expand on that lie. The findings from our analysis of first turns suggest that there might be enough information in the first response alone to distinguish between deceptive and truthful speech; we test this in our classification experiments in Section 6.

5.2 Interviewer Judgments of Deception

In addition to analyzing the linguistic differences between truthful and deceptive speech, we were interested in studying the characteristics of speech that is believed or disbelieved. Since the CXD corpus includes interviewer judgments of deception for each question asked, we have the unique opportunity to study human perception of deception on a large scale. Table 2 shows the features that were statistically significant indicators of truth and deception in interviewee responses - consisting of multiple turns - that were perceived as true or false by interviewers. Here we highlight some interesting findings. There were many features that were prevalent in speech that interviewers perceived as deceptive, which were in fact cues to deception. For example, speech containing more words in a response-segment and more words per sentence was generally perceived as deceptive by interviewers, and indeed, this perception was correct. Disbelieved answers had a greater frequency of filled pauses and hedge words, and greater specificity, all of which were increased in deceptive speech.

There were also several features that were indicators of deception, but were not found in higher rates in statements that were perceived as false. For example, the LIWC dimensions $clout$ and $certain$ were not significantly different in believed vs. disbelieved interviewee responses, but $clout$ was increased in deceptive speech and $certain$ language was increased in truthful speech. There were also features that were significantly different between believed and disbelieved statements, but were not indicators of deception. For example, statements that were perceived as false by interviewers had a greater proportion of $specificDenials$ (e.g. "I did not") than those that were perceived as true; this was not a valid cue to deception. Number of turns was increased in dialogue segments where the interviewer did not ultimately believe the interviewee response. That is, more follow up questions were asked when an interviewer did not believe their interlocutor's response, which is an intuitive behavior. When we compared indicators of speech that was perceived as deceptive across multiple turns to indicators of speech that was perceived as deceptive in just the first turns, we found that, generally, indicators in first turns are a subset of indicators across multiple turns.

On average, human accuracy at judging truth and deception in the CXD corpus was 56.75%, and accuracy at judging deceptive statements only was 47.93%. The average F1-score for humans was 46. Thus, although some cues were correctly perceived by interviewers, humans were generally poor at deception perception. Nonetheless, characterizing the nature of speech that is believed or not believed is useful for applications where we would ultimately like to synthesize speech that is trustworthy.

5.3 Gender and Native Language Differences in Deception Behavior

Having discovered many differences between deceptive and truthful language across all speakers, we were interested in analyzing differences in deceptive language across groups of speakers. Using gender and native language (English or Mandarin Chinese) as group traits, we conducted two types of analysis. First, we directly compared deception performance measures (ability to deceive as interviewee, and ability to detect deception as interviewer) between speakers with different traits, to assess the effect of individual characteristics on deception abilities. In addition, we compared the features of deceptive and truthful language in sub-

Group	Deception	Truth
Male Female	analytic, friend, interrog achieve, adverb, article authentic, cause compare discrep,family, feel focusfuture, percept, power relativ, we	posemo
English	acheve, adverb, affiliation compare, interrog, power relativ, space, swear	
Chinese	analytic, bio cause discrep, feel, health percep, (filler)	certain (informal) (netspeak)

Table 3: Gender-specific and language-specific indicators of deception and truth. We consider a result to approach significance if its uncorrected p value is less than 0.05 and indicate this with () in the table.

sets of the corpus, considering only people with a particular trait, in order to determine group-specific patterns of deceptive language. As before, tests for significance correct for family-wise Type I error by controlling the false discovery rate (FDR) at $\alpha = 0.05$. The k^{th} smallest p value is considered significant if it is less than $\frac{k*\alpha}{n}$.

5.3.1 Gender

There were no significant differences in deception ability between male and female speakers. However, there were many differences in language between male and female speakers. Further, some features were only discriminative between deception and truth for a specific gender. Table 3 shows linguistic features that were significantly different between truthful and deceptive speech, but only for one gender. In some cases the feature was found in different proportions in male and females, and in other cases there was no significant difference. For example, $family$ words were indicative of deception only in female speakers, and these words were also used more frequently by female speakers than male speakers.

The LIWC category of $compare$ was also indicative of deception for females only, and this feature was generally found more frequently in female speech. Article usage was only significantly different between truthful and deceptive speech in females (more articles were found in deceptive speech), but articles were used more frequently in male speech. On the other hand, the LIWC category of $posemo$ (positive emotion) was increased in truthful speech for male speakers only, and there was no significant difference of $posemo$ frequency across gender.

5.3.2 Native Language

Interviewees were more successful at deceiving native Chinese speakers than at deceiving native English speakers ($t(170) = -2.13, p = 0.033$). This was true regardless of interviewee gender and native language, and slightly stronger for female interviewers ($t(170) = -2.22, p = 0.027$). When considering only female interviewers, interviewees were more successful at deceiving non-native speakers than native speakers, but this difference was not significant when considering only male interviewers. As with gender, there were several features that were discriminative between deception and truth for only native speakers of English, or only native speakers of Mandarin. Table 3 shows LIWC categories and their relation to deception, broken down by native language. For example, power words were found more frequently in deception statements, when considering native English speakers only. In general, power words were used more by native Mandarin speakers than by native English speakers. LIWC categories of $compare$, $relative$, and $swear$ were more prevalent in deceptive speech, only for English speakers. On the other hand, $feel$ and $perception$ dimensions were only indicators of deception for native Mandarin speakers, although there was no significant difference in the use of these word categories across native language. $Informal$ and $netspeak$ word dimensions tended to be more frequent in truthful speech for native Chinese speakers only (approaching significance), and these word categories were generally more frequent in native Mandarin speech. Finally, $filler$ words tended to be more frequent in deceptive speech (approaching significance) only for native Mandarin speakers, and these were used more frequently by native Mandarin speakers than native English speakers.

Overall, our findings suggest that deceptive behavior in general, and deceptive language in particular, are affected by a person's individual characteristics, including gender and native language. When building a deception classification system, it is important to account for this variation across speaker groups.

Features	Segmentation	Accuracy	Precision	Recall	F1-score
Human baseline	Multiple turns	56.75	56.50	40.00	46.50
LIWC	Single turn	65.75	65.79	65.74	65.72
	Multiple turns	72.78	72.84	72.74	72.74
Lexical	Single turn	66.95	66.97	66.95	66.94
	Multiple turns	70.33	70.46	70.28	70.25
LIWC+lexical	Single turn	68.35	68.36	68.35	68.35
	Multiple turns	71.66	71.77	71.60	71.58
LIWC+individual	Single turn	67.50	67.50	67.50	67.49
	Multiple turns	71.85	71.93	71.80	71.79
Lexical+individual	Single turn	69.32	69.33	69.32	69.31
	Multiple turns	69.95	70.06	69.89	69.86

	Multiple turns	72.40	72.50	72.34	72.33

Table 4: Random Forest classification of single turn and multiple turn segmentations, using text-based features and individual traits (gender, native language, NEO-FFI personality scores).

6 Deception Classification

Motivated by our analysis showing many significant differences in the language of truthful and deceptive responses to interview questions, we trained machine learning classifiers to automatically distinguish between truthful and deceptive text, using the feature sets described in section 4. We compared classification performance for the two segmentation methods described in section 3.2: first turn and multiple turns. This allowed us to explore the role of context in automatic deception detection. When classifying interviewee response-segments, should the immediate response only be used for classification, or is inclusion of surrounding turns helpful? This has implications not only for deception classification, but for practitioners as well. Should human interviewers make use of responses to follow up questions when determining response veracity, or should the initial response receive the most consideration?

We compared the performance of 3 classification algorithms: Random Forest, Logistic Regression, and SVM (sklearn implementation). In total, there were 7,792 question segments for both single turn and multiple turns segmentations. We divided this into 66% train and 33% test, and used the same fixed test set in experiments for both segmentations in order to directly compare results. The random baseline performance is 50, since the dataset is balanced for truthful and deceptive statements. Another baseline is human performance, which is 46.0 F1 in this corpus. The Random Forest classifier was consistently the best performing, and we only report those results due to space constraints. Table 4 displays the classification performance for each feature set individually, as well as feature combinations, for both single turn and multiple turn segmentations. It also shows the human baseline performance, obtained from the interviewers' judgments of deception in the corpus, which were made after asking each question along with related follow-up questions (i.e. multiple turn segmentation).

The best performance (72.74 F1-score) was obtained using LIWC features extracted from multiple turns. This is a 22.74% absolute increase over the random baseline of 50, and a 26.74% absolute increase over the human baseline of 46. The performance of classifiers trained on multiple turns was consistently better than those trained on single turns, for all feature sets. For multiple turns, LIWC features were better than the lexical feature set, and combining lexical with LIWC features did not improve over the performance of LIWC features alone. Adding individual traits information was also not beneficial. However, when considering the first turn only, the best results (70.87 F1-score) were obtained using a combination of LIWC+lexical+individual features. Using the first turns segmentation, lexical features were slightly better than LIWC features, and interestingly, adding individual traits helped both feature sets. A combination of LIWC and lexical features was better than each on its own.

These results suggest that contextual informa-

tion, in the form of follow up questions, is beneficial for deception classification. It seems that individual traits, including gender, native language, and personality scores, are helpful in deception classification under the condition where contextual information is not available. When the contextual information is available, the the additional lexical content is more useful than individual traits.

7 Conclusions and Future Work

In this paper we presented a study of deceptive language in interview dialogues. Our analysis of linguistic characteristics of deceptive and truthful speech provides insight into the nature of deceptive language. We also analyzed the linguistic characteristics of speech that is *perceived* as deceptive and truthful, which is important for understanding the nature of trustworthy speech. We explored variation across gender and native language in linguistic cues to deception, highlighting cues that are specific to particular groups of speakers. We built classifiers that use combinations of linguistic features and individual traits to automatically identify deceptive speech. We compared the performance of using cues from the single first turn of an interviewee response-segment with using cues from the full context of multiple interviewee turns, achieving performance as high as 72.74% F1-score (about 27% better than human detection performance).

This work contributes to the critical problem of automatic deception detection, and increases our scientific understanding of deception, deception perception, and individual differences in deceptive behavior. In future work, we plan to conduct similar analysis in additional deception corpora in other domains, in order to identify consistent domain-independent deception indicators. In addition, we plan to conduct cross-corpus machine learning experiments, to evaluate the robustness of these and other feature sets in deception detection. We also would like to explore additional feature combinations, such as adding acoustic-prosodic features. Finally, we plan to conduct an empirical analysis of deception behavior across personality types.

Unified Pragmatic Models for Generating and Following Instructions

Daniel Fried Jacob Andreas Dan Klein

Abstract

We show that explicit pragmatic inference aids in correctly generating and following natural language instructions for complex, sequential tasks. Our pragmatics-enabled models reason about why speakers produce certain instructions, and about how listeners will react upon hearing them. Like previous pragmatic models, we use learned base listener and speaker models to build a *pragmatic speaker* that uses the base listener to simulate the interpretation of candidate descriptions, and a *pragmatic listener* that reasons counterfactually about alternative descriptions. We extend these models to tasks with sequential structure. Evaluation of language generation and interpretation shows that pragmatic inference improves state-of-the-art listener models (at correctly interpreting human instructions) and speaker models (at producing instructions correctly interpreted by humans) in diverse settings.

1 Introduction

How should speakers and listeners reason about each other when they communicate? A core insight of computational pragmatics is that speaker and listener agents operate within a cooperative game-theoretic context, and that each agent benefits from reasoning about others' intents and actions within that context. Pragmatic inference has been studied by a long line of work in linguistics, natural language processing, and cognitive science. In this paper, we present a technique for layering explicit pragmatic inference on top of models for complex, sequential instruction-following and instruction-generation tasks. We investigate a range of current data sets for both tasks, showing that pragmatic behavior arises naturally from this inference procedure, and gives rise to state-of-the-art results in a variety of domains.

Consider the example shown in Figure 1a, in which a speaker agent must describe a route to a target position in a hallway. A conventional learned instruction-generating model produces a truthful description of the route (*walk forward four times*). But the pragmatic speaker in this paper, which is capable of reasoning about the listener, chooses to also include additional information (*the intersection with the bare concrete hall*), to reduce potential ambiguity and increase the odds that the listener reaches the correct destination.

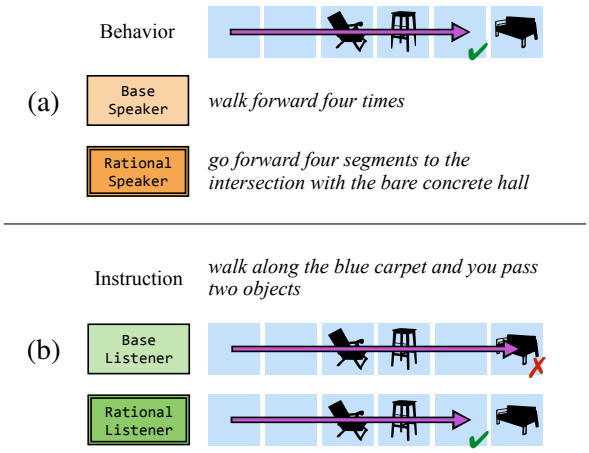

Figure 1: Real samples for the SAIL navigation environments, comparing *base* models, without explicit pragmatic inference, to the *rational* pragmatic inference procedure. (a) The rational speaker, which reasons about listener behavior, generates instructions which in this case are more robust to uncertainty about the listener's initial orientation. (b) The base listener moves to an unintended position (even though it correctly *passes two objects*). The rational listener, which reasons about the speaker, infers that a route ending at the sofa would have been described differently, and stops earlier.

This same reasoning procedure also allows a listener agent to overcome ambiguity in instructions by reasoning counterfactually about the speaker (Figure 1b). Given the command *walk along the blue carpet and you pass two objects*, a conven-

Proceedings of NAACL-HLT 2018, pages 1951–1963
New Orleans, Louisiana, June 1 - 6, 2018.

tional learned instruction-following model is willing to consider all paths that pass two objects, and ultimately arrives at an unintended final position. But a pragmatic listener that reasons about the speaker can infer that the long path would have been more easily described as *go to the sofa*, and thus that the shorter path is probably intended. In these two examples, which are produced by the system we describe in this paper, a unified reasoning process (choose the output sequence which is most preferred by an embedded model of the other agent) produces pragmatic behavior for both speakers and listeners.

The application of models with explicit pragmatic reasoning abilities has so far been largely restricted to simple reference games, in which the listener's only task is to select the right item from among a small set of candidate referents given a single short utterance from the speaker. But as the example shows, there are real-world instruction following and generation tasks with rich action spaces that might also benefit from pragmatic modeling. Moreover, approaches that learn to map directly between human-annotated instructions and action sequences are ultimately limited by the effectiveness of the humans themselves. The promise of pragmatic modeling is that we can use these same annotations to build a model with a different (and perhaps even better) mechanism for interpreting and generating instructions.

The primary contribution of this work is to show how existing models of pragmatic reasoning can be extended to support instruction following and generation for challenging, multi-step, interactive tasks. Our experimental evaluation focuses on four instruction-following domains which have been studied using both semantic parsers and attentional neural models. We investigate the interrelated tasks of instruction following and instruction generation, and show that incorporating an explicit model of pragmatics helps in both cases. Reasoning about the human listener allows a speaker model to produce instructions that are easier for humans to interpret correctly in all domains (with absolute gains in accuracy ranging from 12% to 46%). Similarly, reasoning about the human speaker improves the accuracy of the listener models in interpreting instructions in most domains (with gains in accuracy of up to 10%). In all cases, the resulting systems are competitive with, and in many cases exceed, results from past state-of-the-art systems for these tasks.[1]

2 Problem Formulation

Consider the instruction following and instruction generation tasks shown in Figure 1, where an agent must produce or interpret instructions about a structured world context (e.g. *walk along the blue carpet and you pass two objects*).

In the **instruction following** task, a listener agent begins in a world state (in Figure 1 an initial map location and orientation). The agent is then tasked with following a sequence of direction sentences $d_1 \dots d_K$ produced by humans. At each time t the agent receives a percept y_t, which is a feature-based representation of the current world state, and chooses an action a_t (e.g. move forward, or turn). The agent succeeds if it is able to reach the correct final state described by the directions.

In the **instruction generation** task, the agent receives a sequence of actions $a_1, \cdots a_T$ along with the world state $y_1, \cdots y_T$ at each action, and must generate a sequence of direction sentences $d_1, \dots d_K$ describing the actions. The agent succeeds if a human listener is able to correctly follow those directions to the intended final state.

We evaluate models for both tasks in four domains. The first domain is the SAIL corpus of virtual environments and navigational directions (MacMahon et al., 2006; Chen and Mooney, 2011), where an agent navigates through a two-dimensional grid of hallways with patterned walls and floors and a discrete set of objects (Figure 1 shows a portion of one of these hallways).

In the three SCONE domains (Long et al., 2016), the world contains a number of objects with various properties, such as colored beakers which an agent can combine, drain, and mix. Instructions describe how these objects should be manipulated. These domains were designed to elicit instructions with a variety of context-dependent language phenomena, including ellipsis and coreference (Long et al., 2016) which we might expect a model of pragmatics to help resolve (Potts, 2011).

3 Related Work

The approach in this paper builds upon long lines of work in pragmatic modeling, instruction following, and instruction generation.

[1] Source code is available at http://github.com/dpfried/pragmatic-instructions

Pragmatics Our approach to pragmatics (Grice, 1975) belongs to a general category of rational speech acts models (Frank and Goodman, 2012), in which the interaction between speakers and listeners is modeled as a probabilistic process with Bayesian actors (Goodman and Stuhlmüller, 2013). Alternative formulations (e.g. with best-response rather than probabilistic dynamics) are also possible (Golland et al., 2010). Inference in these models is challenging even when the space of listener actions is extremely simple (Smith et al., 2013), and one of our goals in the present work is to show how this inference problem can be solved even in much richer action spaces than previously considered in computational pragmatics. This family of pragmatic models captures a number of important linguistic phenomena, especially those involving conversational implicature (Monroe and Potts, 2015); we note that many other topics studied under the broad heading of "pragmatics," including presupposition and indexicality, require different machinery.

Williams et al. (2015) use pragmatic reasoning with weighted inference rules to resolve ambiguity and generate clarification requests in a human-robot dialog task. Other recent work on pragmatic models focuses on the referring expression generation or "contrastive captioning" task introduced by Kazemzadeh et al. (2014). In this family are approaches that model the listener at training time (Mao et al., 2016), at evaluation time (Andreas and Klein, 2016; Monroe et al., 2017; Vedantam et al., 2017; Su et al., 2017) or both (Yu et al., 2017b; Luo and Shakhnarovich, 2017).

Other conditional sequence rescoring models that are structurally similar but motivated by concerns other than pragmatics include Li et al. (2016) and Yu et al. (2017a). Lewis et al. (2017) perform a similar inference procedure for a competitive negotiation task. The language learning model of Wang et al. (2016) also features a structured output space and uses pragmatics to improve online predictions for a semantic parsing model. Our approach in this paper performs both generation and interpretation, and investigates both structured and unstructured output representations.

Instruction following Work on instruction following tasks includes models that parse commands into structured representations processed by a rich execution model (Tellex et al., 2011; Chen, 2012; Artzi and Zettlemoyer, 2013; Guu et al., 2017), and models that map directly from instructions to a policy over primitive actions (Branavan et al., 2009), possibly mediated by an intermediate alignment or attention variable (Andreas and Klein, 2015; Mei et al., 2016). We use a model similar to Mei et al. (2016) as our base listener in this paper, evaluating on the SAIL navigation task (MacMahon et al., 2006) as they did, as well as the SCONE context-dependent execution domains (Long et al., 2016).

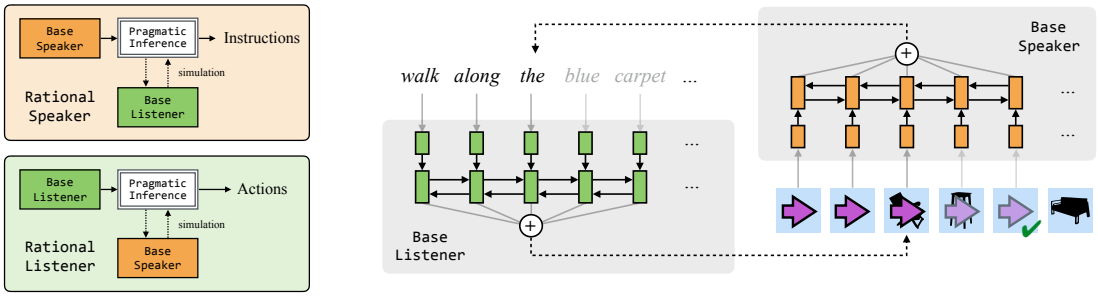
Instruction generation Previous work has also investigated the instruction generation task, in particular for navigational directions. The GIVE shared tasks (Byron et al., 2009; Koller et al., 2010; Striegnitz et al., 2011) have produced a large number of interactive direction-giving systems, both rule-based and learned. The work most immediately related to the generation task in this paper is that of Daniele et al. (2017), which also focuses on the SAIL dataset but requires substantial additional structured annotation for training, while both our base and pragmatic speaker models learn directly from strings and action sequences.

Older work has studied the properties of effective human strategies for generating navigational directions (Anderson et al., 1991). Instructions of this kind can be used to extract templates for generation (Look, 2008; Dale et al., 2005), while here we focus on the more challenging problem of learning to generate new instructions from scratch. Like our pragmatic speaker model, Goeddel and Olson (2012) also reason about listener behavior when generating navigational instructions, but rely on rule-based models for interpretation.

4 Pragmatic inference procedure

As a foundation for pragmatic inference, we assume that we have *base* listener and speaker models to map directions to actions and vice-versa. (Our notation for referring to models is adapted from Bergen et al. (2016).) The base listener, L_0, produces a probability distribution over sequences of actions, conditioned on a representation of the directions and environment as seen before each action: $P_{L_0}(a_{1:T}|d_{1:K}, y_{1:T})$. Similarly, the base speaker, S_0, defines a distribution over possible descriptions conditioned on a representation of the actions and environment: $P_{S_0}(d_{1:K}|a_{1:T}, y_{1:T})$.

Our pragmatic inference procedure requires these base models to produce candidate outputs from a given input (actions from descriptions, for



(a) (b)

Figure 2: (a) Rational pragmatic models embed base listeners and speakers. Potential candidate sequences are drawn from one base model, and then the other scores each candidate to simulate whether it produces the desired pragmatic behavior. (b) The base listener and speaker are neural sequence-to-sequence models which are largely symmetric to each other. Each produces a representation of its input sequence (a description, for the listener; actions with associated environmental percepts, for the listener) using an LSTM encoder. The output sequence is generated by an LSTM decoder attending to the input.

the listener; descriptions from actions, for the speaker), and calculate the probability of a fixed output given an input, but is otherwise agnostic to the form of the models.

We use standard sequence-to-sequence models with attention for both the base listener and speaker (described in Section 5). Our models use segmented action sequences, with one segment (sub-sequence of actions) aligned with each description sentence d_j, for all $j \in \{1 \dots K\}$. This segmentation is either given as part of the training and testing data (in the instruction following task for the SAIL domain, and in both tasks for the SCONE domain, where each sentence corresponds to a single action), or is predicted by a separate segmentation model (in the generation task for the SAIL domain), see Section 5.

4.1 Models

Using these base models as self-contained modules, we derive a *rational speaker* and *rational listener* that perform inference using embedded instances of these base models (Figure 2a). When describing an action sequence, a rational speaker S_1 chooses a description that has a high chance of causing the listener modeled by L_0 to follow the given actions:

$$S_1(a_{1:T}) = \operatorname*{argmax}_{d_{1:K}} P_{L_0}(a_{1:T}|d_{1:K}, y_{1:T}) \quad (1)$$

(noting that, in all settings we explore here, the percepts $y_{1:T}$ are completely determined by the actions $a_{1:T}$). Conversely, a rational listener L_1 follows a description by choosing an action sequence which has high probability of having caused the speaker, modeled by S_0, to produce the description:

$$L_1(d_{1:K}) = \operatorname*{argmax}_{a_{1:T}} P_{S_0}(d_{1:K}|a_{1:T}, y_{1:T}) \quad (2)$$

These optimization problems are intractable to solve for general base listener and speaker agents, including the sequence-to-sequence models we use, as they involve choosing an input (from a combinatorially large space of possible sequences) to maximize the probability of a fixed output sequence. We instead follow a simple approximate inference procedure, detailed in Section 4.2.

We consider also incorporating the scores of the base model used to produce the candidates. For the case of the speaker, we define a *combined rational speaker*, denoted $S_0 \cdot S_1$, that selects the candidate that maximizes a weighted product of probabilities under both the base listener and the base speaker:

$$\operatorname*{argmax}_{d_{1:K}} P_{L_0}(a_{1:T}|d_{1:K}, y_{1:T})^{\lambda} \times P_{S_0}(d_{1:K}|a_{1:T}, y_{1:T})^{1-\lambda} \quad (3)$$

for a fixed interpolation hyperparameter $\lambda \in [0, 1]$. There are several motivations for this combination with the base speaker score. First, as argued by Monroe et al. (2017), we would expect varying degrees of base and reasoned interpretation in human speech acts. Second, we want the descriptions produced by the model to be fluent descriptions of the actions. Since the base models are trained discriminatively, maximizing the probability of an output sequence for a fixed input sequence, their scoring behaviors for fixed outputs paired with inputs dissimilar to those seen in the training set may be

poorly calibrated (for example when conditioning on ungrammatical descriptions). Incorporating the scores of the base model used to produce the candidates aims to prevent this behavior.

To define rational listeners, we use the symmetric formulation: first, draw candidate action sequences from L_0. For L_1, choose the actions that achieve the highest probability under S_0; and for the combination model $L_0 \cdot L_1$ choose the actions with the highest weighted combination of S_0 and L_0 (paralleling equation 3).

4.2 Inference

As in past work (Smith et al., 2013; Andreas and Klein, 2016; Monroe et al., 2017), we approximate the optimization problems in equations 1, 2, and 3: use the base models to generate candidates, and rescore them to find ones that are likely to produce the desired behavior.

In the case of the rational speaker S_1, we use the base speaker S_0 to produce a set of n candidate descriptions $w^{(1)}_{1:K_1} \dots w^{(n)}_{1:K_n}$ for the sequences $a_{1:T}, y_{1:T}$, using beam search. We then find the score of each description under P_{L_0} (using it as the input sequence for the observed output actions we want the rational speaker to describe), or a weighted combination of P_{L_0} and the original candidate score P_{S_0}, and choose the description $w^{(j)}_{1:K_j}$ with the largest score, approximately solving the maximizations in equations 1 or 3, respectively. We perform a symmetric procedure for the rational listener: produce action sequence candidates from the base listener, and rescore them using the base speaker.[2]

As the rational speaker must produce long output sequences (with multiple sentences), we interleave the speaker and listener in inference, determining each output sentence sequentially. From a list of candidate direction sentences from the base speaker for the current subsequence of actions, we choose the top-scoring direction under the listener model (which may also condition on the directions which have been output previously), and then move on to the next subsequence of actions.[3]

5 Base model details

Given this framework, all that remains is to describe the base models L_0 and S_0. We implement these as sequence-to-sequence models that map directions to actions (for the listener) or actions to directions (for the speaker), additionally conditioning on the world state at each timestep.

5.1 Base listener

Our base listener model, L_0, predicts action sequences conditioned on an encoded representation of the directions and the current world state. In the SAIL domain, this is the model of Mei et al. (2016) (illustrated in green in Figure 2b for a single sentence and its associated actions), see "domain specifics" below.

Encoder Each direction sentence is encoded separately with a bidirectional LSTM (Hochreiter and Schmidhuber, 1997); the LSTM's hidden states are reset for each sentence. We obtain a representation h^e_k for the kth word in the current sentence by concatenating an embedding for the word with its forward and backward LSTM outputs.

Decoder We generate actions incrementally using an LSTM decoder with monotonic alignment between the direction sentences and subsequences of actions; at each timestep the decoder predicts the next action for the current sentence $w_{1:M}$ (including choosing to shift to the next sentence). The decoder takes as input at timestep t the current world state, y_t and a representation z_t of the current sentence, updates the decoder state h^d, and outputs a distribution over possible actions:

$$h^d_t = \text{LSTM}_d(h^d_{t-1}, [W_y y_t, z_t])$$
$$q_t = W_o(W_y y_t + W_h h^d_t + W_z z_t)$$
$$p(a_t \mid a_{1:t-1}, y_{1:t}, w_{1:M}) \propto \exp(q_t)$$

where all weight matrices W are learned parameters. The sentence representation z_t is produced using an attention mechanism (Bahdanau et al., 2015) over the representation vectors $h^e_1 \dots h^e_M$

[2] We use ensembles of models for the base listener and speaker (subsection 5.3), and to obtain candidates that are high-scoring under the combination of models in the ensemble, we perform standard beam search using all models in lock-step. At every timestep of the beam search, each possible extension of an output sequence is scored using the product of the extension's conditional probabilities across all models in the ensemble.

[3] We also experimented with sampling from the base models to produce these candidate lists, as was done in previous work (Andreas and Klein, 2016; Monroe et al., 2017). In early experiments, however, we found better performance with beam search in the rational models for all tasks.

for words in the current sentence:

$$\alpha_{t,k} \propto \exp(v \cdot \tanh(W_d h^d_{t-1} + W_e h^e_k))$$
$$z_t = \sum_{k=1}^{M} \alpha_{t,k} h^e_k$$

where the attention weights $\alpha_{t,k}$ are normalized to sum to one across positions k in the input, and weight matrices W and vector v are learned.

Domain specifics For SAIL, we use the alignments between sentences and route segments annotated by Chen and Mooney (2011), which were also used in previous work (Artzi and Zettlemoyer, 2013; Artzi et al., 2014; Mei et al., 2016). Following Mei et al. (2016), we reset the decoder's hidden state for each sentence.

In the SCONE domains, which have a larger space of possible outputs than SAIL, we extend the decoder by: (i) decomposing each action into an action type and arguments for it, (ii) using separate attention mechanisms for types and arguments and (iii) using state-dependent action embeddings. See Appendix A in the supplemental material for details. The SCONE domains are constructed so that each sentence corresponds to a single (non-decomposed) action; this provides our segmentation of the action sequence.

5.2 Base speaker

While previous work (Daniele et al., 2017) has relied on more structured approaches, we construct our base speaker model S_0 using largely the same sequence-to-sequence machinery as above. S_0 (illustrated in orange in Figure 2b) encodes a sequence of actions and world states, and then uses a decoder to output a description.

Encoder We encode the sequence of vector embeddings for the actions a_t and world states y_t using a bidirectional LSTM. Similar to the base listener's encoder, we then obtain a representation h^e_t for timestep t by concatenating a_t and y_t with the LSTM outputs at that position.

Decoder As in the listener, we use an LSTM decoder with monotonic alignment between direction sentences and subsequences of actions, and attention over the subsequences of actions. The decoder takes as input at position k an embedding for the previously generated word w_{k-1} and a representation z_k of the current subsequence of actions and world states, and produces a distribution over words (including ending the description for the current subsequence and advancing to the next). The decoder's output distribution is produced by:

$$h^d_k = \text{LSTM}_d(h^d_{k-1}, [w_{k-1}, z_k])$$
$$q_k = W_h h^d_k + W_z z_k$$
$$p(w_k \mid w_{1:k-1}, a_{1:T}, y_{1:T}) \propto \exp(q_k)$$

where all weight matrices W are learned parameters.[4] As in the base listener, the input representation z_k is produced by attending to the vectors $h^e_1 \ldots h^e_T$ encoding the input sequence (here, encoding the subsequence of actions and world states to be described):

$$\alpha_{k,t} \propto \exp(v \cdot \tanh(W_d h^d_{k-1} + W_e h^e_t))$$
$$z_k = \sum_{t=1}^{T} \alpha_{k,t}\ h^e_t$$

The decoder's LSTM state is reset at the beginning of each sentence.

Domain specifics In SAIL, for comparison to the generation system of Daniele et al. (2017) which did not use segmented routes, we train a route segmenter for use at test time. We also represent routes using a collapsed representation of action sequences. In the SCONE domains, we (i) use the same context-dependent action embeddings used in the listener, and (ii) don't require an attention mechanism, since only a single action is used to produce a given sentence within the sequence of direction sentences. See Appendix A for more details.

5.3 Training

The base listener and speaker models are trained independently to maximize the conditional likelihoods of the actions–directions pairs in the training sets. See Appendix A for details on the optimization, LSTM variant, and hyperparameters.

We use ensembles for the base listener L_0 and base speaker S_0, where each ensemble consists of 10 models trained from separate random parameter initializations. This follows the experimental setup of Mei et al. (2016) for the SAIL base listener.

[4] All parameters are distinct from those used in the base listener; the listener and speaker are trained separately.

listener	Single-sentence Rel	Single-sentence Abs	Multi-sentence Rel	Multi-sentence Abs
past work	69.98 (MBW)	65.28 (AZ)	26.07 (MBW)	35.44 (ADP)
L_0	68.40	59.62	24.79	13.53
$L_0 \cdot L_1$	**71.64**	64.38	**34.05**	24.50
accuracy gain	+3.24	+4.76	+9.26	+10.97

Table 1: Instruction-following results on the SAIL dataset. The table shows cross-validation test accuracy for the base listener (L_0) and pragmatic listeners ($L_0 \cdot L_1$), along with the gain given by pragmatics. We report results for the single- and multi-sentence conditions, under the relative and absolute starting conditions[5], comparing to the best-performing prior work by Artzi and Zettlemoyer (2013) (AZ), Artzi et al. (2014) (ADP), and Mei et al. (2016) (MBW). Bold numbers show new state-of-the-art results.

listener	Alchemy	Scene	Tangrams
GPLL	52.9	46.2	37.3
L_0	69.7	70.9	69.6
$L_0 \cdot L_1$	72.0	72.7	69.6
accuracy gain	+2.3	+1.8	+0.0

Table 2: Instruction-following results in the SCONE domains. The table shows accuracy on the test set. For reference, we also show prior results from Guu et al. (2017) (GPLL), although our models use more supervision at training time.

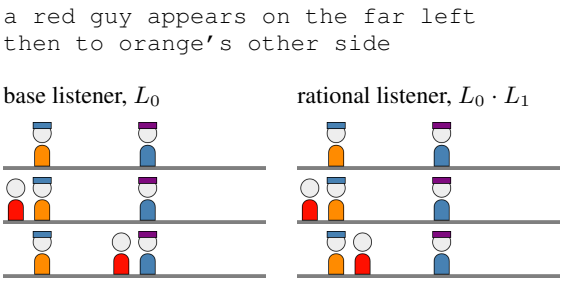


Figure 3: Action traces produced for a partial instruction sequence (two instructions out of five) in the Scene domain. The base listener moves the red figure to a position that is a marginal, but valid, interpretation of the directions. The rational listener correctly produces the action sequence the directions were intended to describe.

6 Experiments

We evaluate speaker and listener agents on both the instruction following and instruction generation tasks in the SAIL domain and three SCONE domains (Section 2). For all domains, we compare the rational listener and speaker against the base listener and speaker, as well as against past state-of-the-art results for each task and domain. Finally, we examine pragmatic inference from a model combination perspective, comparing the pragmatic reranking procedure to ensembles of a larger number of base speakers or listeners.

For all experiments, we use beam search both to generate candidate lists for the rational systems (section 4.2) and to generate the base model's output. We fix the beam size n to be the same in both the base and rational systems, using $n = 20$ for the speakers and $n = 40$ for the listeners. We tune the weight λ in the combined rational agents ($L_0 \cdot L_1$ or $S_0 \cdot S_1$) to maximize accuracy (for listener models) or BLEU (for speaker models) on each domain's development data.

6.1 Instruction following

We evaluate our listener models by their accuracy in carrying out human instructions: whether the systems were able to reach the final world state which the human was tasked with guiding them to.

SAIL We follow standard cross-validation evaluation for the instruction following task on the SAIL dataset (Artzi and Zettlemoyer, 2013; Artzi et al., 2014; Mei et al., 2016).[5] Table 1 shows improvements over the base listener L_0 when using the rational listener $L_0 \cdot L_1$ in the single- and multi-sentence settings. We also report the best accuracies from past work. We see that the largest relative gains come in the multi-sentence setting, where handling ambiguity is potentially more important to avoid compounding errors. The rational model improves on the published results of Mei et al. (2016), and while it is still below the systems of Artzi and Zettlemoyer (2013) and Artzi et al. (2014), which use additional supervision in the form of hand-annotated seed lexicons and logical domain representations, it approaches their results in the single-sentence setting.

SCONE In the SCONE domains, past work has trained listener models with weak supervision

[5]Past work has differed in the handling of undetermined orientations in the routes, which occur in the first state for multi-sentence routes and the first segment of their corresponding single-sentence routes. For comparison to both types of past work, we train and evaluate listeners in two settings: *Abs*, which sets these undetermined starting orientations to be a fixed absolute orientation, and *Rel*, where an undetermined starting orientation is set to be a 90 degree rotation from the next state in the true route.

speaker	SAIL	Alchemy	Scene	Tangrams
DBW	70.9	—	—	—
S_0	62.8	29.3	31.3	60.0
$S_0 \cdot S_1$	**75.2**	**75.3**	**69.3**	**88.0**
accuracy gain	+12.4	+46.0	+38.0	+28.0
human-generated	73.2	83.3	78.0	66.0

Table 3: Instruction generation results. We report the accuracies of human evaluators at following the outputs of the speaker systems (as well as other humans) on 50-instance samples from the SAIL dataset and SCONE domains. DBW is the system of Daniele et al. (2017). Bold numbers are new state-of-the-art results.

speaker	SAIL	Alchemy	Scene	Tangrams
DBW	11.00	—	—	—
S_0	12.04	19.34	18.09	21.75
$S_0 \cdot S_1$	10.78	18.70	27.15	23.03
BLEU gain	-1.26	-0.64	+9.06	+1.28
accuracy gain (from Table 3)	+12.4	+46.0	+38.0	+28.0

Table 4: Gains in how easy the directions are to follow are not always associated with a gain in BLEU. This table shows corpus-level 4-gram BLEU comparing outputs of the speaker systems to human-produced directions on the SAIL dataset and SCONE domains, compared to gains in accuracy when asking humans to carry out a sample of the systems' directions (see Table 3).

(with no intermediate actions between start and end world states) on a subset of the full SCONE training data. We use the full training set, and to use a model and training procedure consistent with the SAIL setting, train listener and speaker models using the intermediate actions as supervision as well.[6] The evaluation method and test data are the same as in past work on SCONE: models are provided with an initial world state and a sequence of 5 instructions to carry out, and are evaluated on their accuracy in reaching the intended final world state.

Results are reported in Table 2. We see gains from the rational system $L_0 \cdot L_1$ in both the Alchemy and Scene domains. The pragmatic inference procedure allows correcting errors or overly-literal interpretations from the base listener. An example is shown in Figure 3. The base listener (left) interprets *then to orange's other side* incorrectly, while the rational listener discounts this interpretation (it could, for example, be better described by *to the left of blue*) and produces the action the descriptions were meant to describe (right). To the extent that human annotators already account for pragmatic effects when generating instructions, examples like these suggest that our model's explicit reasoning is able to capture interpretation behavior that the base sequence-to-sequence listener model is unable to model.

6.2 Instruction generation

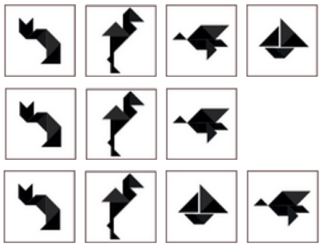
As our primary evaluation for the instruction generation task, we had Mechanical Turk workers carry out directions produced by the speaker models (and by other humans) in a simulated version of each domain. For SAIL, we use the simulator released by Daniele et al. (2017) which was used in their human evaluation results, and we construct simulators for the three SCONE domains. In all settings, we take a sample of 50 action sequences from the domain's test set (using the same sample as Daniele et al. (2017) for SAIL), and have three separate Turk workers attempt to follow the systems' directions for the action sequence.

Table 3 gives the average accuracy of subjects in reaching the intended final world state across all sampled test instances, for each domain. The "human-generated" row reports subjects' accuracy at following the datasets' reference directions. The directions produced by the base speaker S_0 are often much harder to follow than those produced by humans (e.g. 29.3% of S_0's directions are correctly interpretable for Alchemy, vs. 83.3% of human directions). However, we see substantial gains from the rational speaker $S_0 \cdot S_1$ over S_0 in all cases (with absolute gains in accuracy ranging from 12.4% to 46.0%), and the average accuracy of humans at following the rational speaker's directions is substantially higher than for human-produced directions in the Tangrams domain. In the SAIL evaluation, we also include the directions produced by the system of Daniele et al. (2017) (DBW), and find that the rational speaker's directions are followable to comparable accuracy.

We also compare the directions produced by the systems to the reference instructions given by humans in the dataset, using 4-gram BLEU[7] (Pap-

[6] Since the pragmatic inference procedure we use is agnostic to the models' training method, it could also be applied to the models of Guu et al. (2017); however we find that pragmatic inference can improve even upon our stronger base listener models.

[7] See Appendix A for details on evaluating BLEU in the SAIL setting, where there may be a different number of reference and predicted sentences for a given example.



human	take away the last item undo the last step
S_0	remove the last figure add it back
$S_0 \cdot S_1$	remove the last figure add it back in the 3rd position

Figure 4: Descriptions produced for a partial action sequence in the Tangrams domain. Neither the human nor base speaker S_0 correctly specifies where to add the shape in the second step, while the rational speaker $S_0 \cdot S_1$ does.

ineni et al., 2002) in Table 4. Consistent with past work (Krahmer and Theune, 2010), we find that BLEU score is a poor indicator of whether the directions can be correctly followed.

Qualitatively, the rational inference procedure is most successful in fixing ambiguities in the base speaker model's descriptions. Figure 4 gives a typical example of this for the last few timesteps from a Tangrams instance. The base speaker correctly describes that the shape should be added back, but does not specify where to add it, which could lead a listener to add it in the same position it was deleted. The human speaker also makes this mistake in their description. This speaks to the difficulty of describing complex actions pragmatically even for humans in the Tangrams domain. The ability of the pragmatic speaker to produce directions that are easier to follow than humans' in this domain (Table 3) shows that the pragmatic model can generate something different (and in some cases better) than the training data.

6.3 Pragmatics as model combination

Finally, our rational models can be viewed as pragmatically-motivated model combinations, producing candidates using base listener or speaker models and reranking using a combination of scores from both. We want to verify that a rational listener using n ensembled base listeners and n base speakers outperforms a simple ensemble of $2n$ base listeners (and similarly for the rational speaker).

Fixing the total number of models to 20 in each listener experiment, we find that the rational listener (using an ensemble of 10 base listener models and 10 base speaker models) still substantially outperforms the ensembled base listener (using 20 base listener models): accuracy gains are 68.5 $\rightarrow$ 71.6%, 70.1 $\rightarrow$ 72.0%, 71.9 $\rightarrow$ 72.7%, and 69.1 $\rightarrow$ 69.6% for SAIL single-sentence Rel, Alchemy, Scene, and Tangrams, respectively.

For the speaker experiments, fixing the total number of models to 10 (since inference in the speaker models is more expensive than in the follower models), we find similar gains as well: the rational speaker improves human accuracy at following the generated instructions from 61.9 $\rightarrow$ 73.4%, 30.7 $\rightarrow$ 74.7%, 32.0 $\rightarrow$ 66.0%, 58.7 $\rightarrow$ 92.7%, for SAIL, Alchemy, Scene, and Tangrams, respectively.[8]

7 Conclusion

We have demonstrated that a simple procedure for pragmatic inference, with a unified treatment for speakers and listeners, obtains improvements for instruction following as well as instruction generation in multiple settings. The inference procedure is capable of reasoning about sequential, interdependent actions in non-trivial world contexts. We find that pragmatics improves upon the performance of the base models for both tasks, in most cases substantially. While this is perhaps unsurprising for the generation task, which has been discussed from a pragmatic perspective in a variety of recent work in NLP, it is encouraging that pragmatic reasoning can also improve performance for a grounded listening task with sequential, structured output spaces.

Acknowledgments

We are grateful to Andrea Daniele for sharing the SAIL simulator and their system's outputs, to Hongyuan Mei for help with the dataset, and to Tom Griffiths and Chris Potts for helpful comments and discussion. This work was supported by DARPA through the Explainable Artificial Intelligence (XAI) program. DF is supported by a Huawei / Berkeley AI fellowship. JA is supported by a Facebook graduate fellowship.

[8] The accuracies for the base speakers are slightly different than in Table 3, despite being produced by the same systems, since we reran experiments to control as much as possible for time variation in the pool of Mechanical Turk workers.

A Supplemental Material

A.1 SCONE listener details

We factor action production in each of the three SCONE domains, separately predicting the action type and the arguments specific to that action type. Action types and arguments are listed in the first two columns of Table 5. For example, Alchemy's actions involve predicting the action type, a potential source beaker index i and target beaker index j, and potential amount to drain a. All factors of the action (the type and options for each argument) are predicted using separate attention mechanisms, which produce a vector q_f giving unnormalized scores for factor f (e.g. scoring each possible type, or each possible choice for the argument).

We also obtain state-specific embeddings of actions, to make it easier for the model to learn relevant features from the state embeddings (e.g. rather than needing to learn to select the region of the state vector corresponding to the 5th beaker in the action MIX(5) in Alchemy, this action's contextual embedding encodes the current content of the 5th beaker). We incorporate these state-specific embeddings into computation of the action probabilities using a bilinear bonus score:

$$b(a) = q^\top W_{qa} a + w_a^\top a$$

where q is the concatenation of all q_f factor scoring vectors, and W_{qa} and w_a are a learned parameter matrix and vector, respectively. This bonus score $b(a)$ for each action is added to the unnormalized score for the corresponding action a (computed by summing the entries of the q_f vectors which correspond to the factored action components), and the normalized output distribution is then produced using a softmax over all valid actions.

A.2 SAIL speaker details

Since our speaker model operates on segmented action sequences, we train a route segmenter on the training data and then predict segmentations for the test data. This provides a closer comparison to the generation system of Daniele et al. (2017) which did not use segmented routes. The route segmenter runs a bidirectional LSTM over the concatenated state and action embeddings (as in the speaker encoder), then uses a logistic output layer to classify whether the route should be split at each possible timestep. We also collapse consecutive sequences of forward movement actions into single actions (e.g. MOVE4 representing four consecutive forward movements), which we found helped prevent counting errors (such as outputting *move forward three* when the correct route moved forward four steps).

A.3 SCONE speaker details

We use a one-hot representation of the arguments (see Table 5) and contextual embedding (as described in A.1) for each action a_t as input to the SCONE speaker encoder at time t (along with the representation e_t of the world state, as in SAIL). Since SCONE uses a monotonic, one-to-one alignment between actions and direction sentences, the decoder does not use a learned attention mechanism but fixes the contextual representation z_k to be the encoded vector at the action corresponding to the sentence currently being generated.

A.4 Training details

We optimize model parameters using ADAM (Kingma and Ba, 2015) with default hyperparameters and the initialization scheme of Glorot and Bengio (2010). All LSTMs have one layer. The LSTM cell in both the listener and the follower use coupled input and forget gates, and peephole connections to the cell state (Greff et al., 2016). We also apply the LSTM variational dropout scheme of Gal and Ghahramani (2016), using the same dropout rate for inputs, outputs, and recurrent connections. See Table 6 for hyperparameters. We

model	domain	dropout rate	hidden dim	attention dim
L_0	SAIL	0.25	100	100
L_0	Alchemy	0.1	50	50
L_0	Scene	0.1	100	100
L_0	Tangrams	0.3	50	100
S_0	SAIL	0.25	100	100
S_0	Alchemy	0.3	100	–
S_0	Scene	0.3	100	–
S_0	Tangrams	0.3	50	–

Table 6: Hyperparameters for the base listener (L_0) and speaker (S_0) models. The SCONE speakers do not use an attention mechanism.

perform early stopping using the evaluation metric (accuracy for the listener and BLEU score for the speaker) on the development set.

A.5 Computing BLEU for SAIL

To compute BLEU in the SAIL experiments, as the speaker models may choose produce a different number of sentences for each route than in the true description, we obtain a single sequence of words from a multi-sentence description produced for a route by concatenating the sentences, separated by end-of-sentence tokens. We then calculate corpus-level 4-gram BLEU between all these sequences in the test set and the true multi-sentence descriptions (concatenated in the same way).

Hierarchical Structured Model for Fine-to-coarse Manifesto Text Analysis

Shivashankar Subramanian **Trevor Cohn** **Timothy Baldwin**

Abstract

Election manifestos document the intentions, motives, and views of political parties. They are often used for analysing a party's fine-grained position on a particular issue, as well as for coarse-grained positioning of a party on the left–right spectrum. In this paper we propose a two-stage model for automatically performing both levels of analysis over manifestos. In the first step we employ a hierarchical multi-task structured deep model to predict fine- and coarse-grained positions, and in the second step we perform post-hoc calibration of coarse-grained positions using probabilistic soft logic. We empirically show that the proposed model outperforms state-of-art approaches at both granularities using manifestos from twelve countries, written in ten different languages.

1 Introduction

The adoption of NLP methods has led to significant advances in the field of computational social science (Lazer et al., 2009), including political science (Grimmer and Stewart, 2013). Among a myriad of data sources, election manifestos are a core artifact in political analysis. One of the most widely used datasets by political scientists is the Comparative Manifesto Project (CMP) dataset (Volkens et al., 2017), which contains manifestos in various languages, covering over 1000 parties across 50 countries, from elections dating back to 1945.

In CMP, a subset of the manifestos has been manually annotated at the sentence-level with one of 57 political themes, divided into 7 major categories.[1] Such categories capture party positions (FAVORABLE, UNFAVORABLE or NEITHER) on fine-grained policy themes, and are also useful for downstream tasks including calculating manifesto-level (policy-based) left–right position scores (Budge et al., 2001; Lowe et al., 2011; Däubler and Benoit, 2017). An example sentence from the Green Party of England and Wales 2015 election manifesto where they take an UNFAVORABLE position on MILITARY is:

> *We would: Ensure that ... less is spent on military research.*

Elsewhere, they take a FAVORABLE position on WELFARE STATE:

> *Double Child Benefit.*

Such manual annotations are labor-intensive and prone to annotation inconsistencies (Mikhaylov et al., 2012). In order to overcome these challenges, supervised sentence classification approaches have been proposed (Verberne et al., 2014; Subramanian et al., 2017).

Other than the sentence-level labels, the manifesto text also has a document-level score that quantifies its position on the left–right spectrum. Different approaches have been proposed to derive this score, based on alternate definitions of "left–right" (Slapin and Proksch, 2008; Benoit and Laver, 2007; Lo et al., 2013; Däubler and Benoit, 2017). Among these, the RILE index is the most widely adopted (Merz et al., 2016; Jou and Dalton, 2017), and has been shown to correlate highly with other popular scores (Lowe et al., 2011). RILE is defined as the difference between RIGHT and LEFT positions on (pre-determined) policy themes across sentences in a manifesto (Volkens et al., 2013); for instance, UNFAVORABLE position on MILITARY is categorized as LEFT. RILE is popular in CMP in particular, as mapping individual sentences to LEFT/RIGHT/NEUTRAL categories has

Proceedings of NAACL-HLT 2018, pages 1964–1974
New Orleans, Louisiana, June 1 - 6, 2018.

been shown to be less sensitive to systematic errors than other sentence-level class sets (Klingemann et al., 2006; Volkens et al., 2013).

Finally, expert survey scores are gaining popularity as a means of capturing manifesto-level political positions, and are considered to be context- and time-specific, unlike RILE (Volkens et al., 2013; Däubler and Benoit, 2017). We use the Chapel Hill Expert Survey (CHES) (Bakker et al., 2015), which comprises aggregated expert surveys on the ideological position of various political parties. Although CHES is more subjective than RILE, the CHES scores are considered to be the gold-standard in the political science domain.

In this work, we address both fine- and coarse-grained multilingual manifesto text policy position analysis, through joint modeling of sentence-level classification and document-level positioning (or ranking) tasks. We employ a two-level structured model, in which the first level captures the structure within a manifesto, and the second level captures context and temporal dependencies across manifestos. Our contributions are as follows:

- we employ a hierarchical sequential deep model that encodes the structure in manifesto text for the sentence classification task;
- we capture the dependency between the sentence- and document-level tasks, and also utilize additional label structure (categorization into LEFT/RIGHT/NEUTRAL: Volkens et al. (2013)) using a joint-structured model;
- we incorporate contextual information (such as political coalitions) and encode temporal dependencies to calibrate the coarse-level manifesto position using probabilistic soft logic (Bach et al., 2015), which we evaluate on the prediction of the RILE index or expert survey party position score.

2 Related Work

Analysing manifesto text is a relatively new application at the intersection of political science and NLP. One line of work in this space has been on sentence-level classification, including classifying each sentence according to its major political theme (1-of-7 categories) (Zirn et al., 2016; Glavaš et al., 2017a), its position on various policy themes (Verberne et al., 2014; Biessmann, 2016; Subramanian et al., 2017), or its relative disagreement with other parties (Menini et al., 2017). Recent approaches (Glavaš et al., 2017a; Subramanian et al., 2017) have also handled multilingual manifesto text (given that manifestos span multiple countries and languages; see Section 5.1) using multilingual word embeddings.

At the document level, there has been work on using label count aggregation of (manually-annotated) fine-grained policy positions, as features for inductive analysis (Lowe et al., 2011; Däubler and Benoit, 2017). Text-based approaches has used dictionary-based supervised methods, unsupervised factor analysis based techniques and graph propagation based approaches (Hjorth et al., 2015; Bruinsma and Gemenis, 2017; Glavaš et al., 2017b). A recent paper closely aligned with our work is Subramanian et al. (2017), who address both sentence- and document-level tasks jointly in a multilingual setting, showing that a joint approach outperforms previous approaches. But they do not exploit the structure of the text and use a much simpler model architecture: averages of word embeddings, versus our bi-LSTM encodings; and they do not leverage domain information and temporal regularities that can influence policy positions (Greene, 2016). This work will act as a baseline in our experiments in Section 5.

Policy-specific position classification can be seen as related to target-specific stance classification (Mohammad et al., 2017), except that the target is not explicitly mentioned in most cases. Secondly, manifestos have both fine- and coarse-grained positions, similar to sentiment analysis (McDonald et al., 2007). Finally, manifesto text is well structured within and across documents (based on coalition), has temporal dependencies, and is multilingual in nature.

3 Proposed Approach

In this section, we detail the first step of our two-stage approach. We use a hierarchical bidirectional long short-term memory ("bi-LSTM") model (Hochreiter and Schmidhuber, 1997; Graves et al., 2013; Li et al., 2015) with a multi-task objective for the sentence classification and document-level regression tasks. A post-hoc calibration of coarse-grained manifesto position is given in Section 4.

Let D be the set of manifestos, where a manifesto $d \in D$ is made up of L sentences, and a sentence s_i has T words: $w_{i1}, w_{i2}, ...w_{iT}$. The set $D_s \subset D$ is annotated at the sentence-level

with positions on fine-grained policy issues (57 classes). The task here is to learn a model that can: (a) classify sentences according to policy issue classes; and (b) score the overall document on the policy-based left–right spectrum (RILE), in an inter-dependent fashion.

Word encoder: We initialize word vector representations using a multilingual word embedding matrix, W_e. We construct W_e by aligning the embedding matrices of all the languages to English, in a pair-wise fashion. Bilingual projection matrices are built using pre-trained FastText monolingual embeddings (Bojanowski et al., 2017) and a dictionary D constructed by translating 5000 frequent English words using Google Translate. Given a pair of embedding matrices E (English) and O (Other), we use singular value decomposition of $O^T DE$ (which is $U\Sigma V^T$) to get the projection matrix (W^*=UV^T), since it also enforces monolingual invariance (Artetxe et al., 2016; Smith et al., 2017). Finally, we obtain the aligned embedding matrix, W_e, as OW^*.

We use a bi-LSTM to derive a vector representation of each word in context. The bi-LSTM traverses the sentence s_i in both the forward and backward directions, and the encoded representation for a given word $\mathbf{w}_{it} \in s_i$, is defined by concatenating its forward ($\overrightarrow{\mathbf{h}}_{it}$) and backward hidden states ($\overleftarrow{\mathbf{h}}_{it}$), $t \in [1, T]$.

Sentence model: Similarly, we use a bi-LSTM to generate a sentence embedding from the word-level bi-LSTM, where each input sentence s_i is represented using the last hidden state of both the forward and backward LSTMs. The sentence embedding is obtained by concatenating the hidden representations of the sentence-level bi-LSTM, in both the directions, $\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i, \overleftarrow{\mathbf{h}}_i]$, i $\in [1, L]$. With this representation, we perform fine-grained classification (to one-of-57 classes), using a softmax output layer for each sentence. We minimize the cross-entropy loss for this task, over the sentence-level labeled set $D_s \subset D$. This loss is denoted $\mathcal{L}_S$.

Document model: To represent a document d we use average-pooling over the sentence representations $\mathbf{h}_i$ and predicted output distributions ($\mathbf{y}_i$) of individual sentences,[2] i.e., $\mathbf{V}_d = \frac{1}{L}\sum_{i \in d} \begin{bmatrix} \mathbf{y}_i \\ \mathbf{h}_i \end{bmatrix}$. The range of RILE is $[-100, 100]$, which we scale to the range $[-1, 1]$, and model using a final $\tanh$ layer. We minimize the mean-squared error loss function between the predicted $\hat{r}_d$ and actual RILE score r_d, which is denoted as $\mathcal{L}_D$:

$$\mathcal{L}_D = \frac{1}{|D|}\sum_{d=1}^{|D|} \|\hat{r}_d - r_d\|_2^2 \quad (1)$$

Overall, the loss function for the joint model (Figure 1), combining $\mathcal{L}_S$ and $\mathcal{L}_D$, is:

$$\mathcal{L}_J = \alpha\mathcal{L}_S + (1-\alpha)\mathcal{L}_D \quad (2)$$

where $0 \leq \alpha \leq 1$ is a hyper-parameter which is tuned on a development set.

3.1 Joint-Structured Model

The RILE score is calculated directly from the sentence labels, based on mapping each label according to its positioning on policy themes, as LEFT, RIGHT and NEUTRAL (Volkens et al., 2013). Specifically, 13 out of 57 classes are categorized as LEFT, another 13 as RIGHT, and the rest as NEUTRAL. We employ an explicit structured loss which minimizes the deviation between sentence-level LEFT/RIGHT/NEUTRAL polarity predictions $\mathbf{p}$ and the document-level RILE score. The motivation to do this is two-fold: (a) enabling interaction between the sentence- and document-level tasks with homogeneous target space (polarity and RILE); and (b) since we have more documents with just RILE and no sentence-level labels,[3] augmenting an explicit semi-supervised learning objective could propagate down the RILE label to generate sentence labels that concord with the document score.

For the sentence-level polarity prediction (shown in Figure 1), we use cross-entropy loss over the sentence-level labeled set $D_s \subset D$, which is denoted as $\mathcal{L}_{S_P}$. The explicit structured sentence-document loss is given as:

$$\mathcal{L}_{struc} = \frac{1}{|D|}\sum_{d=1}^{|D|}\left(\frac{1}{L_d}\sum_{i \in d}(p_{i_{right}} - p_{i_{left}}) - r_d\right)^2 \quad (3)$$

[2] Preliminary experiments suggested that this representation performs better than using either hidden representations or just the output distribution.

[3] Strictly speaking, for these documents even, sentence annotation was used to derive the RILE score, but the sentence-level labels were never made available.

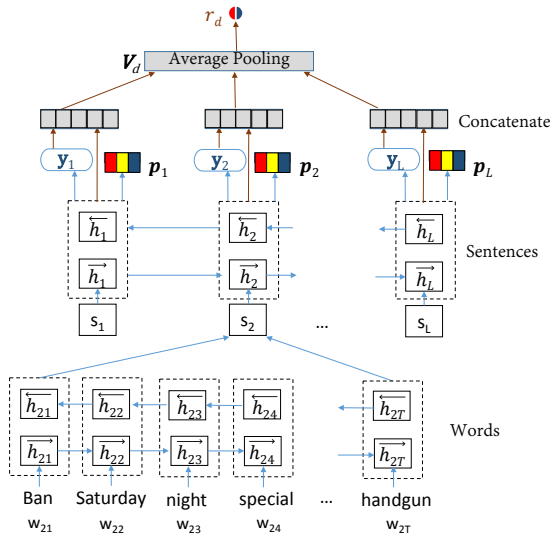

Figure 1: Hierarchical bi-LSTM for joint sentence–document analysis ($\mathbf{y}_i$ denotes the predicted 57-class distribution of sentence s_i; $\mathbf{p}_i$ denotes the distribution over LEFT (in red), RIGHT (in blue) and NEUTRAL (in yellow); r_d denotes the RILE score of d).

where $p_{i_{right}}$ and $p_{i_{left}}$ are the predicted RIGHT and LEFT class probabilities for a sentence s_i ($\in d$), r_d is the actual RILE score for the document d, and L_d is the length of each document, d $\in$ D. We augment the joint model's loss function (Equation (2)) with $\mathcal{L}_{S_P}$ and $\mathcal{L}_{struc}$ to generate a regularized multi-task loss:

$$\mathcal{L}_T = \mathcal{L}_J + \beta\mathcal{L}_{S_P} + \gamma\mathcal{L}_{struc} \quad (4)$$

where $\beta, \gamma \geq 0$ are hyper-parameters which are, once again, tuned on the development set. We refer to the model trained with Equation (2) as "*Joint*", and that trained with Equation (4) as "*Joint*$_{struc}$".

4 Manifesto Position Re-ranking

We leverage party-level information to enforce smoothness and regularity in manifesto positioning on the left–right spectrum (Greene, 2016). For example, manifestos released by parties in a coalition are more likely to be closer in RILE score, and a party's position in an election is often a relative shift from its position in earlier election, so temporal information can provide smoother estimations.

4.1 Probabilistic Soft Logic

To address this, we propose an approach using hinge-loss Markov random fields ("HL-MRFs"), a scalable class of continuous, conditional graphical models (Bach et al., 2013). HL-MRFs have been used for many tasks including political framing analysis on Twitter (Johnson et al., 2017) and user stance classification on socio-political issues (Sridhar et al., 2014). These models can be specified using Probabilistic Soft Logic ("PSL") (Bach et al., 2015), a weighted first order logical template language. An example of a PSL rule is

$$\lambda : \mathtt{P}(\mathtt{a}) \wedge \mathtt{Q}(\mathtt{a}, \mathtt{b}) \rightarrow \mathtt{R}(\mathtt{b})$$

where P, Q, and R are predicates, a and b are variables, and λ is the weight associated with the rule. PSL uses soft truth values for predicates in the interval $[0, 1]$. The degree of ground rule satisfaction is determined using the Lukasiewicz t-norm and its corresponding co-norm as the relaxation of the logical AND and OR, respectively. The weight of the rule indicates its importance in the HL-MRF probabilistic model, which defines a probability density function of the form:

$$P(\mathbf{Y}|\mathbf{X}) \propto \exp\left(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y}, \mathbf{X})\right), \quad (5)$$
$$\phi_r(\mathbf{Y}, \mathbf{X}) = \max\{l_r(\mathbf{Y}, \mathbf{X}), 0\}^{\rho_r},$$

where $\phi_r(\mathbf{Y}, \mathbf{X})$ is a hinge-loss potential corresponding to an instantiation of a rule, and is specified by a linear function l_r and optional exponent $\rho_r \in \{1, 2\}$. Note that the hinge-loss potential captures the distance to satisfaction.[4]

4.2 PSL Model

Here we elaborate our PSL model (given in Table 1) based on coalition information, manifesto content-based features (manifesto similarity and right–left ratio), and temporal dependency. Our target `pos` (calibrated RILE) is a continuous variable $[0, 1]$, where 1 indicates that a manifesto occupies an extreme right position, 0 denotes an extreme left position, and 0.5 indicates center. Each instance of a manifesto and its party affiliation are denoted by the predicates `Manifesto` and `Party`.

Coalition: We model multi-relational networks based on regional coalitions within a given country (`RegCoalition`),[5] and also cross-country coalitions in the European parliament

[4] Degree of satisfaction for the example PSL rule r, $\neg\mathtt{P} \vee \neg\mathtt{Q} \vee \mathtt{R}$, using the Lukasiewicz co-norm is given as $\min\{2 - \mathtt{P} - \mathtt{Q} + \mathtt{R}, 1\}$. From this, the distance to satisfaction is given as $\max\{\mathtt{P} + \mathtt{Q} - \mathtt{R} - 1, 0\}$, where $\mathtt{P} + \mathtt{Q} - \mathtt{R} - 1$ indicates the linear function l_r.

Table 1: PSL Model: Values for `Similarity`, `LwRightLeftRatio` and `pos` are obtained from the joint-structured model (Figure 1). Except for `pos`, other values are fixed in the network. Domain (`y`) for $\texttt{SameElec(x,y)}$ is within the country, and for $\texttt{Recent(x,y)}$ covers all the countries. $\neg$ denotes negation. Distance to satisfaction for each ground rule is obtained using a hinge-loss potential, which is then used inside the HL-MRF model (Equation (5)), where `pos` is $\mathbf{Y}$.

(`EUCoalition`).[6] We set the scope of interaction between manifestos (`x` and `y`) from a country to the same election (`SameElec`). For manifestos across countries, we consider only the most recent manifesto (`Recent`) from each party (`y`), released within 4 years relative to `x`. We use a logistic transformation of the number of times two parties have been in a coalition in the past (to get a value between 0 and 1), for both `RegCoalition` and `EUCoalition`. We also construct rules based on transitivity for both the relational features, i.e., parties which have had common coalition partners, even if they were not allies themselves, are likely to have similar policy positions.

Manifesto similarity: Manifestos that are similar in content are expected to have similar RILE scores (and associated sentence-level label distributions), similar to the modeling intuition captured by Burford et al. (2015) in the context of congressional debate vote prediction. For a pair of recent manifestos (`Recent`) we use the cosine similarity (`Similarity`) between their respective document vectors $\mathbf{V_d}$ (Figure 1).

Right–left ratio: For a given manifesto, we compute the ratio of sentences categorized under RIGHT to OTHERS ($\frac{\#\text{ RIGHT}}{\#\text{ RIGHT}+\#\text{ LEFT}+\#\text{ NEUTRAL}}$), where the categorization for sentences is obtained using the joint-structured model (Equation (4)). We also encode the location of sentence l_s in a document, by weighing the count of sentences for each class C by its location value $\sum_{s \in C} \log(l_s + 1)$ (referred to as *loc_lr*). The intuition here is that the beginning parts of a manifesto tends to contain generic information such as preamble, compared to

[6] http://www.europarl.europa.eu

later parts which are more policy-dense. We perform a logistic transformation of *loc_lr* to derive the `LwRightLeftRatio`.

Temporal dependency: We capture the temporal dependency between a party's current manifesto position and its previous manifesto position (`PreviousManifesto`).

Other than for the look-up based random variables, the network is instantiated with predictions (for `Similarity`, `LwRightLeftRatio` and `pos`) from the joint-structured model (Figure 1). All the random variables, except `pos` (which is the target variable), are fixed in the network. These values are then used inside a PSL model for collective probabilistic reasoning, where the first-order logic given in Table 1 is used to define the graphical model (HL-MRF) over the random variables detailed above. Inference on the HL-MRF is used to obtain the most probable interpretation such that it satisfies most ground rule instances, i.e., considering the relational and temporal dependencies.

5 Evaluation

5.1 Experimental Setup

As our dataset, we use manifestos from CMP for European countries only, as in Section 5.5 we will validate the manifesto's overall position on the left-right spectrum, using the Chapel Hill Expert Survey (CHES), which is only available for European countries (Bakker et al., 2015). In this, we sample 1004 manifestos from 12 European countries, written in 10 different languages — Danish (Denmark), Dutch (Netherlands), English (Ireland, United Kingdom), Finnish (Finland), French (France), German (Austria, Germany), Italian (Italy), Portuguese (Portugal), Spanish (Spain), and Swedish (Sweden). Out of the 1004 manifestos, 272 are annotated with both sentence-level labels and RILE scores, and the remainder only have RILE scores (see Table 2 for further statistics).

There are (less) scenarios where a natural sentence is segmented into sub-sentences and annotated with different classes (Däubler et al., 2012). Hence we use NLTK sentence tokenizer followed by heuristics from Däubler et al. (2012) to obtain sub-sentences. Consistent with previous work (Subramanian et al., 2017), we present results with manually segmented and annotated test documents.

Lang.	# Docs (Anntd.)	# Sents (Anntd.)
Danish	175 (36)	29694 (8762)
Dutch	107 (48)	132524 (70559)
English	117 (27)	86603 (34512)
Finnish	97 (16)	17979 (8503)
French	53 (10)	22747 (5559)
German	117 (46)	111376 (73652)
Italian	98 (15)	41455 (5154)
Portuguese	60 (9)	40922 (11077)
Spanish	85 (50)	145355 (93964)
Swedish	95 (15)	19551 (7938)
Total	1004 (272)	648206 (319680)

Table 2: Statistics of dataset ("Anntd." refers to the number of documents with sentence annotations in the second column, and the number of sentences with annotations in the third column).

5.2 Baseline Approaches

Sentence-level baseline approaches include:

- ***BoW-NN***: TF-IDF-weighted unigram bag-of-words representation of sentences (Biessmann, 2016), and monolingual training using a multi-layer perceptron ("MLP") model.
- ***BoT-NN***: Similar to above, but trigram bag-of-words.
- ***AE-NN***: MLP model with average multilingual word embeddings as the sentence representation (Subramanian et al., 2017).
- ***CNN***: Convolutional neural network ("CNN": Glavaš et al. (2017a)) with multilingual word embeddings.
- ***Bi-LSTM***: Simple bi-LSTM over multilingual word embeddings, last hidden units are concatenated to form the sentence representation, and fed directly into a softmax sentence-level layer. We evaluate two scenarios: (1) with a trainable embedding matrix W_e (***Bi-LSTM(+up)***); and (2) without a trainable W_e.

Document-level baseline approaches include:

- ***BoC***: Bag-of-centroids (BoC) document representation based on clustering the word embeddings (Lebret and Collobert, 2014), fed into a neural network regression model.
- ***HCNN***: Hierarchical CNN, where we encode both the sentence and document using stacked CNN layers.

- ***HNN***: State-of-the-art hierarchical neural network model of Subramanian et al. (2017), based on average embedding representations for sentences and the document.

We present results evaluated under two different settings: (a) 80–20% random split averaged across 10 runs to validate the hierarchical model (Section 5.3 and Section 5.4); and (b) temporal setting, where train- and test-set are split chronologically, to validate both the hierarchical deep model and the PSL approach especially, since we encode temporal dependencies (Section 5.5).

5.3 Hierarchical Sentence- and Document-level Model

We present sentence-level results with a 80–20% random split in Table 3, stratified by country, averaged across 10 runs. For *Bi-LSTM*, we found the setting with a trainable embedding matrix (*Bi-LSTM(+up)*) to perform better than the non-trainable case (*Bi-LSTM*). Hence we use a similar setting for *Joint* and $Joint_{struc}$. We show the effect of α (from Equation (2)) in Figure 2a, based on which we set $\alpha = 0.3$ hereafter. With the chosen model, we study the effect of the structured loss (Equation (4)), by varying γ with fixed $\beta = 0.1$, as shown in Figure 2b. We observe that $\gamma = 0.7$ gives the best performance, and varying β with γ at 0.7 does not result in any further improvement (see Figure 2c). Sentence-level results measured using F-measure, for baseline approaches and the proposed models selected from Figure 2a (*Joint*), Figures 2b and 2c ($Joint_{struc}$) are given in Table 3. We also evaluate the special case of $\alpha = 1$, in the form of sentence-only model $Joint_{sent}$. For the document-level task, results for overall manifesto positioning measured using Pearson's correlation (r) and Spearman's rank correlation (ρ) are given in Table 4. We also evaluate the hierarchical bi-LSTM model with document-level objective only, $Joint_{doc}$.

We observe that hierarchical modeling ($Joint_{sent}$, *Joint* and $Joint_{struc}$) gives the best performance for sentence-level classification for all the languages except Portuguese, on which it performs slightly worse than *Bi-LSTM(+up)*. Also, $Joint_{struc}$, does not improve over $Joint_{sent}$. We perform further analysis to see the effect of joint-structured model on the sentence-level task under sparsely-labeled conditions in Section 5.4. On the other hand, for the document-level task, the joint model (*Joint*) performs better than $Joint_{doc}$ and all the baseline approaches. Lastly, the joint-structured model ($Joint_{struc}$) provides further improvement over *Joint*.

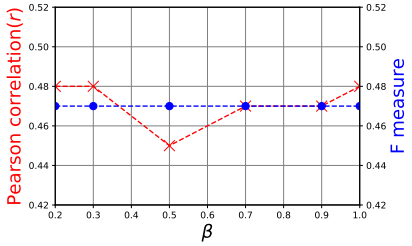
(b) Effect of γ in equation 4.



(c) Effect of β in equation 4.

Figure 2: Effect of hyper-parameters on sentence- and document-level performance. • denotes F-measure (right axis) and × denotes Pearson correlation (left axis).

5.4 Analysis of Joint-Structured Model for Sentence-level task

To understand the utility of joint modeling, especially given that there are more manifestos with document-level labels only than both sentence- and document-level labels, we compare the following two settings: (1) $Joint_{struc}$, which uses additional manifestos with document-level supervision (RILE); and (2) $Joint_{sent}$, which uses manifestos with sentence-level supervision only. We vary the proportion of labeled documents at the sentence-level, from 10% to 80%, to study the effect under sparsely-labeled conditions. Note that 80% is the maximum labeled training data under the cross-validation setting. In other cases, a subset (say 10%) is randomly sampled for train-

ing. From Figure 3, having more manifestos with document-level supervision demonstrates the advantage of semi-supervised learning, especially when the sentence-level supervision is sparse ($\leq$ 40%)— $Joint_{struc}$ performs better than $Joint_{sent}$.

5.5 Manifesto Position Re-ranking using PSL

Finally, we present the results using PSL, which calibrates the overall manifesto position on the left–right spectrum, obtained using the joint-structured model ($Joint_{struc}$). As we evaluate the effect of temporal dependency, we use manifestos before 2008-09 for training (868 in total) and the later ones (until 2015, 136 in total) for testing. This test set covers one recent set of election manifestos for most countries, and two for the Netherlands, Spain and United Kingdom. To avoid variance in right-to-left ratio and the target variable (`pos`, initialized using $Joint_{struc}$) between the training and test sets, we build a stacked network (Fast and Jensen, 2008), whereby we estimate values for the training set using cross-validation across the training partition, and estimate values for the test-set with a model trained over the entire training data. Note that we build the $Joint_{struc}$ model afresh using the chronologically split training set, and the parameters are tuned again using an 80-20 random split of the training set. For a consistent view of results for both the tasks (and stages), we provide micro-averaged results for sentence-classification with the competing approaches (from Table 3): *AE-NN* (Subramanian et al., 2017), *Bi-LSTM(+up)*, and $Joint_{struc}$. Results are presented in Table 5, noting that the results for a given method will differ from earlier due to the different data split.

Approach	F-measure
AE-NN	0.31
Bi-LSTM(+up)	0.36
$Joint_{struc}$	**0.42**

Table 5: Micro-averaged F-measure for manifestos released after 2008-09. Best scores are given in bold.

For the document-level regression task, we also evaluate other approaches based on manifesto similarity and automated scaling with sentence-level policy positions:

- **Cross-lingual scaling (*CLS*)**: A recent unsupervised approach for crosslingual political speech text scoring (Glavaš et al., 2017b), based on TF-IDF weighed average word-embeddings to represent documents, and a graph constructed using pair-wise document

	RILE		CHES	
	r	ρ	r	ρ
CLS	0.11	0.10	0.09	0.07
PCA	0.26	0.17	0.01	−0.02
$Joint_{struc}$	0.46	0.42	0.42	0.42
PSL_{coal}	0.51	0.45	0.49	0.45
$PSL_{coal\ +\ esim}$	0.52	0.47	0.50	0.46
$PSL_{coal\ +\ esim\ +\ ploc}$	**0.54**	0.56	0.53	0.56
$PSL_{coal\ +\ esim\ +\ ploc\ +\ temp}$	**0.54**	**0.57**	**0.55**	**0.61**

Table 6: Manifesto regression task using the two-stage approach. Best scores are given in bold.

similarity. Given two pivot texts (for left and right), label propagation approach is used to position other documents.

- **PCA**: Apply principal component analysis (Gabel and Huber, 2000) on the distribution of sentence-level policy positions (56 classes, without 000), and use the projection on its principal component to explain maximum variance in its sentence-level positions, as a latent manifesto-level position score.

- ***Joint*$_{struc}$**: We evaluate the scores obtained using $Joint_{struc}$, which we calibrate using PSL.

We validate the calibrated position scores using both RILE and CHES[7] scores. We use CHES 2010-14, and map the manifestos to the closest survey year (wrt its election date). CHES scores are used only for evaluation and not during training. We provide results in Table 6 by augmenting features for the PSL model (Table 1) incrementally. We observed that the coalition-based feature, and polarity of sentences with its position information improves the overall ranking (r, ρ). Document similarity based relational feature provides only mild improvement (similarly to Burford et al. (2015)), and temporal dependency provides further improvement against CHES. That is, combining content, network and temporal features provides the best results.

6 Conclusion and Future Work

This work has been targeted at both fine- and coarse-grained manifesto text position analysis. We have proposed a two-stage approach, where in the first step we use a hierarchical multi-task deep model to handle the sentence- and document-level tasks together. We also utilize additional information on label structure, to augment an auxiliary structured loss. Since the first step places the manifesto on the left–right spectrum using text only, we leverage context information, such as coalition and temporal dependencies to calibrate the position further using PSL. We observed that: (a) a hierarchical bi-LSTM model performs best for the sentence-level classification task, offering a 10% improvement over the state-of-art approach (Subramanian et al., 2017); (b) modeling the document-level task jointly, and also augmenting the structured loss, gives the best performance for the document-level task and also helps the sentence-level task under sparse supervision scenarios; and (c) the inclusion of a calibration step with PSL provides significant gains in performance against both RILE and CHES, in the form of an increase from $\rho = 0.42$ to 0.61 wrt CHES survey scores.

There are many possible extensions to this work, including: (a) learning multilingual word embeddings with domain information; and (b) modeling other policy related scores from text, such as "support for EU integration".

Behavior Analysis of NLI Models: Uncovering the Influence of Three Factors on Robustness

V. Ivan Sanchez Carmona and **Jeff Mitchell** and **Sebastian Riedel**
University College London
Department of Computer Science
{i.sanchezcarmona, j.mitchell, s.riedel}@cs.ucl.ac.uk

Abstract

Natural Language Inference is a challenging task that has received substantial attention, and state-of-the-art models now achieve impressive test set performance in the form of accuracy scores. Here, we go beyond this single evaluation metric to examine robustness to semantically-valid alterations to the input data. We identify three factors - *insensitivity*, *polarity* and *unseen pairs* - and compare their impact on three SNLI models under a variety of conditions. Our results demonstrate a number of strengths and weaknesses in the models' ability to generalise to new in-domain instances. In particular, while strong performance is possible on unseen hypernyms, unseen antonyms are more challenging for all the models. More generally, the models suffer from an insensitivity to certain small but semantically significant alterations, and are also often influenced by simple statistical correlations between words and training labels. Overall, we show that evaluations of NLI models can benefit from studying the influence of factors intrinsic to the models or found in the dataset used.

1 Introduction

The task of Natural Language Inference (NLI)[1] has received a lot of attention and has elicited models which have achieved impressive results on the Stanford NLI (SNLI) dataset (Bowman et al., 2015). Such results are impressive due to the linguistic knowledge required to solve the task (LoBue and Yates, 2011; Maccartney, 2009). However, the ever-growing complexity of these models inhibits a full understanding of the phenomena that they capture.

As a consequence, evaluating these models purely on test set performance may not yield enough insight into the complete repertoire of abilities learned and any possible abnormal behaviors (Kummerfeld et al., 2012; Sammons et al., 2010). A similar case can be observed in models from other domains; take as an example an image classifier that predicts based on the image's background rather than on the target object (Zhao et al., 2017; Ribeiro et al., 2016), or a classifier used in social contexts that predicts a label based on racial attributes (Crawford and Calo, 2016). In both examples, the models exploit a bias (an undesired pattern hidden in the dataset) to enhance accuracy. In such cases, the models may appear to be *robust* to new and even challenging test instances; however, this behavior may be due to spurious factors, such as biases. Assessing to what extent the models are robust to these contingencies just by looking at test accuracy is, therefore, difficult.

In this work we aim to study how certain factors affect the robustness of three pre-trained NLI models (a conditional encoder, the DAM model (Parikh et al., 2016), and the ESIM model (Chen et al., 2017)). We call these target factors *insensitivity* (not recognizing a new instance), *polarity* (a word-pair bias), and *unseen pairs* (recognizing the semantic relation of new word pairs). We became aware of these factors based on an exploration of the models' behavior, and we hypothesize that these factors systematically influence the behavior of the models.

In order to systematically test if the above factors affect robustness, we propose a set of challenging instances for the models: We sample a set of instances from SNLI data, we apply a transformation on this set that yields a new set of instances, and we test both how well the models

[1] Also known as Recognizing Textual Entailment.

Proceedings of NAACL-HLT 2018, pages 1975–1985
New Orleans, Louisiana, June 1 - 6, 2018.

classify these new instances and whether the target factors influence the models' behavior. The transformation (swapping a pair of words between premise and hypothesis sentences) is intended to yield both easy and difficult instances to challenge the models, but easy for a human to annotate them.

We draw motivation to study the robustness of NLI models from previous work on evaluating complex models (Isabelle et al., 2017; White et al., 2017). Furthermore, we base our approach on the discipline of behavioral science which provides methodologies for analyzing how certain factors influence the behavior of subjects under study (Epling and Pierce, 1986).

We aim to answer the research questions: How robust is the predictive behavior of the pre-trained models under our transformation to input data? Do the target factors (insensitivity, polarity, and unseen pairs) influence the prediction of the models? Are these factors common across models?

Our results show that the models are robust mainly where the semantics of the new instances do not change significantly with respect to the sampled instances and thus the class labels remain unaltered; i.e., the models are insensitive to our transformation to input data. However, when the class labels change, the models significantly drop accuracy. In addition, the models exploit a bias, polarity, to stay *robust* when facing new instances. We also find that the models are able to cope with unseen word pairs under a hypernym relation, but not with those under an antonym relation, suggesting their inability to learn a symmetric relation.

2 Related Work

2.1 Analysis of Complex Models

Previous works in ML and NLP have analyzed different aspects of complex models using a variety of approaches; for example, understanding input-output relationships by approximating the local or global behavior of the model using an interpretable model (Ribeiro et al., 2016; Craven and Shavlik, 1996), or analyzing the output of the model under lesions of its internal mechanism (Li et al., 2016). Another line of work has analyzed the robustness of NLP models both via controlled experiments to complement the information from the test set accuracy and test abilities of the models (Isabelle et al., 2017; B. Hashemi and Hwa, 2016; White et al., 2017) and via adversarial instances to expose weaknesses (Jia and Liang, 2017). In addition, work has been done to uncover and diminish *gender* biases in datasets captured by structured prediction models (Zhao et al., 2017) and word embeddings (Bolukbasi et al., 2016). However, to the best of our knowledge, there is no previous work to study the robustness of NLI models while analyzing factors affecting their predictions.

2.2 Behavior Analysis

Previous work on behavioral science has focused on understanding how environmental factors influence behaviors in both human (Soman, 2001) and animal (Mench, 1998) subjects with the objective of predicting behavioral patterns or analyzing environmental conditions. This methodology also helps to identify and understand abnormal behaviour by collecting behavioral data without the need to reach any internal component of the subject (Birkett and Newton-Fisher, 2011).

We base our approach in the discipline of behavioral science since some of our research questions and objectives align to those from this discipline; in addition, its methodology to study how factors effect on the subjects' behavior provides statistical guarantees.

3 Background

3.1 Natural Language Inference

NLI, or RTE, is the task of inferring whether a natural language sentence (hypothesis) is entailed by another natural language sentence (premise) (Maccartney, 2009; Dagan et al., 2009; Dagan and Glickman, 2004). More formally, given a pair of natural language sentences $i = (premise, hypothesis)$, a model classifies the type of relation such sentences fall in from three possible classes, *entailment*, where the hypothesis is necessarily true given the premise, *neutral*, where the hypothesis may be true given the premise, and *contradiction*, where the hypothesis is necessarily false given the premise. Solving this task is challenging since it requires linguistic and semantic knowledge, such as co-reference, hypernymy, and antonymy (LoBue and Yates, 2011), as well as pragmatic knowledge and informal reasoning (Maccartney, 2009).

3.2 Behavior Analysis

Behavior analysis seeks to account for the role that factors (independent variables) play in the behavior (dependent variable) of subjects. Testing for

the influence of a factor on the subject's behavior can be done via statistical tests: A null hypothesis states no association between a target factor and behavior, whereas the alternative hypothesis states an association (McDonald, 2014).

4 Dataset and Models

4.1 SNLI Dataset

The Stanford NLI dataset (Bowman et al., 2015) was created with the purpose of training deep neural models while providing human-annotated data. Each instance was created by providing a premise sentence, harvested from a pre-existing dataset, to a crowdsource worker who was instructed to produce three hypothesis sentences, one for each NLI class (entailment, neutral, contradiction). This process yielded a balanced dataset containing around 570K instances.

4.2 Models

Conditional Encoder We use two bidirectional LSTMs; the first LSTM encodes the premise sentence into a fixed-size vector embedding by sequentially reading on a word basis, while the second LSTM encodes the hypothesis sentence conditioned on the representation of the premise sentence. At the final layer we used a softmax over the class labels on top of a 3-layer MLP. All embeddings, of dimensionality $d = 100$, were randomly initialized and learned during training. Accuracy on SNLI's dev set is 0.782.

Decomposable Attention Model DAM (Parikh et al., 2016) consists of 2-layer multilayer-perceptrons (MLPs) factorized in a 3-step process. First, a soft-alignment matrix is created for all the words in both the premise and hypothesis. Then, each word of the premise is paired with the soft-alignment representation of the hypothesis sentence and fed into an MLP, and similarly for each word in the hypothesis with the soft-alignment of the premise. The resulting representations are then aggregated where the vector representations of the premise are summed up and the same for those of the hypothesis; the new representations are then fed to an MLP, followed by a linear layer and a softmax whose output is a class label. We use $d = 300$ dimensional GloVe embeddings (not updated at training time). All layers use the ReLU function. Accuracy on SNLI's dev set is 0.854.

Enhanced Sequential Information Model ESIM (Chen et al., 2017) performs inference in three stages. First, Input Encoding uses BiLSTMs to produce representations of each word in its context within premise or hypothesis. Then, Local Inference Modelling constructs new word representations for each hypothesis (premise) by summing over the BiLSTM hidden states for the premise (hypothesis) words using weights from a soft attention matrix. Additionally, these representations are enhanced with element-wise products and differences of the original hidden states vectors and the new attention based vectors. Finally, Inference Composition uses a BiLSTM, average and max pooling and an MLP output layer to produce predicted labels. Accuracy on SNLI's dev set is 0.882.

5 Methods

We test our main hypothesis (Section 1) by perturbing instances in a controlled, simple, and meaningful way. This alteration, at the instance level, yields new sets of instances which range from *easy* (the semantics and the label of the new instance are the same to those of the original instance) to *challenging* (both semantics and label of the new instance change with respect to those of the original instance), but all of them remain easy to annotate for a human.

To examine how the models generalize from seen instances to transformed instances, we sample our original instances from the SNLI training set, which we refer to as control instances from now on. We then produce new instances which differ either minimally from the control instances, by changing only a single word in the premise and hypothesis, or more substantially, by copying the same sentence structure into the premise and hypothesis with a single word changed. In this way, we produce instances that contain only words seen at training time, within sentence structures also seen at training time. Thus, our evaluation sets are as in-domain as possible, and control for factors associated with novel sentential contexts and vocabulary.

5.1 Basic Procedure and Statistical Analyses

We first sample an instance from the SNLI dataset according to a given criterion, namely we look for a specific word pair in the instance; then, we apply our transformation over the word pair. This pro-

cedure generates a new instance. After that, the models label the new instance, and we statistically analyze which target factors influenced the models to respond in such a way via chi-square (McNemar's, independence, and homogeneity) tests (McDonald, 2014; Alpaydin, 2010). When the sample size is too small we apply Yate's correction or a Fisher test. We use the StatsModels (Seabold and Perktold, 2010) and SciPy (Oliphant, 2007) packages. The level of significance is $p < 0.0001$, unless otherwise stated.[2] This procedure is applied in four experiments, where we study the effect of different word pairs (hypernym, hyponym, and antonyms) and the effect of two types of context words surrounding the word pairs which we refer to as *in situ* and *ex situ* (explained in Section 5.3).

5.2 Transformation and Word Pairs

Given a set of word pairs of the form $W = (w_1, w_2)$, where w_1 and w_2 hold under a semantic relation $s \in \{antonymy, hypernymy, hyponymy\}$, we look through the training set for instances $i_k = (p_k, h_k)$, where p_k and h_k are premise and hypothesis sentences, respectively, such that $w_1 \in p_k$ and $w_2 \in h_k$. For each instance i_k we apply transformation T: we swap w_1 with w_2; this transformation yields an instance $i_m = (p_m, h_m)$ where $w_2 \in p_m, w_1 \in h_m$ and $w_1 \notin p_m, w_2 \notin h_m$.[3]

An example of transformation T on a *contradiction* instance i_k is the following:

(1) p_k : A soccer game occurring at sunset.
h_k : A basketball game is occurring at sunrise.

Where the word pair $(sunset, sunrise)$ are antonyms. After applying transformation T, we obtain the new *contradiction* instance i_m:

(2) p_m : A soccer game occurring at sunrise.
h_m : A basketball game is occurring at sunset.

Consider now the following instance i_l (class label *entailment*):

(3) p_l : A little girl hugs her brother on a footbridge in a forest.
h_l : A pair of siblings are on a bridge.

If we now apply transformation T on the hypernym word pair $(footbridge, bridge)$ we derive the new instance i_n (class *neutral*):

(4) p_n : A little girl hugs her brother on a bridge in a forest.
h_n : A pair of siblings are on a footbridge.

Since swapping word pairs under hypernymy or hyponymy relations may yield a different class label for the new instance, we manually annotate all the instances in the new sample, discarding those that are semantically incoherent.

5.3 Experimental Conditions

We consider two types of sentential context for the word pairs, namely *in situ* and *ex situ*. Examples of instances under the *in situ* condition are Examples 1, 2, 3, and 4 in Section 5.2. The name *in situ* refers to the fact that we analyze the effect of the transformation T within the original context of the premise and hypothesis sentences. This allows to control for confounding factors, such as sentence length and order of the context words.

We also consider an *ex situ* condition in which we remove the word pair from the original premise and hypothesis and analyze the effect of the transformation T within a simplified sentential context which is the same in premise and hypothesis. Specifically, we randomly select either the premise or hypothesis context from the original instance and copy it into both positions. In this way, we obtain a sentence pair where the only difference between the premise and hypothesis is the word pair, which allows us to isolate the effect of this pair from its interaction with the surrounding context; this condition thus allows to control for context words. This process yields a new set of instances, which we refer to as E.

An example of an *ex situ* instance can be constructed from Example 1 (Section 5.2). If the premise sentence is selected, then after performing the procedure described above, the following sentence pair e_k is generated:

(5) p_k : A soccer game occurring at sunset.
h_k : A soccer game occurring at sunrise.

Given a sample E, we apply the transformation T in order to generate a transformed sample E_T where the word pairs are swapped, similar to the procedure applied in Section 5.2 on SNLI control instances in order to generate their transformed instances counterpart. In the latter case, we say that

[2] We apply a Bonferroni correction.

[3] If a word w_1 or w_2 appears more than once, we replace all the appearances with its corresponding pair, w_2 or w_1.

		Whole sample			Subset 1: Gold label changes			Subset 2: Unseen word pairs			Subset 3: Polarity $\neq$ gold label		
Exp	sample	ESIM	DAM	CE	ESIM	DAM	CE	ESIM	DAM	CE	ESIM	DAM	CE
1	I_A	0.970	0.946	0.820							0.900	0.900	0.750
	I_{TA1}	0.933	0.946	0.732				0.600	0.500	0.400	0.681	0.637	0.536
	I_{TA2}	0.721	0.771	0.645	0.554	0.653	0.476						
	I_{TA3}	0.722	0.745	0.646	0.568	0.630	0.535						
2	E_A	0.953	0.958	0.508							0.400	0.500	0.450
	E_{TA}	0.933	0.929	0.480				0.575	0.500	0.175	0.565	0.492	0.260
3	I_H	0.898	0.819	0.828							0.836	0.701	0.733
	I_{TH}	0.648	0.691	0.543	0.315	0.509	0.271	0.694	0.777	0.555	0.719	0.697	0.586
4	E_H	0.771	0.849	0.742							0.715	0.707	0.461
	E_{TH}	0.576	0.788	0.534	0.551	0.783	0.516	0.527	0.666	0.472	0.631	0.674	0.507

Table 1: Accuracy scores of all models. *Exp*: experiment number. *Whole sample*: accuracy scores on the whole sample. *Subset 1*: subset of transformed instances that have different gold label with respect to the control instances they were generated from. *Subset 2*: subset of transformed instances that contain word pairs unseen at training time. *Subset 3*: subset of control or transformed instances containing word pairs whose polarity does not match the instance's gold label.

given a sample of control instances I we generate a transformed sample I_T.

As an example of obtaining a transformed *ex situ* instance, we apply T to $(sunset, sunrise)$ in Example 5 to obtain the new instance e_m:

(6) p_m : A soccer game occurring at sunrise.
h_m : A soccer game occurring at sunset.

We note that for both conditions, *in situ* and *ex situ*, the same word pairs are swapped, so the differences are the surrounding context words and the factors being controlled.

5.4 Test Sets

In each experiment we use two sets of instances in order to measure the robustness of the models and analyze our target factors: 1) The control instances where the target word pair is in its original position and 2) the transformed instances generated after applying transformation T. The name of each set corresponds with the experimental setting it is used in. Samples used in *in situ* experiments are named as I, and E for *ex situ*. Subscripts distinguish both the type of word pairs (A for antonyms and H for hypernym/hyponym) and the type of set (control or transformed). For example, I_A refers to the control *in situ* set whose instances contain antonym word pairs, whereas E_{TH} refers to the *ex situ* transformed test set containing hypernym/hyponym swapped word pairs.

We clarify: a) the sets I_A and I_H are sampled from the SNLI dataset; b) transformed test sets are generated from control sets containing control instances; c) we refer to the sets E_A and E_H as control test sets because the target word pairs are in their original position, and we apply T on them in order to obtain the transformed samples E_{TA} and E_{TH}, respectively.

Details about the sets: In order to build set I_A, we sample only *contradiction* instances (instances in E_A are also *contradictions*). We use the antonym word pairs from (Mohammad et al., 2013) to yield the sets I_{TA1} and E_{TA}, which also only contain *contradictions* since the relation of antonymy is symmetric.[4] We build two more sets, I_{TA2} and I_{TA3} (explained in Section 6.1). Sets I_H, E_H, I_{TH}, and E_{TH} contain instances with any class label. In order to generate sets I_{TH} and E_{TH}, we use the hypernym word pairs from (Baroni et al., 2012). We manually annotate these transformed sets and discard incoherent instances.

5.5 Factors Under Study

We describe the three target factors that we hypothesize that affect the models' response.

Insensitivity is the name we give to the tendency of a model to predict the original label on a transformed instance that is similar to a control instance. Thus a model would be insensitive if, for example, it incorrectly predicts the same class label for both the control instance in Example 3

[4]The word pair $(sunset, sunrise)$ holds in an antonymy relation regardless of the position of the words in premise and hypothesis sentences.

and the transformed instance in Example 4 just because they closely resemble each other. A simple measure of the impact of this effect is to look at the accuracy on the subset of instances in which the gold label was changed by the transformation. We show this effect by statistically correlating the rate of correct predictions with changes in the labels predicted.

Unseen Word Pairs are another factor we can use to evaluate robustness. In this case, we are interested in the subset of transformed instances where the swapped word pair is now in an order within premise and hypothesis that was unseen in the training data. An example is Example 2 which contains the unseen word pair $(sunrise, sunset)$; i.e., no instance in the training set contains the word *sunrise* in the premise and the word *sunset* in the hypothesis. Poor performance on this subset reflects an inability to exploit the symmetry (antonym pairs) or anti-symmetry (hypernym pairs) of the word pairs involved. We show models' abilities to cope with unseen pairs by statistically associating proportions of instances containing unseen pairs with incorrect predictions rates.

Polarity is the name we give to the association between a word pair and the most frequent class it is found in across training instances. For example, we associate the word pair $(sunset, sunrise)$ with polarity *contradiction* because it mainly appears on training instances with label *contradiction*. We define four main categories of polarity: *neutral*, *contradiction*, *entailment*, and *none* for unseen word pairs.[5] Accuracy on the subset of instances where polarity and gold label disagree is an indicator of the extent to which a model is influenced by this factor. For example, a model incorrectly predicting label *entailment* for the instance in Example 4 (class *neutral*) based on the polarity of class *entailment* of its word pair $(bridge, footbridge)$ indicates that the model is influenced by this factor. We show this influence by statistically correlating labels predicted with polarities.

6 Experiments and Results

Table 1 presents the performance of the models across the different test sets. In general, DAM and ESIM seem to be more robust than CE, with the latter's accuracy degrading to essentially random performance on the most challenging subsets. However, this general trend is reversed in a single row of the table. On E_{TH}, ESIM shows a comparable performance to CE. And on Subset 3 of I_H, DAM appears to rely on a bias (polarity) in the same way as CE. Overall, all models are affected by the three target factors, dropping performance up to 0.25, 0.20, and 0.28 for ESIM, DAM, CE, respectively, just by virtue of our simple transformation of swapping words.

6.1 Experiment 1: Swapping Antonyms in *In Situ* Instances

In this experiment we use sets I_A and I_{TA1}. Swapping antonyms seems to have no effect on the overall performance of the DAM model on I_{TA1} when compared to I_A, and little effect on ESIM. Thus these two models appear to be robust to this transformation. Nonetheless, further analysis will not support the conclusion that both models have learned that antonymy is symmetric, and we will show that this seemingly robust behavior is due to confounding factors and not due to inference abilities. Accuracy scores of CE model seem to reveal that it is much less robust to the antonym swap, with performance significantly dropping by roughly 10.5% according to a McNemar's test.

Insensitivity Because instances in I_{TA1} are *contradiction*, we perform a proxy experiment to understand the models' sensitivity. From I_A, we substitute one of the antonyms in each word pair (in each instance) with a hyponym, hypernym, or synonym[6] of the other. Doing this on both the premise and hypothesis yields two new samples, I_{TA2} and I_{TA3}, which we manually annotate.

Examples of control (Example 7) and transformed (Example 8) instances are given below, showing the replacement of *young*, in the hypothesis, with *aged*, a synonym of *elderly* from the premise. This transformation changes gold-label from *contradiction* to *neutral*. Approximately, half the sample yields such changes in gold-label.

(7) p_k : An elderly woman sitting on a bench.
h_k : A young mother sits down.

(8) p_m : An elderly woman sitting on a bench.
h_m : An aged mother sits down.

[5] We also define categories when a word pair appears the same number of times in two classes, such as *entailment-neutral*, though these cases are rare.

[6] We manually select these from WordNet such that it appears at least $t = 10$ times in the training set on either the premise sentences or the hypothesis sentences.

This transformation leads to a considerable drop in overall performance for all models when accuracy scores on sets I_{TA2} and I_{TA3} are compared to the accuracy on the control instances in I_A: up to 0.175 (CE), 0.201 (DAM), and 0.24 (ESIM) points (Table 1). To test if insensitivity to the transformation is associated with these behaviors, we measure accuracy only on those instances that changed gold-label (Subset 1 from the sets I_{TA2} and I_{TA3}), where we see a further reduction in performance for all models. 2-way tests of independence provide strong evidence for the insensitivity of the models (CE: $\chi^2(1) = 73.33$, DAM: $\chi^2(1) = 108.30$, ESIM: $\chi^2(1) = 175.34$).

Table 2 shows the case for ESIM: most of its incorrect predictions are due to predicting the same label on both control and transformed instances when these two type of instances have different gold labels. Paradoxically, this effect works in the models' favour in the antonym swapping case (I_{TA1}) because all the gold-labels remain as *contradiction*. Thus ignoring the transformation will avoid any loss in performance.

	Distribution of predictions	
Labels predicted	correct	incorrect
change	155	31
no change	8	100

Table 2: Contingency table for ESIM: Predictions on transformed instances with different gold labels from those of the control instances.

Unseen Word Pairs The results in the column Subset 2 of I_{TA1} (Table 1) suggest that performance on unseen word pairs is weak. However, only 40 instances within I_{TA1} contain unseen antonym pairs; thus the impact of this result may be limited. 2-way tests of homogeneity show that the difference in accuracy of predictions in instances containing seen or unseen word pairs is nonetheless significant for all models (CE: $\chi^2(1) = 19.46$, DAM: $\chi^2(1) = 74.16$, ESIM: $\chi^2(1) = 39.33$). In other words, the models struggle to recognize the reversed antonym pairs, even though they were all seen in their original order at training time. This effect can be seen, for example, in the contingency table for DAM in Table 3.

Polarity Only 11% of the instances in the transformed sample I_{TA1} contain word pairs that have polarity other than *contradiction*. Thus, a model relying only on this factor could achieve an accuracy of 89%. We investigate if the predicted labels on instances in I_{TA1} are associated with the polarity of the transformed word pair. For all models, independence tests are highly significant (CE: $\chi^2(6) = 30.69$, DAM: $\chi^2(6) = 101.26$, ESIM: $\chi^2(6) = 64.40$). Table 4 shows that the predictions of DAM change according to the polarity of the word pairs. For example, when the polarity is *contradiction*, around 98.5% of the predictions are *contradictions*; however, this figure changes when the polarity is *neutral* where the rate of correct predictions (*contradictions*) fall to 80.7%, and a more dramatic fall is observed when the word pairs are unseen (polarity *none*) where only 50% of the predictions are correct. This is strong evidence that the models learned to rely on polarity.

We note that a model with perfect accuracy on I_{TA1}, would lead to a statistic that does not reject the null hypothesis, showing in this case that the predictions are independent of polarity.

	Word pairs	
Predictions	seen	unseen
correct	567	20
incorrect	13	20

Table 3: Contingency table for DAM: Predictions distributed according to instances containing a seen or an unseen antonym word pair.

Polarity \ Prediction	Neutral	Contradiction	Entailment
Neutral	5	21	0
Contradiction	5	543	3
Entailment	0	3	0
None	8	20	12

Table 4: Contingency table for DAM: Predictions distributed according to the polarity of target word pairs found in the transformed instances.

6.2 Experiment 2: Swapping Antonyms in *Ex Situ* Instances

In this experiment, we use samples E_A and E_{TA}. Swapping antonyms has little effect on the performance of all models, where the biggest drop comes from DAM (0.029 points). However, the CE model performs quite poorly at both samples (0.508 and 0.48 accuracy points on E_A and E_{TA});

this drop in performance, with respect to the *in situ* condition, suggests that the repeated sentence context is too different from the structure of the training instances for the CE model to generalize effectively.

In this condition, we refrain from analyzing the effect of insensitivity, since doing so would require a transformation similar to that in the *in situ* condition, which might add an extra layer of change and the results may turn difficult to interpret.

Unseen Word Pairs Accuracy scores strongly suggest that the models are weak at dealing with unseen antonym pairs (Subset 2 of E_{TA} in Table 1); drops in performance on this subset range from 0.315 up to 0.429 points across the three models. Tests of homogeneity show strong evidence of this weakness for all models (CE: $\chi^2(1) = 15.91$, DAM: $\chi^2(1) = 59.17$, ESIM: $\chi^2(1) = 44.72$). Comparing results on this subset with those of Subset 2 in I_{TA1}, we notice that ESIM and DAM keep similar behavior, but CE seems to be strongly affected by this context type.

Polarity All models perform poorly in the subset of instances where polarity disagrees with gold label of the instance (Subset 3 of E_{TA}), showing that the models' behavior rely on this bias. These results are highly significant (CE: $\chi^2(6) = 34.37$, DAM: $\chi^2(6) = 136.99$, ESIM: $\chi^2(6) = 103.47$). This is further evidence that the models get *confused* with a simple reversal of an antonym pair.

6.3 Experiment 3: Swapping Hypernyms and Hyponyms in *In Situ* Instances

We now study the effect on the robustness of the systems when we swap hypernym and hyponym word pairs in *in situ* instances. Whole sample accuracy scores in Table 1 significantly drop, according to McNemar's tests, by 0.25 (ESIM), 0.285 (CE), and 0.128 (DAM) points when we compare scores on control instances (I_H) with those on transformed instances (I_{TH}). We investigate the role of our target factors on these behaviors.

Insensitivity Around 42% of the instances in I_{TH} (Subset 1) have different gold label from those in I_H. On these instances, the models' results are severely impaired: CE and ESIM models' performances drop to close-to-random (0.271 and 0.315), while DAM decreases by 0.18 points. All models' errors on this subset are strongly associated with failure to change the predicted class (CE:$\chi^2(1) = 90.73$, DAM:$\chi^2(1) = 101.52$, ESIM:$\chi^2(1) = 150.92$). In contrast to the case in Experiment 1, insensitivity acts in detriment of the models' robustness when gold labels change after the transformation.

Unseen Word Pairs Whereas model performance was significantly worse on unseen antonym pairs, this effect is not obvious on the hyponym-hypernym results (Subset 2 of I_{TH}). In fact, all models have a slightly higher accuracy on this subset than overall. Homogeneity tests find no evidence of an association between unseen word pairs and incorrect predictions for any model (CE:$\chi^2(1) = 0.00036, p = 0.98$, DAM:$\chi^2(1) = 0.98, p = 0.32$, ESIM:$\chi^2(1) = 0.178, p = 0.67$). This effect may be explained by the models exploiting information from word embeddings. It has been shown that word embeddings are able to capture hypernymy (Sanchez and Riedel, 2017); thus the models may use this information to generalize to unseen hypernym pairs.

Polarity We find very strong evidence for an association between polarity and class label predicted on sample I_H for all models (CE:$\chi^2(10) = 168.40$, DAM:$\chi^2(10) = 182.76$, ESIM:$\chi^2(10) = 157.76$). However, for sample I_{TH}, only DAM keeps this strong correlation ($\chi^2(14) = 47.71$). In the case of CE, we find weak evidence in favour of this correlation on instances of I_{TH} ($\chi^2(14) = 25.27, p = 0.03$). For ESIM we find no evidence of correlation ($\chi^2(14) = 22.72, p = 0.06$), thus we do not reject the null hypothesis. Polarity's influence can be observed in Subset 3 of I_H (Table 1), where we observe a drop in accuracy for instances whose gold labels do not match the polarity of the word pairs, compared to the accuracy of the whole sample; this means that when the models have polarity as a cue, they improve performance.

6.4 Experiment 4: Swapping Hypernyms and Hyponyms in *Ex Situ* Instances

All models' performance significantly drop ($p < 0.01$) after our transformation by 0.208 (CE), 0.061 (DAM) and 0.195 (ESIM) points, where performance of ESIM is comparable to that of CE on both samples, E_H and E_{TH}. Compared to the *in situ* condition, DAM's performance improves, opposite to CE's and ESIM's behavior.

Insensitivity The drop in performance described above can be partially explained by insensitivity to changes in gold label, since around 93% of the instances in E_{TH} changed gold-label with respect to E_H. We find strong statistical evidence for this hypothesis (CE:$\chi^2(1) = 175.19$, DAM:$\chi^2(1) = 158.62$, ESIM:$\chi^2(1) = 252.27$). However, in the case of DAM, this factor seems to play a small role on its behavior as seen when we compare accuracy on Subset 1 with that of the whole transformed sample.

Insensitivity seems to have a bigger influence on the models when the transformed instances are closer to the training set: Accuracy scores on Subset 1 from I_{TH} are smaller than those on Subset 1 from E_{TH}.

Unseen Word Pairs Similar to the *in situ* condition, our homogeneity tests show no evidence for incorrect predictions being due to unseen word pairs (CE:$\chi^2(1) = 0.35, p = 0.55$, DAM:$\chi^2(1) = 2.43, p = 0.11$, ESIM:$\chi^2(1) = 0.183, p = 0.66$). We posit the same explanation as before: Models may use hypernymy information contained in the embeddings.

Polarity We find statistically high correlation of the models' predictions with the polarity of the word pairs in the instances from both samples, E_H (CE:$\chi^2(10) = 261.77$, DAM:$\chi^2(10) = 312.67$, ESIM:$\chi^2(10) = 176.38$) and E_{TH} (CE:$\chi^2(14) = 56.52$, DAM:$\chi^2(14) = 258.09$, ESIM:$\chi^2(10) = 105.70$). This evidence indicates that all models use, to some extent, the polarity as a feature for predicting class labels.

7 Discussion and Conclusions

Although all three models achieve strong results on the original SNLI development set (CE: 0.782, DAM: 0.854, ESIM: 0.882), each model exhibits particular weaknesses on the transformed training instances. Notably, all perform poorly on I_{TH} instances in which the gold label is changed, with ESIM and CE performing below the level of chance. Thus, on these instances, the models tend to predict the label of the original unaltered training instance and inference in this case is similar to nearest-neighbour prediction.

On the other hand, much better performance is obtained for the DAM and ESIM models on I_{TH} instances containing unseen word pairs, indicating these models have learned to infer hypernym/hyponym relations from information in the pre-trained word embeddings. In contrast, performance on the unseen word pairs in I_{TA1} and E_{TA} suggests that inferring antonymy from the embeddings is more difficult.

Weak performance is seen again on the E_A and E_{TA} instances where the polarity of the antonym pair is not consistent with the gold label. For these cases, the only difference between premise and hypothesis is the antonym pair, and the models tend to fall back on predicting the most frequent gold label seen for that word pair.

One result that remains anomalous is the overall performance of the ESIM model on the whole E_{TH} sample. While this sample contains unseen word pairs and instances in which the gold label changes or is inconsistent with polarity, these effects do not by themselves explain the poor performance overall. Neither is this weakness explained by the *ex situ* structure, in which premise and hypothesis differ by only one word, as performance on the control *ex situ* sample, E_H, is much stronger. The effect, then, appears to be due to an interaction of the *ex situ* structure in combination with the transformation.

In the present work, we have limited ourselves to examining single influences independently. However, there are undoubtedly manifold interactions contributing to model performance. In fact, the complexities of these models (LSTMs, attention mechanisms and MLPs) are specifically intended to capture the interactions between the words in the premise and hypothesis. Further work is required to understand what these interactions are and how they contribute to performance. Fully uncovering these factors in current NLI datasets is a pre-requisite for the construction of more effective resources in the future.

Acknowledgments

We thank Raul Ortiz Pulido and Erick Sanchez Carmona for insightful discussions, Pasquale Minervini for providing the implementations of DAM and ESIM, Pontus Stenetorp for providing valuable feedback on the manuscript, and Johannes Welbl for insightful comments. Abstract

We present a novel approach for determining learners' second language proficiency which utilizes behavioral traces of eye movements during reading. Our approach provides standalone eyetracking based English proficiency scores which reflect the extent to which the learner's gaze patterns in reading are similar to those of native English speakers. We show that our scores correlate strongly with standardized English proficiency tests. We also demonstrate that gaze information can be used to accurately predict the outcomes of such tests. Our approach yields the strongest performance when the test taker is presented with a suite of sentences for which we have eyetracking data from other readers. However, it remains effective even using eyetracking with sentences for which eye movement data have not been previously collected. By deriving proficiency as an automatic byproduct of eye movements during ordinary reading, our approach offers a potentially valuable new tool for second language proficiency assessment. More broadly, our results open the door to future methods for inferring reader characteristics from the behavioral traces of reading.

1 Introduction

It is currently estimated that over 1.5 billion people are learning English as a Second Language (ESL) worldwide. Their learning progress is commonly evaluated with classroom tests prepared by language instructors, quizzes in language learning software such as Duolingo and Rosetta Stone, and by official standardized language proficiency tests such as TOEFL, IELTS, MET and others. In "high stakes" scenarios, official language proficiency tests are the de-facto standards for language assessment; they are accepted by educational and professional institutions, and are taken by millions of language learners every year (for example, in 2016 over three million people took the IELTS test (IELTS, 2017)). These tests probe language proficiency based on performance on various linguistic tasks, including grammar and vocabulary exams, reading and listening comprehension questions, as well as essay writing and speaking assignments.

Despite their ubiquity, traditional approaches to language proficiency testing have several drawbacks. First, such tests are typically prepared manually and require extensive resources for test development. Moreover, their validity can be undermined by test specific training, prior knowledge of the evaluation mechanisms (Powers et al., 2002), as well as plain cheating via unauthorized access to test materials. Further, the utilized testing and evaluation methodologies vary across different tests, and test materials are in most cases inaccessible to the research community. Perhaps most crucially, the reliance of these tests on the end products of linguistic tasks makes it challenging to study learners' language processing patterns and the difficulties they encounter in real time.

In this work we propose a novel methodology for language proficiency assessment which marks a significant departure from traditional language proficiency tests and addresses many of their drawbacks. In our approach, we determine language proficiency from broad coverage analysis of *eye movements during reading of free-form text in a foreign language*, a special case of the general problem of inferring comprehender characteristics and cognitive state from the measurable traces of real-time language processing. Our framework does not require the test taker to prepare for the test or to perform any hand-crafted linguistic tasks, but simply to attentively read an arbitrary set of sentences. To the best of our knowledge, this work is the first to propose and implement such an approach, yielding a novel language proficiency evaluation scheme which relies solely

Proceedings of NAACL-HLT 2018, pages 1986–1996
New Orleans, Louisiana, June 1 - 6, 2018.

on ordinary reading.

Our framework builds on previous research in psycholinguistics demonstrating that the eyetracking record reflects how readers interact with the text and how language processing unfolds over time (Frazier and Rayner, 1982; Rayner, 1998; Rayner et al., 2012). In particular, it has been shown that key aspects of the reader's characteristics and cognitive state, such as mind wandering during reading (Reichle et al., 2010), dyslexia (Rello and Ballesteros, 2015) and native language (Berzak et al., 2017) can be inferred from their gaze record. Despite these advances, the potential of the rich and highly informative behavioral signal obtainable from human reading for automated inference about readers, and specifically about their linguistic proficiency has thus far been largely unutilized.

Here, we first introduce EyeScore, an independent measure of ESL proficiency which reflects the extent to which a learner's English reading patterns resemble those of native speakers. Second, we present a regression model which uses gaze features to predict the learner's scores on specific external proficiency tests. We address each of our tasks in two data regimes: *Fixed Text*, which requires eyetracking training data for the specific sentences presented to the test taker, as well as the more general and challenging *Any Text* regime, where the test taker is presented with arbitrary sentences for which no previous eyetracking data is available. To enable prediction mechanisms in both regimes, we utilize previously proposed gaze features, and develop new linguistically and psychologically motivated feature sets which capture the interaction between eye movements and linguistic properties of the text.

We demonstrate the effectiveness of our approach via score comparison to standardized English proficiency tests. Our primary benchmark test, taken in lab by 145 ESL participants, are the grammar and listening sections of the Michigan English Test (MET) whose scores range from 0 to 50. EyeScore yields 0.5 Pearson's correlation to MET in the Fixed Text regime, and 0.48 in the Any Text regime. Our regression model for predicting MET scores from eye movement features obtains a correlation of 0.7 and a Mean Absolute Error (MAE) of 3.31 points in the Fixed Text regime, and 0.49 correlation and 4.11 MAE in the Any Text regime. Our results are substantially stronger compared to a baseline using only raw reading speed, and are reasonably close to correlations among traditional proficiency tests. These outcomes confirm the promise of the proposed methodology to reliably measure language proficiency.

This paper is structured as follows. Section 2 describes the data and the experimental setup. In section 3 we delineate our feature sets for charactering eye movements in human reading. Section 4 introduces EyeScore, a second language proficiency metric which is based on similarity of reading patterns to native speakers. In section 5 we use eyetracking patterns to predict scores on MET and TOEFL. In section 6 we survey related work. Finally, we conclude and discuss future work in section 7.

2 Experimental Setup

Our study uses the dataset of eye movement records and English proficiency scores introduced in Berzak et al. (2017)[1], which we describe here in brief. The dataset contains gaze recordings of 37 native English speakers and 145 ESL speakers belonging to four native language backgrounds: 36 Chinese, 36 Japanese, 36 Portuguese and 37 Spanish. Participants were presented with free-form English sentences appearing as one-liners. To encourage attentive reading each sentence was followed by a yes/no comprehension question. During the experiment participants held a controller with buttons for indicating sentence reading completion and answering the sentence comprehension questions. Participants' eye movements were recorded using a desktop mount EyeLink 1000 eyetracker (SR Research) at a sampling rate of 1000Hz.

2.1 Procedure and Reading Materials

An experimental trial for a sentence starts with a presentation of a target circle at the center left of a blank screen. A 300ms fixation on this circle triggers a one-liner sentence on a new screen starting at the same location. After completing reading the sentence, participants are presented with the letter Q on a blank screen. A 300ms fixation on this letter triggers a question about the sentence on a new screen. Participants provide a yes/no answer to the question and are subsequently informed if

[1]The data was collected under IRB approval, and all the participants provided written informed consent.

they answered correctly. The first trial of the experiment was presented to familiarize participants with the experimental setup, and is discarded from the analysis.

Each participant read a total of 156 English sentences, randomly drawn from the Wall Street Journal Penn Treebank (WSJ-PTB) (Marcus et al., 1993). The maximal sentence length was set to 100 characters, yielding an average sentence length of 11.4 words. All the sentences include the manual PTB annotations of POS tags (Santorini, 1990) and phrase structure trees, as well as Google universal POS tags (Petrov et al., 2012) and dependency trees obtained from the Universal Dependency Treebank (UDT) (McDonald et al., 2013).

2.2 Experimental Regimes

Half of the 156 sentences presented to each participant belong to the *Fixed Text* regime, and the other half belong to the *Any Text* regime. Sentences from the two regimes were interleaved randomly and presented to all participants in the same order.

Fixed Text In this regime, all the participants read the same suite of 78 pre-selected sentences (900 words). The Fixed Text regime supports *token-level* comparisons of reading patterns for specific words in the same contexts across readers. It enables the construction of a proficiency test which relies on a fixed battery of reading materials for which previous eyetracking data was collected.

Any Text In the second, Any Text regime, different participants read different sets of 78 sentences each (880 words on average). This regime generalizes the Fixed Text scenario; predicting reader characteristics in this regime requires formulating *type-level* abstractions that would allow meaningful comparisons of reading patterns across different sentences. It corresponds to a proficiency test in which the sentences presented to the test taker are completely arbitrary, and no prior eyetracking data is available for them.

2.3 Standardized English Tests

We use participants' performance on the Michigan English Test (MET) and TOEFL as external benchmarks of their English proficiency.

Michigan English Test (MET) Our primary indicator of English proficiency is the listening and grammar sections of the MET (Form-B), which were administered by Berzak et al. (2017) in-lab, and taken by all the 145 non-native participants upon completion of the reading experiment. The test has a total of 50 multiple choice questions, comprising 20 listening comprehension questions and 30 written grammar questions. The test score is computed as the number of correct answers for these questions, with possible scores ranging from 0 to 50. The mean MET score in the dataset is 41.46 (std 6.27).

TOEFL Berzak et al. (2017) also collected self-reported scores on the most recently taken official English proficiency test, which we use here as a secondary evaluation benchmark. We focus on the most commonly reported test, the TOEFL-iBT whose scores range from 0 to 120. We take into account only test results obtained less than four years prior to the experiment, yielding 33 participants. We sum the scores of the reading and listening sections of test, with a total possible score range of 0 to 60. In cases where participants reported only the overall score, we divided that score by two. We further augment this data with 20 participants who took the TOEIC Listening and Reading test within the same four years range, resulting in a total of 53 external proficiency scores. The TOEIC scores were converted to the TOEFL scale by fitting a third degree polynomial on an unofficial score conversion table[2] between the tests. The converted scores were then divided by two. Henceforth we refer to both TOEFL-iBT and TOEIC scores converted to TOEFL-iBT scale as TOEFL scores. The mean TOEFL score is 47.6 (std 9.55). The Pearson's r correlation between the TOEFL and MET scores in the dataset is 0.74.

2.4 Data Split

We divide the ESL speakers into training/development and test sets in the following manner. For MET, we split our 145 ESL participants into a training/development set of 88 participants and a test set of 57 participants. The test set consists of an entire held out native language – 36 speakers of Portuguese – as well as 7 participants randomly sampled from each of the remaining three native languages. Our test set is thus particularly challenging due to the large fraction of participants belonging to the held out language, a design which emphasizes

[2] http://theedge.com.hk/conversion-table-for-toefl-ibt-pbt-cbt-tests/ Although both TOEFL and TOEIC are administered by the same company (ETS), to the best of our knowledge there is no publicly available official conversion table between the two tests.

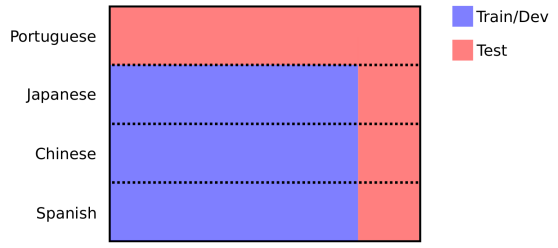

Figure 1: Illustration of the data split for MET into a training/development set (88 participants) and a test set (57 participants).

generalization to language learner populations which are not part of the training set. Figure 1 presents a schematic overview of our MET split. For TOEFL, due to the limited available data, in Section 4 we report EyeScore correlations for all the 53 test takers, and in Section 5 we perform regression experiments using leave-one-out cross validation.

3 Eye Movement Features

In order to capture behavioral psycholinguistic traces of language proficiency we utilize several linguistically and psychologically motivated feature representations of eye movements in reading. We include features introduced in prior work (see Words in Fixed Context and Syntactic Clusters (Berzak et al., 2017)) as well as newly developed feature sets (see Word Property Coefficients and Transitions). All our features rely on the well established division of gaze trajectories into fixations (stops) and saccades (movements between fixations) that characterizes human reading (Rayner, 1998).

Our fixation based features make use of several standard metrics of fixation times, defined below.

- *First Fixation duration (FF)* Duration of the first fixation on a word.
- *First Pass duration (FP)* Time spent from first entering a word to first leaving it (including re-fixations within the word).
- *Total Fixation duration (TF)* The sum of all fixation times on a word.
- *Regression Path duration (RP)* Time from first entering a word until proceeding to its right.

Our feature sets are divided into two groups. The first group consists of type-level features, applicable both in the Any Text and Fixed Text regimes. The second group of feature sets is token-based and can be extracted only in the Fixed Text regime, because it presupposes the same textual input for all participants.

3.1 Type-Level Features

Word Property Coefficients (WP-Coefficients)

This new feature set quantifies the influence of three key word characteristics on reading times of individual readers: word length, word frequency and surprisal. The last measures the difficulty of processing a word in a sentence (Hale, 2001; Levy, 2008), and is defined as its negative log probability given a sentential context:

$$surprisal(w_i|w_{1...i-1}) = -\log(w_i|w_{1...i-1}) \quad (1)$$

In the reading literature, these three characteristics were suggested as the most prominent linguistic factors influencing word reading times (e.g. Inhoff and Rayner, 1986; Rayner and Well, 1996; Pollatsek et al., 2008; Kliegl et al., 2004; Rayner et al., 2004, 2011; Smith and Levy, 2013; Luke and Christianson, 2016); whereby longer, less frequent and contextually less predictable words are fixated longer.

To derive this feature set, we measure length as the number of characters in the word. Word (log) frequencies are obtained from the BLLIP-WSJ corpus (Charniak et al., 2000). Estimates of surprisal are obtained from a trigram language model with Chen and Goodman's modified Kneser-Ney smoothing trained on the BLLIP-WSJ using SRILM (Stolcke et al., 2002). We then fit for each participant four regression models that use these three word characteristics to predict the word's raw FF, FP, TF and RP durations. The regression models are fitted using Ordinary Least Squares (OLS). We also train a logistic regression model for predicting word skips. Finally, we extract the weights and intercepts of these models and encode them as features. As each of the five models has three coefficients and one intercept term, the resulting WP-Coefficients feature set has 20 features.

Syntactic Clusters (S-Clusters)

Following Berzak et al. (2017), we extract average word reading times clustered by POS tags and

syntactic functions. We utilize three metrics of reading times, FF, FP and TF durations. We then cluster words according to three types of syntactic criteria, Google Universal POS tags, PTB POS tags, and the syntactic function label of the word to its head word. To derive the feature set, we average the word fixation times of each cluster. An example of an S-Cluster feature is the average TF duration for words with the PTB POS tag DT. We take into account only cluster labels that appear at least once in the reading input of all the participants, yielding a total of 312 S-Clusters features in the Fixed Text regime. In the Any Text regime we obtain 156 S-Clusters features for MET and 165 S-Clusters features for TOEFL.

3.2 Token-Level Features

Transitions

Transitions is a new feature set which summarizes the sequence of saccades between words in a sentence. Given a sentence with n words, we construct an $n \times n$ matrix T. A matrix entry $t_{i,j}$ records the number of saccades whose launch site falls within word i and landing site falls within word j. With a total of 11,616 possible transitions in the Fixed Text sentences, the resulting feature set contains 9,077 features with a non-zero value for at least one participant for MET, and 8,132 such features for TOEFL.

Words in Fixed Context (WFC)

This feature set was previously used in Berzak et al. (2017) and consists of reading times for words within fixed contexts. We extract FP and TF durations for the 900 words in the Fixed Text sentences, resulting in a total of 1,800 WFC features.

4 English Proficiency Scoring Based on Eye Movements in Reading

We hypothesize that language proficiency influences the way that learners process a second language, which in turn will be reflected in eye movement patterns in reading. Specifically, we propose to examine whether the more proficient is an ESL learner, the more similar are their reading patterns to those of native English speakers. We operationalize the notion of native-like reading in the following manner. First, given a feature representation of choice and a dataset D comprising ESL learners D_{L2} and native speakers D_{L1} we Z score each feature in D using a Z scaler derived from D_{L2}. We then obtain a prototype feature vector of native reading v_{L1} by averaging the feature vectors of the native speakers.

$$v_{L1} = \frac{1}{|D_{L1}|} \sum_{y \in D_{L1}} v_y \tag{2}$$

Finally, we obtain an eyetracking based proficiency score of an ESL learner by computing the cosine similarity of their feature vector to the native reading prototype. Hereafter we refer to this measure as EyeScore.

$$EyeScore_{y \in D_{L2}} = \frac{v_y \cdot v_{L_1}}{\|v_y\| \|v_{L1}\|} \tag{3}$$

Reading Speed Normalization To reduce bias towards fast readers, the feature representations used for Eyescore are normalized to be invariant to the reading speed of the participant. Specifically, for the S-Clusters and WFC feature sets we follow the normalization procedure of Berzak et al. (2017), where for a given participant, the reading time of a word w_i according to a fixation metric M is normalized by $S_{M,C}$, the metric's fixation time per word in the linguistic context C:

$$S_{M,C} = \frac{1}{|C|} \sum_{w \in C} M_w \tag{4}$$

The linguistic context is defined as the surrounding sentence in the Fixed Text regime, and the entire textual input in the Any Text regime. The normalized fixation time is then obtained as:

$$Mnorm_{w_i} = \frac{M_{w_i}}{S_{M,C}} \tag{5}$$

For the WC-Coefficients features we take into account only the 15 model coefficients, and omit the 5 intercept features which capture the reading speed of the participant. Finally, we also normalize the Transitions features matrix T by the total number of saccades in the sentence to obtain T_{norm} in which $\sum_{i,j} t_{norm_{i,j}} = 1$.

4.1 Correlation with MET and TOEFL

We evaluate the ability of EyeScore to capture language proficiency by comparing it against our two external proficiency tests, MET and TOEFL. Table 1 presents the Pearson's r correlation of EyeScore with MET and TOEFL for the feature sets described in section 3 using the MET training/development set and all the participants who took TOEFL.

	MET		TOEFL	
Features	Fixed	Any	Fixed	Any
Reading Speed	0.28	0.27	0.15	0.13
WP-Coefficients	0.38	0.37	0.21	0.13
S-Clusters	0.45	**0.48**	0.50	**0.45**
Transitions	0.45	NA	0.44	NA
WFC	**0.50**	NA	**0.54**	NA

Table 1: Pearson's r of EyeScore for different feature sets with MET (training/development set, 88 participants) and TOEFL (all 53 participants). Fixed denotes the Fixed Text regime in which all the participants read the same sentences, and Any denotes the Any Text regime where different readers read different sentences.

The strongest correlations, 0.5 for MET and 0.54 for TOEFL, are obtained in the Fixed Text regime using the WFC features. This outcome confirms the effectiveness reading time comparisons when the presented sentences are shared across participants. To illustrate the quality of this result, Figure 2 presents a comparison of EyeScore and MET scores in the Fixed Text and WFC features setup. We further note good performance of the Transitions and S-Clusters features in this regime across both proficiency tests. The strongest performance in the Any Text regime is obtained using the S-Clusters features, yielding 0.48 correlation with MET and 0.45 correlation with TOEFL. These results are competitive with the WFC feature set in the Fixed Text regime, suggesting that reliable EyeScores can be obtained even when no prior eyetracking data is available for the sentences presented to the test taker.

In order to contextualize the correlations obtained with the EyeScore approach, we first compare our results to raw reading speed, an informative baseline which does not rely on eyetracking. EyeScore substantially outperforms this baseline for nearly all the feature sets on both MET and TOEFL, clearly showing the benefit of eye movement information for our task. Next, we consider possible upper bounds for our correlations. While obtaining such upper bounds is challenging, we can use correlations between different traditional standardized proficiency tests as informative reference points. First, as mentioned previously, in our dataset the MET and reported TOEFL scores have a Pearson's r correlation of 0.74. We further note an external study conducted by the testing company Education First (EF) which measured the correlation of their flagship standardized English

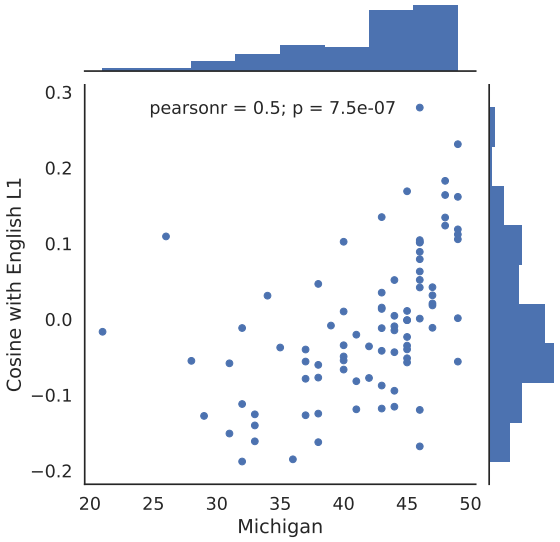

Figure 2: Comparison of MET (training/development set, 88 participants) with EyeScore using Words in Fixed Context (WFC) features in the Fixed Text regime.

proficiency test EFSET-PLUS with TOEFL-iBT (Luecht, 2015). Using 384 participants who took both tests, the study found a Pearson's r of 0.63 for the reading comprehension and 0.69 for the listening comprehension sections of these tests. Despite the radical difference of our testing methodology, our strongest feature sets obtain rather competitive results relative to these correlations, further strengthening the evidence for the ability of our approach to capture language proficiency.

5 Predicting Performance on MET and TOEFL

In section 4 we introduced EyeScore as an independent metric of language proficiency which is based on eye movements during reading. Here, we examine whether eye movements can also be used to explicitly *predict* the performance of participants on specific external standardized language proficiency tests. This task is of practical value for development of predictive tools for standardized proficiency tests, and constitutes an alternative framework for studying the relevance of eye movement patterns in reading to language proficiency.

To address this task, we use Ridge regression to predict overall scores on an external proficiency test from eye movement features in reading. The model parameters θ are obtained by minimizing

	MET				TOEFL			
	Fixed		Any		Fixed		Any	
Features	r	MAE	r	MAE	r	MAE	r	MAE
Reading Speed	0.27	4.58	0.24	4.62	0.09	7.92	0.06	7.96
WP-Coefficients	0.43	4.11	0.44	4.14	0.34	7.76	0.31	**7.49**
S-Clusters	0.56	3.87	**0.49**	**4.11**	**0.55**	7.45	**0.50**	7.76
Transitions	0.52	3.93	NA	NA	0.38	7.11	NA	NA
WFC	**0.70**	**3.31**	NA	NA	0.50	**6.68**	NA	NA

Table 2: Pearson's r and Mean Absolute Error (MAE) for prediction of MET scores (test set, 57 participants) and TOEFL scores (leave-one-out cross validation, all 53 participants) from eye movement patterns in reading. We consider two baselines which do not use eyetracking information: (1) the average proficiency score in the training set, which yields 4.82 MAE on MET and 8.29 MAE on TOEFL, and (2) the reading speed of the participant.

the following loss objective:

$$\sum_i (y_i - \theta \cdot f(x_i))^2 + \lambda \|\theta\|_2^2 \qquad (6)$$

where y_i is a participant's test score, x_i is their eye movement record, and $f(x_i)$ are the extracted eye movement features. To calibrate the model with respect to native English speakers, we augment each training set $D_{L2_{tr}}$ with the group of 37 native speakers D_{L1} whose proficiency scores are assigned to the maximum grade of the respective test (50 for MET and 60 for TOEFL)[3]. Based on MET performance on the train/dev set, the features used for predicting scores on both tests are not normalized for speed[4]. As a preprocessing step, we fit a Z scaler for each feature using the ESL participants in the training set, and apply it to all the participants in the training and test sets.

Results

We evaluate prediction accuracy using Pearson's r and Mean Absolute Error (MAE) from the true proficiency test scores. The λ parameter for MET is optimized for MAE on 10 fold cross validation within the training/development set. For TOEFL, which has a relatively small number of participants, we report results on leave-one-out cross validation with λ set to 1.

Table 2 presents the results for both proficiency tests. We consider two baselines; the first is assigning all test set participants with the average score of the training participants. This baseline yields an MAE of 4.82 on MET and 8.29 on TOEFL. The second baseline uses reading speed as the sole feature for prediction. In all cases, our eyetracking based features outperform the average score and reading speed baselines.

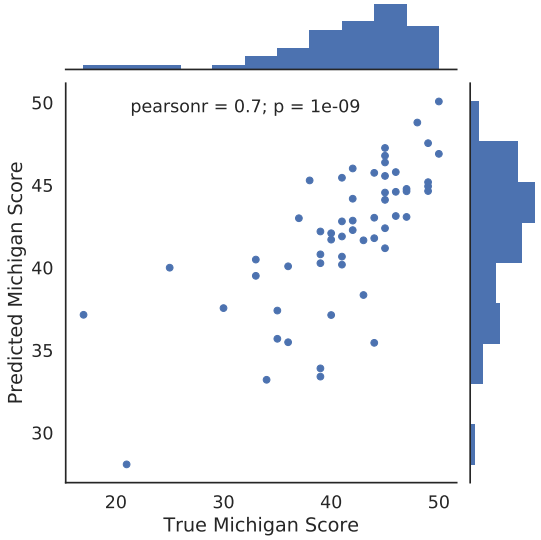

Figure 3: Comparison of MET scores (test set, 57 participants) with predicted MET scores using Words in Fixed Context (WFC) eye movement features in the Fixed Text regime.

The performance of the different feature sets is in most cases consistent across the two proficiency tests and is largely in line with the correlations of EyeScore reported in Table 1. Similarly to the EyeScore outcomes, the best performance in the Fixed Text regime is obtained using the WFC feature set, with a Pearson's r of 0.7 and MAE of 3.31 for MET. This result is highly competitive with correlations between different standardized English proficiency tests. Figure 3 depicts a com-

[3]Our experiments on the training/development set indicate that this training data augmentation step leads in most cases to improved regression performance.

[4]We note that in line with the low correlation of reading speed with TOEFL, speed normalized features tend to be better predictors of TOEFL scores, obtaining r 0.59 and MAE 6.47 with WFC features in the Fixed Text regime, and r 0.58 and MAE 7.19 with S-Clusters in the Any Text regime.

parison between MET scores and our MET predictions in this setup. On TOEFL, WFC features obtain the strongest MAE of 6.68, while S-Clusters have a higher r coefficient of 0.55.

In the Any Text regime, differently from EyeScore, we obtain comparable results for the S-Clusters and WP-Coefficients feature sets. Overall, the improvements of both feature sets over the baselines in the Any Text regime further support the ability of type-level features to generalize the task of language proficiency prediction to arbitrary sentences.

6 Related Work

Our work lies on the intersection of language proficiency assessment, second language acquisition (SLA), the psychology of reading and NLP. Automated language proficiency assessment from free-form linguistic performance has been studied mainly in language *production* (Dikli, 2006; Williamson, 2009; Shermis and Burstein, 2013). Over the past several decades, multiple essay and speech scoring systems have been developed for learner language using a wide range of linguistically motivated feature sets (e.g. Lonsdale and Strong-Krause, 2003; Landauer, 2003; Xi et al., 2008; Yannakoudakis et al., 2011). Some of these systems have been deployed in official language proficiency tests, for example the *e-rater* essay scoring system (Attali and Burstein, 2004) used in TOEFL (Ramineni et al., 2012). While this line of work focuses on assessment of language production, here we introduce and address for the first time automated language assessment during online language *comprehension*.

In SLA, there has been considerable interest in eyetracking, where studies have mostly focused on controlled experiments examining processing of specific linguistic phenomena such as syntactic ambiguities, cognates and idioms (Dussias, 2010; Roberts and Siyanova-Chanturia, 2013). A notable exception is (Cop et al., 2015) who used free-form reading to study differences in fixation times and saccade lengths between native and non-native readers. Our work also adopts broad coverage analysis of reading patterns, which we use to formulate predictive models of language proficiency.

Our study draws on a large body of work in the psychology of reading (see Rayner, 1998; Rayner et al., 2012, for overview) which has suggested that eye movement patterns during reading are systematically influenced by a broad range of linguistic characteristics of the text, and reflect how readers mentally engage with the text (Frazier and Rayner, 1982; Rayner and Frazier, 1989; Reichle et al., 1998; Engbert et al., 2005; Demberg and Keller, 2008; Reichle et al., 2009; Levy et al., 2009, among many others). Prior work on reading has also demonstrated that gaze provides valuable information about various characteristics of the reader and their cognitive state. For example, Reichle et at. (2010) have shown that eye movement patterns are categorically different in attentive versus mindless reading. In Rello and Ballesteros (2015) eye movements were used to distinguish between readers with and without dyslexia. Berzak et al. (2017) collected the dataset used in our work and used it to predict the first language of non-native English readers from gaze. We build on these studies to motivate our task and design feature representations which encode linguistic factors known to affect the human reading process.

Related work in NLP developed predictive models of reading times in reading of free-form text (e.g. Nilsson and Nivre, 2009; Hara et al., 2012; Hahn and Keller, 2016). In a complementary vein, eyetracking signal has been used for linguistic annotation tasks such as POS tagging (Barrett and Søgaard, 2015a; Barrett et al., 2016) and prediction of syntactic functions (Barrett and Søgaard, 2015b). Both lines of investigation provide further evidence for the tight interaction between eye movements and linguistic properties of the text, which we leverage in our work for inference about the linguistic knowledge of the reader.

7 Conclusion and Discussion

We present a novel approach for automated assessment of language proficiency which relies on eye movements during reading of free-form text. Our EyeScore test captures the similarity of language learners' gaze patterns to those of native speakers, and correlates well with the standardized tests MET and TOEFL. A second variant of our approach accurately predicts participants' scores on these two tests. To the best of our knowledge, the proposed framework is the first proof-of-concept for a system which utilizes eyetracking to measure linguistic ability.

In future work, we plan to extend the analysis of the validity and consistency of our approach, and further explore its applications for language

proficiency evaluation. In particular, we will examine the impact of factors that can undermine the validity of language proficiency tests, such as test specific training, familiarity with the evaluation system's features (Powers et al., 2002), and cheating via unauthorized prior access to test materials. Since participants are less likely to be able to manipulate their eye movements in an informed and systematic manner—readers are generally not even aware that their eye movements are saccadic—and since our test can be performed on arbitrary sentences, we expect it to be robust to prior exposure to the test materials and testing methodology. We will further study the consistency of our scores for repeated tests by the same participants. A preliminary split-half analysis indicates that eyetracking based scores are expected to be highly consistent across tests. Finally, our approach can be combined with traditional proficiency testing methodologies, whereby gaze will be recorded while the participant is taking a standardized language proficiency test. This will enable developing novel approaches to language proficiency assessment which will integrate task based performance with real time monitoring of cognitive and linguistic processing.

Abstract

Speakers often have more than one way to express the same meaning. What general principles govern speaker choice in the face of optionality when near semantically invariant alternation exists? Studies have shown that optional reduction in language is sensitive to contextual predictability, such that the more predictable a linguistic unit is, the more likely it is to get reduced. Yet it is unclear to what extent these cases of speaker choice are driven by audience design versus toward facilitating production.

Here we argue that for a different optionality phenomenon, namely classifier choice in Mandarin Chinese, Uniform Information Density and at least one plausible variant of availability-based production make opposite predictions regarding the relationship between the predictability of the upcoming material and speaker choices. In a corpus analysis of Mandarin Chinese, we show that the distribution of speaker choices supports the availability-based production account, and not Uniform Information Density.

1 Introduction

The expressivity of natural language often gives speakers multiple ways to convey the same meaning. Meanwhile, linguistic communication takes place in the face of environmental and cognitive constraints. For instance, language users have limited memory and cognitive resources, the environment is noisy, and so forth. What general principles govern speaker choice in the face of alternations that are (nearly) semantically invariant? To the extent that we are able to provide a general answer to this question it will advance our fundamental knowledge of human language production.

Studies have shown that alternations are very often sensitive to contextual predictability. For well-studied cases of optional REDUCTION in language, the following trend is widespread: the more predictable a linguistic unit is, the more likely it is to get reduced. Predictable words are phonetically reduced (Jurafsky et al., 2001; Bell et al., 2009; Seyfarth, 2014) and have shorter lexical forms (Piantadosi et al., 2011), and optional function words are more likely to be omitted when the phrase they introduce is predictable (Jaeger, 2010). Yet it is unclear to what extent speakers' choices when faced with an alternation are made due to audience design or to facilitate production. For example, the above pattern of predictability sensitivity in optional reduction phenomena is predicted by both the Uniform Information Density (UID) hypothesis (Levy and Jaeger, 2007), a theory which that the speaker aims to convey information at a relatively constant rate and which can be motivated via considerations of optimality from the comprehender's perspective (e.g., Smith and Levy, 2013), and by the speaker-centric availability-based production hypothesis (Bock, 1987; Ferreira and Dell, 2000), which hypothesizes that the dominant factor in determining speaker choice is that the speaker uses whatever material is readily available when it comes time to convey a particular part of a planned message.

Here we argue that for a different optionality phenomenon, namely classifier choice in Mandarin Chinese, UID and availability-based production make opposite predictions regarding the relationship between the predictability of upcoming material and speaker choice. In a corpus analysis of Mandarin Chinese, we show that the distribution of speaker choices supports the availability-based production account, and not UID.

Proceedings of NAACL-HLT 2018, pages 1997–2005
New Orleans, Louisiana, June 1 - 6, 2018.

2 Uniform Information Density and Availability-based Production

In Sections 2 and 3, we explain why the UID and availability-based production accounts make the same predictions in many cases, but can be potentially disentangled using Chinese classifier choice. Here we exemplify predictions of these two accounts in the case of optional function word omission.

For optional function word omission such as *that*-omission ((1) and (2)), predictability effects have been argued to be consistent with both the speaker-oriented account of AVAILABILITY-BASED PRODUCTION (Bock, 1987; Ferreira and Dell, 2000) and the potentially audience-oriented account of UNIFORM INFORMATION DENSITY (Levy and Jaeger, 2007). On both accounts, but for different reasons, the less predictable the clause introduced by the functional word, the more likely the speaker will be to produce the function word *that*.

(1) The student (that) you tutored graduated.

(2) The woman thought (that) we were crazy.

The UID hypothesis claims that within boundaries defined by grammar, when multiple options are available to encode a message, speakers prefer the variant that distributes information density most uniformly, thus lowering the chance of information loss or miscommunication (Levy and Jaeger, 2007; Jaeger, 2010). In (1), if the function word *that* is omitted, the first word of the relative clause *you* serves two purposes: signaling the onset of the relative clause, and conveying part of the contents of the relative clause itself. These both contribute to the information content of the first relative clause-internal word. If one or both is high-surprisal, then the first relative clause-internal word might be a peak in information density, as illustrated in Figure 1 (top left). If instead the function word *that* is produced, *that* signals the onset of the relative clause, and *you* only communicates part of the content of the relative clause itself. This could help eliminate any sharp peak in information density, as illustrated in Figure 1 (bottom left). Thus, if the speaker's goal is to transfer information as smoothly as possible, the less predictable the upcoming clause, the more inclined the speaker would be to produce the function word *that*.

On the availability-based production hypothesis, speaker choice is governed by the relationship by the relative time-courses of (i) when a part of a message needs to be expressed within an utterance, and (ii) when the linguistic material to encode that part of the message becomes available for production. If material that specifically encodes a part of the message is available when it comes time to convey that part of the message, it will be used—that is the PRINCIPLE OF IMMEDIATE MENTION of Ferreira and Dell (2000). If, on the other hand, that material is not yet available, then other available material consistent with the grammatical context produced thus far and that does not cut off the speaker's future path to conveying the desired content will be used. In (1), assuming the function word *that* is always available when the speaker plans to produce a relative clause, the speaker will produce *that* when the upcoming relative clause or the first part of its contents are not yet available. If phrase structures and phrase contents take longer to become available when they are lower-predictability—an assumption consistent with the literatures on picture naming (Oldfield and Wingfield, 1965) and word naming (Balota and Chumbley, 1985)—then the less predictable the relative clause, the lower the probability that its first word, w_1, will be available when the time comes to begin the relative clause, as illustrated in Figure 2 (left). Under these circumstances, the speaker would choose to produce other available material, namely function word *that*. If, in contrast, the upcoming relative clause is predictable, then w_1 will be more likely to be available, and the speaker would be more likely to omit the function word *that* and immediately proceed with w_1.

While these two accounts differ at many levels, they make the same prediction for function word omission in syntactic reduction such as (1) and (2). It is difficult to disentangle these accounts empirically.[1] Below we will show that for a different optionality phenomenon, namely classifier choice in Mandarin, these accounts may make different predictions.

[1] Prior work (Jaeger, 2010) acknowledged this entanglement of the predictions of these accounts, and attempted to tease the accounts apart via joint modeling using logistic regression. The present study builds on these efforts by exploring a case involving a starker disentanglement of the accounts' predictions.

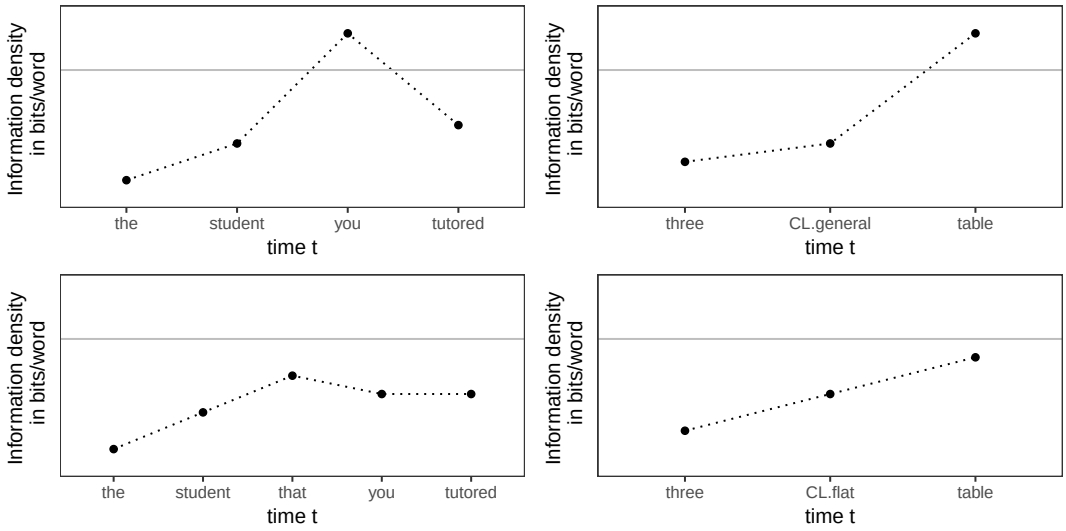

Figure 1: Schematic illustrations of Uniform Information Density in the context of relative clause (left) and classifier choice (right). The grey lines indicate a hypothetical channel capacity.

3 Classifiers in Mandarin Chinese

Languages in the world can be broadly grouped into classifier languages and non-classifier languages. In non-classifier languages, such as English and other Indo-European languages, a numeral modifies a noun directly: e.g., *three tables, two projects*. In Mandarin Chinese and other classifier languages, a numeral classifier is obligatory when a noun is to be preceded with a numeral (and often obligatory with demonstratives): e.g., *san zhang zhuozi* "three CL.flat table", *liang xiang gongcheng* "two CL.item project". Although it has been hypothesized that numeral classifiers play a functional role analogous to that of the singular–plural distinction in other languages (Greenberg, 1972), it is not clear whether there is a meaningful correlation between the presence of numeral classifiers and plurality among the languages of the world (Dryer and Haspelmath, 2013).

In Mandarin, classifiers, together with their associated numeral or demonstrative, precede the head noun of a noun phrase. There are about 100 individual numeral classifiers (Ma, 2015). While different nouns are compatible with different SPECIFIC classifiers, there is a GENERAL classifier *ge*(个) that can be used with most nouns. In some cases, the alternating options between using a general or a specific classifier with the same noun are almost semantically invariant. Table 1 shows examples of classifier options in fragments of naturally occuring texts.

Yet these options have different effects on the information densities of the following nouns. A specific classifier is more likely to reduce the information density of the upcoming noun than a general classifier because a specific classifier constrains the space of possible upcoming nouns more tightly (Klein et al., 2012). Consider the following pair of classifier examples (3) and (4).

(3) 我 买了 三 张 桌子
wo mai-le san zhang zhuozi
I bought three CL.flat table ("I bought three tables")

(4) 我 买了 三 个 桌子
wo mai-le san ge zhuozi
I bought three CL.general table ("I bought three tables")

As shown in Figure 1 (top right), while a general classifier has some information (e.g., signaling there will be a noun), it has relatively low information density—it is the most frequent and generally the highest-probability classifier in many contexts. In comparison, as illustrated in Figure 1 (bottom right), a specific classifier has higher information density—specific classifiers are less frequent than the general classifier and typically lower-predictability—but, crucially, it constrains the hypothesis space for the identity of the upcoming noun, since the noun's referent must meet certain semantic requirement that the classifier is associated with. The UID hypothesis predicts that speakers choose a **specific** classifier more often when the predictability of the noun would other-

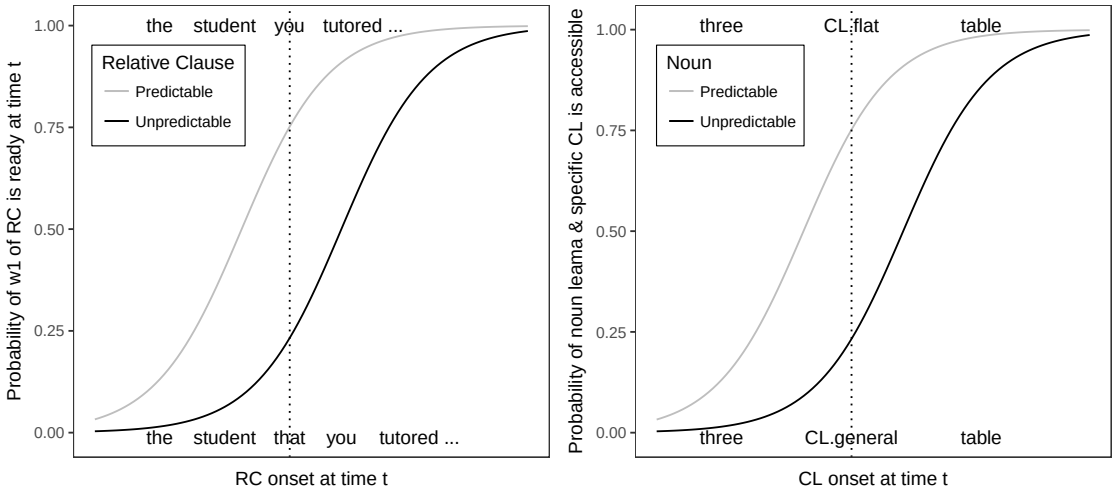

Figure 2: Schematic illustrations of availability-based production in the context of relative clause (left) and classifier choice (right). X axis presents the progression of time. The dotted lines indicate onset times for relative clause and classifier respectively.

wise be low.

Availability-based production, provided three plausible assumptions, makes different predictions than UID. The first assumption is that a speaker must access a noun lemma in order to access its appropriate specific classifier. The second assumption is that unpredictable noun lemmas are harder and/or slower to access (as described in Section 2, this assumption is supported by findings from the naming literature). The third assumption is that the general classifier is *always* available, regardless of the identity of the upcoming noun, as it is compatible with virtually every noun. Under these assumptions, for unpredictable nouns, specific classifiers will less often be available to the speaker when the time comes to initiate production of classifier, as shown in Figure 2 (right). Since noun lemmas need to be accessed before their associated specific classifiers, the less predictable the noun, the less likely the noun lemma and hence the associated specific classifier is to be available by the classifier onset time t. The general classifier, in contrast, is always accessible. Under these assumptions, the availability-based production hypothesis thus predicts that speakers choose a **general** classifier more often when the following noun is less predictable.

4 Data and Processing

To provide data for this study, we created a corpus of naturally occurring classifier-noun pairs from SogouCS, a collection of online news texts from various channels of Sohu News (Sogou, 2008). The deduplicated version of the corpus (see Section 4.1 for deduplication details) has 11,548,866 sentences. To parse and annotate the data, we built a pipeline to 1) clean and deduplicate the data, 2) part-of-speech tag and syntactically parse the clean text, and 3) extract and filter classifier-noun pairs from the parsed text. We are aware that a spoken corpus would be ideal to investigate speaker choice, but nothing this big is available. Instead we used SogouCS to approximate the language use of native speakers.

4.1 Cleaning and deduplication

Since the data contain web pages, many snippets are not meaningful content but automatically generated text such as legal notices. To use this corpus as a reasonable approximation of language experience of speakers, we performed deduplication on the data, following similar practice adopted by other work dealing with web-based corpora (Buck et al., 2014). After cleaning the text, we removed repeated lines in the corpus.

4.2 Word segmentation, POS-tagging and syntactic parsing

We used the Stanford CoreNLP toolkit for word segmentation, part-of-speech tagging, and syntactic parsing (Manning et al., 2014). We used CoreNLP's Shift-Reduce model for parsing (Zhu et al., 2013). We also got dependency parsing results as part of the Stanford CoreNLP output.

Noun	个 (ge, CL.general)	项 (xiang, CL.item)	张 (zhang, CL.flat)
公告 announcement	一 口 气 发布 11 个 公告 a CL breath release 11 CL announcement “release 11 announcements at one go”	连续 发布 三 项 公告 consecutively release three CL announcement “release three announcements in a” row”	门口 贴了 一 张 公告 door paste a CL announcement “there is an announcement on the door”
账单 bill	女儿 拿着 一 个 账单 就 过来了 daughter carry a CL bill at once come “daughter came with a bill at once”	not co-occurring	在 一 张 账单 上 解决 所有 收费 问题 on a CL bill solve all charge problem “solve all charge problems on a bill”
工程 project	跟 圆明园 有关 的 一 个 工程 to Yuanmingyuan related de a CL project “a project related to Yuanmingyuan”	抓好 六 项 重点 工程 grasp six CL key project “manage six key projects”	not co-occurring
活动 activity	昨天 我 参加了 一 个 活动 yesterday I attend a CL activity “yesterday I attended an activity”	广州市 今天 开展 的 一 项 活动 Guangzhou today hold de a CL activity “an activity held by Guangzhou today”	not co-occurring

Table 1: Examples from development set of available classifier options that are semantically (near-)invariant

4.3 Extracting and filtering classifier-noun pairs

From the parsed corpus, we extracted all observations where the head noun has a `nummod` relation with a numeral and the numeral has a `mark:clf` relation with a classifier. Figure 3 illustrates two such examples. We included classifiers in the list of 105 individual classifiers identified by Ma (2015) that are identified by the Stanford CoreNLP toolkit. For the purpose of restricting our data to cases of (nearly) semantically invariant alternation, we excluded classifiers such as *zhong* (“CL.kind”) that would introduce a clear truth-conditional change in utterance meaning, compared with the general classifier *ge*. We did further filtering to get nouns that can be used with both the general classifier and at least one specific classifier. This left us 1,479,579 observations of classifier-noun pairs.

To construct the development set, we randomly sampled about 10% of the noun types (1,179) and extracted all observations with of these noun types. We manually checked and filtered applicable classifiers for these noun types and we ended up with 713 noun types for the development set. For the test set, we also randomly sampled about 10% of the noun types (1,093) and extracted all observations with these noun types. We did not perform manual filtering of the test set. We reserve the remaining 80% for future work.

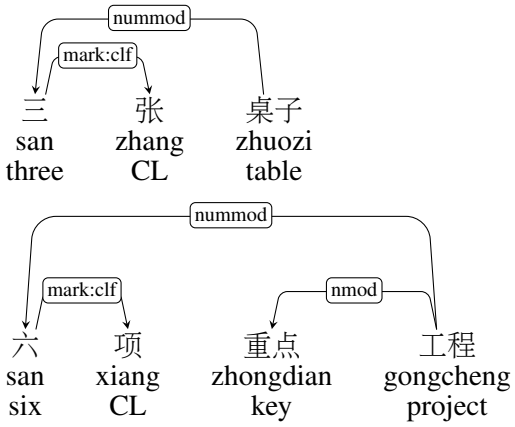

Figure 3: Classifier examples where the head noun has a nummod relation with a numeral and the numeral has a `mark:clf` relation with the classifier

5 Model estimation

We use SURPRISAL, the negative log probability of the word in the context (Hale, 2001; Levy, 2008; Demberg and Keller, 2008; Frank and Bod, 2011; Smith and Levy, 2013), generated from a language model to estimate noun predictability. Since classifiers occur before their corresponding nouns, to avoid circularity, we mapped all target classifiers to the same token, `CL`, in the segmented text for language modeling, analogous to the procedure used in (Levy and Jaeger, 2007) and similar studies. We implemented 5gram modified Kneser-Ney smoothed models with the SRI Lan-

guage Modeling toolkit (Stolcke, 2002) and performed ten-fold cross-validation to estimate noun surprisal.

We used a mixed-effect logit model to investigate the relationship between noun predictability and classifier choice. The dependent variable was the binary outcome of whether a general or a specific classifier was used. For each noun type, we also identified its most frequently used specific classifier. We included two predictors in the analysis: noun surprisal and noun log frequency.[2] We included noun frequency as a control factor for two reasons. First, noun frequency has shown effects on many aspects of speaker behavior. Second, surprisal and frequency of a word are intrinsically correlated. Taken together, these two reasons make noun frequency an important potential confound to be controlled for in investigating any potential effect of noun surprisal on classifier choice.

We included noun and potential specific classifier as random factors, both with random intercepts and random slopes for noun surprisal. This random effect structure is maximal with regard to testing effects of noun surprisal, which varies within noun and within classifier (Barr et al., 2013). We then applied the model to the test set. The full formula in the style of `R`'s `lme4` package (Bates et al., 2014) is:

```
cl_choice~noun_surprisal+log_noun_freq
+(1+noun_surprisal|noun)
+(1+noun_surprisal|potential_spec_cl)
```

We used Markov chain Monte Carlo (MCMC) methods in the `R` package `MCMCglmm` (Hadfield et al., 2010) for significance testing, an based our p-values on the posterior distribution of regression model parameters using an uninformative prior and determining the largest possible symmetric posterior confidence interval on one side of zero, as is common for MCMC-based mixed model fitting (Baayen et al., 2008).

6 Results

In both the development set and the test set, overall we saw more observations with a specific classifier than with a general classifier (55.4% vs. 44.6% in the development set, 63.1% vs. 36.9% in the test set). For the development set, we find that the less predictable the noun, the less likely a specific classifier is to be used ($\beta = -0.038,\ p < 0.001$, Figure 4). There was no effect of noun frequency ($\beta = 0.018,\ p = 0.51$, Figure 5). For the test set, the result of noun predictability replicates ($\beta = -0.059,\ p < 0.001$, Figure 6).[3] In the test set but not in the development set, we also found an effect of noun frequency ($\beta = -0.11,\ p < 0.001$, Figure 7): the more frequent the noun, the less likely a specific classifier is to be used. Further analysis suggests that this effect of noun frequency in the test set is likely to be an artifact of incorrect noun–classifier associations that would disappear were we to filter the test set in the same way as we filtered the development set.[4] The consistent effect of noun surprisal on classifier choice in both our development and test sets supports the availability-based production hypothesis, and is inconsistent with the predictions of UID.

One potential concern regarding the above conclusion that noun predictability drives classifier choice is that it might not fully take into account effects of the frequencies of classifiers themselves on availability. The availability-based production hypothesis does not exclude the possibility that a classifier's accessibility is substantially dependent on its frequency, and the general classifier is indeed the most frequently used classifier. However, if specific classifier frequency were confounding the apparent effect of noun surprisal that we see in our analysis, there would have to be a correlation in our dataset between specific classifier frequency and noun surprisal. Our inclusion of a by-specific-classifier random intercept largely rules out the possibility that even a correlation that the above-mentioned one could be driving our effect. To be thorough, we tried a version of our regression analysis that also include a fixed effect for the log frequency of potential specific classifier as a control. We did not find any qualitative change to

[2] We used base 2 here to be consistent with the base used in noun surprisal.

[3] As can be seen in Figure 6, there is a bump at bin 27 in the rate of using a specific classifier. We consider this likely to be due to data sparsity: the number of observations is small in the last two bins of noun surprisal ($n = 27$ and $n = 3$), and there is no such bump in the development set.

[4] We found a marginal effect of noun frequency in our unfiltered development set, where the more frequent the noun was, the less likely it was used with a specific classifier. We did further analysis with the dev set and found that the"nouns" (some of them were misclassified as nouns from the results of the automatic parsing) that were excluded tend to have a higher frequency compared to the ones that were included, and the excluded ones also had a lower rate of concurring with a specific classifier. This tendency suggests that in the unfiltered test set, illegible nouns may contribute at least partially to the noun frequency effect.

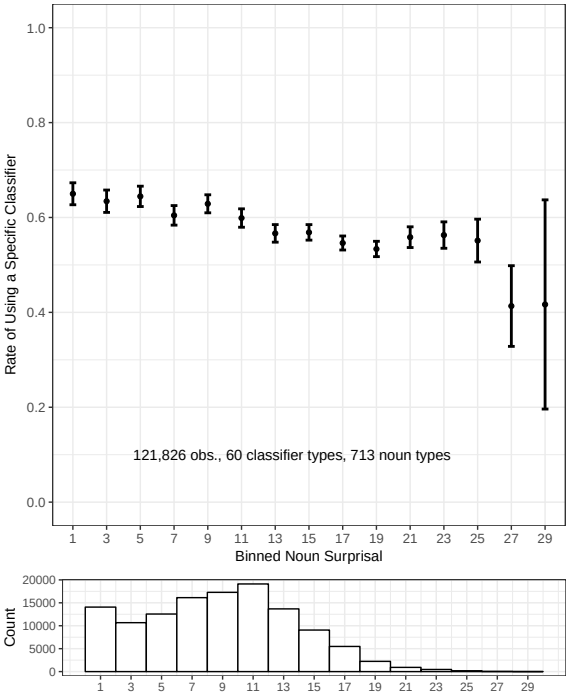

Figure 4: Dev set: N-gram estimated noun surprisal and the rate of using a specific classifier (as opposed to the general classifier *ge*).

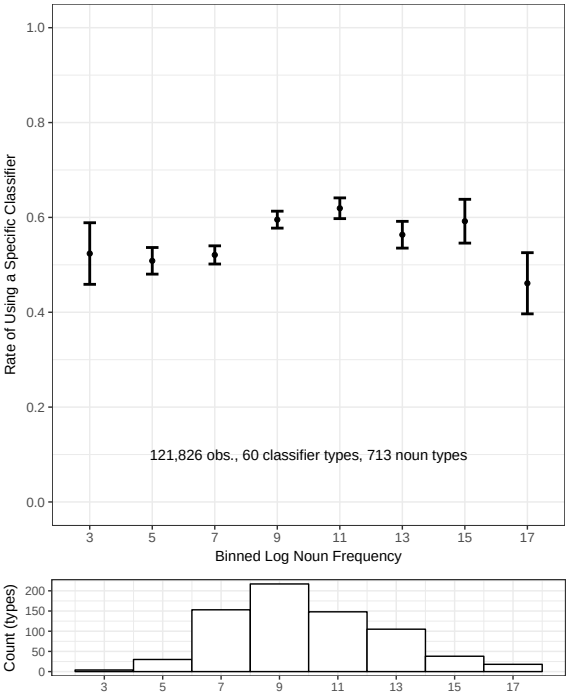

Figure 5: Dev set: Noun frequency (log scale) and the rate of using a specific classifier (as opposed to the general classifier *ge*).

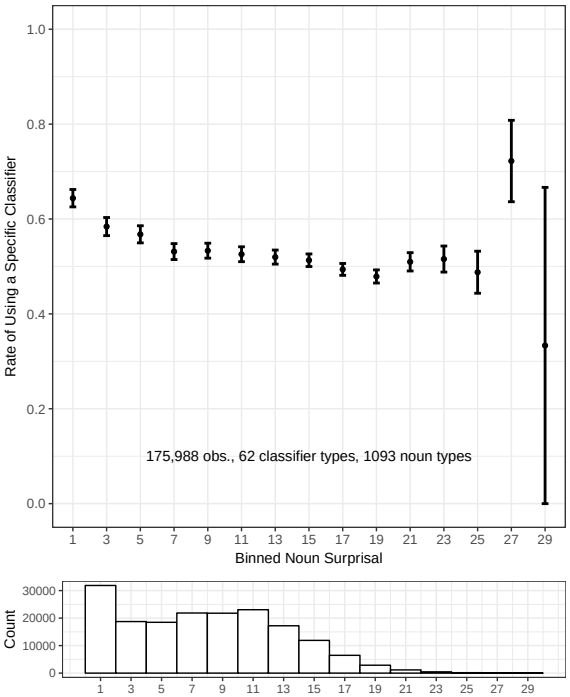

Figure 6: Test set: N-gram estimated noun surprisal and the rate of using a specific classifier.

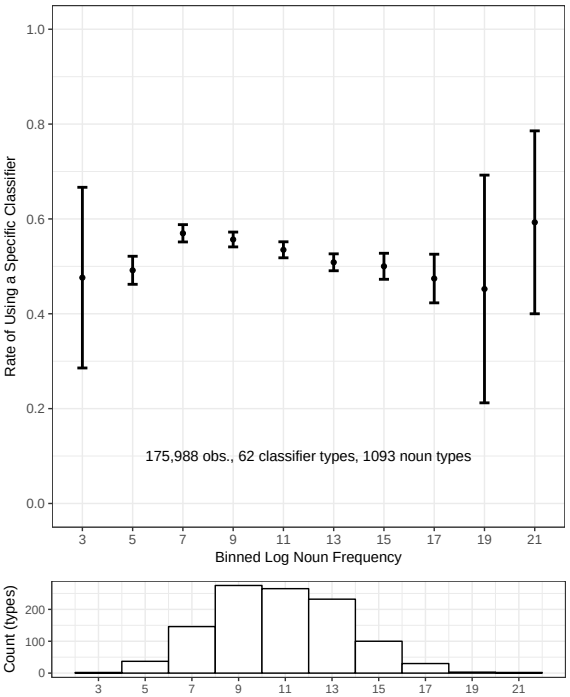

Figure 7: Test set: Noun frequency (log scale) and the rate of using a specific classifier.

the results: the effect of noun surprisal on specific classifier choice remains the same. We also note that in this new analysis, we do not find a significant effect of specific classifier log frequency on classifier choice ($p = 0.629$ for the dev set and $p = 0.7$ for the test set). This additional analysis suggests that it is unlikely that the effect of specific classifier frequency to be driving the effect of noun surprisal.

Overall, we did not find evidence for the UID hypothesis at the level of alternating options with different information density, in our case, a specific classifier versus a general classifier. We demonstrate that within the scope of near semantically invariant alternation, classifier choice is modulated by noun predictability with the tendency to facilitate speaker production. Our results lend support to an availability-based production model. We did not find consistent evidence for the effect of noun frequency on classifier choice. The effect of noun frequency remains unclear and we will need to test it with a larger sample of noun types.

7 Conclusion

Though it has proven difficult to disentangle UID and availability-based production through optional word omission phenomena, we have demonstrated here that the two accounts can potentially be distinguished through at least one word alternation phenomenon. The UID hypothesis predicts that predictable nouns favor the *general* classifier whereas availability-based production predicts that predictable nouns favor a *specific* classifier. Our empirical results favor the availability-based production account.

To the best of our knowledge, this is the first study that demonstrates contextual predictability is correlated with classifier choice. This study provides a starting point to understand the cognitive mechanisms governing speaker choices as manifested in various language optionalities. Ultimately we plan to complement our corpus analysis with real-time language production experiments to more throughly test hypotheses about speaker choice.

Spotting Spurious Data with Neural Networks

Hadi Amiri, Timothy A. Miller, Guergana Savova
Boston Children's Hospital Informatics Program, Harvard Medical School
{firstname.lastname}@childrens.harvard.edu

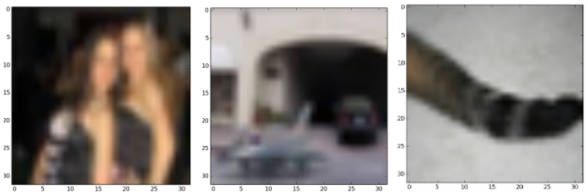
Abstract

Automatic identification of spurious instances (those with potentially wrong labels in datasets) can improve the quality of existing language resources, especially when annotations are obtained through crowdsourcing or automatically generated based on coded rankings. In this paper, we present an effective approach inspired by queueing theory and psychology of learning to automatically identify spurious instances in datasets. Our approach discriminates instances based on their "difficulty to learn," determined by a downstream learner. Our method can be applied to *any* dataset assuming the existence of a neural network model for the target task of the dataset. Our best approach outperforms competing state-of-the-art baselines and has a MAP of 0.85 and 0.22 in identifying spurious instances in synthetic and carefully-crowdsourced real-world datasets respectively.

1 Introduction

The importance of error-free language resources cannot be overstated as errors can inversely affect interpretations of the data, models developed from the data, and decisions made based on the data. Although the quality of language resources can be improved through good annotation guidelines, test questions, etc., annotation noise still exists (Gupta et al., 2012; Lasecki et al., 2013). For example, Figure 1 shows sample spurious instances (those with potentially wrong labels) in CIFAR-10 (Krizhevsky, 2009) which is a benchmark dataset for object classification. Spurious instances can mislead systems, and, if available in test data, lead to unrealistic comparison among competing systems.

Previous works either directly identify noise in datasets (Hovy et al., 2013; Dickinson and Meurers, 2003; Eskin, 2000; Loftsson, 2009), or develop models that are more robust against noise (Guan et al., 2017; Natarajan et al., 2013; Zhu et al., 2003; Zhu and Wu, 2004). Furthermore, recent works on adversarial perturbation have tackled this problem (Goodfellow et al., 2015; Feinman et al., 2017). However, most previous approaches require either annotations generated by each individual annotator (Guan et al., 2017), or both task-specific and instance-type (genuine or adversarial) labels for training (Hendrik Metzen et al., 2017; Zheng et al., 2016), or noise-free data (Xiao et al., 2015). Such information is often not available in the final release of most datasets.



(a) Truck (b) Airplane (c) Cat

Figure 1: Spurious instances in CIFAR-10. (a) not a truck, (b) missing annotation for car as another object category, (c) incomplete image of a cat.

Current approaches utilize prediction probability/loss of instances to tackle the above challenges in identifying spurious instances. This is because prediction probability/loss of spurious instances tend to be lower than that of genuine instances (He and Garcia, 2009). In particular, the Bayesian Uncertainty model (Feinman et al., 2017) defines spurious instances as those that have greater uncertainty (variance) in their stochastic predictions, and the Variational Inference model (Rehbein and Ruppenhofer, 2017; Hovy et al., 2013) expects greater posterior entropy in predictions made for spurious instances.

In this paper, our hypothesis is that spurious instances are *frequently* found to be difficult to

Proceedings of NAACL-HLT 2018, pages 2006–2016
New Orleans, Louisiana, June 1 - 6, 2018.

learn during training process. This difficulty in learning stems from the intrinsic discrepancy between spurious and the cohort of genuine instances which frequently makes a learner less confident in predicting the *wrong* labels of spurious instances. Based on this hypothesis, we present two frameworks which are inspired by findings in queueing theory and psychology, namely Leitner queue network (Leitner, 1974) and Curriculum Learning (Bengio et al., 2009). Our frameworks can be considered as schedulers that schedule instances to train a downstream learner (e.g. a neural network) with respect to "easiness"/"difficulty" of instances - determined by the extent to which the learner can correctly label (e.g. classify) instances during the training process. The two frameworks, however, differ in their views on the theory of learning as we describe below:

Curriculum learning is inspired by the learning principle that humans can learn more effectively when training starts with *easier* concepts and gradually proceeds with more difficult ones (Bengio et al., 2009). On the other hand, Leitner system is inspired by *spaced repetition* (Dempster, 1989; Cepeda et al., 2006), the learning principle that effective and efficient learning can be achieved by working more on difficult concepts and less on easier ones. Both frameworks are effective, conceptually simple, and easy to implement.

The contributions of this paper are as follows: (a) we develop a cognitively-motivated and effective algorithm for identifying spurious instances in datasets, (b) our approach can be applied to *any* dataset without modification if there exists a neural network architecture for the target task of the dataset, and (c) we release a tool that can be easily used to generate a ranked list of spurious instances in datasets.[1] Our tool requires a dataset and its corresponding network architecture to generate a ranked list of spurious instances in the dataset.

Our best approach (Leitner model) has a mean average precision (MAP) of 0.85 and 0.22 in identifying spurious instances on real-world and synthetic datasets and outperforms competing state-of-the-art baselines.

2 Method

We assume that our learner is a neural network which trains for k iterations until convergence. Furthermore, we assume that spurious and genuine instances are mixed at training time and the network is only provided with task-specific but not genuine/spurious labels for the instances.

Algorithm 1. Curriculum Spotter

Input: $\mathbf{H}$: training data, $\mathbf{V}$: validation data, k : number of iterations
Output: Ranked list of spurious instances

$batch = \mathbf{H}$
$S^0[h_j] = 0$ for $h_j \in \mathbf{H}$
For $epoch = 1$ to k:
  $model = \mathbf{train}(batch, \mathbf{V})$
  $loss = \mathbf{Loss}(model, \mathbf{H})$
  $\lambda = \mathbf{compute\_lambda}(model, loss, \mathbf{H})$
  $easy\_batch = \mathbf{sample\_easy}(\lambda, loss, \mathbf{H})$
  $hard\_batch = \mathbf{H} - easy\_batch$
  $batch = easy\_batch + \mathbf{top}(\frac{epoch}{k}, hard\_batch)$
  $S^{epoch} = \mathbf{update\_stat}(S^{epoch-1}, hard\_batch, loss)$
End for
return $\mathbf{sort}(S^k, \mathbf{H}, loss)$

Figure 2: Curriculum Spotter. $\mathbf{Loss}(.)$ computes loss of a network with respect to given instances, $\mathbf{compute\_lambda}(.)$ computes the average loss of current model for correctly classified instances, $\mathbf{sample\_easy}(.)$ creates list of easy instances using current loss values, $\mathbf{top}(.)$ returns $epoch/k$ fraction of easiest hard instances, $\mathbf{update\_stat}(.)$ scores instances according to Eq. (1), and $\mathbf{sort}(.)$ ranks instances based on the resulting scores S updated by Eq. (2).

2.1 Curriculum Learning

Bengio et al. (2009) and Kumar et al. (2010) developed training paradigms which are inspired by the learning principle that humans can learn more effectively when training starts with easier concepts and gradually proceeds with more difficult ones. Since easiness of information is not readily available in most datasets, previous approaches used heuristic techniques (Spitkovsky et al., 2010; Basu and Christensen, 2013) or optimization algorithms (Jiang et al., 2015, 2014) to quantify easiness for instances. These approaches consider an instance as easy if its prediction loss is smaller than a threshold (λ). Given a neural network as the learner, we adopt curriculum learning to identify spurious instances as follows (see Figure 2):

At each iteration i, we divide all instances into *easy* and *hard* batches using the iteration-specific threshold λ_i and the loss values of instances at iteration i, obtained from the current partially-trained network. All instances with a loss smaller than λ_i are considered as easy and the rest are consid-

ered as hard. All easy instances in conjunction with $\delta_i \in [0, 1]$ fraction of easiest hard instances (those with smallest loss values greater than λ_i) are used for training at iteration i. We set each λ_i to the average[2] loss of training instances that are correctly classified by the current partially-trained network. Furthermore, at each iteration $i > 1$, we set $\delta_i = i/k$ where k is the total number of iterations. In this way, difficult instances are gradually introduced to the network at every new iteration.

The $\mathbf{update\_stat}(.)$ function in Figure 2 scores instances based on their frequency of occurrence in the hard batch. In particular, for each instance h_i:

$$S^e(h_i) = S^{e-1}(h_i) + \mathbb{1}_{hard\_batch^e}(h_i) \times \Big(\frac{1}{|hard\_batch^e|} + loss^e(h_i)\Big), \quad (1)$$

where $S^e(h_i)$ is the score of h_i at iteration e, $\mathbb{1}_Y(x)$ is an indicator function which is 1 when $x \in Y$ and otherwise 0, $hard\_batch^e$ indicates the set of hard instances at iteration e, and $loss^e(h_i)$ is the loss of the network for h_i at iteration e. The above function assigns higher scores to instances that are frequently considered as hard instances by the curriculum learning framework (such instances are ranked higher in the final ranked list of spurious instances). It also assigns a final score of $S^k(h_i) = 0$ to instances that are treated as easy instances throughout the training process, i.e. those that have a loss smaller than the iteration-specific threshold λ_i at each iteration i and, therefore, are always placed in the $easy\_batch$. To break the tie for these instances in the final ranking, we resort to their final loss values as follows:

$$S^k(h_i) = loss^k(h_i), \text{if } S^k(h_i) = 0. \quad (2)$$

2.2 Leitner System

The Leitner System is inspired by the broad evidence in psychology that shows human ability to retain information improves with repeated exposure and exponentially decays with delay since last exposure (Cepeda et al., 2006). Spaced repetition forms the building block of many educational devices, such as flashcards, in which small pieces of information are repeatedly presented to a learner on a schedule determined by a spaced repetition algorithm. Such algorithms show that human learners can learn efficiently and effectively by increasing intervals of time between subsequent reviews of previously learned materials (Dempster, 1989; Novikoff et al., 2012). We adopt the Leitner system to identify spurious instances as follows:

Algorithm 2. Leitner Spotter

Input: $\mathbf{H}$: training data, $\mathbf{V}$: validation data, k : number of iterations, n : number of queues
Output: Ranked list of spurious instances

$Q = [q_0, q_1, \ldots, q_{n-1}]$
$q_0 = [\mathbf{H}]$, $q_i = []$ for $i \in [1, n-1]$
$S^0[h_j] = 0$ for $h_j \in \mathbf{H}$
For $epoch = 1$ to k:
  $batch = []$
  For $i = 0$ to $n - 1$:
    If $epoch\%2^i == 0$:
      $batch = batch + q_i$
  End For
  $promos, demos, loss = \mathbf{train}(batch, \mathbf{V})$
  $\mathbf{update\_queue}(Q, promos, demos)$
  $S^{epoch} = \mathbf{update\_stat}(S^{epoch-1}, Q, loss)$
End for
return $\mathbf{sort}(S^k, \mathbf{H}, loss)$

q_0 epochs = $\{1, 2, 3, 4, 5, \ldots\}$
q_1 epochs = $\{2, 4, 6, 8, 10, \ldots\}$
q_2 epochs = $\{4, 8, 12, 16, 20, \ldots\}$
...

Figure 3: Leitner Spotter. The $\mathbf{train}(.)$ function trains the network using instances in the current $batch$, $\mathbf{update\_queue}(.)$ promotes the correctly classified instances–$promos$–to their next queues and demotes the wrongly classified ones–$demos$–to q_0, $\mathbf{update\_stat}(.)$ scores instances according to Eq. (3), and $\mathbf{sort}(.)$ ranks instances based on resulting scores S updated by Eq. (4).

Suppose we have n queues $\{q_0, q_1, \ldots, q_{n-1}\}$. The Leitner system initially places all instances in the first queue, q_0. As Figure 3 shows, the system trains with instances of q_i at every 2^i iterations. At each iteration, only instances in the selected queues will be used for training the network. During training, if an instance from q_i is correctly classified by the network, the instance will be "promoted" to q_{i+1}, otherwise it will be "demoted" to the first queue, q_0. Therefore, as the network trains through time, higher queues will accumulate easier instances which the network is most accurate about, while lower queues carry either hard or potentially spurious instances. This is because of the intrinsic discrepancy between spurious instances and the cohort of genuine instances which makes the network less confident in predicting the wrong labels of spurious instances. Figure 3 (bot-

[2] We also considered maximum and median loss, but average loss led to greater training gain in terms of effectiveness.

tom) provides examples of queues and their corresponding processing epochs.

The **update_stat**(.) function in Figure 3 scores instances based on their occurrence in q_0. In particular, for each instance h_i:

$$S^e(h_i) = S^{e-1}(h_i) + \mathbb{1}_{q_0^e}(h_i) \times \Big(\frac{1}{|q_0^e|} + loss^e(h_i)\Big), \quad (3)$$

where $|q_0^e|$ indicates the number of instance in q_0 at iteration e. The above function assigns higher scores to instances that frequently occur in q_0. It also assigns a final score of $S^k(h_i) = 0$ (at the last iteration) to instances that have never been demoted to q_0. To break the tie for such instances, we use their final loss value as follows:

$$S^k(h_i) = loss^k(h_i), \text{if } S^k(h_i) = 0. \quad (4)$$

3 Experiments

3.1 Evaluation Metrics

We employ a TREC-like evaluation setting to compare models against each other. For this, we create a pool of K most spurious instances identified by different models. If needed, e.g. in case of real-world datasets, we manually label all instances in the pool and come to agreement about their labels. Then, we compare the resulting labels with the original labels in the dataset to determine spurious/genuine instances. We compare models based on the standard TREC evaluation measures, namely mean average precision (MAP), precision after r instances are retrieved (P@r), and, only for synthetic data, precision after all spurious instances are retrieved (Rprec). We use the `trec-eval` toolkit to compute performance of different models.[3]

3.2 Datasets

We develop synthetic and real-world datasets for our experiments. Since, in contrast to real-world datasets, (most[4]) synthetic datasets do not contain any noisy instances, we can conduct large-scale evaluation by injecting spurious instances into such datasets. Table 1 shows detail information about our datasets.

[3] http://trec.nist.gov/trec_eval/

[4] Some synthetic datasets may contain noise, see sample inconsistencies that our model identified in the bAbi dataset (Weston et al., 2016) in Table 3.

Dataset	Train/Val	SpRatio	Input	Output
Synthetic Dataset				
Addition	10K/2K	$\alpha \in (0, 0.5]$	$(x,y \geq 0)$	$x+y$
Real-world Datasets				
Twitter	10K/1K	0.30	brand tweet	pos/neg
Reddit	4K/400	0.23	cancer post	rel/irel

Table 1: Dataset Information. "SpRatio" shows the fraction of spurious instances in the TREC pool; size of the pool for Addition is 10K instances with no limit on the top K retrieved instances; the corresponding value for Twitter and Reddit datasets are 198 and 152 posts respectively for top $K = 50$.

3.2.1 Synthetic Dataset

The Addition dataset, initially developed by Zaremba and Sutskever (2014), is a synthetic dataset in which an input instance is a pair of non-negative integers smaller than 10^l and the corresponding output is the arithmetic sum of the input; we set $l = 4$ in our experiments. Since this dataset contains only genuine instances, we create noisy datasets by injecting $\alpha \times N$ spurious instances into $(1 - \alpha) \times N$ genuine instances, where $N = 10K$ is the total number of training instances and $\alpha \leq 0.5$ indicates the noise level in the dataset. We create spurious instances as follows: given three random numbers $x_i, x_j, x_k \in [0, 10^l)$ such that $x_j \neq x_k$, the wrong sum (output) for the pair (x_i, x_j) is computed as:

$$\max(0, x_i + (-1)^o \times x_k),$$

where o is a random variable that takes values from $O = \{1, 2\}$ with equal probability.

3.2.2 Real-world Datasets

We crowdsource annotations for two real-world datasets, namely Twitter and Reddit posts (see Table 1). For quality control, we carefully develop annotation schemas as well as high quality test questions (see below) to minimize the chances of spurious labels in the resulting annotations.

The Twitter dataset contains tweets about a telecommunication brand. Tweets contain brand name or its products and services. Annotators are instructed to label tweets as positive/negative if they describe positive/negative sentiment about the target brand. We use 500 labeled instances for annotation quality assurance and ignore data generated by annotators who have less than 80% accuracy on these instances. The resulting Fleiss' kappa (Fleiss, 1971) is $\kappa = 0.66$ on our Twitter dataset which indicates substantial agreement.

The Reddit dataset includes posts about colon, breast, or brain cancer. These posts contain phrases like *colon cancer*, *breast cancer*, or *brain cancer*. Annotators are instructed to label a post as "relevant" if it describes a patient's experience (including sign and symptoms, treatments, etc.,) with respect to the cancer. In contrast, "irrelevant" posts are defined as generic texts (such as scientific papers, news, etc.,) that discuss cancer in general without describing a real patient experience. We use 300 labeled instances for annotation quality assurance and ignore annotations generated by users who have less than 80% accuracy on these instances. The resulting Fleiss' kappa is $\kappa = 0.48$ for the Reddit dataset which indicates moderate agreement.

3.3 Settings

For the synthetic Addition dataset, we set the size of the TREC pool to $K = 10,000$ (size of training data) which indicates there is no limitation on the number of spurious instances that a model can retrieve; note that we have a spurious/genuine label for each instance in the Addition dataset and therefore do not need to label the resulting TREC pool manually. Furthermore, we consider the LSTM network developed by Sutskever et al. (2014) as the downstream learner.[5] Without noise in data, this network obtains a high accuracy of 99.7% on the Addition task.

For the real-world datasets, we allow each model to submits its top 50 most spurious instances to the TREC pool (we have five models including our baselines). As mentioned before, we manually label these instances to determine their spurious/genuine labels. This leads to TREC pools of size 198 and 152 posts (with 59 and 35 spurious instances) for the Twitter and Reddit datasets respectively.

We use the MLP network `fastText` (Joulin et al., 2017) as the downstream learner - for more effective prediction, we add a `Dense` layer of size 512 before the last layer of `fastText`. This network obtains accuracy of 74.6% and 70.2% on Twitter and Reddit datasets respectively.

Finally, for the Leitner system, we experiment with different queue lengths, $n = \{3, 5, 7\}$, and set $n = 5$ in the experiments as this value leads to slightly better performance in our experiments.

[5] http://github.com/fchollet/keras/blob/master/examples/addition_rnn.py

3.4 Baselines

We consider the following baselines; each baseline takes a dataset and a model as input and generates a ranked list of spurious instances in the dataset:

• **Prediction Probability (PP)**: Since prediction loss of spurious instances tend to be higher than that of genuine ones (He and Garcia, 2009; Hendrycks and Gimpel, 2016), this baseline ranks instances in descending order of their prediction loss after networks are trained through standard (rote) training.

• **Variational inference (VI)** (Hovy et al., 2013; Rehbein and Ruppenhofer, 2017): This model approximates posterior entropy from several predictions made for each individual instance (see below).[6]

• **Bayesian Uncertainty (BU)** (Feinman et al., 2017): This model ranks instances with respect to the uncertainty (variance) in their stochastic predictions.[7]

BU estimates an uncertainty score for each individual instance by generating $T = 50$ predictions for the instance from a distribution of network configurations. The prediction disagreement tends to be common among spurious instances (high uncertainty) but rare among genuine instances (low uncertainty). Uncertainty of instance x with predictions $\{\mathbf{y}_1, \ldots, \mathbf{y}_T\}$ is computed as follows:

$$\frac{1}{T}\sum_{i=1}^{T}\mathbf{y}_i^\top\mathbf{y}_i - \Big(\frac{1}{T}\sum_{i=1}^{T}\mathbf{y}_i\Big)^\top\Big(\frac{1}{T}\sum_{i=1}^{T}\mathbf{y}_i\Big).$$

Variational inference (VI) (Rehbein and Ruppenhofer, 2017; Hovy et al., 2013) detects spurious instances by approximating the posterior $p(y|x)$ with a simpler distribution $q(y)$ (called variational approximation to the posterior) which models the prediction for each instance. The model jointly optimizes the two distributions through EM: in the E-step, q is updated to minimize the divergence between the two distributions, $D(q||p)$; in the M-step, q is kept fixed while p is adjusted. The two steps are repeated until convergence. Instances are then ranked based on their posterior entropies. Similar to BU, we generate $T = 50$ predictions for each instance.

For both BU and VI baselines, we apply a dropout rate of 0.5 after the first and last hidden

[6] http://isi.edu/publications/licensed-sw/mace/

[7] http://github.com/rfeinman/detecting-adversarial-samples

layers of our downstream networks to generate predictions. See (Gal and Ghahramani, 2016) for the ability of dropout neural networks in representing model uncertainty.

3.5 Experimental Results

The overall mean average precisions (MAPs) of different models on synthetic and real-world datasets are reported in Table 2. For the synthetic dataset (Addition), we report average MAP across all noise levels, and for real-world datasets (Twitter and Reddit), we report average MAP at their corresponding noise levels obtained from corresponding TREC pools. We use t-test for significance testing and asterisk mark (*) to indicate significant difference at $\rho = 0.05$ between top two competing systems.

The results show that Leitner (Lit) and Bayesian uncertainty (BU) models considerably outperform prediction probability (PP) and curriculum learning (CL) on both synthetic and real-world datasets. In case of real-world datasets, we didn't find significant difference between top two models perhaps because of the small size of corresponding TREC pools (198 Twitter posts and 152 Reddit posts, see Table 1). Overall, BU and Lit show average MAP of 0.81, and 0.85 on the synthetic dataset and 0.15, 0.22 on real-world datasets respectively. The higher performance of Lit indicates that spurious instances often appear in q_0. The lower performance of CL, however, can be attributed to its training strategy which may label spurious instances as easy instances if their loss values are smaller than the loss threshold (section 2.1). The large difference between the performances of Lit and CL (two methods based on repeated scoring across training epochs) shows that the way that repetition is utilized by different methods largely affects their final performance in spotting spurious instances. In addition, VI shows lower performance than BU and Lit on synthetic data, but comparable performance to BU on real-world datasets.

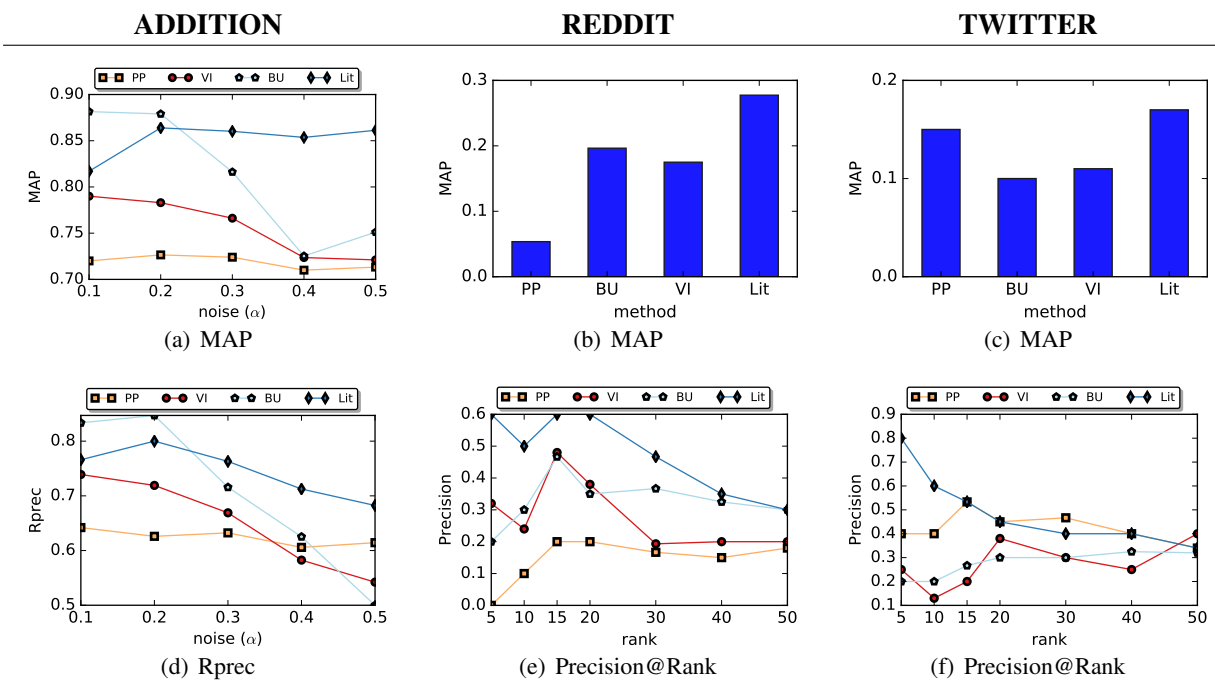
Furthermore, the results show that the performance of all models are considerably lower on real-world datasets than the synthetic dataset. This could be attributed to the more complex nature of our real-world datasets which leads to weaker generalizability of downstream learners on these datasets (see next section for discussion on training performance). This can in turn inversely affect the performance of different spotters, e.g. by encouraging most instances to be considered as hard and thus placed in lower queues of Lit or in the hard batch of CL, or by increasing the prediction uncertainty and entropy in case of BU and VI respectively. In addition, as we mentioned before, we carefully setup the annotation task to minimize the chances of spurious labels in the resulting annotations. Therefore, we expect a considerably smaller fraction of spurious instances in our real-world datasets.

	Synthetic noise = $[0.1, 0.5]$	**Real-world** noise = $\{0.28, 0.35\}$
PP	0.719	0.100
CL	0.718	0.067
VI	0.757	0.142
BU	0.811	0.148
Lit	**0.851***	**0.225**

Table 2: Average overall MAP performance across datasets and noise levels.

Figures 4(a) and 4(d) report MAP and precision after all spurious instances have been retrieved (Rprec) on Addition at different noise levels respectively; note that $\alpha = 0.5$ means equal number of spurious and genuine instances in training data (here, we do not report the performance of CL due to its lower performance and for better presentation). First, the results show that Lit and BU considerably outperform PP and VI. Furthermore, BU shows considerably high performance at lower noise levels, $\alpha \leq 0.2$, while Lit considerably outperforms BU at greater noise levels, $\alpha > 0.2$. The lower performance of BU at higher noise levels might be because of the poor generalizability of LSTM in the context of greater noise which may increase the variance in the prediction probabilities of most instances (see section 3.6 for our note on training performance). In terms of average Rprec, the overall performance of PP, CL, VI, BU, and Lit models is 0.62, 0.57, 0.65, 0.70, and 0.74 respectively on the Addition dataset across all noise levels (see the corresponding values for MAP in Table 2). The lower Rprec values than MAP indicate that some spurious instances are ranked very low by models. These are perhaps the most difficult spurious instances to identify.

For the real-world datasets, we only report MAP and P@r (precision at rank r) as spurious/genuine labels are only available for those instances that make it to the TREC pool but not for all instances. The results on Reddit, Figures 4(b) and 4(e) respectively, show that Lit outperforms other mod-



(a) MAP (b) MAP (c) MAP

(d) Rprec (e) Precision@Rank (f) Precision@Rank

Figure 4: Models performance across datasets. MAP indicates mean average precision, Rprec indicates precision after all spurious instances are retrieved, and P@r indicates precision after r instances are retrieved. In (a) and (b) performance values are reported at different noise levels $\alpha \in (0, 0.5]$.

els, but VI and BU show comparable MAP (in contrast to their performance on Addition). Furthermore, Figure 4(e) shows that Lit generates a more accurate ranked list of spurious instances and consistently outperforms other models at almost all ranks. In particular, it maintains a MAP of around 60% at rank 20, while other models have consistently lower MAP than 50% at all ranks.

The results on the Twitter dataset, Figures 4(c) and 4(f), show that Lit outperforms other models. However, interestingly, PP outperforms BU in terms of both MAP and P@r across almost all ranks. This result could be attributed to the substantial annotation agreement on Twitter dataset (Fleiss' $\kappa = 0.66$) which could make network predictions/loss values more representative of gold labels. Figure 4(f) also shows that Lit is the most precise model in identifying spurious instances. Note that P@5 is an important metric in search applications and as Figures 4(e) and 4(f) show, at rank 5, Lit is 2-3 times more precise than the best-performing baseline on our real-world datasets.

Given *any* dataset and its corresponding neural network, our Leitner model simultaneously trains the network and generates a ranked list of spurious instances in the dataset. For this purpose, the model tracks loss values and occurrences of instances in the lower Leitner queue during training.

3.6 Notes on Training Performance

Figure 5(a) shows the accuracy of the LSTM network (Sutskever et al., 2014) trained with different training regimes on the validation data of Addition with different noise levels; note that Rote represents standard training where at each iteration all instances are used to train the network. As the results show, at lower noise levels, the training performance (i.e. the generalizability/accuracy of the LSTM network) is generally high and comparable across different training regimes, e.g. close to 100% at $\alpha = 0$. However, Lit leads to a slightly weaker training performance than CL and Rote as the noise level increases. This is because Lit learns from spurious instances more frequently than genuine ones. This may decrease the training performance of Lit, especially with greater amount of noise in data. However, this training strategy increases the spotting performance of Lit as spurious instances seem to occur in lower queues of Leitner more frequently, see Figure 4.

In addition, the accuracy of `fastText` (Joulin et al., 2017) is reported in Figure 5(b). The results show that different training regimes lead to comparable performance on both datasets (accuracy of around 75% and 70% on Twitter and Reddit respectively). The relatively lower training per-

formance on these datasets can contribute to the weaker performance of spotters on these datasets.

3.7 Discussion

We first report insights on why prediction loss alone is not enough to identify spurious instances. For this analysis, we track the loss of spurious and genuine instances at each training iteration.[8] Figure 6(a) shows the number of spurious/genuine instances with low/high loss at each epoch; where, we use the average loss of *correctly* classified training instances at each epoch as a pivot value to determine the low and high loss values for that epoch. Initially, almost all spurious and genuine instances have high loss values (see SH and GH in Figure 6(a)). However, the sheer imbalance of genuine instances relative to spurious instances means that there will still be a relatively large number of genuine instances with large loss - these are simply difficult instances. Furthermore, the number of spurious instances with lower loss values (SL) slowly increases as the network gradually learns the wrong labels of some spurious instances; this, in turn, decreases the expected loss of such instances. Since PP merely ranks instances based on loss values, the above two factors may cause some spurious instances to be ranked *lower* than genuine ones by PP; see Figure 6(b) for MAP of PP in detecting spurious instances at every iteration. Using queue information from the Leitner system adds information that loss alone does not; we suspect that the learner can find principled solutions that trade off losses between one difficult genuine instance and another (causing them to bounce between q_0 and higher queues) without harming total loss, but that the more random nature of spurious instances means that they are consistently misclassified, staying in q_0. Verifying this hypothesis will be the subject of future work.

For our second analysis, we manually inspect highly ranked instances in q_0 of Lit. We use the synthetic dataset bAbi (Weston et al., 2016) which is a systematically generated QA dataset for which the task is to generate an answer given a question and its corresponding story. As the learner, we use an effective LSTM network specifically developed for this task.[9] Table 3 shows sample instances from bAbi which are highly ranked by

[8] Here we use Addition with $N = 10$K training instances and noise level of $\alpha = 0.2$.

[9] https://github.com/fchollet/keras/blob/master/examples/babi_rnn.py

Story: Mary traveled to the garden. Daniel went to the garden. Mary journeyed to the kitchen. Mary went **back to the hallway**. Daniel traveled to the office. Daniel moved to the garden. Sandra went back to the kitchen. John traveled to the bathroom. **Question**: Where is Mary? **Answer**: hallway
Story: John went to the office. Daniel journeyed to the office. Sandra picked up the football **there**. Sandra went to the bedroom. Sandra left the football there. Sandra went **back to the kitchen**. Sandra traveled to the hallway. Sandra moved to the garden. **Question**: Where is the football? **Answer**: bedroom

Table 3: Sample inconsistencies in bAbi dataset.

Lit. We observe inconsistencies in the given stories. In the first case, the story contains the sentence "Mary went *back* to the hallway," while the previous sentences indicate that Mary was in the "garden/kitchen" but not "hallway" before. In the second case, the sentence "Sandra picked up the football *there*" is inconsistent with story because the word "there" doesn't refer to any specific location. We conjecture that these inconsistencies can mislead the learner or at least make the learning task more complex. Our model can be used to explore language resources for such inconsistencies.

4 Related Work

There is broad evidence in psychology that shows human ability to retain information improves with repeated exposure and exponentially decays with delay since last exposure. Ebbinghaus (1913, 2013), and recently Murre and Dros (2015), studied the hypothesis of the exponential nature of forgetting in humans. Three major indicators were identified that affect memory retention in humans: delay since last review of learning materials and strength of human memory (Ebbinghaus, 1913; Dempster, 1989; Wixted, 1990; Cepeda et al., 2006; Novikoff et al., 2012), and, more recently, difficulty of learning materials (Reddy et al., 2016).

The above findings show that human learners can learn efficiently and effectively by increasing intervals of time between subsequent reviews of previously learned materials (spaced repetition). In (Amiri et al., 2017), we built on these findings to develop efficient and effective training paradigms for neural networks. Previous research also investigated the development of cognitively-motivated training paradigms named curriculum learning for artificial neural networks (Bengio et al., 2009; Kumar et al., 2010). The difference between the above models is in their views to learning: curriculum learning is inspired by the learning principle that training starts with *easier* concepts and gradually proceeds with more difficult ones (Bengio et al., 2009). On the other hand, spaced repetition models are inspired by the learning principle that effective and efficient learning can be achieved by working more on difficult concepts and less on easier ones.

In this research, we extend our spaced repetition training paradigms to simultaneously train artificial neural networks and identify training instances with potentially wrong labels (spurious instances) in datasets. Our work is important because spurious instances may inversely affect interpretations of the data, models developed from the data, and decisions made based on the data. Furthermore, spurious instances lead to unrealistic comparison among competing systems if they exist in test data.

5 Conclusion and Future Work

We present a novel approach based on queueing theory and psychology of learning to identify spurious instances in datasets. Our approach can be considered as a scheduler that iteratively trains a downstream learner (e.g. a neural network) and detects spurious instances with respect to their difficulty to learn during the training process. Our approach is robust and can be applied to any dataset without modification given a neural network designed for the target task of the dataset.

Our work can be extended by: (a) utilizing several predictions for each training instance, (b) investigating the extent to which a more sophisticated and effective downstream learner can affect the performance of different spotters, (c) developing models to better distinguish hard genuine instances from spurious ones, and (d) developing ranking algorithms to improve the performance of models on real-world datasets.

University Park, PA
jrcole,reitter@psu.edu

Abstract

This paper explores the time course of lexical memory retrieval by modeling fluent language production. The duration of retrievals is predicted using the ACT-R cognitive architecture. In a large-scale observational study of a spoken corpus, we find that language production at a time point preceding a word is sped up or slowed down depending on activation of that word. This computational analysis has consequences for the theoretical model of language production. The results point to interference between lexical and phonological stages as well as a quantifiable buffer for lexical information that opens up the possibility of non-sequential retrievals.

1 Introduction

Speech varies greatly in fluency, and some of its speed variation can be traced to the utterance spoken (Jespersen, 1992). Low-frequency words, for instance, are known to slow down speech (e.g., Bell et al., 2009). Variables correlated with fluency give valuable cues to the architecture of the language processing system. However, a model to explain these data has yet to emerge.

In this paper, we propose a cognitive model of fluency, in which lexical memory retrievals may explain some of the variability in speech rates. In particular, frequency, context and recent uses together have the potential to quantify retrieval delays through *activation* (Anderson, 1991). Activation, in its most common usage, refers to the way nodes in semantic networks become easier to retrieve after adjacent nodes have been activated, typically through a presentation (Collins and Loftus, 1975). In particular, activation makes a direct claim that more highly activated words require less time to retrieve, and vice versa (Anderson, 1983).

The language production process as a whole likely requires some amount of sequential processing. For instance, the standard model proposes that an idea is generated, lexicalized, grammatically and morphologically encoded, and only then phonologically encoded (Bock and Levelt, 2002). Still, most models of language production presuppose some amount of planning of output (e.g., Pickering and Garrod, 2013), so we could instead divide language production into planning this output and the actual process of outputting. The overlap and relationship of these processes is not fully understood, but given that most output is likely planned, the scale at which the planning takes place and the amount of time between planned output and the actual process of outputting remains unclear. However, if interactions between processes are observed, then we can likewise see when they overlap in time.

To summarize, we are suggesting that some of the variance in speech rate is not due to the linguistic properties of the words currently or about to be outputted, but the words still in the planning phase. We propose a model that uses a buffer of several words between initial retrieval and output, during which grammatical and morphological encoding take place. We examine this by calculating retrieval activation for a word and evaluating the influence of that activation on the empirical speech timing several words beforehand, using the Switchboard corpus. The effect of activation is distributed over preceding words in a way that is characteristic of a shared-resource, buffer-based account of language production.

2 Related Work

2.1 Stages of Language Production

Grammatical encoding can be divided into *functional* and *positional* processing steps (Bock and Levelt, 2002). The functional step selects lexical items and assigns functions, while

Proceedings of NAACL-HLT 2018, pages 2017–2027
New Orleans, Louisiana, June 1 - 6, 2018.

the positional step then combines the items to produces constituents. In our account, we expect that these mutually dependent steps work in parallel.

An important early part of functional processing retrieves lexical information, which we will examine in this paper. We evaluate the consequences of lexical access, which is assumed to be affected by the cost associated with any retrieval from declarative memory. Much discussion in this area has concerned the question whether lexical access happens in a single stage (Dell et al., 1997) or in multiple stages and overlaps with grammatical encoding (Caramazza, 1997; Roelofs et al., 1998; Caramazza, 2006). Here, we follow ACT-R's serial and partially symbolic nature, which in turn leads to some theoretical commitments to non-parallel processing: language production is staged and discrete. Nonetheless, each stage can be composed of several steps, and steps from syntactic and phonological processing likely interleave. This is compatible with empirical findings and the overall theoretical debate (Ferreira and Slevc, 2007). The precise timeline of processing is unclear, but as we will argue in this paper, large-scale speech data can give us usable clues to that effect.

2.2 Incrementality in Language Production

The second issue we address concerns the timing of memory retrievals, which is also related to the idea of incremental processing. It is a commonly implied assumption that language processing proceeds incrementally. In grammatical encoding, this property concerns when and in which order syntactic choices are made. For instance, all of them could be made before phonological processing starts (non-incremental case), or they could be made in order as necessary. Existing high-level models of language production proceed incrementally at various steps in a chain of content selection, aggregation and sentence realization (e.g., Bock and Levelt, 2002; Guhe, 2007).

Ferreira (1996) makes an argument for incrementality, based on the observation that competitive syntactic alternatives facilitate production rather than making it more difficult. An incremental account of sentence realization would predict such an effect, as syntactic "flexibility" introduced by the alternatives makes it easier to find a workable syntactic decision. By contrast, without incremental commitment to each structure, competing material slows down the process, because it would lead to combinatory explosion. However, later results establish nuance. Ferreira and Swets (2002) show that incremental production is possible, but it is "under strategic control"; it depends on semantic information, and it could be modulated by external factors, such as stress.

If processing were fully incremental, then it would follow that lexical memory retrievals are also fully incremental. The order words are retrieved in would be the same as the order words are eventually outputted in. However, if other features modulate this, then it would imply that incremental processing is instead variable, as suggested by earlier accounts.

2.3 Speech Rates

Several studies have illustrated the effects of frequency, recency, and context (Bell et al., 2009; Arnon and Priva, 2014) on speech rates. These studies motivated our modelling choices, as recency, frequency, and context are also the key components of the ACT-R theory of memory.

Recent research has found a correlation between rate of speech and the information content of that speech. (e.g., Arnon and Cohen Priva, 2013). Thus far, this correlation lacks a precise theory with a cognitive explanation. By producing a cognitive model of these speech rates, we provide evidence for such a theory.

2.4 Lexical Retrieval

This paper examines the time course of lexical retrieval for the case of fluent, naturalistic speech. Different facets of language can interfere with lexical retrieval in different contexts, which provides evidence toward an architecture: Schriefers et al. (1990) found that semantic, but not phonological material can cause interference, suggesting that the two are represented separately. Ratcliff and McKoon's (1989) study focuses on sentence retrieval and found that semantic information is also retrieved in stages. Here, we seek to model the retrieval process in the context of fluent speech.

There are a number of memory models in the literature that provide accounts of the timing of lexical access. For instance, classic models such as Dell's (1986)'s model of spreading activation during language production and Levelt et al.'s (1999) WEAVER++ model both provide quantitative values for retrieval times based on the form of a word.

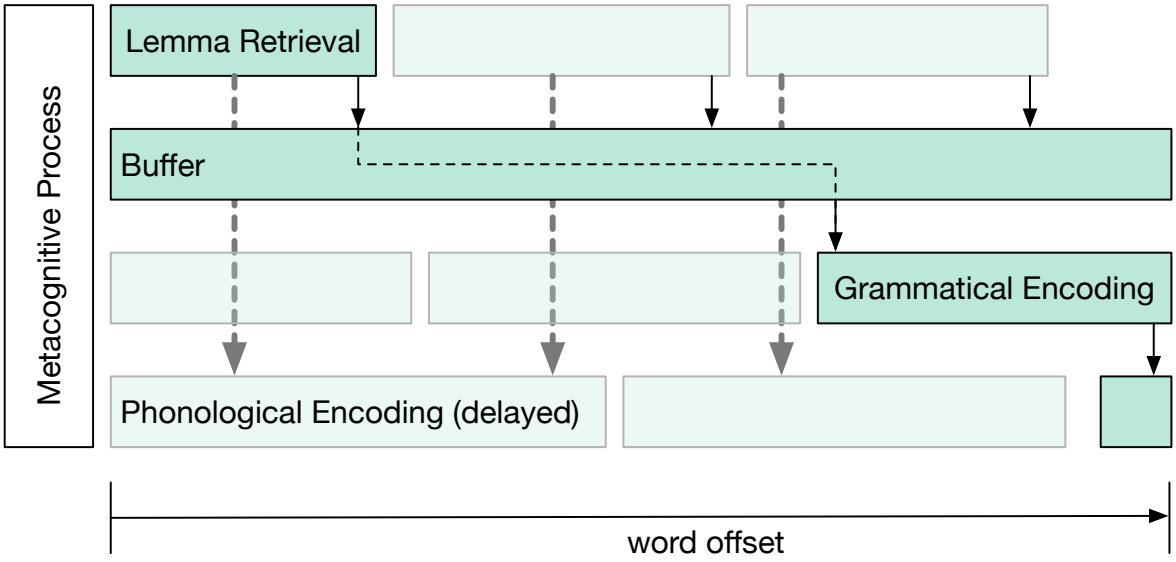

Figure 1: Our psychological model assumes that language production involves several parallel processes, and that retrieval of lemmas can interact with concurrent retrieval and/or encoding of phonological representations (dashed arrows) due to concurrent resource usage. Lemmas are retrieved several words before they are spoken. Their exact point of retrieval could depend on other factors. Likewise, while we represent phonological retrieval/encoding as a separate process for clarity, we make no claim to what extent these processes overlap.

Models such as Rapp and Goldrick (2000) focus on modeling speech errors based on word activation and context. Our model differs from these in that it attempts to model retrievals from fluent speech rates, rather than single word lexical retrieval based on picture naming tasks. Finally, while speech errors are likely related to failed lexical memory retrievals, we focus on speech that was eventually successfully retrieved and produced.

More relevantly, Dell and O'Seaghdha (1992) examine the time course of lexical access in language production. In particular, they use series of three words and EEG data to estimate lexical retrieval time. However, the lab setting it took place in precluded it as a study of naturalistic speech. Further, their model of the effects of word-properties relied on primarily qualitative attributes, such as semantic or phonetic relatedness. In particular, they find additional evidence for lemma and phonological retrieval taking place in separate stages, based on inhibition and facilitation effects. The goal of the present study is to expand the examined time frame in the hopes of replicating their argument on naturalistic speech while viewing effects found throughout, rather than just a three word window.

3 ACT-R Model

To motivate the corpus-based empirical analysis, we first describe our high-level model of the language production process. Our method primarily relies on simulating the state of lexical declarative memory during language production. After we simulate the memory retrievals for each word, we can compare this information to the actual empirical timing data in the corpus. In particular, we rely on Anderson's (1983) original account of memory. This framework was selected rather than newer or more task-specific frameworks as it is the same underlying memory model of ACT-R, which has been used to explain a wide variety of language phenomena (e.g., Vasishth and Lewis, 2004; Reitter et al., 2011), but also has been used to explain everything from decision-making (e.g., Marewski and Mehlhorn, 2011) to visual attention in graphical user interfaces (e.g., Byrne et al., 1999). Thus, by using this model, our work naturally builds upon a large body of work, using the same mechanisms to explain a variety of tasks.

Figure 1 illustrates how lemma retrieval of a target word affects phonological encoding of speaking of an earlier word. Retrieval timing is computationally estimated using the cognitive architecture ACT-R, and we assume that this retrieval

time proportionally affects phonological encoding. This can take place strategically, via a metacognitive process that coordinates these different modules, or via interference because both processes share declarative memory resources.

Our model of lexical memory is principally based on Anderson (1983)'s discussion of recency, frequency, and context effects. Activation (A) within the context of the ACT-R system is generally described by the sum of *base-level learning* (bll) and *spreading activation* (sa), which we adopt for our model as well (Anderson et al., 2004). Activation, can be defined as a linear combination of spreading activation base-level learning:

$$A(x) = sa(x) + bll(x) \tag{1}$$

For our purposes, we consider x to refer to an individual word. Base-level learning refers to the frequency and recency effects. In the base-level learning equation, it can refer to both because of the *decay* parameter, d, which causes more recent presentations to be more important, with older presentations (signified by their time of presentation, t) becoming exponentially less relevant. These older presentations, when considered together, add to the equation through their sheer quantity, providing the frequency effect, defined as:

$$bll(x) = \log\left(\sum_{i \in P_x} t_i^{-d}\right) \tag{2}$$

In this equation, P_x refers to the list of x's presentations, so t_i is the time from that presentation to the present. Naturally, for something with as many presentations as any given word, it is infeasible to computationally manage that sum. However, the full equation can be approximated using only the total number of presentations and the k most recent presentations and $n_x = |P_x|$ (Petrov, 2006).

$$bll(x) \approx \log\left[\sum_{i}^{k} t_i^{-d} + \frac{(n_x - k)\left(t_{n_x}^{1-d} - t_k^{1-d}\right)}{(1-d)\left(t_{n_x} - t_k\right)}\right] \tag{3}$$

While Petrov (2006) shows that the equation is close even for $k = 1$, we used $k = 5$ to more closely approximate the original equation. We then use the ACT-R default for the decay parameter, 0.5. Note that it has been suggested (e.g., Lewis and Vasishth, 2005; Cole et al., 2017) that this decay parameter could be different for language processing. In this work, we are only concerned with relative, rather than absolute values for a word's activation in memory.

In order to compute the total number of presentations, we relied on a fairly simple estimate. We multiply the number of seconds a person has been alive with the average speaking rate and that word's frequency to obtain an estimate of the amount of times a person has encountered that word; it is difficult to measure the difference between being exposed to the lexical form of the word compared to the phonological form, and it is even harder to measure any subsymbolic exposure due to thought. Still, using this formula, a unigram score computed by SRILM (Stolcke, 2002) applied to the British National Corpus, the average speaking rate of Switchboard participants (197 words/minute) as computed by Yuan et al. (2006), and the average age of Switchboard participants (37) (Godfrey et al., 1992), we can compute a baseline number of presentations for every word in Switchboard.

Next, computing spreading activation on a corpus as described in Anderson (1983) would likewise be computationally intractable. However, Pirolli et al. (2006) showed that for large sample sizes of language, Pointwise-Mutual Information is nearly identical. Therefore, we use Semilar's PMI database computed on the Wikipedia corpus (Rus et al., 2013; Church and Hanks, 1990).

In the ACT-R system, generally only items currently in working memory affect memory retrievals (Anderson et al., 2004). Likewise, we maintain the n previous words in a buffer to compute their spreading activation to the next word. We used $n = 5$ as an estimate for working memory size in language, as found in a reading task (Daneman and Carpenter, 1980). For our model, we compute the spreading activation between retrieved word, x, and each word in working memory, y, as:

$$sa(x) \approx \sum_{y}^{n} pmi(x, y) = \sum_{y}^{n} \log \frac{p(x, y)}{p(x)p(y)} \tag{4}$$

Once we have a value for activation, it's fairly simple to compute an estimate for retrieval time (RT) using the same equations from Anderson

(1983).

$$RT = I + 1/A - \frac{Ke^{-KA}}{(1 - e^{-KA})} \quad (5)$$

In this equation, I is an intercept, easily fitted with a linear model. As a parameter, K represents the cutoff time (in seconds) before there is a retrieval failure. This equation actually only represents the time required in the case of successful retrievals, which is nonetheless bounded by K, which in that sense could be thought of as the maximum possible time for a successful retrieval. While retrieval failures are part of normal ACT-R processing, they are not relevant to our model. Since our model is formed of already spoken words, they cannot represent retrieval failures. Thus, while the equation only represents successful retrievals, it is appropriate for our model. We chose the architectural default of 1.0 for K.

4 Methods

4.1 Corpus Analysis

The empirical speech data was taken from the Switchboard corpus (Godfrey et al., 1992) which is part of the Penn Treebank corpus (Marcus et al., 1993). This dataset consists of telephone conversations between strangers on a random topic, annotated to include the start and finish time for every word that has been spoken. Using our model of lexical memory as described in the previous section, we trace through the model and compute the activation of each word at its onset time.

Once the activation was computed for each word at the point when it was spoken, our goal was to observe its effect on overall speaking rates. In order to estimate when x was retrieved, we examined the speech some number of *words* back from word x. If words are spoken systematically more slowly or quickly based on word x's activation and their positional relationship to word x, then we can assume where words are spoken more slowly, retrievals are taking place. Where words are spoken more quickly, retrievals have finished. Importantly, since this is being computed at every sentence position, this should not capture positional effects. See Figure 1 for a visual depiction of our model of interference during lexical retrieval, which allows us to infer retrieval based on such interference.

While a naive model may expect lexical retrieval to occur immediately before grammatical or phonological encoding, this is not necessarily the case. Indeed, the amount of time before encoding may not be constant and may vary from word to word.

Our analysis of the corpus requires computing each word's *delay*, which is defined as the amount of time between the onsets of two sequential words, including any disfluencies that occur. As words themselves naturally can require different amounts of time to speak, we instead use the *adjusted* delay which is computed by taking the average of all of the durations of that word (as found in Switchboard) and subtracting it from the given duration. Thus, the adjusted delay could be a positive or a negative number, representing slowdowns and speedups, respectively. Throughout this paper, we use the term *delay* to actually refer to this adjusted delay. The delay referred to in Figure 1 is thus the adjusted delay: the difference between the expected delay based on the word form and the actual observed delay. To be clear, that means that if a delay term is not zero, there was a variation from the normal speed of processing, to either be quicker (negative delay) or slower (positive delay).

These speedups and slowdowns, and their relationship to retrieval time, allow us to make an argument about the interaction between lexical and phonological processing. From a statistical point of view, as we are comparing retrieval time and slowdowns in the same units, our linear model could be thought of as the percentage of retrieval time that is behaviorally reflected in language production.

4.2 Experiment

Data were analyzed with two related models. Initially, we tested an *interaction* model in order to test our hypothesis of the interaction between delay and offset (see Table 1). From this information, we use exploratory data analysis in the form of a *discrete* model, in order to explore the critical regions of the graph (see Table 2). From this exploratory data analysis, we present the pooled version of the discrete model for easier interpretation of our found effects (see Table 3). For both models, the activation of a target word and its expected retrieval time burden was computed, as were the delays for the n words preceding the target word. Importantly, note that in both models, when we refer to the expected retrieval time or activation, we

are referring to the target word, not any of the preceding words. Both models are concerned with the word *offset* (*i*), which refers to the number of interceding words between the given delay and the target word, such that $\mathrm{i} = 0$ refers to the word immediately before the target word.

In the interaction model, we are interested in the interaction term between word offset and delay: its goal is to show how the correlation changes with offset. In this model, every observation only uses a single offset, chosen randomly, for each target word. All of the other observations for that word are discarded. This is to ensure the observations are independent. The correlation coefficients of interest are the correlation of delay as a whole, and its interaction effect with offset. In general, the coefficient of offset by itself is likely capturing some distributional information about the data, rather than anything interesting with how it relates to memory retrievals. As a linear model:

$$RT \sim \text{delay} * \text{offset}$$

Meanwhile, the discrete model's observations consist of a word's expected retrieval time and the delays from previous words. Then, we make a linear model using each of the delays as a predictor. Note that in this notation, delay_i refers to the delay of offset word i. To reiterate, i represents how many interceding words there are between that offset word and the target word. As a linear model, this would be:

$$RT \sim \text{delay}_0 + \text{delay}_1 + ... + \text{delay}_n$$

The goal of the interaction model is to show the robustness of the slope associated with index, while the goal of the discrete model is to allow for a non-linear relationship between offset and the effect of delay on activation, examining up to 25 previous words. Exploring this non-linear relationship allowed us to infer the critical regions of this effect. Importantly, the discrete model's goal was to explore the significant relationship found in the interaction model more deeply, rather than to itself justify the effect.

Under the model shown in Figure 1, we expect that longer retrieval times of the target word are associated with slowdowns of speech production at some time before the target word is spoken. Earlier than that point, the target word should have no influence on speech production.

5 Results and Discussion

If one focuses on the interaction model, our experiments yield a relatively counterintuitive result: namely, delay is correlated in the direction opposite to what is expected. One would imagine that delay and retrieval time should be positively correlated: if people are speaking words more slowly (positive delay), then likewise, their retrieval time should be higher. However, we discovered a robust effect in the opposite direction: higher delays imply shorter expected retrieval times, and shorter delays imply longer expected retrieval times. In other words, when people are expected to need the longest to retrieve words, they actually speak more quickly, and vice versa.

Table 3: Pooled version of discrete linear model, based on critical regions from the graph. Regions are broken at 3, 5, and 14 respectively.

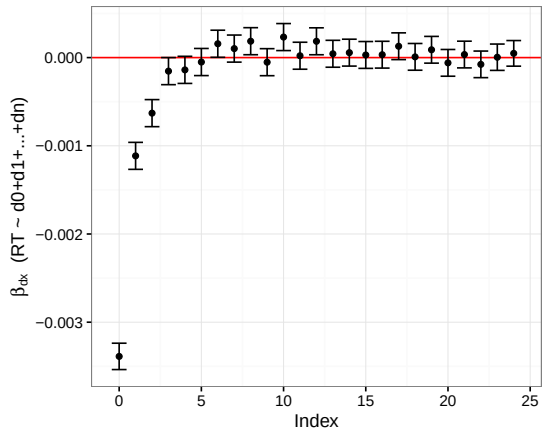

Figure 2: The discrete model's linear predictors (see also Table 2). Error bars represent normal 95% confidence intervals. This graph and Figure 3 have similar critical regions, which informed the pooled model presented in Table 3: 0-2 appear significant and negative, 3-4 are not significant (slightly negative), 5-14 are significant and positive, 15+ is not significant.

Examining the effect for larger offsets, however, we observe that the effect reverses before disappearing. Thus, we see an effect in the expected direction for the delays of word offsets 4 through 14. This is commensurate with word planning that takes place several words in advance rather than immediately before the word; likewise, the effect also disappears in the interaction model based on the interaction effect.

See also Figure 2 and Figure 3, which are visualizations of the discrete and interaction model, respectively. These graphs show how the relationship between activation of a word and speech delay develops over the offsets, i, before the word. While Figure 2 has its effects pulled directly from Table 2, Figure 3 is produced by raw data, defined by:

$$y(j,i) = \frac{A_j - \beta_0}{\text{delay}_i} \tag{6}$$

These graphs were designed to demonstrate how the effect switches from positive to negative as we move back from immediately before the word to earlier in the utterance. With the interaction model, we wanted to show statistical evidence for the pattern of effects; the discrete model quantifies the gradual fade to zero. We interpret the models as follows.

1. There is a strong negative correlation of the word delays with expected retrieval time for the words immediately before the target word. Since retrieval time is a function of activation, this would imply that the observable phonological effect happens later for more activated words, which are likely retrieved shortly before their use.
2. There is a weaker but significant positive correlation of the word delays with expected retrieval time for words about 5-14 words preceding the target word. These delays likely occur for words with less activation, whose retrievals are likely initiated early to ensure that there is enough time.
3. For words very far away from the target word, there is no reliable effect, implying that this is not just an effect of a cyclical information distribution.

6 General Discussion

These results confirm some classical findings on lexical retrieval, while adding a subtle but reliable new effect. Further, these findings have some implications for incrementality and uniform information density.

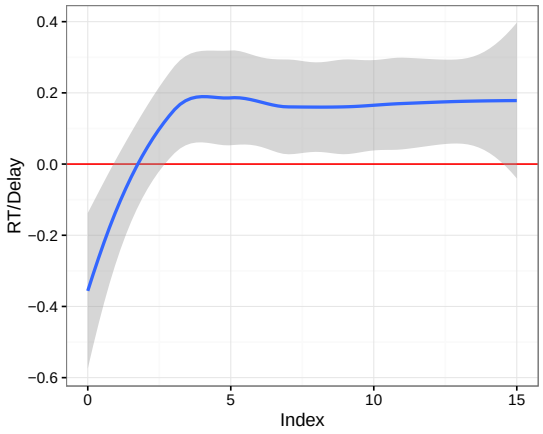

Figure 3: Smoothed correlation between delay and expected retrieval time across offset, created using a sample of raw data (representative of the interaction model). Effect disappears after offset 15, but full graph is not shown to avoid smoothing small but significant effects with non-significant effects.

In our discussion, we will frequently refer to the *activation* of a word. Recall that activation in the ACT-R sense is the inverse of the expected retrieval time: higher activation implies a shorter expected retrieval time. While retrieval time makes more sense in a time-predictive linear model, it is easier to interpret our results based on its relationship to activation.

6.1 Lexical Retrieval

It is difficult to separate the lexical retrieval effects we found into the two categories of retrievals described by Levelt (1992): a lemma retrieval and a later phonological retrieval. However, this is not to claim that they cannot be, but simply that our methodology did not easily allow us to. A commonly implied assumption is that lemma retrievals shouldn't interfere with phonological processes (e.g., Schriefers et al., 1990), though it is difficult to know if a speech slowdown is due to a phonological or semantic interference due to our experimental setup. However, since in our experiment, effects are still observed at large distances from the target words, either phonological forms can be retrieved in a non-incremental way (possibly even before lemmas for other words are retrieved), or the retrieval of the lemma does interfere with phonological encoding in some way; for instance, by activating related phonological forms. Still, we ultimately find the same pattern of effects as Dell and O'Seaghdha (1992): facilitatory effects close to the target word, with inhibitory effects further away. The primary difference is the time frame, which is possibly due to their experimental setup.

6.2 Process Model

We found a surprising effect: words with higher activation are not spoken more quickly, but more slowly. This also applies to the words that immediately precede them. However, if we look further back, we see a robust effect in the expected direction: if the approaching word has a high activation, they are said more quickly, but if the approaching word has a low activation, they are said more slowly. We argue that this slowdown is the result of shared resources between phonological and grammatical encoding, and as activation directly predicts retrieval time, we posit that word retrievals are part of what causes slowdowns. The corresponding speedups could be because the work of planning the sentence up to that point is then done. The most important prediction of this is that it means low activation words are retrieved earlier, which would imply that there is some cognitive strategy facilitating the necessity of initiating early retrievals for low activation words.

6.3 Incrementality

These results provide information about the timing of memory retrievals, given that such retrievals are related to activation. As activation is inherently related with how long a memory retrieval should take, it makes sense there are some cognitive strategies for coping with this disparity in order to produce seemingly fluent dialogue. That strategy involves buffering: retrieving and storing the words that will need longer to retrieve, based on the structure of the sentence.

Further, this type of buffering strategy could be part of the strategy that Ferreira and Swets (2002) refer to, when they propose the incrementality of language production is under "strategic control." While a purely incremental strategy might have interlocutors retrieve in a purely incremental fashion, there are some hiccups: certain words take longer to retrieve than others. By this logic, if grammatical encoding proceeds in a purely incremental fashion, then lexical retrieval does not, and vice versa. Thus, it is reasonable to believe that the grading of incrementality found in natural human discourse is not only variable from situation to situation, but it may be variable amongst competing processes for any given situation.

6.4 Uniform Information Density

Let's consider an additional explanation. The *Constant Entropy Rate* Hypothesis (Genzel and Charniak, 2002) posits that lexical material is distributed across a sentence (and other units) such that its information is held approximately constant. Could a difficult-to-retrieve, slow word at position j be likely to be combined with easier-to-retrieve, high-frequency words at positions $j-4...j-1$, causing the significantly increased speech rate we found there?

The model of buffered retrievals, along with the empirical evidence, may provide a cognitive mechanism that results in an approximately constant entropy rate. Thus, Uniform Information Density (UID, e.g., Jaeger, 2010) could be considered a consequence of the cognitive procedures involved in retrieving syntactic-lexical items from

declarative memory while grammatically encoding those materials retrieved earlier.

7 Future Work

Our work opens up several possible avenues for future research. While it is unclear if syntax rules are retrieved from some form of implicit memory (e.g., Reitter et al., 2011), lexical items clearly are. Syntactic processing could potentially adapt to working memory, rather than itself guide lexical retrievals (e.g., Cole and Reitter, 2017). By this argument, memory retrieval is a largely automatic, rather than attention-driven process, and syntax makes use of what is available to produce fluent dialogue. In this type of model, the constant size of the retrieval buffer would provide a clear corollary to Uniform Information Density.

Furthermore, this paper does not clearly differentiate between lemma and phonological retrieval. Although we do not expect phonological forms to be retrieved as early as the effects we are seeing, we also do not expect lemma retrieval to have effects on phonological encoding. A computationally implemented process model could explore these effects in more detail.

Lastly, this study provides another mechanism by which non-sequential dependencies in language production are observed. It seems possible that non-incremental language processing can be explained as a process that involves general memory mechanisms including cue-based memory retrieval. What is in question is whether we really process local syntax using structured, memory-hungry models (i.e., with syntax trees); we note that in natural language processing, skip-grams can capture local, non-incremental relationships among words. Thus, the relationship between working memory, syntax trees, and skip-grams appears to be of continued interest.

8 Conclusions

In this paper, we explore the process of lexical memory retrieval in the context of language production. In contrast to previous work, we look at a corpus of natural speech and do not rely on single word retrievals in an experimental setting. This allows us to observe how certain processes involved in fluent language production overlap. In particular, the data support a model according to which lexical retrievals can happen quite early. By using the formalism defined by the empirically-validated ACT-R framework, we show when memory retrievals are taking place through the effect on speaking rates, seeing facilitation early and inhibition later. We conclude that low-activation words can be retrieved as early as 14 words before they are spoken. As low activation words are higher information and require longer to retrieve, this has theoretical implications for some empirical findings of language processing.

Abstract

When learning POS taggers and syntactic chunkers for low-resource languages, different resources may be available, and often all we have is a small tag dictionary, motivating type-constrained unsupervised induction. Even small dictionaries can improve the performance of unsupervised induction algorithms. This paper shows that performance can be further improved by including data that is readily available or can be easily obtained for most languages, i.e., eye-tracking, speech, or keystroke logs (or any combination thereof). We project information from all these data sources into shared spaces, in which the union of words is represented. For English unsupervised POS induction, the additional information, which is not required at test time, leads to an average error reduction on Ontonotes domains of 1.5% over systems augmented with state-of-the-art word embeddings. On Penn Treebank the best model achieves 5.4% error reduction over a word embeddings baseline. We also achieve significant improvements for syntactic chunk induction. Our analysis shows that improvements are even bigger when the available tag dictionaries are smaller.

1 Introduction

It is a core assumption in linguistics that humans have knowledge of grammar and that they use this knowledge to generate and process language. Reading, writing, and talking leave traces of this knowledge and in psycholinguistics this data is used to analyze our grammatical competencies. Psycholinguists are typically interested in falsifying a specific hypothesis about our grammatical competencies and therefore collect data with this hypothesis in mind. In NLP, we typically require big, representative corpora. NLP usually has induced the models from expensive corpus annotations by professional linguists, but recently, a few researchers have shown that data traces from human processing can be used directly to improve NLP models (Klerke et al., 2016; Barrett et al., 2016; Plank, 2016).

In this paper, we investigate whether unsupervised POS induction and unsupervised syntactic chunking can be improved using human text processing traces. We also explore what traces are beneficial, and how they are best combined. Our work supplements psycholinguistic research by evaluating human data on larger scale than usual, but more robust unsupervised POS induction also contributes to NLP for low-resource languages for which professional annotators are hard to find, and where instead, data from native speakers can be used to augment unsupervised learning.

We explore three different modalities of data reflecting human processing plus standard, pretrained distributional word embeddings for comparison, but also because some modalities might fare better when combined with distributional vectors. Data reflecting human processing come from reading (two different eye-tracking corpora), speaking (prosody), and typing (keystroke logging). We test three different methods of combining the different word representations: a) canonical correlation analysis (CCA) (Faruqui and Dyer, 2014b) and b) singular value decomposision and inverted softmax feature projection (SVD+IS) (Smith et al., 2017) and c) simple concatenation of feature vectors.

Contributions We present experiments in unsupervised POS and syntactic chunk induction using multi-modal word representations, obtained from records of reading, speaking, and writing. Individually, all modalities are known to contain syntactic processing signals, but to the best of our

Lea Frermann carried out this work while at the University of Edinburgh.

Proceedings of NAACL-HLT 2018, pages 2028–2038
New Orleans, Louisiana, June 1 - 6, 2018.

knowledge, we are the first to combine them in one model. Our work extends on previous work in several respects: (a) We compare using data traces from gaze, speech, and keystrokes. (b) We consider three ways of combining such information that do not require access to data from all modalities for all words. (c) While some previous work assumed access to gaze data at test time, our models do not assume access to any modalities at test time. (d) We evaluate how much the additional information helps, depending on the size of the available tag dictionary. (e) While related work on keystrokes and prosody focused on a single feature, all our word representations are multi-dimensional and continuous.

2 Related work

Eye-tracking data reflect the eye movements during reading and provide millisecond-accurate records of the readers fixations. It is well established that the duration of the fixations reflect the processing load of the reader (Rayner, 1998). Words from closed word classes are usually fixated less often and for shorter time than words from open word classes (Rayner and Duffy, 1988). Psycholinguistics, however, is generally not interested in covering all linguistic categories, and psycholinguists typically do not study corpora, but focus instead on small suites of controlled examples in order to explore human cognition. This is in contrast with NLP. Some studies have, however, tried to bridge between psycholinguistics and NLP. Demberg and Keller (2008) found that eye movements reflected syntactic complexity . Barrett and Søgaard (2015a) and Barrett and Søgaard (2015b) have tried to–respectively–predict a full set of syntactic classes and syntactic functions across domains in supervised setups. Barrett et al. (2016), which is the work most similar to ours, used eye-tracking features from the Dundee Corpus (Kennedy et al., 2003), which has been augmented with POS tags by Barrett et al. (2015). They tried for POS induction both on token-level and type-level features. They found that eye-tracking features significantly improved tagging accuracy and that type-level eye-tracking features helped more than token-level. We use the same architecture as Barrett et al. (2016).

Keystroke logs also reflect the processing durations, but of writing. Pauses, burst and revisions in keystroke logs are used to investigate the cognitive process of writing (Matsuhashi, 1981; Baaijen et al., 2012). Immonen and Mäkisalo (2010) found that for English-Finnish translation and monolingual Finnish text production, predicate phrases are often preceded by short pauses, whereas adpositional phrases are more likely to be preceded by long pauses. Pauses preceding noun phrases grow with the length of the phrase. They suggest that the difference is explained by the processing of the predicate begins before the production of the clause starts, whereas noun phrases and adpositional phrases are processed during writing. Pre-word pauses from keystroke logs have been explored with respect to multi-word expressions (Goodkind and Rosenberg, 2015) and have also been used to aid shallow parsing (Plank, 2016) in a multi-task bi-LSTM setup.

Prosodic features provide knowledge about how words are pronounced (tone, duration, voice etc.). Acoustic cues have already been used to improve unsupervised chunking (Pate and Goldwater, 2011) and parsing (Pate and Goldwater, 2013). Pate and Goldwater (2011) cluster the acoustic signal and use cluster label as a discrete feature whereas Pate and Goldwater (2013) use a quantized word duration feature.

Plank (2016) and Goodkind and Rosenberg (2015) also used a single keystroke feature (keystroke pre-word pause) and the former study also discretized the feature. Our work, in contrast, uses acoustic and keystroke features as multi-dimensional, continuous word representations.

3 Modalities

In our experiments, we begin with five sets of word representations: prosody, keystroke, gaze as recorded in the GECO corpus, gaze as recorded in the Dundee corpus, as well as standard, text-based word embeddings from eigenwords. See below for details and references. All modalities except the pre-trained word embeddings reflect human processing of language. For all modalities, we use type-level-averaged features of lower-cased word types.

The choice of using type-averaged features is motivated by Barrett et al. (2016), who tried both token-level and type-averaged eye-tracking features for POS induction and found that type-level gaze features worked better than token-level. Type-averaged features also have the advantage of not relying on access to the auxillary data at test

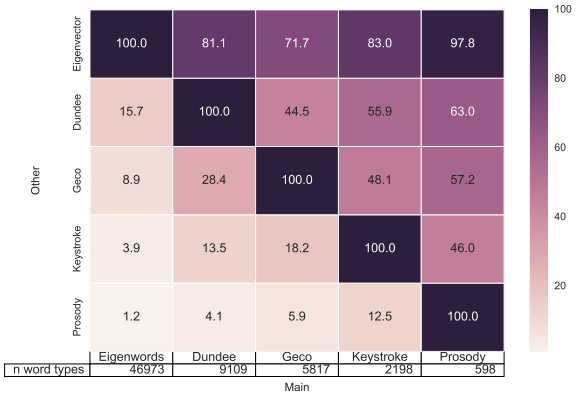

Figure 1: The percentage of overlapping word types for pairs of modalities. Overlapping words are used for projecting word representations into a shared space. Read column-wise. E.g. when combining eigenwords and prosody, only 1.2% of the 46973 eigenvector word types are overlapping (bottom left), and 97.8% of the 598 prosody word types are overlapping (top right).

time. Type-level averages are simply looked up in an embedding file for all previously seen words. On the other hand, type-level features obviously do not represent ambiguities, e.g., *beat* as a verb and a noun separately. All our features, except log-transformed word frequencies were normalized.

We run unsupervised induction experiments for all ($2^5 - 1 = 31$) combinations of our five data sources on the development sets to determine which data types contribute to the task. We consider three different ways of combining modalities, two of which learn a projection into a shared space using word overlap as supervision, and one simply concatenates the embedding spaces. The combination methods are further described in §4.

We list the number of word types per modality and percentage of pair-wise overlapping words in Figure 1. We only use existing data from native speaking participants, for reproducibility and in order not to get learner effects ie. biases introduced by non-native speakers. §3.2-3.5 describe each modality in detail, and how we compute the word representations. §3.1 describes a set of basic features used in all of our experiments.

3.1 Basic features

Like Li et al. (2012), we append a small set of basic features to all our feature sets: features relating to orthography such as capitalization, digits and suffix. Furthermore we append log word frequency and word length. Word frequencies per million are

Modality	n found pairs	Weigh. av. cor.
Prosody	31	0.369
Keystroke	1082	0.060
GECO	2449	-0.030
Dundee	4066	-0.035
Eigenwords	9828	0.197

Table 1: Results on word association norms from wordvectors.org Correlation weighted by number of found pairs per word embedding type.

obtained from British National corpus (BNC) frequency lists (Kilgarriff, 1995). Word length and word frequency explain around 70% of the variance in the eye movement (Carpenter and Just, 1983) and are therefore also important for estimating the impact of gaze features beyond such information. Plank (2016) used keystroke features for shallow chunking and did not find any benefit of normalizing word length by pre-word pause before typing each word, but Goodkind and Rosenberg (2015) did find a strong logarithmic relationship between word length and pre-word pause as well as between word frequency and pre-word pause.

3.2 Dundee and GECO eye-tracking corpora

We use two different eye-tracking corpora. The GECO corpus (Cop et al., 2017) and the Dundee Corpus (Kennedy et al., 2003) are the two largest eye movement corpora with respect to word count. We use the native English part of the GECO corpus and the English part of the Dundee Corpus. The GECO corpus is publicly available[1] and the Dundee Corpus is available for research purposes.

Participants and data The Dundee Corpus is described in Kennedy and Pynte (2005). The Dundee Corpus consists of the eye movements of 10 readers as they read the same 20 newspaper articles. For GECO, all 14 participants in the native English part read a full Agatha Christie novel. Both corpora contain > 50.000 words per reader. All participants for both corpora are adult, native speakers of English and skilled readers.

Self-paced reading Both eye-tracking corpora reflect natural reading by making the reading self-paced and using naturally-occurring, contextualized text.

[1] http://expsy.ugent.be/downloads/geco/

Features Eye movements–like most features reflecting human processing–are very susceptible to experiment-specific effects e.g. instructions and order effects such as fatigue. Furthermore, the GECO corpus has a slightly different eye movement feature set than what we have for the Dundee corpus. Therefore we treat the two eye movement corpora as two individual modalities in order to assess their individual contributions. GECO has 34 features reflecting word-based processing. Dundee has 30 word-based features that were extracted from the raw data and previously used for POS induction by Barrett et al. (2016). For GECO, we use the features that are already extracted by the authors of the corpus. Both corpora include five word-based features e.g., first fixation duration (which is a measure said to reflect early syntactic and semantic integration), total fixation time and fixation probability. The Dundee Corpus has more features concerning the context words whereas GECO has pupil size and many features distinguishing the different passes over a word.

3.3 Prosody

The prosody features are described in detail in Frermann and Frank (2017) and are freely available.[2] They are derived from the Brent (Brent and Siskind, 2001) and Providence (Demuth et al., 2006) portions of the CHILDES corpus (MacWhinney, 2000), comprising longitudinal datasets of raw speech directed to 22 children, and its transcription. Word-level speech-text alignments were obtained automatically using forced alignment. For each token-level audio snippet, a set of 88 prosody features was extracted based on a previously established feature set (Eyben et al., 2016), including standard features derived from F0–F3 formants, spectral shape and rhythm features, intensity and MFCC features among others. Type-level prosody features were obtained as averaged token-level features for each word type.

3.4 Keystroke features

We extracted keystroke features from the publicly available data from Killourhy and Maxion (2012). This data contains key hold times and pauses of all key presses of 20 subjects as they completed transcription and free composition tasks. We only used data from the free composition part. A pause is defined by the authors as the duration from keydown to keydown. The free composition data consists of a total of 14890 typed words and 2198 word types.

For each word, we extracted the following features: (i) average key hold duration of all characters associated with producing the word, (ii) pre-word pause, (iii) hold duration of space key before word, (iv) pause length of space key press pause before word, and (v) ratio of keypresses used in the word production to length of the final word. For each word, we also included these five features for up to 3 words before. In total, we have $5 * 4 = 20$ keystroke features. We use lower-cased word type averages, as with the other modalities.

3.5 Eigenwords

Eigenwords are standard, pre-trained word embeddings, induced using spectral-learning techniques (Dhillon et al., 2015). We used the 30-dimensional, pre-trained eigenvectors.[3]

3.6 Preliminary evaluation

Our application of these word representations and their combinations is unsupervised POS and syntactic chunk induction, but before presenting our projection methods in §4 and our experiments in §5, we present a preliminary evaluation of the different modalities using word association norms.

Table 1 shows the weighted correlation between cosine distances in the representations and the human ratings in the word association norm datasets available at `wordvectors.org` (Faruqui and Dyer, 2014a). Eigenwords, not surprisingly, correlates better than the representation based on processing data – with the exception of prosody. The correlation with prosody is non-significant, however, because of the small sample size.

4 Combining datasets

We now have word representations from different, complementary modalities, with very different coverages, but all including a small overlap. We assume that the different modalities contain complementary human text processing traces because they reflect different cognitive processes, which motivates us to combine these different sources of information. Our assumption is confirmed in the evaluation. The fact that we have very low coverage for some modalities, and the

[2] https://github.com/ColiLea/prosodyAOA

[3] http://www.cis.upenn.edu/~ungar/eigenwords/

fact that we have an overlap between all our vocabularies, specifically motivates an approach, in which we use the intersection of word types to learn a projection from two or more of these modalities into a shared space. Obviously, we can also simply concatenate our representations, but because of the low coverage of some modalities and because co-projecting modalities has some regularization effect, we hypothesize that it is better to learn a projection into a shared space. This hypothesis is verified by the results in §6.

4.1 Concatenating modalities

The simplest way of combining the modalities is concatenating the corresponding vectors for each word. The different modalities have different dimensionalities, so we would need to perform dimensionality reduction to sum or average vectors, and the non-overlapping words don't allow for e.g. taking the outer product, so we simply concatenate the vectors instead. We use 0 for missing values.

4.2 CCA

§4.2 and §4.3 describe two different projection methods for projecting the representations in the different modalities into a shared space. We use the intersection of the lower-cased vocabulary for the alignment, i.e., as a supervision signal. For example, if the words *man*, *dog* and *speak* exist in both eigenword and keystroke data, from these 2 x 3 vectors, CCA estimate the transformation for the vectors for *house*, *cat* and *boy*, which (in this example) only exists in the keystroke data.

Canonical Correlation Analysis (CCA), as originally proposed by Hotelling (1936), is a method of finding the optimum linear combination between two sets of variables, so the set of variables are transformed onto a projected space while the correlation is maximized. We use the implementation of Faruqui and Dyer (2014b) made for creating bilingual embeddings. We use modalities instead of languages. The size of the projected space is smaller than or equal to the original dimension.

We incrementally combine modalities and project them to new, shared spaces using the intersection of the lower-cased vocabulary. We add them by the order of word type count starting with the modality with most word types. For the first projection only, we reduce the size of the projected space. We set the ratio of the first projected space (only two modalities) to 0.6 based on POS induction results on development data using the setup described in §5.

4.3 SVD and Inverted Softmax

As an alternative to CCA, but closely related, we also use a projection method proposed and implemented by Smith et al. (2017), which uses singular value decomposition and inverted softmax (SVD+IS). This method uses a reference space, rather than projecting all modalities into a new space. Smith et al. (2017) apply SVD+IS to obtain an orthogonal transformation matrix that maps the source language into the target language. In addition, in order to estimate their confidence on the predicted target, they use an inverted softmax function for determining the probability that a target word translates back into a source word.

Like for CCA, we incrementally project datasets onto each other starting with the most word-type rich modality. We use the highest dimensionality of any of our representations (88 dimensions).

5 Experiments

This section presents our POS and syntactic chunk induction experiments. We present the datasets we used in our experiments, the sequence tagging architecture, based on second-order hidden Markov models, as well as the dictionary we used to constrain inference at training and test time.

5.1 Data

For unsupervised POS induction, we use Ontonotes 5.0 (Weischedel et al., 2013) for training, development and test. We set all hyper-parameters on the newswire (NW) domain, optimizing performance on the development set. Size of the development set is 154,146 tokens. We run individual experiments on each of the seven domains, with these hyper-parameters, reporting performance on the relevant test set. The domains are broadcast conversation (BC), broadcast news (BN), magazines (MZ), newswire (NW), the Bible (PT), telephone conversations (TC), and weblogs (WB). We also train and test unsupervised POS induction on the CoNLL 2007 (Nivre et al., 2007) splits of the Penn Treebank (Marcus et al., 1993) using the hyper-parameter settings from Ontonotes. We mapped all POS labels to Google's coarse-grained, universal POS tagset (Petrov et al., 2012). For model selection, we select based both on best results on Ontonotes

Rules

PRT	→	NP|PRT
CONJ	→	O|NP
ADP	→	PP|VP|SBAR

Table 2: Heuristics for expanding our POS dictionary to chunks

NW development as well as Penn Treebank development sets.

For syntactic chunk induction, we use the bracketing data from Penn Treebank with the standard splits for syntactic chunking. We tune hyperparameters for chunking on the development set and select best models based on the development result.

5.2 Model

We used a modification of the implementation of a type-constrained, second-order hidden Markov model with maximum entropy emissions from Li et al. (2012) (SHMM-ME). It is a second-order version of the first order maximum entropy HMM presented in (Berg-Kirkpatrick et al., 2010) with the important addition that it is constrained by a crowd-sourced tag dictionary (Wiktionary). This means that for all words in the Wiktionary, the model is only allowed to predict one of the tags listed for it in Wiktionary

The same model was used in Barrett et al. (2016) to improve unsupervised POS inducing using gaze data from the Dundee Corpus, and in Bingel et al. (2016) to augment an unsupervised POS tagger with features from fMRI recordings.

The number of EM iterations used for inducing our taggers was tuned using eigenvector embeddings on the development data, considering values 1..50. PoS performance peaked at iterations 30 and 31. We use 30 in all our POS experiments. For syntactic chunking, we use 48 iterations, which led to the best performance on the PTB development data using only eigenword embeddings.

5.3 Wiktionary

The Wiktionary constrains the predicted tags in our model. The better the Wiktionary, the better the predictions.

For POS-tagging we used the same Wiktionary dump[4] that Li et al. (2012) used in their original experiments. The Wiktionary dump associated word types with Google's universal parts-of-speech labels.

For chunking, Wiktionary does not provide direct information about the possible labels of words. We instead apply simple heuristics to relate POS information to syntactic chunking labels. Since we already know the relation between words and POS labels from Wiktionary, we can compute the transitive closure in order to obtain a dictionary relating words with syntactic chunking labels. We present the heuristics in Table 2.

Note that the rules are rather simple. We do not claim this is the best possible mapping. We are relying on these simple heuristics only to show that it is possible to learn syntactic chunkers in an unsupervised fashion by relying on a combination of features from different modalities and a standard, crowd-sourced dictionary.

Feature set	TA
No embeddings	60.32
Eigenwords	59.26
Best combined models	
CCA Dun_GECO_Pros	**63.33***†
SVD+IS GECO_Key_Pros	62.91*
Concat Eig_GECO_Key	61.16

Table 3: Chunk tagging accuracy. Best models from CCA, SVD+IS and concatenation. Model section on development set. * $p < .001$ Mcnemar mid-p test when comparing to no embeddings. † $p < .001$ Mcnemar mid-p test when comparing to Eigenwords.)

6 Results

All our POS tagging accuracies can be seen in Table 4. Our first observation is that human processing data helps unsupervised POS induction. In fact, the models augmented with processing data are *consistently* better than the baseline without vector representations, as well as better than only using distributional word embeddings.

Generally, CCA seems to find the best projection into a common space for system combinations. For Penn Treebank, the CCA-aligned model is the best and this result is significant ($p <$

Table 4: POS tagging accuracies for baselines and the model combinations that performed best on newswire development data (NW). Best performance per domain is boldfaced. *) $p < .001$ McNemar mid-p test when compared to the no embeddings condition for the corresponding test set. †) $p < .001$ McNemar mid-p test when compared to eigenwords for the corresponding test set.

.001) when comparing both to no embeddings and eigenwords. For Ontonotes 5.0, CCA is better than the other projection methods in 4/7 domains, but when averaging, concatenation gets the higher result.

The standard embeddings are often part of the best combinations, but the human processing data contributes with important information; in 4/7 domains as well as on PTB data, we see a significantly better performance ($p < .001$) with a combination of modalities when comparing to eigenwords.

Aligning Dundee with eigenwords is the best POS model both according to the Ontonotes 5.0 NW development set and the Penn Treebank development set. Dundee is the most frequent modality in the six best POS induction models with five appearances. Eigenwords is second most frequent with four appearances.

The syntactic chunking accuracies are in Table 3. Also here CCA is the better combination method. For chunking, all combined models are better than no embeddings and eigenwords. The improvement is significant compared to no embeddings for concatenation $p < .001$. For CCA, the result is significantly better than no embeddings and eigenwords.

For chunking, GECO data appears in all best models and is thus the most frequent modalities. Keystroke and prosody appears in two best models each.

CCA all	13.98	3.72	3.09

Table 5: Graph similarities in $[0, \infty)$, $0 =$ identical.

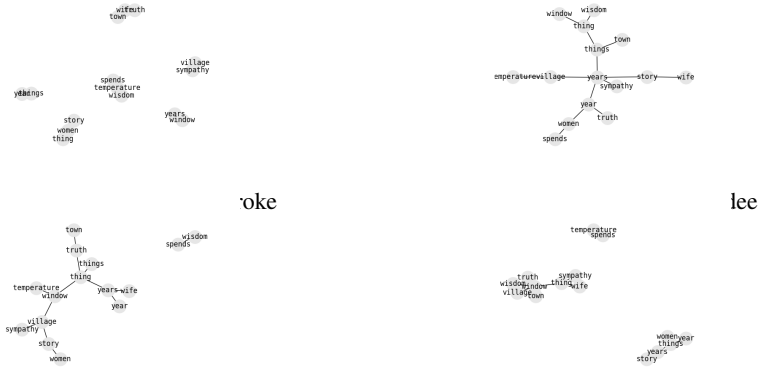
7 Analysis

7.1 What is in the vectors?

Nearest neighbor graphs We include a detailed analysis of subgraphs of the nearest neighbor graphs in the embedding spaces of keystrokes, Dundee, GECO, and CCA projection of all modalities. Specifically, we consider the nearest neighbor graphs among the 15 most frequent unambigous nouns, according to Wiktionary.[5] See Figure 2 for plots of the nearest neighbor graphs. The prosody features containing less than 600 word types only contained 2 of the 15 nouns and is therefore not included in this analysis.

Projecting word representations into a shared space using linear methods assumes approximate isomorphism between the embedding spaces - or at least their nearest neighbor graphs. We use the VF2 algorithm (Cordella et al., 2001) to verify that the subgraphs are *not* isomorphic, but this can also be seen directly from Figure 2. Neither keystroke and gaze embeddings, nor the two different gaze-induced embeddings are isomorphic.

[5] Wiktionary is a crowd-sourced, imperfect dictionary, and one of the "unambiguous nouns" is *spends*, which, we assume, you are more likely to encounter as a verb.



(c) Geco (d) CCA projection, all modalities

Figure 2: Nearest neighbor graphs for 15 frequent nouns.

Since none of the modalities induce isomorphic nearest neighbor graphs, this does not tell us much about similarities between modalities. To quantify the similarity of non-isomorphic graphs, we use *eigenvector similarity* Shigehalli and Shettar (2011), which we calculate by computing the Laplacian eigenvalues for the nearest neighbors, and for each graph, find the smallest k such that the sum of the k largest eigenvalues is $<90\%$ of the eigenvalues. We then take the smallest k of the two, and use the sum of the squared differences between the largest k eigenvalues as our similarity metric.

Using this metric to quantify graph similarity, we see in Table 5 that, not surprisingly, the gaze graphs are the most similar. The projected space is more similar to the gaze spaces, but balances gaze and keystroke information. The GECO embeddings agree more with the keystrokes than the Dundee embeddings does.

t-SNE plots We take words that–according to the Wiktionary–can only have one tag and sort them by BNC frequency (Kilgarriff, 1995) in descending order. For these words and their POS tags we get the feature vector of the POS model yielding the highest result on both Ontonotes and PTB: CCA-projected eigenwords and Dundee features. For the first 200 occurrences of the frequency-sorted list, we reduce dimensionality using t-Distributed Stochastic Neighbor Embedding (t-SNE) (Maaten and Hinton, 2008) and plot the result. Figure 3 shows that 200 most frequent content words cluster with respect to their POS tag, somewhat distinguishing verbs from nouns and adjectives from adverbs in CCA space.

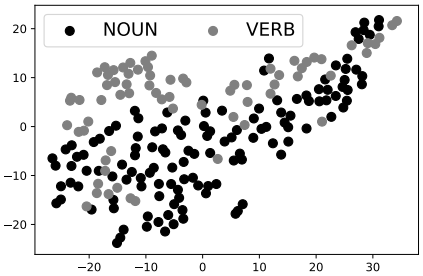
7.2 How big a Wiktionary do we need?

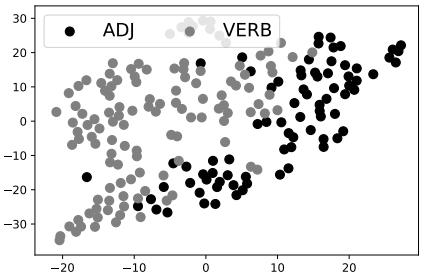
Our Wiktionary for English contains POS information for 72,817 word types. Word types have 6.2 possible POS categories on average meaning we have over 450.000 entries in our POS dictionary. For Penn Treebank, 70.0% of wordtypes of the test set are covered by the dictionary. For the chunking data, 70.4% of wordtypes of the test set are covered by the dictionary. The English Wiktionary is thus much bigger than wiktionaries for low-resource language (Garrette and Baldridge, 2013). How big a dictionary is needed to achieve good performance, and can we get away with a smaller dictionary if we have processing data? This section explores the performance of the model as a function of the Wiktionary size.

We sorted the Wiktionary by word frequency obtained from BNC (Kilgarriff, 1995) and increased the Wiktionary size for the best POS system starting with 0 (no dictionary). For each Wiktionary size, we compare with the baseline without access to processing data and eigenwords. The learning curve can be seen in Figure 4a and Figure 4b. We observe that having entries for the most frequent words is a lot better than having no dictionary, and that the difference between our best system and the baseline exists across all dictionary sizes. With 10,000 entries, all systems seems to reach a plateau.

8 Discussion

Genres and domains When collecting our human language processing data, we did not control for genre. Our data sets span child-directed speech, free text composition, and skilled adults reading fiction and newspaper articles. The





(b) ADJ and VERB

(b) 0-150,000 entries

Figure 4: Learning curve assuming Wiktionary entries for k most frequent words, comparing our best PoS induction system against our baseline. On Ontonotes WB development data, 30 training iterations.

Dundee corpus (newspaper articles) matches the genre of at least some of the Ontonotes test set. Immonen and Mäkisalo (2010) found that for keystroke, genre does seem to have an effect on average pause length, be it sentence initial, word initial, clause initial or phrase initial. Texts organized linearly–e.g. reports and narratives–require less pausing than texts with a global approach, like expository, persuading and generalizing text. Our results show that human processing features transfer across genres, but within-genre data would probably be beneficial for results.

Richer representations The type-level features we use, do not take context into account, and the datasets we use, are too small to enrich our representations. Human processing data is more and more readily available, however. Eye trackers are probably built into the next generation of consumer hardware, and speech records and keystroke logs are recordable with existing technology.

9 Conclusion

We have shown how to improve unsupervised POS induction and syntactic chunking significantly using data reflecting human language processing. Our model, which is a second-order hidden Markov model, is the first to combine multidimensional, continuous features of eye movements, prosody and keystroke logs. We have shown that these features can be combined using projection techniques, even when they only partially overlap in word coverage. None of our models require access to these features at test time. We experimented with all combinations of modalities, and our results indicate that eye tracking is useful for both chunking and POS induction. Finally, we have shown that the potential impact of human processing data also applies in a low-resource setting, i.e., when available tag dictionaries are small.

Challenging Reading Comprehension on Daily Conversation: Passage Completion on Multiparty Dialog

Kaixin Ma, Tomasz Jurczyk, Jinho D. Choi
Math and Computer Science
Emory University
Atlanta, GA 30322, USA
{kaixin.ma, tomasz.jurczyk, jinho.choi}@emory.edu

Abstract

This paper presents a new corpus and a robust deep learning architecture for a task in reading comprehension, passage completion, on multiparty dialog. Given a dialog in text and a passage containing factual descriptions about the dialog where mentions of the characters are replaced by blanks, the task is to fill the blanks with the most appropriate character names that reflect the contexts in the dialog. Since there is no dataset that challenges the task of passage completion in this genre, we create a corpus by selecting transcripts from a TV show that comprise 1,681 dialogs, generating passages for each dialog through crowdsourcing, and annotating mentions of characters in both the dialog and the passages. Given this dataset, we build a deep neural model that integrates rich feature extraction from convolutional neural networks into sequence modeling in recurrent neural networks, optimized by utterance and dialog level attentions. Our model outperforms the previous state-of-the-art model on this task in a different genre using bidirectional LSTM, showing a 13.0+% improvement for longer dialogs. Our analysis shows the effectiveness of the attention mechanisms and suggests a direction to machine comprehension on multiparty dialog.

1 Introduction

Reading comprehension that challenges machine's ability to understand a document through question answering has gained lots of interests. Most of the previous works for reading comprehension have focused on either children's stories (Richardson et al., 2013; Hill et al., 2016) or newswire (Hermann et al., 2015; Onishi et al., 2016). Few approaches have attempted comprehension on small talks, although they are evaluated on toy examples not suitable to project real-life performance (Weston et al., 2015). It is apparent that the main stream of reading comprehension has not been on the genre of multiparty dialog although it is the most common and natural means of human communication. The volume of data accumulating from group chat or messaging continues to outpace data accumulation from other writing sources. The combination of available and rapidly developing analytic options, a marked need for dialogue processing, and the disproportionate generation of data from conversations through text platforms inspires us to create a corpus consisting of multiparty dialogs and develop learning models that make robust inference on their contexts.

Passage completion is a popular method of evaluating reading comprehension that is adapted by several standardized tests (e.g., SAT, TOEFL, GRE). Given a document and a passage containing factual descriptions about the contexts in the document, the task replaces keywords in the passage with blanks and asks the reader to fill in the blanks. This task is particularly challenging when the document is in a form of dialog because it needs to match contexts between colloquial (dialog) and formal (passage) writings. Moreover, a context that can be described in a short passage, say a sentence, tends to be expressed across multiple utterances in dialog, which requires discourse-level processing to make the full interpretation of the context.

This paper introduces a new corpus for passage completion on multiparty dialog (Section 3), and a deep learning architecture that produces robust results for understanding dialog contexts (Section 4). Our experiments show that models trained by this architecture significantly outperform the previous state-of-the-art model using bidirectional LSTM, especially on longer dialogs (Section 5). Our analysis highlights the comprehension of our models for matching utterances in dialogs to words in passages (Section 6). To the best of our knowledge, this is the first time that the sentence completion task is thoroughly examined with a challenging dataset on multiparty dialog using deep learning models.

Proceedings of NAACL-HLT 2018, pages 2039–2048
New Orleans, Louisiana, June 1 - 6, 2018.

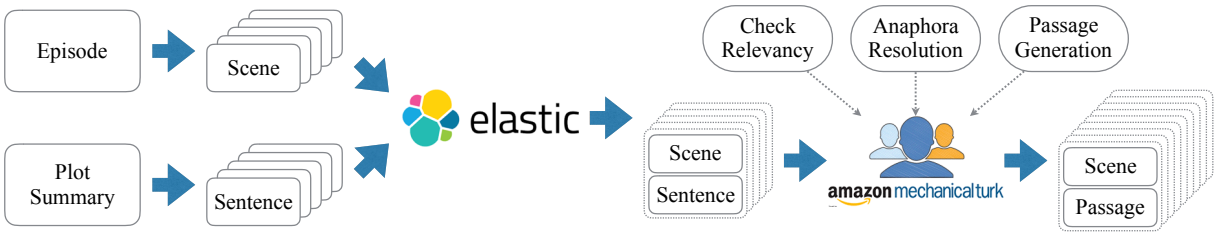

Figure 1: The overview of passage generation. Each episode is split into scenes, and each summary is segmented to sentences. Elasticsearch passes the scene-sentence pairs to crowd workers who are asked to check the relevancy, replace all pronouns with the corresponding names, and generate new passages for the scenes (Section 3.1).

2 Related Work

Hermann et al. (2015) introduced the CNN/Daily Mail dataset where documents and passages were news articles and their summaries respectively, and evaluated neural models with three types of readers. Chen et al. (2016) proposed the entity centric model and the bidirectional LSTM model using attention, and conducted a thorough analysis on this dataset. Trischler et al. (2016) presented the EpiReader that combined a reasoner with an extractor for encoding documents and passages using both CNN and RNN. Dhingra et al. (2017) proposed the gated-attention reader that incorporated attention on multiplicative interactions between documents and passages. At last, Cui et al. (2017) introduced the attention-over-attention reader that placed document-to-passage attention over passage-to-document attention.

Hill et al. (2016) released the Children Book Test dataset where documents were children's book stories and passages were excerpts from those stories. Paperno et al. (2016) introduced the LAMBADA dataset comprising novels from the Book corpus. Onishi et al. (2016) introduced the Who-did-What dataset consisting of articles from the LDC English Gigaword newswire corpus. All corpora described above provide queries, that are passages where certain words are masked by blanks, for the evaluation of passage completion. More datasets are available for another type of a reading comprehension task, that is multiple choice question answering, such as MCTest (Richardson et al., 2013), TriviaQA (Joshi et al., 2017), RACE (Lai et al., 2017), and SQuAD (Rajpurkar et al., 2016).

Unlike the other corpora where documents and passages are written in a similar writing style, they are multiparty dialogs and plot summaries in our corpus, which have very different writing styles. This raises another level of difficulty to match contexts between documents and queries for the task of passage completion.

3 Corpus

The Character Mining project provides transcripts of the TV show *Friends* for ten seasons in the JSON format.[1] Each season contains ≈24 episodes, each episode is split into ≈13 scenes, where each scene comprises a sequence of ≈21 utterances. Chen et al. (2017) annotated the first two seasons of the show for an entity linking task, where personal mentions (e.g., *she*, *mom*, *Rachel*) were identified by their corresponding characters. Jurczyk and Choi (2017) collected plot summaries of all episodes for the first eight seasons to evaluate a document retrieval task that returned a ranked list of relevant documents given any sentence in the plot summaries.

For the creation of our corpus, we collect more plot summaries for the last two seasons of *Friends* from the fan sites suggested by Jurczyk and Choi (2017), generate passages for each dialog using the plot summaries and crowdsourced descriptions (Section 3.1), then annotate mentions of all characters in both the dialogs and the passages for passage completion (Section 3.2).

3.1 Passage Generation

An episode consists of multiple scenes, which may or may not be coherent. In our corpus, each scene is considered a separate dialog. The lengths of the scenes vary from 1 to 256 utterances; we select only scenes whose lengths are between 5 and 25 utterances as suggested by the previous works (Chen and Choi, 2016; Jurczyk and Choi, 2017), which notably improves the readability for crowd workers, resulting higher quality annotation.

The plot summaries collected from the fan sites are associated with episodes, not scenes. To break down the episode-level summaries into scene-level, they are segmented into sentences by the tokenizer in NLP4J.[2] Each sentence in the plot summaries

Table 1: An example dialog and its passages and queries from our corpus. All mentions are encoded by their entity IDs. The queries are generated by replacing each unique entity in every passage with the variable x (Section 3.2). @ent01: Joey, @ent02: Rachel, @ent03: Ross, @ent04: Neuman, @ent05: Paul.

is then queried to Elasticsearch that has indexed the selected scenes, and the scene with the highest relevance is retrieved. Finally, the retrieved scene along with the queried sentence are sent to a crowd worker who is asked to determine whether or not they are relevant, and perform anaphora resolution to replace all pronouns in the sentence with the corresponding character names. The sentence that is checked for the relevancy and processed by the anaphora resolution is considered a passage.

Out of 6,014 sentences collected from the plot summaries, 2,994 of them got turned into passages; in other words, about a half of the sentences could not be paired with relevant scenes by Elasticsearch. In addition to these pseudo-generated passages, two more sets of passages are created. For the first set, crowd workers are asked to generate new passages including factual descriptions different from the ones that are pseudo-generated. This produced additional 615 passages; however, passages in this set could be biased toward the dominant characters. To increase the diversity of the character entities in the passages, crowd workers are asked to generate the second set of passages that include factual descriptions related to only non-dominant characters. A total of 1,037 passages are generated in this set, which makes passage completion even more challenging since the chance of the dominant characters being the answers becomes much lower with this second set. Figure 1 shows the overview of passage generation. Note that Amazon Mechanical Turk is used for all crowdsourcing.

3.2 Mention Annotation

For all dialogs and their passages, mentions are first detected automatically by the named entity recognizer in NLP4J (Choi, 2016) using the PERSON entity, then manually corrected. For each passage including multiple mentions, a query is created for every mention by replacing it with the variable x:

Rachel misses dating, so *Joey* offers to take *Rachel* out.
⇒ $\boldsymbol{x}$ misses dating, so *Joey* offers to take *Rachel* out.
⇒ *Rachel* misses dating, so $\boldsymbol{x}$ offers to take *Rachel* out.
⇒ *Rachel* misses dating, so *Joey* offers to take $\boldsymbol{x}$ out.

Following Hermann et al. (2015), all mentions implying the same character are encoded by the same entity ID. A different set of entity IDs are randomly generated for each dialog; for the above example, *Joey* and *Rachel* may be encoded by **@ent01** and **@ent02** in this dialog (Table 1), although they can be encoded by different entity IDs in other dialogs. This random encoding prevents learning models from overfitting to certain types of entities. On the other hand, the same set of entity IDs are applied to the passages associated with the dialog.

One issue still remains that characters in this dataset are often mentioned by several aliases (e.g., nicknames, honorifics) such that it is not trivial to cluster mentions implying the same character using simple string matching. Thus, an entity dictionary is created for each character whose key is the name of the character and the value is a list of aliases for the character, manually inspected throughout the entire show. This entity dictionary is then used to link mentions in both the dialogs and the passages to their character entities.

Type	Count
# of dialogs	1,681
# of passages	4,646
# of queries	13,487
Avg. # of utterances per dialog	15.8
Avg. # of tokens per dialog/passage	290.8 / 19.9
Avg. # of mentions per dialog/passage	24.4 / 3.0
Avg. # of entities per dialog/passage	5.4 / 2.2
Max # of mentions per dialog/passage	117 / 15
Max # of entities per dialog/passage	16 / 7

Table 2: The overall statistics of our corpus.

Table 2 shows the overall statistics of our corpus. It is relatively smaller than the other corpora (Section 2). However, it is the largest, if not the only, corpus for the evaluation of passage completion on multiparty dialog that still gives enough instances to develop meaningful models using deep learning.

4 Approach

This section presents our deep learning architecture that integrates rich feature extraction from convolutional neural networks (CNN) into robust sequence modeling in recurrent neural networks (RNN) (Section 4.1). The combination of CNN and RNN has been adapted by several NLP tasks such as text summarization (Cheng and Lapata, 2016), essay scoring (Dong et al., 2017), sentiment analysis (Wang et al., 2016), or even reading comprehension (Dhingra et al., 2017). Unlike previous works that feed a sequence of sentences encoded by CNN to RNN, a sequence of utterances is encoded by CNN in our model, where each utterance is spoken by a distinct speaker and contains one or more sentences that are coherent in topics. Our best model is optimized by both the utterance (Section 4.2) and the dialog (Section 4.3) level attentions, showing significant improvement over the pure CNN+RNN model.

4.1 CNN + LSTM

Each utterance comes with a speaker label encoded by the entity ID in our corpus (Table 1). This entity ID is treated as the first word of the utterance in our models. Before training, random embeddings are generated for all entity IDs and the variable x with the same dimension d as word embeddings. All utterances and queries are zero-padded to their maximum lengths m and n, respectively.

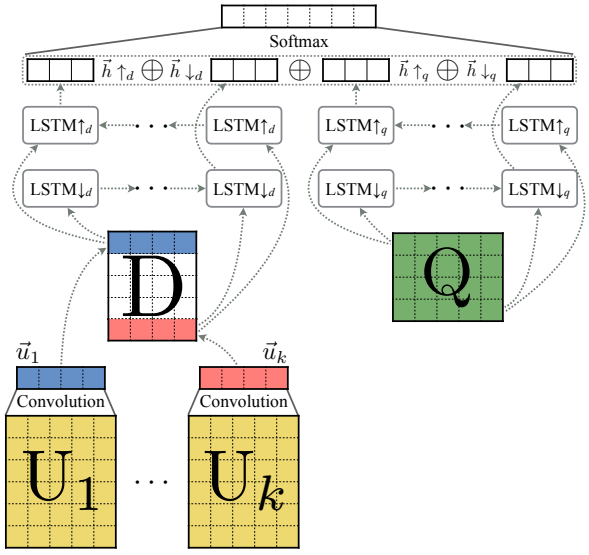

Figure 2: The overview of the CNN+LSTM model.

Given a query and a dialog comprising k-number of utterances, the query matrix $\mathrm{Q} \in \mathcal{R}^{n \times d}$ and the utterance matrix $\mathrm{U}_i \in \mathcal{R}^{m \times d}$ are created using the

word, entity, and variable embeddings $\forall i \in [1, k]$. For each U_i, 2D convolutions are performed for 2-5 grams, where each convolution takes f-number of filters and the output of every filter is max-pooled, resulting a vector of the size f. These vectors are concatenated to create the utterance embedding $\vec{u}_i \in \mathcal{R}^{1\times 4\cdot f}$, then the utterance embeddings are stacked to generate the dialog matrix $\mathrm{D} \in \mathcal{R}^{k\times 4\cdot f}$. This dialog matrix is fed into a bidirectional LSTM consisting of two networks, $\texttt{LSTM}{\downarrow_d}$ and $\texttt{LSTM}{\uparrow_d}$, that process the sequence of utterance embeddings in both directions. In parallel, Q is fed into another bidirectional LSTM with $\texttt{LSTM}{\downarrow_q}$ and $\texttt{LSTM}{\uparrow_q}$ that process the sequence of word embeddings in Q. Each LSTM returns two vectors from the last hidden states of $\texttt{LSTM}{\downarrow_*}$ and $\texttt{LSTM}{\uparrow_*}$:

$$\vec{h}\downarrow_d = \texttt{LSTM}\downarrow_d(\mathrm{D}) \quad \vec{h}\uparrow_d = \texttt{LSTM}\uparrow_d(\mathrm{D})$$
$$\vec{h}\downarrow_q = \texttt{LSTM}\downarrow_q(\mathrm{Q}) \quad \vec{h}\uparrow_q = \texttt{LSTM}\uparrow_q(\mathrm{Q})$$

All the outputs of LSTMs are concatenated and fed into the softmax layer that predicts the most likely entity for x in the query, where each dimension of the output layer represents a separate entity:

$$\mathrm{O} = \mathrm{softmax}(\vec{h}\downarrow_d \oplus \vec{h}\uparrow_d \oplus \vec{h}\downarrow_q \oplus \vec{h}\uparrow_q)$$
$$\mathrm{predict}(\mathrm{U}_1, \ldots, \mathrm{U}_k, \mathrm{Q}) = \mathrm{argmax}(\mathrm{O})$$

Figure 2 demonstrates our CNN+LSTM model that shows significant advantage over the pure bidirectional LSTM model as dialogs get longer.

4.2 Utterance-level Attention

Inspired by Yin et al. (2016), attention is applied to every word pair in the utterances and the query. First, the similarity matrix $\mathrm{S}_i \in \mathcal{R}^{m\times n}$ is created for each utterance matrix U_i by measuring the similarity score between every word in U_i and Q:

$$\mathrm{S}_i[r, c] = \mathrm{sim}(\mathrm{U}_i[r, :], \mathrm{Q}[c, :])$$
$$\mathrm{sim}(x, y) = 1/(1+\|x-y\|)$$

The similarity matrix is then multiplied by the attention matrix $\mathrm{A} \in \mathcal{R}^{n\times d}$ learned during the training. The output of this multiplication produces another utterance embedding $\mathrm{U}'_i \in \mathcal{R}^{m\times d}$, which is channeled to the original utterance embedding U_i and generates the 3D matrix $\mathrm{V}_i \in \mathcal{R}^{2\times m\times d}$ (Figure 3):

$$\mathrm{U}'_i = \mathrm{S}_i \cdot \mathrm{A}$$
$$\mathrm{V}_i = \mathrm{U}_i \oslash \mathrm{U}'_i$$

V_i is fed into the CNN in Section 4.1 instead of U_i and constructs the dialog matrix D.

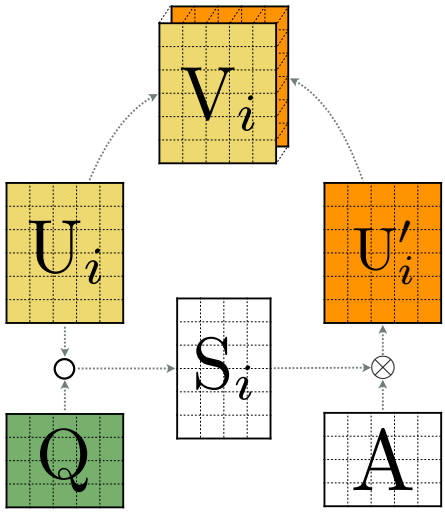

Figure 3: The overview of the utterance-level attention.

4.3 Dialog-level Attention

The utterance-level attention is for the optimization of local contents through word similarities between the query and the utterances. To give a global view to the model, dialog-level attention is applied to the query matrix Q and the dialog matrix D. First, 1D convolutions are applied to each row in Q and D, generating another query matrix $\mathrm{Q}' \in \mathcal{R}^{n\times e}$ and dialog matrix $\mathrm{D}' \in \mathcal{R}^{m\times e}$, where e is the number of filters used for the convolutions.

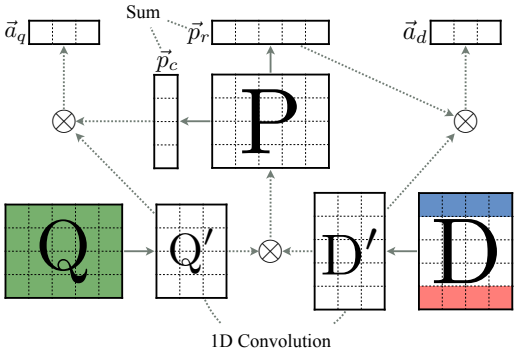

Figure 4: The overview of the dialog-level attention.

Q' is then multiplied to D'^T, resulting another similarity matrix $\mathrm{P} \in \mathcal{R}^{n\times m}$. Furthermore, the sum of each row in P is concatenated to create $\vec{p}_c \in \mathcal{R}^{n\times 1}$, and the sum of each column in P is also concatenated to create $\vec{p}_r \in \mathcal{R}^{1\times m}$:

$$\mathrm{P} = \mathrm{Q}' \cdot \mathrm{D}'^T$$
$$\vec{p}_c[r] = \sum_{j=1}^{m} P[r, j]$$
$$\vec{p}_r[c] = \sum_{j=1}^{n} P[j, c]$$

$\vec{p}_c^T$ is multiplied to Q' and $\vec{p}_r$ is multiplied to D', producing the attention embeddings $\vec{a}_q \in \mathcal{R}^{1\times e}$

Model	Development Set				Evaluation Set			
	Org.	25	50	100	Org.	25	50	100
Human Evaluation	-	-	-	-	**74.02**	-	-	-
Majority	28.61	27.65	21.57	19.79	30.08	28.23	21.58	17.59
Entity Centric	52.28	45.29	45.82	42.17	47.36	43.83	45.56	42.47
Bi-LSTM	72.24	68.90	64.51	55.17	71.21	67.37	62.95	53.76
CNN+LSTM	70.97	70.24	69.40	65.43	70.28	69.20	68.35	64.13
CNN+LSTM+UA	**72.42**	71.73	70.67	66.46	71.84	69.88	69.18	**66.99**
CNN+LSTM+DA	72.24	71.30	70.21	66.37	71.46	69.88	69.30	65.51
CNN+LSTM+UA+DA	72.21	**72.14**	**71.45**	**67.86**	**72.42**	**71.01**	**69.98**	**66.99**

Table 3: Results on the development and the evaluation sets from all models.

and $\vec{a}_d \in \mathcal{R}^{1\times e}$, respectively. Finally, these attention embeddings are concatenated with the outputs of the LSTMs in Section 4.1 then fed into the softmax layer to make the prediction:

$$\vec{a}_q = \vec{p}_c^{\,T} \cdot \mathrm{Q}'$$
$$\vec{a}_d = \vec{p}_r \cdot \mathrm{D}'$$
$$\mathrm{O} = \mathrm{softmax}(\vec{h}\downarrow_d \oplus \vec{h}\uparrow_d \oplus \vec{h}\downarrow_q \oplus \vec{h}\uparrow_q \oplus \vec{a}_d \oplus \vec{a}_q)$$
$$\mathrm{predict}(\mathrm{U}_1, \ldots, \mathrm{U}_k, \mathrm{Q}) = \mathrm{argmax}(\mathrm{O})$$

Similar attentions have been proposed by Yin et al. (2016) and evaluated on NLP tasks such as answer selection, paraphrase identification, and textual entailment; however, they have not been adapted to passage completion. It is worth mentioning that we have tried many other kinds of attention mechanisms and empirically found that the combination of these two attentions yields the best result for the passage completion task.

5 Experiments

The Glove 100-dimensional pre-trained word embeddings (Pennington et al., 2014) are used for all experiments ($d = 100$). The maximum lengths of utterances and queries are $m = 92$ and $n = 126$, and the maximum number of utterances is $k = 25$. For the 2/1D convolutions in Sections 4.1 and 4.3, $f = e = 50$ filters are used, and the `ReLu` activation is applied to all convolutional layers. The dimension of the LSTM outputs $\vec{h}\downarrow\uparrow_*$ is 32, and the `tanh` activation is applied to all hidden states of LSTMs. Finally, the `Adam` optimizer with the learning rate of 0.001 is used to learn the weights of all models. Table 4 shows the dataset split for our experiments that roughly gives 80/10/10% for training/development/evaluation sets.

	Train	Develop	Evaluate	Total
Queries	10,785	1,349	1,353	13,487

Table 4: Dataset split for our experiments, where each query is considered a separate instance.

5.1 Utterance Pruning

Most utterances in our corpus are relatively short except for a few ones so that padding all utterances to their maximum length is practically inefficient. Thus, pruning is used for those long utterances. For any utterance containing more than 80 words, that is about 1% of the entire dataset, stopwords are removed. If the utterance still has over 80 words, all words whose document frequencies are among the top 5% in the training set are removed. If the length is still greater than 80, all words whose document frequencies are among the top 30% in the training set are removed. By doing so, we reduce down the maximum length of utterances from 1,066 to 92, which dramatically speeds up the modeling without compromising the accuracy.

5.2 Datasets with Longer Dialogs

The average number of utterances per dialog is 15.8 in our corpus, which is relatively short. To demonstrate the model robustness for longer dialogs, three more datasets are created in which all dialogs have the fixed lengths of 25, 50, and 100 by borrowing utterances from their consecutive scenes. The same sets of queries are used although models need to search through much longer dialogs in order to answer the queries for these new datasets. The three pseudo-generated datasets as well as the original dataset are used for all our experiments.

5.3 Human Evaluation

Human performance is examined on the evaluation set of the original length using crowdsourcing. The workers are presented with passages and the corresponding dialogs and asked to choose the answer from the list of entities that appear in the dialog. For fair comparisons, the encoded input where the character names are replaced with the entity IDs are used for this evaluation as well, to minimize the bias from external knowledge.

5.4 Baselines

Three models are used to establish comprehensible baseline results:

Majority This model picks the dominant entity in the dialog as the answer for each query.

Entity Centric This is our reimplementation of Chen et al. (2016)'s entity centric model. Our entity centric model was evaluated on the CNN/Daily Mail dataset and showed a comparable result to the previous work.

Bi-LSTM This is the bidirectional LSTM model introduced by Chen et al. (2016), which outperforms their entity centric model by a large margin. We use their implementation of this model;[3] the input to this model is a list of words across all utterances within the dialog. All hyperparameters are tuned using the development set.

5.5 Results

Table 3 shows the results from all models. The human performance on the evaluation set is only 1.6+% higher than the best performing model, which on part shows the difficulty of the task. It should be noted that character anonymization process makes it harder to for people to find the answer. However, it also possible that some participants of the evaluation may enter the answer randomly (i.e the results may not truly reflect human performance). Notice that the performance of the majority model on our dataset is similar to the ones in the CNN/Daily Mail dataset, which validates the level of difficulty in our corpus. As expected, the entity centric model sets its performance in between the majority model and the other deep learning models. For all of our models and Bi-LSTM, experiments are run three times with different random seeds and the accuracies are averaged. The accuracy of Bi-LSTM reported on the CNN dataset is 72.4, which is similar to its performance on our dataset. Our models coupled with both the utterance-level and the dialog-level attentions (CNN+LSTM+UA+DA) outperform all the other models except for the one on the development set of the original dataset. Our models show significant advantage over Bi-LSTM as the length of the dialog gets larger.

Figure 5 shows the learning curves from Bi-LSTM and CNN+LSTM+UA+DA on the original dataset. The red circle and the black star mark the peaks of CNN+LSTM+UA+DA and Bi-LSTM, respectively. Although the accuracies between these models are very similar, our model converges in fewer epochs. Figure 6 shows the learning curves from both models in 3 trials on the length-100 dataset. Our models take fewer epochs to converge and the variance of performance across trials is smaller, implying that our models are not as sensitive to the hyperparameter tuning as Bi-LSTM.

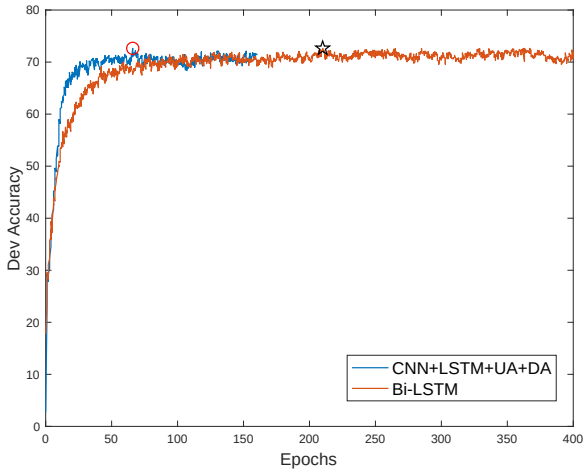

Figure 5: Training curves on the original dataset.

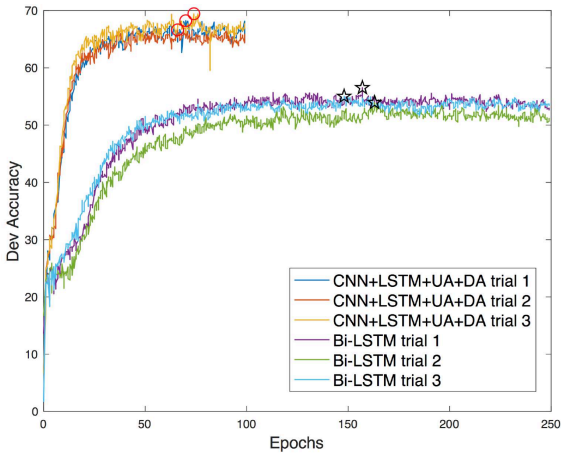

Figure 6: Training curves on the length-100 dataset.

6 Analysis

6.1 Attention Visualization

Figure 7 depicts the dialog-level attention matrix, that is P in Section 4.3, for the example in Table 1. The x-axis and y-axis denote utterances and words in the query, respectively. Each cell represents the attention value between a word in the query and an utterance. From this visualization, we see that query words such as *misses*, *take*, *good*, and *time*

[3] github.com/danqi/rc-cnn-dailymail

have the most attention from utterances as they are the keywords to find the answer entity. The utterances 14, 15 and 17 that give out the answer also get relatively high attention from the query words. This illustrates the effectiveness of the dialog-level attention in our model.

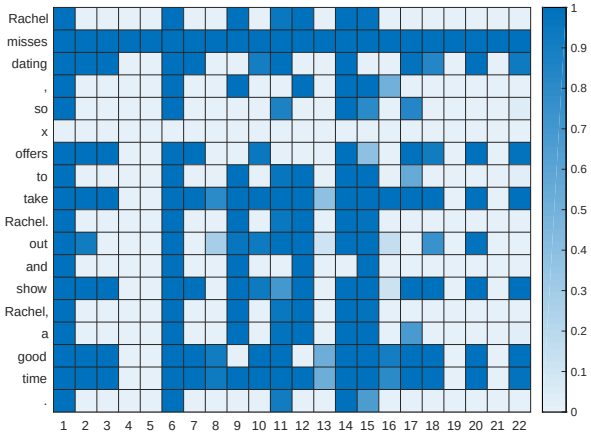

Figure 7: Visualization of the dialog-level attention matrix P for the example in Table 1.

6.2 Comparisons

Table 5 shows the confusion matrix between Bi-LSTM and CNN+LSTM +UA+DA on the original dataset. During the error analysis, it is noticed that Bi-LSTM is better at capturing exact string matches or paraphrases. As shown by the first two examples in Table 6, it is clear that those queries can be answered by capturing just the snippets of the dialogs. In the first example, "$\boldsymbol{x}$ makes up his mind about something" in the query matches "@ent06 sets his mind on something" in the dialog.

Model	Bi-LSTM: T	Bi-LSTM: F
C+L+U+D: T	850	133
C+L+U+D: F	118	252

Table 5: The confusion matrix between Bi-LSTM and CNN+LSTM+UA+DA.

In the second example, query phrase "the closet that $\boldsymbol{x}$ and @ent03 were in" also has the exact string match"the closet @ent18 and @ent03 were in" in the dialog. Although these cues are usually parts of sentences in long utterances, since Bi-LSTM is based on only words, it still is able to locate them correctly. On the other hand, our model encodes each utterance and then feeds encoded vectors to LSTMs, so the high level representation of the cues are mixed with other information, which hinders the model's ability to find the exact string matches. Our model is better at answering queries that require inference from multiple utterances. As shown by the last two examples in Table 6, the cues to the answers distribute across several utterances and there is no obvious match of words or phrases. In the third example, the model needs to infer that in the sentence "(She reaches over to look at the label on the box)", she refers to @ent18 and connect this information with the later utterance by @ent18 "This is addressed to Mrs. @ent16 downstairs" in order to answer the query. In the last example, finding the correct answer requires the model to interpret that the utterances "What the hell was that?!" and "(They both scream and jump away.)" reflect the outcome of *startles*, which is the verb in the query. As dialogs become longer in the padded datasets, because of the utterance encoding procedure, our model's ability's ability to locate relevant part of dialog is not influenced as much, whereas it becomes much more difficult for Bi-LSTM to find the matches.

6.3 Discussion

It is worth mentioning that besides the models presented in Section 4, the attention-over-attention reader was also experimented with our dataset, which outperformed various neural systems by a large margin on both the CNN news dataset and the Children Book Test dataset (Cui et al., 2017). We first reimplemented their model and experimented on the CNN dataset and achieved similar results as reported in the previous paper. We then experimented this model on our original length dataset. However, even after an extensive hyperparameter turning on the development set, this model did not achieve results comparable to those of either Bi-LSTM or our models, so we did not make a further analysis on this model.

7 Conclusion

We introduce a new corpus consisting of multiparty dialogs and crowdsourced annotation for the task of passage completion. To the best of our knowledge, this is the first corpus that can challenge deep learning models for passage completion on this genre. We also present a deep learning architecture combining convolutional and recurrent neural networks, coupled with utterance-level and dialog-level attentions. Models trained by our architecture significantly outperform the one trained by the pure bidirectional LSTM, especially on longer

Model	Query	Dialog
Bi-LSTM	@ent12 says that once ***x*** makes up his mind about something, @ent06 will have xxx with it.	Because you know as well as I do that once **@ent06** sets his mind on something, more often than not, he 's going to have sex with it.
Bi-LSTM	@ent06 points out that people are screwing in the closet that ***x*** and @ent03 were in.	Oh, by the way. Two people screwing in there (points to the closet **@ent18** and @ent03 were in) if you want to check that out.
CNN+LSTM +UA+DA	***x*** saw on the box that the cheesecake was addressed to Mrs. @ent16.	**@ent18** This is the best cheesecake I have ever had. Where did you get this? (She reaches over to look at the label on the box.) @ent10 It was at the front door. When I got home. Somebody sent it to us. **@ent18** @ent10, this is not addressed to you. This is addressed to Mrs. @ent16 downstairs. ...
CNN+LSTM +UA+DA	@ent17 startles @ent02 and ***x*** in the hallway to prove @ent17' point, which sets off an on-going competition of psuedo-attacks.	@ent17 DANGER !!! DANGER !!!!! @ent02 @ent17 !!! **@ent03** What the hell was that ?! (They both scream and jump away.)

Table 6: Examples for model comparison. The first column denotes the model that makes the correct prediction.

dialogs. Our analysis demonstrates the comprehension of our model using the attention matrix. For the future work, we will expand the annotation for more entity types and automatically link mentions with respect to their entities using an entity linker. All our resources including the annotated corpus and source codes of the models are available at: https://github.com/emorynlp/reading-comprehension.

Abstract

In this paper, we propose a generalizable dialog generation approach that adapts *multi-turn reasoning*, one recent advancement in the field of document comprehension, to generate responses ("answers") by taking current conversation session context as a "document" and current query as a "question". The major idea is to represent a conversation session into memories upon which attention-based memory reading mechanism can be performed multiple times, so that (1) user's query is properly extended by contextual clues and (2) optimal responses are step-by-step generated. Considering that the speakers of one conversation are not limited to be one, we separate the single memory used for document comprehension into different groups for speaker-specific topic and opinion embedding. Namely, we utilize the queries' memory, the responses' memory, and their unified memory, following the time sequence of the conversation session. Experiments on Japanese 10-sentence (5-round) conversation modeling show impressive results on how multi-turn reasoning can produce more diverse and acceptable responses than state-of-the-art single-turn and non-reasoning baselines.

1 Introduction

Dialogue systems such as chatbots are a thriving topic that is attracting increasing attentions from researchers (Sordoni et al., 2015; Serban et al., 2016; Li et al., 2015; Wen et al., 2016). Recent achievements, such as deep neural networks for text generating, user profiling (Li et al., 2014), and natural language understanding, have accelerated the progresses of this field, which was historically approached by conventional rule-based and/or statistical response ranking strategies.

Response ranking models retrieve the most suitable response(s) from a fixed set of (question, answer) pairs given a dialogue context and current query from a user (Banchs and Li, 2012; Lowe et al., 2015). Learning-to-rank approaches were applied to compute the similarity scores of between (query, context) and indexed candidate (question, answer) pairs to return the optimal "answer" to the user. These ranking-based retrieval strategies have been well-applied as an important approach to dialogue systems, yet the set of scripted responses are limited and are short at generalization. On the other hand, statistical machine translation (SMT) systems have been applied to dialogue systems (Ritter et al., 2011), taking user's query as a source language sentence and the chatbot's response as a target language sentence. Labeled data for learning-to-ranking training will not be necessary anymore and all we need is the large-scale (question, answer) pairs.

The sequence-to-sequence model proposed in (Sutskever et al., 2014) applied end-to-end training of neural networks to text generation. This model, further enhanced by an attention mechanism (Bahdanau et al., 2014), was generic and allowed its application to numerous sequence-to-sequence learning tasks such as neural machine translation (NMT) (Cho et al., 2014; Bahdanau et al., 2014), image captioning (Donahue et al., 2015; Mao et al., 2015), speech recognition (Chan et al., 2015) and constituency parsing (Vinyals et al., 2015). The simplicity of these models makes them attractive, since "translation" and "alignment" are learned jointly on the fly.

Specially, Vinyals and Le (2015) applied the sequence-to-sequence model to conversational modeling and achieved impressive results on various datasets. Their model was trained to predict a response given the previous sentence (s). Shang et al. (2015) combined local and global attentions

New Orleans, Louisiana, June 1 - 6, 2018.

and reported better results than retrieval based systems. Sordoni et al. (2015) explored three different end-to-end approaches for the problem of predicting the response given a query attached with a single message context.

Multi-turn conversation modeling is considered to be more difficult than machine translation, since there are many more acceptable responses for a given (context, query) input and these often rely on external knowledge and/or contextual reasoning. Dialogue systems trained with a maximum likelihood estimation (MLE) objective function, as most SMT utilizes, often learn to reply generic sentences as "I don't know" or "sounds good", which have a high incidence in the "answer" part of (question, answer) style training datasets. There have been various attempts at *diversifying* the responses (Li et al., 2016a; Yu et al., 2016; Li et al., 2017) but the lack of variations in the responses remains as an essential challenge. We wonder that if this stress can be relieved by modeling the prior context in a rather fine-grained way.

In document comprehension fields, multi-turn reasoning (also called multi-hop reasoning) has delivered impressive results by assimilating various pieces of information to produce an unified answer (Hill et al., 2015; Dhingra et al., 2016). Through multi-turn reading the document's memory using attention models, current question can be extended with much richer knowledge. This makes it easier to figure out the correct answer from that document. Different documents need to be read different times to yield out the correct answer for the input question. Specially, Shen et al. (2016) use a dynamic number of turns by introducing a termination gate to control the number of iterations of reading and reasoning.

Motivated by the reasoning network for document comprehension (Shen et al., 2016), we propose multi-turn reasoning neural networks that generate the proper response (or, "answer") by attention-based reasoning from current conversation session ("document") and current query (identical to "question" in document comprehension) from the user. In particular, our networks utilize conversation context and explicitly separate speakers' interventions into sentence-level and conversation-level memories. Our first model uses plain single-turn attention to integrate all the memories, and the second approach integrates multi-turn reasoning. The formulation of our proposed approach is designed in a generalized way, allowing for inclusion of additional information such as external knowledge bases (Yih and Ma, 2016; Ghazvininejad et al., 2017; Han et al., 2015) or emotional memories (Zhou et al., 2017). Moreover, our approach for two-speaker scenario can be easily extended to group chatting by a further speaker-specific memory splitting.

We evaluate the performances of our methods by comparing three configurations trained on a Japanese twitter conversation session dataset. Each conversation session contains 10 sentences which are 5-round between two real-world speakers. The results provide evidences that multi-turn reasoning neural networks can help improving the consistency and diversity of multi-turn conversation modeling.

This paper is structured as follows: Section 2 gives a general description of multi-turn conversation modeling; Section 3 describes background neural language modeling, text generation, and attention mechanisms; Section 4.1 first introduces a model with multiple attention modules and then explains how the multi-turn reasoning mechanism can be further integrated into the previous models; Sections 5, 6 and 7 describe the experimental settings and results using automatic evaluation metrics, detailed human-evaluation based analysis, and conclusions, respectively.

2 Multi-turn Conversation Modeling

Consider a dataset $\mathcal{D}$ consisting of a list of conversations between two speakers. Each conversation $d \in \mathcal{D}$ is an ordered sequence of sentences s_i, where $i \in [1, T_d]$ and T_d is the number of sentences in d, produced by two speakers alternately. In this way, for $s_i, s_j \in d$, both sentences are from the same speaker if and only if $i \equiv j \pmod 2$. Note that, our definition includes the case that one speaker continuously expresses his/her message through several sentences. We simply concatenate these sentences into one to ensure that the conversation is modeled with alternate speakers.

A multi-turn conversation model is trained to search parameters that maximize the likelihood of every sentence $s_i \in d$ where $i \geq 2$, supposing that the beginning sentence s_1 is always given as a precondition:

$$\theta_M = \arg\max_{\theta} \{\mathcal{L}(\theta, \mathcal{D})\}, \quad (1)$$

where

$$\mathcal{L}(\theta, \mathcal{D}) = \sum_{d \in \mathcal{D}} \prod_{i=2}^{T_d} p(s_i | s_{<i}). \quad (2)$$

Here, $s_{<i}$ are sentences $s_j \in d$ and $j < i$.

The probability of each sentence, $p(s_i|s_{<i})$, is frequently estimated by a conditional language model. Note that, traditional single-turn conversation models or NMT models are a special case of this model by simply setting T_d to be 2. That is, the generation of the next sentence is session-insensitive and is only determined by the former single sentence. Another aspect of understanding this contextual conversation model is that, the number of reference contextual sentences $s_{<i}$ is not limited to be one. Suppose there are already 9 sentences known in one conversation session and we want to generate the 10-th sentence, then from $p(s_1)$ to $p(s_9)$ are all preconditions and we will only need to focus on estimating $p(s_{10}|s_{<10})$.

We adapt sequence-to-sequence neural models (Sutskever et al., 2014) for multi-turn conversation modeling. They are separated into an encoder part and a decoder part. The encoder part applies a RNN on the input sequence(s) $s_{<i}$ to yield prior information. The decoder part estimates the probability of the generated output sequence s_i by employing the last hidden state of the encoder as the initial hidden state of the decoder. Sutskever et al. (2014) applied this technique to NMT and impressive experimental results were reported thereafter.

Using Equation 2, we are modeling two chatbots talking with each other, since all the $s_{2,\ldots,T_d}$ are modeled step-by-step on the fly. However, we can add constraints to determine whose responses to be generated, either one speaker or both of them. That is, when i takes odd integers of 1, 3, 5 and so on, we are modeling the first speaker. Even integers of i indicates a generation of responses for the second speaker.

3 Language Modeling and Text Generation

Language models (LM) are trained to compute the probability of a sequence of tokens (words or characters or other linguistic units) being a linguistical sentence. Frequently, the probability of a sentence s with T_s tokens is computed by the production of the probabilities of each token $y_j \in s$ given its contexts $y_{<j}$ and $y_{>j}$:

$$p(s) = \prod_{j=1}^{T_s} p(y_j | y_{<j}, y_{>j}). \quad (3)$$

When generating a sequence based on a LM, we can generate one word at a time based on the previously predicted words. In this situation, only the previously predicted words are known and the probability of current sequence is approximated by dropping the posterior context. That is,

$$p(y_j | y_{<j}, y_{>j}) \approx p(y_j | y_{<j}). \quad (4)$$

We construct a sequence generation LM using sequence-to-sequence neural network f. The neural network intercalates linear combinations and non-linear activate functions to estimate the probability of mass function. Then, in the encoder part of f, the contextual information is represented by a fixed-size hidden vector h_j:

$$p(y_j | y_{<j}, y_{>j}) \approx f(y_{j-1}, h_j, \theta_f), \quad (5)$$

where θ_f represents f's trainable parameters.

To embed the previous word sequence into a fixed-size vector, recurrent neural networks (RNN) such as long short term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) or gated recurrent units (GRU) (Cho et al., 2014) are widely used. These networks repeat a recurrent operation on each input word:

$$h_j = g(h_{j-1}, y_{j-1}, \theta_g), \quad (6)$$

where θ_g represents the trainable parameters of a RNN function g, and h_j is the hidden state of the RNN at time j.

3.1 Conditional Language Modeling

The hidden state h of a RNN can accumulate information from previous words ($y_j \in s$ and $j < T_s$) or previous sentences ($s_i \in d$ and $i < T_d$) which ensures the encoding and decoding processes in sequence-to-sequence models. Since the contextual sentences are known already, the encoder can represent them in both forward ($\vec{h}_j$) and backward ($\overleftarrow{h}_j$) directions. The results from both recursions can be combined by a concatenated operation. This is referred to as bidirectional RNN shorted as BiRNN (Schuster and Paliwal, 1997).

$$h_j = [\vec{h}_j^\top ; \overleftarrow{h}_j^\top]^\top. \quad (7)$$

For each sentence $s_i \in d$ ($i < T_d$), we annotate the combination of the final states of each RNN direction as a memory vector $m_i = [(\vec{h}^{(i)}_{T_{s_i}})^{\mathrm{T}}; (\overleftarrow{h}^{(i)}_1)^{\mathrm{T}}]^{\mathrm{T}}$. A projection of annotation m_i can be used as the decoder's initial state t_0 such as $t_0 = \tanh(W_s m_{T_{d'}})$ and $T_{d'} < T_d$. W_s here is a weight matrix that projects $m_{T_{d'}}$ into a vector that shares a same dimension with t_0. In (Bahdanau et al., 2014) for NMT, $\overleftarrow{h}_1$, backward encoding of a single source sentence, was used to initialize $t_0 = \tanh(W_s \overleftarrow{h}_1)$.

3.2 Attention Mechanism

Summarizing all contextual information into one single fixed-length vector becomes weaker to guide the generation of the target sentence as the contextual information grows longer. To tackle this problem, an attention mechanism (Bahdanau et al., 2014) was applied to NMT for learning to align and translate jointly. In this attention-based model, the conditional probability in Equation 4 is defined as:

$$p(y_j|y_{<j}) = f(y_{j-1}, t_j, c_j, \theta_f), \tag{8}$$

where

$$t_j = g(t_{j-1}, y_{j-1}, c_j, \theta_g) \tag{9}$$

is a RNN hidden state in the decoder part for time j and $c_j = \sum_{i=1}^{T_s} \alpha_i^{(j)} h_i$ is a *context vector*, a weighted combination of the annotation set memory $(h_1, ..., h_{T_s})$ produced by encoding a source sentence s with length T_s. The weight $\alpha_i^{(j)}$ of each (source) annotation h_i is computed by

$$\alpha_i^{(j)} = \frac{\exp(e_i^{(j)})}{\sum_{l=1}^{T_s} \exp(e_l^{(j)})}. \tag{10}$$

where $e_i^{(j)}$ is an *alignment model* and is implemented by a feed-forward network a:

$$e_i^{(j)} = a(h_i, t_{j-1}). \tag{11}$$

This method was applied to single-turn conversation modeling (Vinyals and Le, 2015). We use this model, with attention over each immediately previous sentence $s_{i-1} \in d$ for generating s_i, as a baseline for our experiments. We annotate this model as `SIMPLE` subsequently in this paper.

4 Multi-turn Reasoning Network with Multiple Type Memories

The attention mechanism described in Equations 8 and 9 is performed in a single-turn feed-forward fashion. However, for complex context and complex queries, human readers often revisit the given context in order to perform deeper inference after one turn reading. This real-world reading phenomenon motivated the multi-turn reasoning networks for document comprehension (Shen et al., 2016). Considering dialog generation scenario with given rich context, we intuitively think if the attentions can be performed multi-turns so that the conversation session is better understood and the simple query, which frequently omits unknown number of context-sensitive words, can be extended for a better generation of the response. The domain adaptation from document comprehension to dialog generation is feasible by taking the rich context of the speakers as a "document", current user's query as a "question" and the chatbot's response as an "answer".

However, there are still several major challenges for this domain adaptation. First, a document is frequently written by a single author with one (hidden) personality, one writing style, and one distribution of the engagement rates of the topics appearing in that document. These are not the case for conversation scenario in which at least two speakers are involved with different (hidden) personalities, personalized speaking styles, and diverse engagement rate distributions of the topics in that conversation session. Second, for document comprehension, the output is frequently a single named entity (Shen et al., 2016) and thus a single softmax function can satisfy this one-shot ranking problem. However, we will need a RNN decoder utilizing context vectors for generating the target response sentence being a sequence of tokens (words or characters) instead of one single named entity.

We tackle the first challenge by separating the context into multiple type memories upon which attention models are performed. For the second difference, we replace the simple softmax output layer by a GRU decoder employing reasoning-attention context vectors.

4.1 Separation of contextual information

The `SIMPLE` model can use multiple turns of context to infer the response by concatenating them

during decoding, using a separator symbol such as EOS for end-of-sentence. Sordoni et al. (2015) separated the query message and the previous two context messages when conditioning the response. The previous context messages were concatenated and treated as a single message.

In our proposed models, we use more than three turns for the context. We separate the last message (the query) from the previous turns to produce a set of annotations h, one per character[1] in the sentence. While encoding the contextual information, we separate the m_i from each speaker into two sets. The motivation is to capture individual characteristics such as personalized topical information and speaking style (Li et al., 2016b). We refer to the set of annotations from the same speaker as one memory. That is, the sentences for which the probabilities are being predicted as M_r (response memory, specially corresponds to the chatbot's side) and the question set as M_q (query memory, specially corresponds to the user's side). We further apply a RNN on top of m_i to produce one more set of vectors M_c (context memory):

$$M_c = \bigcup_{i=0}^{T_c} \{m_i^{(c)}\}, \tag{12}$$

in which,

$$m_i^{(c)} = \text{RNN}(m_i, m_{i-1}^{(c)}), \tag{13}$$

where T_c is the number of turns (sentences) in the conversation. The initial state $m_0^{(c)}$ is a trainable parameter.

We apply an attention mechanism on each of the memories M_q, M_r, M_c and M_h (of current query) separately. Refer to Figure 1 for an intuitive illustration of these memories. Following (Shen et al., 2016), we choose projected cosine similarity function as the attention module. The attention score $a_{j,i}^q$ on memory $m_i^q \in M_q$ for a RNN hidden state t_j in the decoder part is computed as follows:

$$a_{j,i}^q = \text{softmax}_{i=1,\ldots,|M_q|} \cos(W_1^q m_i^q, W_2^q t_j), \tag{14}$$

where W_1^q and W_2^q are weight vectors associated with m_i^q and t_j, respectively. Consequently, the attention vector on the query sequences is given by:

$$c_j^q = \sum_{i=1}^{|M_q|} a_{j,i}^q m_i^q. \tag{15}$$

[1]Most Japanese characters, such as Kanji, have independent semantic meanings other than English letters

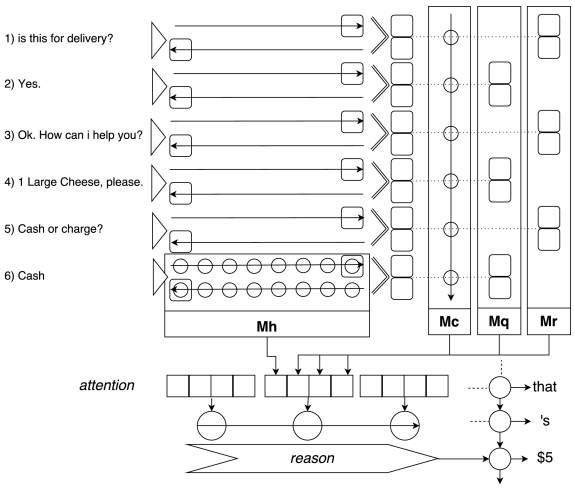

Figure 1: Illustration of the architecture of our REASON model. In the example conversation session, six context sentences are encoded independently by a biRNN. The character-specific annotations from the sixth sentence (i.e., current query) compose the only *sentence-level* M_h memory. $M_{r,q,c}$ are *conversation-level* memories. The last m_i from each sentence are distributed alternately in M_q and M_r memories. Also, $m_{1,\ldots,6}$ are iterated sequentially by a single-direction RNN to produce six context annotations in M_c using Equation 13. In the bottom of the diagram, a reasoning module (Figure 2) is used instead of the plain attention used in MULTI.

Similarly, the attention scores and attention vectors on the other three memories can be derived by replacing q with r, c, and h in Equations 14, 15.

We then concatenate these resulting attention vectors into a final context vector c_j^M, which is consequently applied to Equations 8 and 9. Since the dimension of the updated context vector c_j^M is four times larger, its weight matrix C will need to be enlarged with a same column dimension with the dimension of c_j^M so that Cc_j^M still aligns with the dimension of the hidden layer vector t_j. More details of the GRU function style definition of t_j using c_j can be found in (Bahdanau et al., 2015). We refer to this model that integrates multiple types of memories through separated attention mechanisms as MULTI.

Note that, by separately embedding conversation context into multiple type memories following the number of speakers, we can easily extend this two speaker scenario into group chatting in which tens or hundreds of speakers can be engaged in. The only extension is to further separate M_q by speakers. Consequently, the context vector can be concatenated using the attention vectors by read-

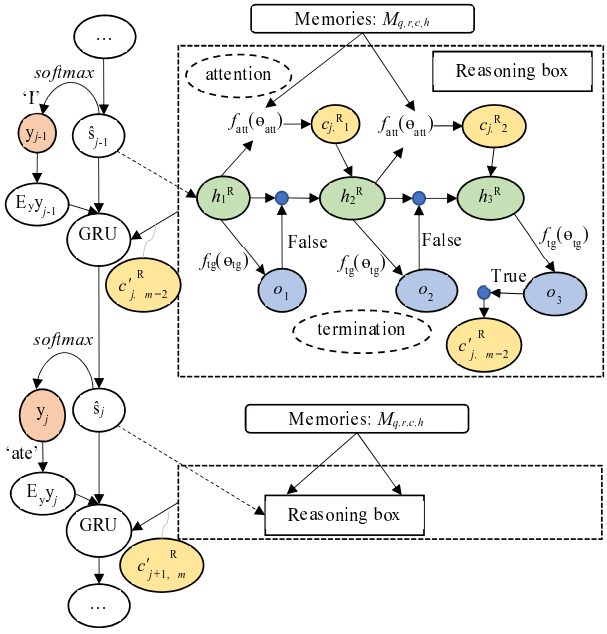

Figure 2: Illustration of the *reason* part of the REASON model. This figure is drawn by partially referring Figure 1 in (Shen et al., 2016).

ing all the memories. The theoretical benefit is that the chatbot can softly keep track of each individual speaker's topics and then make a decision of how to response to that speaker. Another extension will be using a reinforcement learning policy to determine when to let the chatbot to give a response to which speaker in current group chatting.

Generally, the number and type of memories can be enlarged in a reasonable way, such as by introducing external knowledge (Yih and Ma, 2016; Ghazvininejad et al., 2017; Han et al., 2015) or performing sentiment analysis to the "fact memories" to yield emotional memories (Zhou et al., 2017). A detailed description and experimental testifying is out of the scope of this paper.

4.2 Reasoning Neural Dialogue System

As illustrated in Figure 2, we apply a multi-turn reasoning mechanism, following Shen et al. (2016), to the multiple-type annotation memories. This reasoning mechanism replaces the single-turn attention mechanism. We adapt the idea of using a termination state during the inference to dynamically determine how many turns to reason. The termination module can decide whether to continue to infer the next turn (of re-reading the four types of memories) after digesting intermediate topical and speaker-specific information, or to terminate the whole inference process when it concludes that existing information is sufficient to generate the next word in a response. Generally, the idea is to construct a reasoning attention vector that works as a context vector during generating the next word. This idea is included in the "Reasoning box" in Figure 2. Specially, y_{j-1} stands for a former word generated by the hidden state $\hat{s}_{j-1}$ in the GRU decoder. E_y is the embedding matrix. We use a full-connection layer to map from $\hat{s}_{j-1}$ to the initial reasoning hidden state h_1^{R}, since h_m^{R} should be with the same length alike each memory vector in $M_{q,r,c,h}$ and $\hat{s}_{j-1}$'s dimension is smaller than that. Thus, (1) outside the "reasoning box", we use a GRU decoder to yield $\hat{s}_j$ so that a next word y_j can be generated, and (2) inside the "reasoning box", we read the memories to yield the "optimal" contextual vector. The "reasoning box" takes the memories $M_{q,r,c,h}$ and $\hat{s}_{j-1}$ as inputs and finally outputs $c_{j,m}^{\mathrm{R}}$.

The number of reasoning turns for yielding the "reasoning attention vectors" (c_j^{R} which is further indexed by reasoning steps of 1, 2 in Figure 2) during the decoding inference is dynamically parameterized by both the contextual memories and current query, and is generally related to the complexities of the conversation context and current query.

The training steps are performed as per the general framework as described in Equations 8 and 9. For each reasoning hidden state h_m^{R}, the termination probability o_m is estimated by $f_{tg}(h_m^{\mathrm{R}}; \theta_{tg})$, which is

$$o_m = (1 - o_{m-1}) * \sigma(w_t^\top h_m^{\mathrm{R}} + b_t), \qquad (16)$$

where $\theta_{tg} = \{w_t, b_t\}$, w_t is a weight vector, b_t is a bias, and σ is the sigmoid logistic function. Then, different hidden states h_m^{R} are first weighted by their termination probabilities o_m and then summed to produce a reasoning-attention context vector c_j^{R} (using the equations as described previously in Section 3.2), which is consequently used to construct the next reasoning step's h_2^{R} = RNN(h_1^{R}, $c_{j,1}^{\mathrm{R}}$). The final $c_{j,m}^{\mathrm{R}}$ ($m \geq 1$ is the final reasoning step) will be used in Equations 8 and 9 in a way alike former attention vectors. During our experiments, we instead used a sum of from $o_2 \times c_{j,1}^{\mathrm{R}}$ to $o_{m+1} \times c_{j,m}^{\mathrm{R}}$ as the final $c_{j,m}^{\prime\mathrm{R}}$ for next word generation.

During generating each word in the response, our network performs a response action r_m at the m-th step, which implies that the termination gate variables $o_{1:m} = (o_1 = 0, o_2 =$

```
A: i'm bored
B: boooring
A: isn't it? (^_^)
B: everybody is asleep
A: really?
   (^_^) my friends are still awake! :P
B: lucky!
   xD feels lonely with everyone asleep
A: almost everyone is awake (^v^)
B: whyyy?!
   my friends go early to bed.
   Or is it me that's late? xD
A: it's us who are late! xD
B: true, very true xD
```

$0, ..., o_{m-1} = 0, o_m = 1$). A stochastic policy $\pi((o_m, r_m)|h^{\mathrm{R}}_m, t_j; \theta)$ with parameters θ to get a distribution of termination actions, to continue reading the conversation context (i.e., $M_{q,r,c,h}$) or to stop, and of response actions r_m for predicting the next word if the model decides to stop at current step. In our experiments, we set a maximum step parameter T_{max} to be 5 for heuristically avoiding too many reasoning times. We follow (Shen et al., 2016) to compute the expected reward and its gradient for one instance. We refer to this model with multi-turn reasoning attentions as REASON.

5 Experiments

In our experiments, we used a dataset consisting of Japanese twitter conversations. Each conversation contains 10 sentences from two real-world alternating speakers. Given the origin of the dataset, it is quite noisy, containing misspelled words, slang and *kaomoji* (multi-character sequences of facial emoticons) among meaningful words and characters. Preliminary experiments by using a word-based approach resulted in the vocabulary size being too big and with too many word breaking errors, we instead used a character-based approach. Figure 3 shows a sample 10-sentence conversation in which original Japanese sentences were translated into English and similar spelling patterns were kept in a sense (such as booooring for boring and whyyy for why).

We kept the conversations in which all sentences were no more than 20 characters. This filtering strategy resulted in a dataset of 254K conversations from which 100 (1K sentences) where taken out for testing and another 100 for validating and hyper-parameter tuning. The training set contains 6,214 unique characters, which are used as our vocabulary with the addition of two special symbols, an UNK (out-of-vocabulary unknown word) and an EOS (end-of-sentence). Table 1 shows major statistics of the dataset.

The training minimizes negative log-likelihood (NLL) per character on the nine sentences $s_{2,...,10}$ of each conversation. One configuration in MULTI and REASON is that, we respectively use the reference contexts (instead of former automatically generated sentences) to generate current sentence. That is, when generating s_i, we use the golden contextual sentences of from s_1 to s_{i-1}. These three systems were respectively trained 3 epochs (10,000 iterations) on an AdaDelta (Zeiler, 2012) optimizer. Character embedding matrix was shared by both the encoder and the decoder parts. All the hidden layers, in the encoding/decoding parts and the attention models, were of size 200 and the character embeddings were of size 100. The recurrent units that we used were GRU. The gradients were clipped at the maximum gradient norm of 1. The reasoning module's maximum steps $T_{\max}$ was set to be 5. The data was iterated on mini-batches of less than 1,500 symbols each.

We initialized the recurrent weight matrices in GRUs as random orthogonal matrices. Unless specially mentioned, all the elements of the 0-indexed vectors and all bias vectors were initialized to be zero. Any other weight matrices were initialized by sampling from the Gaussian distribution of mean 0 and variance 0.01.

Figure 4 shows the progression of the NLLs per

		SIMPLE	MULTI	REASON
BLEU-4	Train	1.98	1.97	**2.30**
	Validation	1.80	2.12	**2.62**
	Test	2.20	2.13	**2.89**
BLEU-2	Train	6.77	6.78	**7.03**
	Validation	6.67	6.89	**8.14**
	Test	7.19	7.24	**7.97**

Table 2: Character-level BLEU-2/4 (%) scores.

character during training. The validation costs begun converging in the third epoch for the three models. The plot roughly shows lower cost for more complex models.

Galley et al. (2015) obtained better correlation with human evaluation when using BLEU-2 rather than BLEU-4. We thus report both of these scores for automatic evaluation and comparison. The character-level BLEU-4 and BLEU-2 scores for the trained models are reported in Table 2. The REASON model achieved consistently better BLEU-2 and BLEU-4 scores in the three datasets. MULTI performed slightly better than SIMPLE on the validation set yet that performance is less stable than REASON.

Figure 4 also reflects that, (1) the final training costs of SIMPLE and MULTI are quite close with each other at iteration 10,000; (2) there is a big margin of between the final training cost of REASON and that of SIMPLE or MULTI; and (3) the validation costs exactly follows an order of SIMPLE > MULTI > REASON.

6 Analysis

Figure 5 illustrates an English translation of a conversation and the responses suggested by each of the described models. This conversation is extracted from the test set. The three responses are different from the reference response, but the one from REASON looks the most consistent with the given context. The response from MULTI is contradicting the context of speaker B as he/she said *Not at all* in a former sentence.

As it has been shown in (Liu et al., 2016) that BLEU doesn't correlate well with human judgments, we asked three human evaluators to respectively examine 900 responses from each of the models given their reference contexts. The evaluators were asked to judge (1) whether one response is acceptable and (2) whether one response is better than the other two responses. A summary of this evaluation is displayed in Table 3. The *acceptable* column refers to the percentage of responses

A: I feel nostalgic. This was so cute. B: It's gross. What's that picture? A: It's cute! It used to be on TV. B: Isn't that from a children's show? A: Yes B: I know that one!! A: Isn't it cute? B: Not at all A: Uh! I can't believe it...

SIMPLE (B:)	MULTI (B:)	REASON (B:)
Uh! it isn't.	It's cute!	Do you think it's cute?

Reference
B: Are you asking me whether the picture is cute?

Figure 5: Sample responses generated by the three models and the recorded reference response, translated to English. Both MULTI and REASON include *cute*, yet MULTI contradicts a previous response *Not at all*.

	acceptable	best-of-three †	> SIMPLE‡	> MULTI‡
SIMPLE	42%	25%	-	45%
MULTI	52%	29%	55%	-
REASON	**65%**	**46%**	**59%**	**58%**

Table 3: Human evaluation of the responses generated by the three models. † Percentage over the conversations that had at least one response accepted. ‡ From the cases where any of both compared models was acceptable. > = "better than".

that were considered acceptable by at least two of the human evaluators while the *best-of-three* columns refers to the percentage of times that each model's response was considered by at least two evaluators to be better than the other two's, from the contexts that had at least one acceptable response. The last two columns make one-to-one comparisons. In 18% of the contexts, none of the models produced an acceptable response.

This human evaluation shows that complexer models are more likely to produce acceptable responses. The MULTI and REASON models are only different in the attention mechanism of multi-turn reasoning. The reasoning module performed better than single-turn attention 58% of the times.

Table 4 contains the character-level *distinct-n* (Li et al., 2016a) metrics for n-grams where $1 \leq n \leq 5$. This metric measures the number of distinct n-grams divided by the total number of n-grams in the generated responses. The displayed results are computed on the concatenation of all the responses to the test-set contexts. The *Reference* column was computed on the reference responses and represents the optimal human-like ratio.

SIMPLE performed the best at uni-gram diver-

	SIMPLE	MULTI	REASON	Reference
distinct-1	**.039**	.028	.032	.088
distinct-2	.112	.095	**.121**	.407
distinct-3	.199	.180	**.238**	.588
distinct-4	.248	.241	**.310**	.587
distinct-5	.255	.265	**.328**	.530

Table 4: N-gram diversity metrics of between (1) the responses generated to the test set and (2) their reference responses.

sity. For n-grams $n \geq 2$, REASON produced the most diverse outputs. While the results for REASON were consistently better than the other two models, the results for MULTI were not always better than SIMPLE. This indicates MULTI does not always benefit from the augmented context without the multi-turn reasoning attentions.

7 Conclusions

We have presented a novel approach to multi-turn conversation modeling. Our approach uses multiple explicitly separated memories to represent rich conversational contexts. We also presented multi-turn reasoning attentions to integrate various annotation memories. We run experiments on three different models with and without the introduced approaches and measured their performances using automatic metrics and human evaluation.

Experimental results verified that the increased contexts are able to help producing more acceptable and diverse responses. Driven by the depth of the reasoning attention, the diversities of the responses are significantly improved. We argue that the reasoning attention mechanism helps integrating the multiple pieces of information as it can combine them in a more complex way than a simple weighted sum. We further observed that as the accuracy of the conversation model improves, the diversity of the generated responses increases.

The proposed approach of multi-turn reasoning over multiple memory attention networks is presented in a general framework that allows the inclusion of memories of multiple resources and types. Applying to group chatting with more than two speakers and reasoning over emotion embeddings or knowledge vectors included from an external knowledge base/graph are taken as our future directions.

Abstract

In this work, we present a hybrid learning method for training task-oriented dialogue systems through online user interactions. Popular methods for learning task-oriented dialogues include applying reinforcement learning with user feedback on supervised pre-training models. Efficiency of such learning method may suffer from the mismatch of dialogue state distribution between offline training and online interactive learning stages. To address this challenge, we propose a hybrid imitation and reinforcement learning method, with which a dialogue agent can effectively learn from its interaction with users by learning from human teaching and feedback. We design a neural network based task-oriented dialogue agent that can be optimized end-to-end with the proposed learning method. Experimental results show that our end-to-end dialogue agent can learn effectively from the mistake it makes via imitation learning from user teaching. Applying reinforcement learning with user feedback after the imitation learning stage further improves the agent's capability in successfully completing a task.

1 Introduction

Task-oriented dialogue systems assist users to complete tasks in specific domains by understanding user's request and aggregate useful information from external resources within several dialogue turns. Conventional task-oriented dialogue systems have a complex pipeline (Rudnicky et al., 1999; Raux et al., 2005; Young et al., 2013) consisting of independently developed and modularly connected components for natural language understanding (NLU) (Mesnil et al., 2015; Liu and Lane, 2016; Hakkani-Tür et al., 2016), dialogue state tracking (DST) (Henderson et al., 2014c; Mrkšić et al., 2016), and dialogue policy learning (Gasic and Young, 2014; Shah et al., 2016; Su et al., 2016, 2017). These system components are usually trained independently, and their optimization targets may not fully align with the overall system evaluation criteria (e.g. task success rate and user satisfaction). Moreover, errors made in the upper stream modules of the pipeline propagate to downstream components and get amplified, making it hard to track the source of errors.

To address these limitations with the conventional task-oriented dialogue systems, recent efforts have been made in designing end-to-end learning solutions with neural network based methods. Both supervised learning (SL) based (Wen et al., 2017; Bordes and Weston, 2017; Liu and Lane, 2017a) and deep reinforcement learning (RL) based systems (Zhao and Eskenazi, 2016; Li et al., 2017; Peng et al., 2017) have been studied in the literature. Comparing to chit-chat dialogue models that are usually trained offline using single-turn context-response pairs, task-oriented dialogue model involves reasoning and planning over multiple dialogue turns. This makes it especially important for a system to be able to learn from users in an interactive manner. Comparing to SL models, systems trained with RL by receiving feedback during users interactions showed improved model robustness against diverse dialogue scenarios (Williams and Zweig, 2016; Liu and Lane, 2017b).

A critical step in learning RL based task-oriented dialogue models is dialogue policy learning. Training dialogue policy online from scratch typically requires a large number of interactive learning sessions before an agent can reach a satisfactory performance level. Recent works (Henderson et al., 2008; Williams et al., 2017; Liu et al., 2017) explored pre-training the dialogue model using human-human or human-machine dialogue

* Work done while the author was an intern at Google.
† Work done while at Google Research.

Proceedings of NAACL-HLT 2018, pages 2060–2069
New Orleans, Louisiana, June 1 - 6, 2018.

corpora before performing interactive learning with RL to address this concern. A potential drawback with such pre-training approach is that the model may suffer from the mismatch of dialogue state distributions between supervised training and interactive learning stages. While interacting with users, the agent's response at each turn has a direct influence on the distribution of dialogue state that the agent will operate on in the upcoming dialogue turns. If the agent makes a small mistake and reaches an unfamiliar state, it may not know how to recover from it and get back to a normal dialogue trajectory. This is because such recovery situation may be rare for good human agents and thus are not well covered in the supervised training corpus. This will result in compounding errors in a dialogue which may lead to failure of a task. RL exploration might finally help to find corresponding actions to recover from a bad state, but the search process can be very inefficient.

To ameliorate the effect of dialogue state distribution mismatch between offline training and RL interactive learning, we propose a hybrid imitation and reinforcement learning method. We first let the agent to interact with users using its own policy learned from supervised pre-training. When an agent makes a mistake, we ask users to correct the mistake by demonstrating the agent the right actions to take at each turn. This user corrected dialogue sample, which is guided by the agent's own policy, is then added to the existing training corpus. We fine-tune the dialogue policy with this dialogue sample aggregation (Ross et al., 2011) and continue such user teaching process for a number of cycles. Since asking for user teaching at each dialogue turn is costly, we want to reduce this user teaching cycles as much as possible and continue the learning process with RL by collecting simple forms of user feedback (e.g. a binary feedback, positive or negative) only at the end of a dialogue.

Our main contributions in this work are:

- We design a neural network based task-oriented dialogue system which can be optimized end-to-end for natural language understanding, dialogue state tracking, and dialogue policy learning.
- We propose a hybrid imitation and reinforcement learning method for end-to-end model training in addressing the challenge with dialogue state distribution mismatch between offline training and interactive learning.

The remainder of the paper is organized as follows. In section 2, we discuss related work in building end-to-end task-oriented dialogue systems. In section 3, we describe the proposed model and learning method in detail. In Section 4, we describe the experiment setup and discuss the results. Section 5 gives the conclusions.

2 Related Work

Popular approaches in learning task-oriented dialogue include modeling the task as a partially observable Markov Decision Process (POMDP) (Young et al., 2013). RL can be applied in the POMDP framework to learn dialogue policy online by interacting with users (Gašić et al., 2013). The dialogue state and system action space have to be carefully designed in order to make the policy learning tractable (Young et al., 2013), which limits the model's usage to restricted domains.

Recent efforts have been made in designing end-to-end solutions for task-oriented dialogues, inspired by the success of encoder-decoder based neural network models in non-task-oriented conversational systems (Serban et al., 2015; Li et al., 2016). Wen et al. (Wen et al., 2017) designed an end-to-end trainable neural dialogue model with modularly connected system components. This system is a supervised learning model which is evaluated on fixed dialogue corpora. It is unknown how well the model performance generalizes to unseen dialogue state during user interactions. Our system is trained by a combination of supervised and deep RL methods, as it is shown that RL may effectively improve dialogue success rate by exploring a large dialogue action space (Henderson et al., 2008; Li et al., 2017).

Bordes and Weston (2017) proposed a task-oriented dialogue model using end-to-end memory networks. In the same line of research, people explored using query-regression networks (Seo et al., 2016), gated memory networks (Liu and Perez, 2017), and copy-augmented networks (Eric and Manning, 2017) to learn the dialogue state. These systems directly select a final response from a list of response candidates conditioning on the dialogue history without doing slot filling or user goal tracking. Our model, on the other hand, explicitly tracks user's goal for effective integration with knowledge bases (KBs). Robust dialogue state tracking has been shown (Jurčíček et al., 2012) to

be critical in improving dialogue success in task completion.

Dhingra et al. (2017) proposed an end-to-end RL dialogue agent for information access. Their model focuses on bringing differentiability to the KB query operation by introducing a "soft" retrieval process in selecting the KB entries. Such soft-KB lookup is prone to entity updates and additions in the KB, which is common in real world information systems. In our model, we use symbolic queries and leave the selection of KB entities to external services (e.g. a recommender system), as entity ranking in real world systems can be made with much richer features (e.g. user profiles, location and time context, etc.). Quality of the generated symbolic query is directly related to the belief tracking performance. In our proposed end-to-end system, belief tracking can be optimized together with other system components (e.g. language understanding and policy) during interactive learning with users.

Williams et al. (2017) proposed a hybrid code network for task-oriented dialogue that can be trained with supervised and reinforcement learning. They show that RL performed with a supervised pre-training model using labeled dialogues improves learning speed dramatically. They did not discuss the potential issue of dialogue state distribution mismatch between supervised pre-training and RL interactive learning, which is addressed in our dialogue learning framework.

3 Proposed Method

Figure 1 shows the overall system architecture of the proposed end-to-end task-oriented dialogue model. We use a hierarchical LSTM neural network to encode a dialogue with a sequence of turns. User input to the system in natural language format is encoded to a continuous vector via a bidirectional LSTM utterance encoder. This user utterance encoding, together with the encoding of the previous system action, serves as the input to a dialogue-level LSTM. State of this dialogue-level LSTM maintains a continuous representation of the dialogue state. Based on this state, the model generates a probability distribution over candidate values for each of the tracked goal slots. A query command can then be formulated with the state tracking outputs and issued to a knowledge base to retrieve requested information. Finally, the system produces a dialogue action, which is conditioned on information from the dialogue state, the estimated user's goal, and the encoding of the query results . This dialogue action, together with the user goal tracking results and the query results, is used to generate the final natural language system response via a natural language generator (NLG). We describe each core model component in detail in the following sections.

3.1 Utterance Encoding

We use a bidirectional LSTM to encode the user utterance to a continuous representation. We refer to this LSTM as the utterance-level LSTM. The user utterance vector is generated by concatenating the last forward and backward LSTM states. Let $\mathbf{U}_k = (w_1, w_2, ..., w_{T_k})$ be the user utterance at turn k with T_k words. These words are firstly mapped to an embedding space, and further serve as the step inputs to the bidirectional LSTM. Let $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$ represent the forward and backward LSTM state outputs at time step t. The user utterance vector U_k is produced by: $U_k = [\overrightarrow{h_{T_k}}, \overleftarrow{h_1}]$, where $\overrightarrow{h_{T_k}}$ and $\overleftarrow{h_1}$ are the last states in the forward and backward LSTMs.

3.2 Dialogue State Tracking

Dialogue state tracking, or belief tracking, maintains the state of a conversation, such as user's goals, by accumulating evidence along the sequence of dialogue turns. Our model maintains the dialogue state in a continuous form in the dialogue-level LSTM ($\mathrm{LSTM_D}$) state s_k. s_k is updated after the model processes each dialogue turn by taking in the encoding of user utterance U_k and the encoding of the previous turn system output A_{k-1}. This dialogue state serves as the input to the dialogue state tracker. The tracker updates its estimation of the user's goal represented by a list of slot-value pairs. A probability distribution $P(l_k^m)$ is maintained over candidate values for each goal slot type $m \in M$:

$$s_k = \mathrm{LSTM_D}(s_{k-1},\ [U_k,\ A_{k-1}]) \quad (1)$$

$$P(l_k^m \mid \mathbf{U}_{\leq k},\ \mathbf{A}_{<k}) = \mathrm{SlotDist}_m(s_k) \quad (2)$$

where $\mathrm{SlotDist}_m$ is a single hidden layer MLP with $\mathrm{softmax}$ activation over slot type $m \in M$.

3.3 KB Operation

The dialogue state tracking outputs are used to form an API call command to retrieve information from a knowledge base. The API call command is

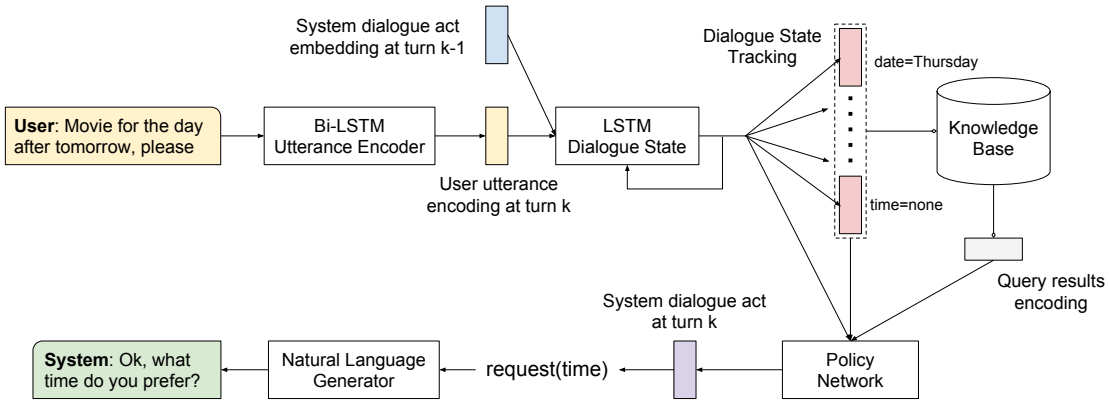

Figure 1: Proposed end-to-end task-oriented dialogue system architecture.

produced by replacing the tokens in a query command template with the best hypothesis for each goal slot from the dialogue state tracking output. Alternatively, an n-best list of API calls can be generated with the most probable candidate values for the tracked goal slots. In interfacing with KBs, instead of using a soft KB lookup as in (Dhingra et al., 2017), our model sends symbolic queries to the KB and leaves the ranking of the KB entities to an external recommender system. Entity ranking in real world systems can be made with much richer features (e.g. user profiles, local context, etc.) in the back-end system other than just following entity posterior probabilities conditioning on a user utterance. Hence ranking of the KB entities is not a part of our proposed neural dialogue model. In this work, we assume that the model receives a ranked list of KB entities according to the issued query and other available sources, such as user models.

Once the KB query results are returned, we save the retrieved entities to a queue and encode the result summary to a vector. Rather then encoding the real KB entity values as in (Bordes and Weston, 2017; Eric and Manning, 2017), we only encode a summary of the query results (i.e. item availability and number of matched items). This encoding serves as a part of the input to the policy network.

3.4 Dialogue Policy

A dialogue policy selects the next system action in response to the user's input based on the current dialogue state. We use a deep neural network to model the dialogue policy. There are three inputs to the policy network, (1) the dialogue-level LSTM state s_k, (2) the log probabilities of candidate values from the belief tracker v_k, and (3) the

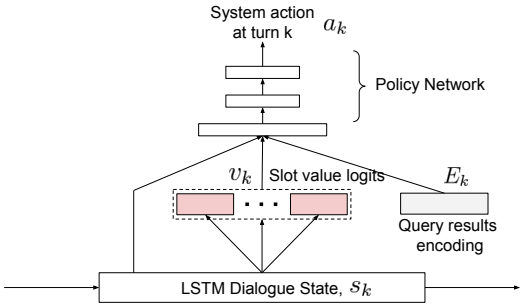

Figure 2: Dialogue state and policy network.

encoding of the query results summary E_k. The policy network emits a system action in the form of a dialogue act conditioning on these inputs:

$$P(a_k \mid U_{\leq k},\ A_{<k},\ E_{\leq k}) = \text{PolicyNet}(s_k, v_k, E_k) \quad (3)$$

where v_k represents the concatenated log probabilities of candidate values for each goal slot, E_k is the encoding of query results, and PolicyNet is a single hidden layer MLP with softmax activation function over all system actions.

The emitted system action is finally used to produce a system response in natural language format by combining the state tracker outputs and the retrieved KB entities. We use a template based NLG in this work. The delexicalised tokens in the NLG template are replaced by the values from either the estimated user goal values or the KB entities, depending on the emitted system action.

3.5 Supervised Pre-training

By connecting all the system components, we have an end-to-end model for task-oriented dialogue. Each system component is a neural network that takes in underlying system component's outputs

in a continuous form that is fully differentiable, and the entire system (utterance encoding, dialogue state tracking, and policy network) can be trained end-to-end.

We first train the system in a supervised manner by fitting task-oriented dialogue samples. The model predicts the true user goal slot values and the next system action at each turn of a dialogue. We optimize the model parameter set θ by minimizing a linear interpolation of cross-entropy losses for dialogue state tracking and system action prediction:

$$\min_{\theta} \sum_{k=1}^{K} -\Big[\sum_{m=1}^{M} \lambda_{l^m} \log P(l_k^{m*} | \mathbf{U}_{\leq k}, \mathbf{A}_{<k}, \mathbf{E}_{<k}; \theta) + \lambda_a \log P(a_k^* | \mathbf{U}_{\leq k}, \mathbf{A}_{<k}, \mathbf{E}_{\leq k}; \theta) \Big] \quad (4)$$

where λs are the linear interpolation weights for the cost of each system output. l_k^{m*} is the ground truth label for the tracked user goal slot type $m \in M$ at the kth turn, and a_k^* is the true system action in the corpus.

3.6 Imitation Learning with Human Teaching

Once obtaining a supervised training dialogue agent, we further let the agent to learn interactively from users by conducting task-oriented dialogues. Supervised learning succeeds when training and test data distributions match. During the agent's interaction with users, any mistake made by the agent or any deviation in the user's behavior may lead to a different dialogue state distribution than the one that the supervised learning agent saw during offline training. A small mistake made by the agent due to this covariate shift (Ross and Bagnell, 2010; Ross et al., 2011) may lead to compounding errors which finally lead to failure of a task. To address this issue, we propose a dialogue imitation learning method which allows the dialogue agent to learn from human teaching. We let the supervised training agent to interact with users using its learned dialogue policy $\pi_\theta(a|s)$. With this, we collect additional dialogue samples that are guided by the agent's own policy, rather than by the expert policy as those in the supervised training corpora. When the agent make mistakes, we ask users to correct the mistakes and demonstrate the expected actions and predictions for the agent to make. Such user teaching precisely addresses the limitations of the currently learned dialogue model, as these newly collected dialogue samples are driven by the agent's own policy. Specifically, in this study we let an expert user to correct the mistake made by the agent in tracking the user's goal at the end of each dialogue turn. This new batch of annotated dialogues are then added to the existing training corpus. We start the next round of supervised model training on this aggregated corpus to obtain an updated dialogue policy, and continue this dialogue imitation learning cycles.

Algorithm 1 Dialogue Learning with Human Teaching and Feedback

1: Train model end-to-end on dialogue samples D with MLE and obtain policy $\pi_\theta(a|s)$ ▷ eq 4
2: **for** learning iteration $k = 1 : K$ **do**
3: Run $\pi_\theta(a|s)$ with user to collect new dialogue samples D_π
4: Ask user to correct the mistakes in the tracked user's goal for each dialogue turn in D_π
5: Add the newly labeled dialogue samples to the existing corpora: $D \leftarrow D \cup D_\pi$
6: Train model end-to-end on D and obtain an updated policy $\pi_\theta(a|s)$ ▷ eq 4
7: **end for**
8: **for** learning iteration $k = 1 : N$ **do**
9: Run $\pi_\theta(a|s)$ with user for a new dialogue
10: Collect user feedback as reward r
11: Update model end-to-end and obtain an updated policy $\pi_\theta(a|s)$ ▷ eq 5
12: **end for**

3.7 Reinforcement Learning with Human Feedback

Learning from human teaching can be costly, as it requires expert users to provide corrections at each dialogue turn. We want to minimize the number of such imitation dialogue learning cycles and continue to improve the agent via a form of supervision signal that is easier to obtain. After the imitation learning stage, we further optimize the neural dialogue system with RL by letting the agent to interact with users and learn from user feedback. Different from the turn-level corrections in the imitation dialogue learning stage, the feedback is only collected at the end of a dialogue. A positive reward is collected for successful tasks, and a zero reward is collected for failed tasks. A step penalty is applied to each dialogue turn to encour-

age the agent to complete the task in fewer steps. In this work, we only use task-completion as the metric in designing the dialogue reward. One can extend it by introducing additional factors to the reward functions, such as naturalness of interactions or costs associated with KB queries.

To encourage the agent to explore the dialogue action space, we let the agent to follow a softmax policy during RL training by sampling system actions from the policy network outputs. We apply REINFORCE algorithm (Williams, 1992) in optimizing the network parameters. The objective function can be written as $J_k(\theta) = \mathbb{E}_\theta[R_k] = \mathbb{E}_\theta\left[\sum_{t=0}^{K-k}\gamma^t r_{k+t}\right]$, with $\gamma \in [0,1)$ being the discount factor. With likelihood ratio gradient estimator, the gradient of the objective function can be derived as:

$$\begin{aligned}\nabla_\theta J_k(\theta) &= \nabla_\theta \mathbb{E}_\theta[R_k] \\ &= \sum_{a_k} \pi_\theta(a_k|s_k)\nabla_\theta \log \pi_\theta(a_k|s_k) R_k \\ &= \mathbb{E}_\theta[\nabla_\theta \log \pi_\theta(a_k|s_k) R_k]\end{aligned} \tag{5}$$

This last expression above gives us an unbiased gradient estimator.

4 Experiments

4.1 Datasets

We evaluate the proposed method on DSTC2 (Henderson et al., 2014a) dataset in restaurant search domain and an internally collected dialogue corpus[1] in movie booking domain. The movie booking dialogue corpus has an average number of 8.4 turns per dialogue. Its training set has 100K dialogues, and the development set and test set each has 10K dialogues.

The movie booking dialogue corpus is generated (Shah et al., 2018) using a finite state machine based dialogue agent and an agenda based user simulator (Schatzmann et al., 2007) with natural language utterances rewritten by real users. The user simulator can be configured with different personalities, showing various levels of randomness and cooperativeness. This user simulator is also used to interact with our end-to-end training agent during imitation and reinforcement learning stages. We randomly select a user profile when conducting each dialogue simulation. During model evaluation, we use an extended set of natural language surface forms over the ones used during training time to evaluate the generalization capability of the proposed end-to-end model in handling diverse natural language inputs.

[1]The dataset can be accessed via https://github.com/google-research-datasets/simulated-dialogue

4.2 Training Settings

The size of the dialogue-level and utterance-level LSTM state is set as 200 and 150 respectively. Word embedding size is 300. Embedding size for system action and slot values is set as 32. Hidden layer size of the policy network is set as 100. We use Adam optimization method (Kingma and Ba, 2014) with initial learning rate of 1e-3. Dropout rate of 0.5 is applied during supervised training to prevent the model from over-fitting.

In imitation learning, we perform mini-batch model update after collecting every 25 dialogues. System actions are sampled from the learned policy to encourage exploration. The system action is defined with the act and slot types from a dialogue act (Henderson et al., 2013). For example, the dialogue act "$confirm(date = monday)$" is mapped to a system action "$confirm\_date$" and a candidate value "$monday$" for slot type "$date$". The slot types and values are from the dialogue state tracking output.

In RL optimization, we update the model with every mini-batch of 25 samples. Dialogue is considered successful based on two conditions: (1) the goal slot values estimated from dialogue state tracking fully match to the user's true goal values, and (2) the system is able to confirm with the user the tracked goal values and offer an entity which is finally accepted by the user. Maximum allowed number of dialogue turn is set as 15. A positive reward of +15.0 is given at the end of a successful dialogue, and a zero reward is given to a failed case. We apply a step penalty of -1.0 for each turn to encourage shorter dialogue for task completion.

4.3 Supervised Learning Results

Table 4.3 and Table 4.3 show the supervised learning model performance on DSTC2 and the movie booking corpus. Evaluation is made on DST accuracy. For the evaluation on DSTC2 corpus, we use the live ASR transcriptions as the user input utterances. Our proposed model achieves near state-of-the-art dialogue state tracking results on DSTC2 corpus, on both individual slot tracking and joint slot tracking, comparing to the recent published

results using RNN (Henderson et al., 2014b) and neural belief tracker (NBT) (Mrkšić et al., 2016). In the movie booking domain, our model also achieves promising performance on both individual slot tracking and joint slot tracking accuracy. Instead of using ASR hypothesis as model input as in DSTC2, here we use text based input which has much lower noise level in the evaluation of the movie booking tasks. This partially explains the higher DST accuracy in the movie booking domain comparing to DSTC2.

Model	Area	Food	Price	Joint
RNN	92	86	86	69
RNN+sem. dict	92	86	92	71
NBT	90	84	94	72
Our SL model	90	84	92	72

Table 1: Dialogue state tracking results on DSTC2

Goal slot	Accuracy
Num of Tickets	98.22
Movie	91.86
Theater Name	97.33
Date	99.31
Time	97.71
Joint	84.57

Table 2: DST results on movie booking dataset

4.4 Imitation and RL Results

Evaluations of interactive learning with imitation and reinforcement learning are made on metrics of (1) task success rate, (2) dialogue turn size, and (3) DST accuracy. Figures 3, 4, and 5 show the learning curves for the three evaluation metrics. In addition, we compare model performance on task success rate using two different RL training settings, the end-to-end training and the policy-only training, to show the advantages of performing end-to-end system optimization with RL.

Task Success Rate As shown in the learning curves in Figure 3, the SL model performs poorly. This might largely due to the compounding errors caused by the mismatch of dialogue state distribution between offline training and interactive learning. We use an extended set of user NLG templates during interactive evaluation. Many of the test NLG templates are not seen by the supervised training agent. Any mistake made by the agent in understanding the user's request may lead to compounding errors in the following dialogue

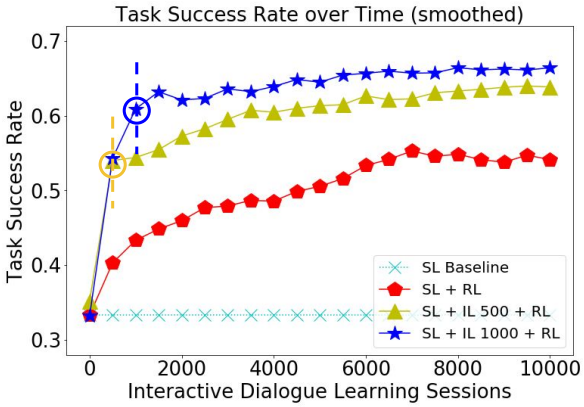

Figure 3: Interactive learning curves on task success rate.

turns, which cause final task failure. The red curve (`SL + RL`) shows the performance of the model that has RL applied on the supervised pre-training model. We can see that interactive learning with RL using a weak form of supervision from user feedback continuously improves the task success rate with the growing number of user interactions. We further conduct experiments in learning dialogue model from scratch using only RL (i.e. without supervised pre-training), and the task success rate remains at a very low level after 10K dialogue simulations. We believe that it is because the dialogue state space is too complex for the agent to learn from scratch, as it has to learn a good NLU model in combination with a good policy to complete the task. The yellow curve (`SL + IL 500 + RL`) shows the performance of the model that has 500 episodes of imitation learning over the SL model and continues with RL optimization. It is clear from the results that applying imitation learning on supervised training model efficiently improves task success rate. RL optimization after imitation learning increases the task success rate further. The blue curve (`SL + IL 1000 + RL`) shows the performance of the model that has 1000 episodes of imitation learning over the SL model and continues with RL. Similarly, it shows hints that imitation learning may effectively adapt the supervised training model to the dialogue state distribution during user interactions.

Average Dialogue Turn Size Figure 4 shows the curves for the average turn size of successful dialogues. We observe decreasing number of dialogue turns in completing a task along the growing number of interactive learning sessions. This shows that the dialogue agent learns better strategies in successfully completing the task with fewer

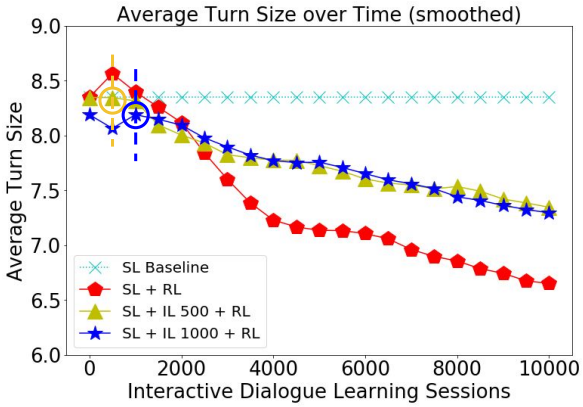

Figure 4: Interactive learning curves on average dialogue turn size.

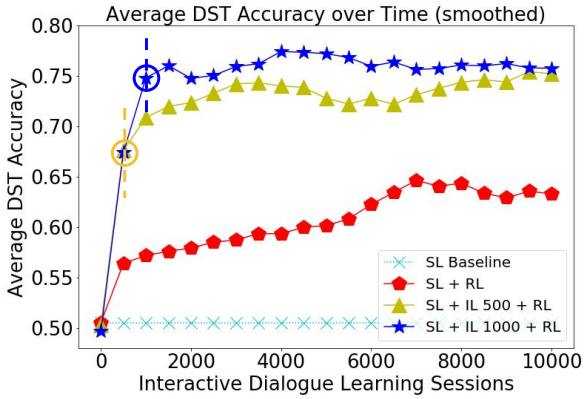

Figure 5: Interactive learning curves on dialogue state tracking accuracy.

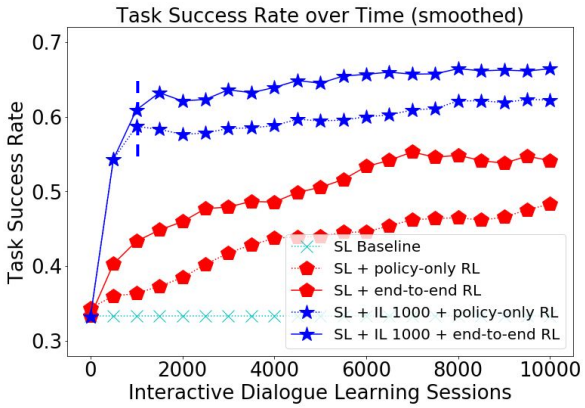

Figure 6: Interactive learning curves on task success rate with different RL training settings.

number of dialogue turns. The red curve with RL applied directly after supervised pre-training model gives the lowest average number of turns at the end of the interactive learning cycles, comparing to models with imitation dialogue learning. This seems to be contrary to our observation in Figure 3 that imitation learning with human teaching helps in achieving higher task success rate. By looking into the generated dialogues, we find that the `SL + RL` model can handle easy tasks well but fails to complete more challenging tasks. Such easy tasks typically can be handled with fewer number of turns, which result in the low average turn size for the `SL + RL` model. On the other hand, the imitation plus RL models attempt to learn better strategies to handle those more challenging tasks, resulting in higher task success rates and also slightly increased dialogue length comparing to `SL + RL` model.

Dialogue State Tracking Accuracy Similar to the results on task success rate, we see that imitation learning with human teaching quickly improves dialogue state tracking accuracy in just a few hundred interactive learning sessions. The joint slots tracking accuracy in the evaluation of SL model using fixed corpus is 84.57% as in Table 4.3. The accuracy drops to 50.51% in the interactive evaluation with the introduction of new NLG templates. Imitation learning with human teaching effectively adapts the neural dialogue model to the new user input and dialogue state distributions, improving the DST accuracy to 67.47% after only 500 imitation dialogue learning sessions. Another encouraging observation is that RL on top of SL model and IL model not only improves task success rate by optimizing dialogue policy, but also further improves dialogue state tracking performance. This shows the benefits of performing end-to-end optimization of the neural dialogue model with RL during interactive learning.

End-to-End RL Optimization To further show the benefit of performing end-to-end optimization of dialogue agent, we compare models with two different RL training settings, the end-to-end training and the policy-only training. End-to-end RL training is what we applied in previous evaluation sections, in which the gradient propagates from system action output layer all the way back to the natural language user input layer. Policy-only training refers to only updating the policy network parameters during interactive learning with RL, with all the other underlying system parameters fixed. The evaluation results are shown in Figure 6. From these learning curves, we see clear advantage of performing end-to-end model update in achieving higher dialogue task success rate during interactive learning comparing to only updating the policy network.

4.5 Human User Evaluations

We further evaluate the proposed method with human judges recruited via Amazon Mechanical Turk. Each judge is asked to read a dialogue between our model and user simulator and rate each system turn on a scale of 1 (frustrating) to 5 (optimal way to help the user). Each turn is rated by 3 different judges. We collect and rate 100 dialogues for each of the three models: (i) SL model, (ii) SL model followed by 1000 episodes of IL, (iii) SL and IL followed by RL. Table 3 lists the mean and standard deviation of human scores overall system turns. Performing interactive learning with imitation and reinforcement learning clearly improves the quality of the model according to human judges.

Model	Score
SL	3.987 ± 0.086
SL + IL 1000	4.378 ± 0.082
SL + IL 1000 + RL	4.603 ± 0.067

Table 3: Human evaluation results. Mean and standard deviation of crowd worker scores (between 1 to 5).

5 Conclusions

In this work, we focus on training task-oriented dialogue systems through user interactions, where the agent improves through communicating with users and learning from the mistake it makes. We propose a hybrid learning approach for such systems using end-to-end trainable neural network model. We present a hybrid imitation and reinforcement learning method, where we firstly train a dialogue agent in a supervised manner by learning from dialogue corpora, and continuously to improve it by learning from user teaching and feedback with imitation and reinforcement learning. We evaluate the proposed learning method with both offline evaluation on fixed dialogue corpora and interactive evaluation with users. Experimental results show that the proposed neural dialogue agent can effectively learn from user teaching and improve task success rate with imitation learning. Applying reinforcement learning with user feedback after imitation learning with user teaching improves the model performance further, not only on the dialogue policy but also on the dialogue state tracking in the end-to-end training framework.

Abstract

It has been proven that automatic conversational agents can be built up using the End-to-End Neural Response Generation (NRG) framework, and such a data-driven methodology requires a large number of dialog pairs for model training and reasonable evaluation metrics for testing. This paper proposes a Large Scale Domain-Specific Conversational Corpus (LSDSCC) composed of high-quality query-response pairs extracted from the domain-specific online forum, with thorough pre-processing and cleansing procedures. Also, a testing set, including multiple diverse responses annotated for each query, is constructed, and on this basis, the metrics for measuring the diversity of generated results are further presented. We evaluate the performances of neural dialog models with the widely applied diversity boosting strategies on the proposed dataset. The experimental results have shown that our proposed corpus can be taken as a new benchmark dataset for the NRG task, and the presented metrics are promising to guide the optimization of NRG models by quantifying the diversity of the generated responses reasonably.

1 Introduction

Conversational agents (a.k.a. Chat-bots) are effective media to establish communications with human beings and have received much attention from academic and industrial experts in recent years (Serban et al., 2017). One essential fact promoting the research work on conversational agents is the explosive growth of human interaction data accumulated in the social network services, such as Twitter[1] and Reddit[2]. So, it is possible to build Chat-bots based on data-driven approaches (Serban and Pineau, 2015).

[1]https://twitter.com/
[2]https://www.reddit.com/

Nevertheless, there still remains a great challenge for building such conversational agents: at present, the automatic evaluation metrics of NRG models can hardly afford to measure the semantic relevance and diversity of generated results reasonably, and even the latter evaluation aspect has been paid little attention. The widely accepted evaluating methods employed by the existing NRG models can be categorized as: a) metrics inherited from Machine Translation, e.g., BLEU, Perplexity, etc. (Yao et al., 2015; Lowe et al., 2017; Wu et al., 2018); b) discrete scores measuring the quality of generated results by human labeling (Shang et al., 2015; Serban et al., 2016; Xu et al., 2017); and c) case study comparing the generated results of different NRG models (Shang et al., 2015; Wang et al., 2017). The disappointing situation is that these evaluating methods have not revealed tangible difference among NRG models, the reasons for which can be reflected by the example given in Table 1.

Query: Where did you get that from?
Ground-truth responses: I got it from her.
– I do not know. – Cloverfield wiki. – New York Times. – From movie theatre.
Query: Airplane is now available on Netflix!
Ground-truth responses: Thank you!
– Is it worth watching? – Thank you for that I'll add it to my list. – Awesome, I haven't watched it!

Table 1: Cases of queries with diverse responses.

For each query in Table 1, one response from the testing set is taken as the ground truth, together with responses with more morphological and semantic variations, marked with the symbol "–". These samples indicate that the numerical metrics inherited from NMT which discard the diver-

Proceedings of NAACL-HLT 2018, pages 2070–2080
New Orleans, Louisiana, June 1 - 6, 2018.

sity among responses, cannot reflect marginal differences among generative models, which is supported by the research work of Liu et al. (2016). Thus, an NRG model with good capability to produce diverse and meaningful responses is possible to be judged as a poor one by the BLEU/Perplexity based evaluations. Meanwhile, the metrics based on human labeling are still promising, yet the expensive cost and inconsistency among labelers limit the scale of human-annotation. Therefore, it becomes a necessity to develop reasonable automatic evaluation metrics, that can be taken to measure both candidate response's diversity and its relevance to the given query, to effectively guide the training of NRG models towards the state of promoting meaningful and diverse responses (Li et al., 2016a; Shao et al., 2017; Freitag and Al-Onaizan, 2017).

In order to evaluate the performance of NRG models automatically and reasonably, a well-annotated testing set should be built first. But then, building such a high-quality testing set is a non-trivial task indeed. On one hand, most existing source datasets cover various domains, making it difficult to evaluate the generated results in case that the domain of the generated response is different from that of the reference. On the other hand, a large number of noises, typos, and slangs distribute in existing large-scale datasets, such as Twitter corpus (Ritter et al., 2011) and Ubuntu dialog corpus (Kadlec et al., 2015). For instance, there are many file directories with computer names in Ubuntu dialog corpus. Therefore, qualified domain-specific datasets are desperately required to evaluate NRG models with different architectures reasonably.

To address the above issues, we build a high-quality and domain-specific dialog corpus composed of a carefully prepared training set, and meanwhile, a testing set is constructed by collecting multiple reference responses for each query and conducting group-aware human annotation on collected responses. On this basis, we proposed three discriminative metrics: `MaxBLEU`, Mean Diversity Score (`MDS`), and Probabilistic Diversity Score (`PDS`), to primarily evaluate the diversity of generated responses with relevance also considered. To further assess the performance and effectiveness of the test set cooperating with the proposed metrics, the widely applied Sequence-to-Sequence (Seq2Seq) (Bahdanau et al., 2014; Sutskever et al., 2014) based models with the available diversity promotion methods are implemented, and experiments are conducted on the proposed Large Scale Domain-Specific Conversational Corpus (LSDSCC) dataset. The experimental results stay consistent with the previous experience acquired from human-labeled sets, and the performance of these models suggests that the LSDSCC corpus and discriminative metrics will provide insights for future research in the field of NRG.

2 Related Work

Seq2Seq based conversation modeling approaches have been proven to be able to generate response directly (Vinyals and Le, 2015; Shang et al., 2015). However, these models tend to produce generic responses to any given queries, namely the *deficient diversity problem* (Shao et al., 2017). Recent studies attempt to constrain these universal replies and promote more diverse responses with various strategies during the procedure of training or inference (Li et al., 2016a,b; Mou et al., 2016; Xing et al., 2017; Shao et al., 2017). Besides, there still exits another meaningful option, that is, to employ reasonable diversity oriented evaluation metrics to guide the optimization of models.

The quality of testing sets is a primary factor for such evaluation of NRG models. Existing large-scale corpora contain the Movie Dialogue, Ubuntu, Twitter, and Reddit corpus (Banchs, 2012; Uthus and Aha, 2013; Ritter et al., 2010; Schrading et al., 2015). The Ubuntu corpus is built by scraping a large scale tech support dialogues from Ubuntu IRC forum for building response ranking models (Kadlec et al., 2015). Similarly, Sordoni et al. (2015) provide external context information for message response pairs from Twitter FireHose. Besides, Dodge et al. (2016) and Schrading et al. (2015) collect real conversations from movie categories of Reddit community, which are integrated into a multi-task corpus on movie for the ranking task and discourse analysis. In the above corpora, there are only one or two reference responses for most query, which is completely unlike that of the practical conversation scenario (Li et al., 2017b). By contrast, this paper construct a high-quality testing set, including multi-references for each query. In this regard, our testing set is more close to the real-world setting.

Besides the testing set, evaluation metrics are also important for the performance measurement of NRG models. Most frequently applied evaluation metrics for NRG models are inherited from NMT to measure the fluency and relevance of generated responses, such as Perplexity, BLEU (Papineni et al., 2002) and deltaBLEU (Galley et al., 2015). Although these metrics demonstrate the relevance between the given query and the generated responses, they overlook the reply's diversity that is of great importance in conversation setting. Thus, efforts are devoted to simulate the human subjective judgment, which is similar with the response ranking task in retrieval-based chat agents (Lowe et al., 2017; Tao et al., 2018), but unavoidable uncertainty and errors are brought into the systems (Hu et al., 2014). In addition, automatic evaluation metrics (e.g. BLEU, deltaBLEU, etc.) are limited by the fact that each query only has references with the exact same meaning and many overlapped phrases, which is unreasonable in the conversational scenario.

3 Data Processing and Analysis

Previous studies indicate that more focused topics and less diverged domain is helpful to guide NRG models away from the state of producing universal responses (Mou et al., 2016; Xing et al., 2017), so we compose a domain-specific corpora by constraining the domain of crawled dialogues from Reddit to its movie discussion board[3]. The quality of the data in Reddit movie category has been discussed by Stoddard (2015) and Jamnik and Lane (2017), who point out that the popularity is a good indication of relative quality and the movie category is one of the most popular boards in Reddit. Thus, the data in Reddit movie category is originally high-quality. In this section, the pipeline for building the LSDSCC dataset will be discussed in detail, and necessary statistical indicators are collected to demonstrate its distribution. Moreover, human evaluation is conducted to measure the quality of the obtained training set.

3.1 Data Processing

Data Cleansing. We crawl threads from the movie discussion board of Reddit that includes human-to-human conversations as the raw dataset, and conduct the following cleansing operations:

a) For each thread, we strip away the *markdown* and *html* syntax tokens, e.g., "[word](url)" is transformed to "word", ">" is reformed to ">", etc. Meanwhile, all forms of urls, emails and digits withing the paragraphs are normalized as "url", "email" and "digits" tokens respectively;

b) As emoticons in the data originated from social media services always provide essential emotional information of users, we propose to convert the same groups of emoticons into corresponding words (e.g., ":-)" will be reverted to "happy") to preserve such emotion knowledge;

c) Finally, replicated words or characters (e.g., "cooool" and "ahahaha", etc.) are substituted with its normal form using regular expressions.

Query Vocabulary	Size	Coverage (%)
overlong words	17,084	10.32 %
non-ascii words	58,720	35.46 %
Response Vocabulary	**Size**	**Coverage (%)**
overlong words	15,914	7.94 %
non-ascii words	71,997	35.94 %

Table 2: Composition of noise words in the query and response vocabulary of the raw data.

Vocabulary Truncation. After the above preprocessing operations, there still exist redundant unformatted slang and noisy strings (e.g., "Iloveyou"), which have low-frequency in the crawled raw data. Consequently, the vocabulary size of the dataset is exceeding $160K$ as shown in Table 2. Keeping a such large vocabulary for Seq2Seq based models will consume excessive memory and make those models difficult to converge, while pruning low-frequency unformatted slang and noisy strings into "UNK" symbols would directly harm the performance of the model since excessive knowledge hidden in these strings are ignored in the training process. To address this issue, we break these slangs and noises into several frequent words in our corpus and eliminate non-ASCII tokens. In this way, sufficient information of the dataset is maintained for model training. Finally, the vocabulary sizes of the dataset are reduced to around $50K$.

Dialog Pruning. Statistical results on the sentence length of query-response pairs in the cleaned corpus are illustrated in Fig. 1. Concerning the fact that recurrent neural networks can not efficiently capture the semantics of over-long sentences and previous studies indicate that such re-

[3]https://www.reddit.com/r/movies/, selected from https://www.reddit.com/r/datasets

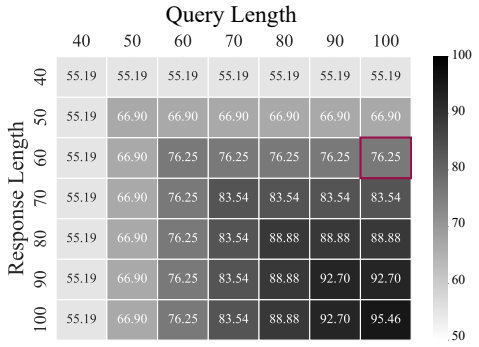

Figure 1: Sentence length coverage of queries and responses within the dataset.

sponses would make the decoder hard to converge (Greff et al., 2017), it is necessary to prune the pairs containing very long sentences. After the sentences are tokenized using the *NLTK toolkits*[4], the cases with queries longer than 100 or responses exceeding 60 words are pruned directly, and 76.25% of the dataset are finally reserved.

After pruning the corpus, there remain 738,095 single-turn and 346,543 multi-turn conversations. Since this paper focuses on the single-turn dialogs, the evaluative testing set and detailed experiments in the following sections are designed for single-turn corpus. As the testing set will select pairs from the preprocessed data, the corresponding tuples will be deleted to avoid coverage.

3.2 Query-Response Relevance of the Dataset

As one of the most important qualities of the conversational corpus, the query-response relevance demonstrates the overall quality of the dataset. Human evaluations of the query-response relevance are conducted to validate the quality of the dataset used in this paper. Nine experienced annotators are invited to evaluate the query-response relevance of 500 single-turn dialogs uniformly sampled from the whole dataset obtained in Subsection 3.1. In the evaluation, we ask each annotator to label whether the response is appropriate to the corresponding query in the given query-response pair. A pair is tagged as "Unsure" if the annotator could not confirm the degrees of relevance without related context and background movie knowledge. The labeled result is shown in Table 3. It is observed that 85% samples in the query-response relevance task are confirmed to keep high relevance between the query and the corresponding responses. Moreover, there exist only about 6.6% irrelevant noises. So, the resource can be considered as a high-quality one and can be used in the practical task.

[4]http://www.nltk.org/

Category	Relevant	Unsure	Irrelevant
Numbers	427	40	33
Percentage	85.4%	8%	6.6%

Table 3: Query-Response Relevance on the single-turn training set.

4 Testing Set and Evaluation Metrics

Existing evaluation metrics of dialog agents measure the quality of the generated sentences only by referring to the existing responses, which obeys the same principle with NMT models' metrics. However, one essential difference between NRG and NMT lies in the fact that, a large group of responses can be considered as relevant to a given query in conversations, while the number of references to a translation result is quite limited for NMT models. So the diversity degree of candidates which have not covered by NMT oriented evaluation metrics, is supposed to be quantified and measured in NRG models.

Currently, few studies focus on the evaluation based on the group of references, which is more meaningful and reasonable for NRG models. Therefore, we proposed three metrics: `MaxBLEU`, Mean Diversity Score, and Probabilistic Diversity Score, to quantify both the relevance and diversity of the generated responses. Since these metrics are based on the multi-reference, we first describe the procedure of building testing set, with multi-references for each query. Then, the metrics for NRG models are detailed based on the multi-reference testing set.

4.1 Multi-Reference Testing Set Construction

Fig. 2 illustrates the response quantity distribution of queries in the preprocessed data. While the testing set is randomly sampled from the preprocessed data, the response quantity distribution of the testing set is the same as that in Fig. 2. In this case, the multi-reference testing set for NRG evaluation is difficult to construct by directly extracting samples from the dialog corpus, since there are too few queries that contain more than three responses. Roughly choosing samples from such data is possible to bring topic bias into the testing set, and manually filtering suitable candidate pairs from

them is also time-consuming and expensive. Nevertheless, there exist large amounts of queries that are highly semantically similar or correlated with each other. This indicates that the multiple references can be obtained by selecting responses of queries that are semantically identical to the original query. What's more, the human-annotation is involved to proofread the filtered pairs' quality and complete the final labeling.

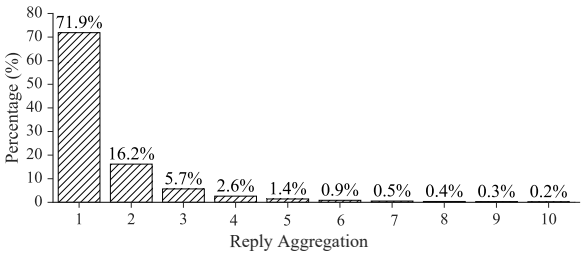

Figure 2: Distribution of reply quantities in training set.

When constructing the testing set, the very first step is getting semantically similar (or even identical) queries with the given ones. For this purpose, this paper adopts the TF-IDF similarity and semantic embedding based distance to measure the similarity between queries. The procedure of gaining similar queries is divided into two stage: In the first stage, we employ Apache Lucene[5] to exploit the word-level TF-IDF patterns within queries, and then extract the top 100 similar queries with highest scores given by Lucene for each query. Yet, these candidates only capture n-gram level similarity with the probably diverged semantics. Thus, in the second stage, we utilize paragraph vector algorithm (a.k.a Doc2vec[6]) (Le and Mikolov, 2014) to resort the selected similar queries in the semantic space and only queries of similarity score higher than a certain threshold (i.e., 0.9) are reserved. Table 4 lists several identical queries filtered by Lucene and Doc2vec methods with the given query. It should be noted that the Lucene index and Doc2vec need to be initialized by feeding all the sentences in the dialogue corpus.

To reserve as much information as possible and balance the distribution of the composed testing set, we divide the dataset into several subsets based on the response number of queries, and then sample testing data from each subset uniformly. Concretely, according to the response number, queries of the dataset are divided into three subsets: a) queries with less than 3 responses, b) queries with 3 to 5 responses, and c) queries with more than 5 responses. We randomly sample 100 queries from each subset, and thus 300 queries are obtained as the testing set. Aiming at building a multiple references testing set, each query in the testing set is assigned with 15 responses, including the original responses and the ones of the most similar queries obtained by the procedure of last paragraph.

Similar Queries	Similarity
If you haven't already, watch the animatrix.	0.97
Do not watch the animatrix, you may leave you house.	0.95
I don't have much to ad except, that people really should watch animatrix.	0.94
I recommend you watch the matrix.	0.91

Table 4: Filtered queries identical to the original query: "**You should watch the animatrix.**"

Afterwards, three skilled and experienced labelers familiar with movies are employed and carefully trained to crosswise annotate the filtered testing set. In addition, labelers can also obtain some background of the corresponding query since there are additional details for most queries in Reddit. In this case, the quality of selected samples can be guaranteed. Besides, the annotators are asked not only to label the relevance of query and reference responses, but also reorganize the independent references into groups by the semantic similarity subjectively. The grouping strategy is introduced for the purpose of evaluating the diversity of responses generated by different models.

In the relevance oriented annotation procedure, the labelers are first asked to judge whether a candidate response is appropriate and natural to the input query. If a candidate response is grammatically correct and semantically relevant with the corresponding query from the annotators' perspective, it should be labeled as "**1**". Otherwise, the annotators have to give "**0**" label to the candidate. Then, for each query, the annotators need to split responses labeled with "**1**" into different groups based on word overlapping between them, with stop-word overlapping ignored. Finally, the groups with the similar semantics are merged into a larger group by the annotators, so as to get the final grouped responses.

[5]https://lucene.apache.org/

[6]https://radimrehurek.com/gensim/models/doc2vec.html

At last, we obtain a high-quality testing set, in which each query is assigned with different numbers of reference responses. Fig. 3 shows the distribution of the response numbers in the testing set. Comparing to the original response number distribution in Fig. 2, the replies distribution of the testing set is much more appropriate for the conversational scenario. Furthermore, responses to the corresponding query are categorized into several groups. In this case, NRG models can be evaluated reasonably using such a testing set. One sampled case in the testing set is shown in the left phase of Fig. 4, and there are eight responses in the labeled data divided into four groups. The different metrics in this figure will be introduced in the following sections. It should be noted that both the single-turn dialogs and the annotated testing set are released[7].

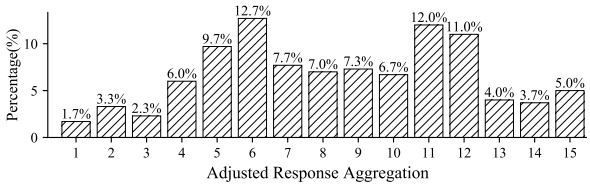

Figure 3: Aggregated responses per query in testing set.

4.2 The Metric on Response Relevance

Since the NRG architecture is analogous to the NMT models, introducing the BLEU scores to evaluate the semantic relevance of the generated results is acceptable. However, it is not reasonable to average the BLEU scores of the generated response to each reference, because the semantic of each reference varies significantly. Aiming at revealing the variation and diversity among responses, which have not yet covered at the NMT models, we propose a `MaxBLEU` metric customized for response generation based on the Multi-BLEU metric (Madnani et al., 2008). Noticing that the metrics inherited from SMT, like BLEU, is not able to evaluate the diversity of responses, we propose the specified metrics for diversity evaluation, which will be described in the next subsection.

Given an input query, the NRG model is able to generate a set of hypothesis $\{h_i\}$[8]. Meanwhile, according to the human-annotation strategy described in Subsection 4.1, the set of references can be reorganized, based on their semantic similarity, into the groups with the format of $\{r_{ij}\}$, where r_{ij} denotes the j-th reference in the i-th group. On this basis, the `MaxBLEU` metric is defined as:

$$\texttt{MaxBLEU}(h_i) = \arg\max_k \text{Multi-BLEU}(h_i, r_{k\cdot}) \quad (1)$$

where $r_{k\cdot}$ denotes all the references in the k-th group. That is, we begin by calculating all the multi-BLEU scores between each hypothesis and grouped references, and pick the score for the sentence with the highest BLEU as the score for this set of hypothesis, so that we make an alignment between generated hypothesis h to the group-aware references r. For simplicity, one response can only be aligned to one group reference, and multi-group references are not considered in this work.

4.3 Metrics on Response Diversity

Given a query, the diversity degree of candidate responses is an essential criterion for evaluating the performances of NRG models. Currently, most studies tend to demonstrate the diversities of different models by sampling and comparing the generated results, or labeling the diversity of the generated samples, which makes it difficult to benchmark and automatically evaluate different models. Although Li et al. (2017a) propose to calculate the number of distinct unigrams and bigrams of generated responses, such scores do not align well with human inspection (Serban et al., 2017).

Algorithm 1 Two Response Diversity Metrics.

Input:
hypothesis set `H` and reference set `R` ;
Output:
Mean Diversity Score (`MDS`);
Probabilistic Diversity Score (`PDS`);
for all $r_{i\cdot} \in$ `R` **do** ▷ Initialize
  $p_i = 1/|\texttt{R}|$,
  $p'_i = |r_{i\cdot}|/\sum_j |r_{j\cdot}|$.
end for
for all $h_i \in$ `H` **do** ▷ Compute alignment
  $k = \arg\max_j$ Multi-BLEU$(h_i, r_{j\cdot})$.
  $\texttt{MDS}(k) = p_k$,
  $\texttt{PDS}(k) = p'_k$.
end for
return $\sum_k \texttt{MDS}(k), \sum_k \texttt{PDS}(k)$

Therefore, we propose two evaluative metrics based on the `MaxBLEU` metric for diversity measurement: a) Mean Diversity Score (`MDS`) and b) Probabilistic Diversity Score (`PDS`). Basically, the

[7] https://drive.google.com/file/d/1nbpbnhwNP14xAc4SAc1-NN5lvEr01dQb/view?usp=sharing

[8] Following the terms in machine translation, this part takes "hypothesis" to represent "response".

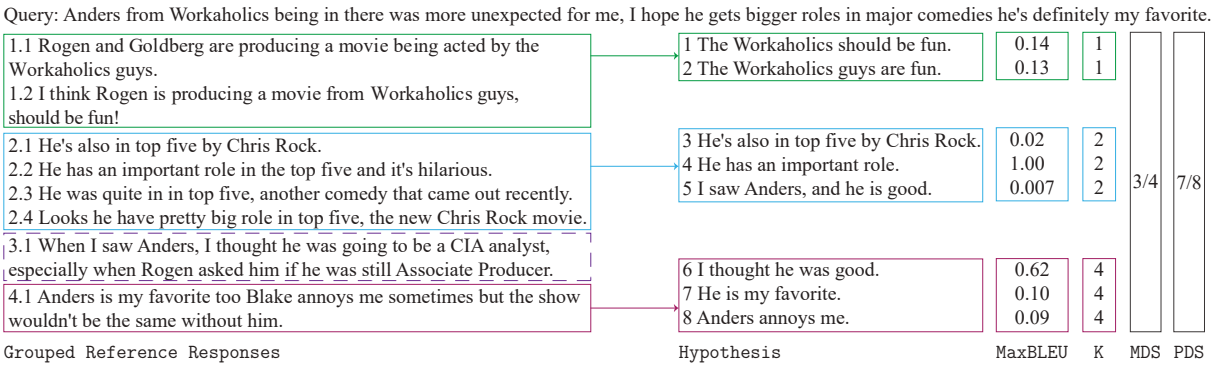

Figure 4: A sampled testing case including a given query, the grouped reference responses and the generated ones (hypothesis) with the proposed metrics, among which "K" is obtained by performing $\arg\max$ upon MaxBLEU scores. The MDS metric is calculated with the partitioned groups and PDS metric is calculated with the weight of each group in the overall the candidate set.

two metrics aim at measuring the overall diversity of the whole set of generation results (hypothesis) by taking them as an entirety, and the detailed calculation steps of the proposed metrics are illustrated in Algorithm 1. According to the algorithm, the PDS metric assumes that the weight of each reference group is distributed uniformly, regardless of the reference number in each group. Similarly, the MDS metric takes the count of the members in each group as the weight of the corresponding group, and actually compute the weighted coverage upon the reference group.

5 Experiments and Analysis

In this section, we present the detailed experiments on the single-turn dialog dataset and analysis on generated results, in accordance to the proposed metrics.

5.1 Baselines and Experimental Setups

Experiments are conducted using the popular Seq2Seq based models with the currently available diversity prompting strategies as follows:

1) **Basic Seq2Seq.** We employ the basic Seq2Seq to build the encoder-decoder architecture running on the proposed dataset, by taking the bidirectional LSTM cell as the encoder to address the input sentences ordering problem and classic LSTM cell as the decoder (Vinyals and Le, 2015).

2) **Attention-Seq2Seq.** As proposed by Vinyals and Le (2015); Luong et al. (2015), a concatenated version of attention mechanism is applied upon the basic Seq2Seq model.

3) **Greedy-Seq2Seq.** Based on the basis Seq2Seq model, the diversity promotion strategy proposed by Li et al. (2016b) is applied in the generating procedure, and the training procedure stays the same. Hyper parameter γ, a.k.a. *diversity rate*, are set with empirical experiments (i.e., $\gamma = 0.1, 0.8$) to reveal the efforts.

4) **Greedy-Attn-Seq2Seq.** Following the work of Li et al. (2016b), the greedy diversity promotion strategy is applied on the Seq2Seq model with attention mechanism similar with model 2, and we set hyper parameter $\gamma = 0.1, 0.8$.

5) **MMI-Seq2Seq.** In the generation procedure, Maximum Mutual Information (MMI) model is applied in the decoder to prune generic answers on the basic Seq2Seq model (Li et al., 2016a).

In our research, we implement these models on the TensorFlow platform[9], and Adam optimizer (Kingma and Ba, 2015) is employed for gradient optimization during training. Besides, we choose to prune the words whose frequencies are below 2, so the source and target vocabulary are set to $42,257$ and $46,865$ respectively.

In addition, we set the batch size to 50, hidden size of encoder to 256, hidden size of decoder to 512 and learning rate to $2e-4$. The gradients are clipped within $[-3.0, 3.0]$ to avoid the gradient explosion problem. Every model runs on a single GPU separately for at least one week before convergence. Afterwards, for all these methods, we generate a set of hypothesis sentences with beam size set to $k = 50$, and the evaluation scores are obtained using the proposed metrics.

After running through 25 epochs on the dataset, the training log-loss of the basic Seq2Seq mod-

[9]https://www.tensorflow.org

Models	MaxBLEU	MDS	PDS
Seq2Seq (Vinyals and Le, 2015)	1.30	0.230	0.253
Attention-Seq2Seq (Luong et al., 2015)	1.42	0.235	0.262
Greedy-Seq2Seq ($\gamma = 0.1$) (Li et al., 2016b)	1.88	0.249	0.243
Greedy-Seq2Seq ($\gamma = 0.8$)	1.72	0.297	0.291
Greedy-Attn-Seq2Seq ($\gamma = 0.1$) (Li et al., 2016b)	**2.27**	0.252	0.248
Greedy-Attn-Seq2Seq ($\gamma = 0.8$)	2.05	0.285	0.287
MMI-Seq2Seq (Li et al., 2016a)	2.15	**0.311**	**0.329**

Table 5: Performances of different models trained on the LSDSCC dataset with three metrics: MaxBLEU, MDS, PDS.

els converge to about 4.2 and the Seq2Seq models augmented with attention converge to 3.1. Also, we set the dropout rate to 0.5, which enables us to tune the models though much more epochs and avoid the over-fitting problems.

5.2 Relevance Analysis

The semantic relevance of the generated responses is represented by the MaxBLEU scores, which are listed in the corresponding column of Table 5. From this benchmarking table, it can be observed that the attention mechanism is helpful for decoders to improve the relevance of the generated responses, since the *Attention-Seq2Seq* performs better than the basic Seq2Seq on the dataset, in terms of all the three metrics. However, the relative gain of the attention layer is limited, indicating that modeling relation of query and response by attention module is not able to directly solve the learning paradigm of conversations.

In accordance to the results of Greedy-Seq2Seq ($\gamma = 0.1$) and Greedy-Seq2Seq ($\gamma = 0.8$), the hyper-parameter γ actually plays an important role in the generation steps of the decoder. Since γ is introduced to constrain the selection probability of the next-step word by performing the re-ranking process, and the larger value of this parameter will lead to the greater impact upon generating steps and produce more diverse sentences, we evaluate this greedy strategy with γ set with two empirical value. It can be seen that the model with the smaller γ performs better than the one with the larger parameter, which can be attributed to the fact that responses with more diversity are less similar to references. Similar observation can be get from the results of models Greedy-Attn-Seq2Seq ($\gamma = 0.1$) and Greedy-Attn-Seq2Seq ($\gamma = 0.8$). Besides, the reason for setting $\gamma = 0.1, 0.8$ in this part is that they are well represented for the poor diversity and good diversity, which the exact score of γ will vary under different configurations and structures of model.

In addition, the MMI model is proved to be promising to enhance the generation models, by improving both the relevant and diversity of generated responses. Even though the *MMI-Seq2Seq* model has not got the highest MaxBLEU, it outperforms the other ones on diversity, which will be discussed in the following subsection.

5.3 Diversity Analysis

Table 5 also illustrates the MDS and PDS score of each benchmark. It is observed that the greedy strategies in the generating procedure with the greater parameter γ can boost the diversity of generated responses obviously. This phenomenon is attributed to the inter-sibling ranking policy in the decoding procedure, which tends to choose hypotheses from diverse parents. In addition, the MMI strategy gets the highest MDS and PDS, because the MMI criterion relieves the constraint of the language model, under which general responses always get a higher generative probability.

Meanwhile, the PDS metric aligns well with the basic MDS, but the relative gap becomes larger within the Greedy-Seq2Seq ($\gamma = 0.1$) and Greedy-Seq2Seq ($\gamma = 0.8$) models. The reason for enlarging relative gap between different models, is to distinguish the performance of similar models and evaluate the performance of specific module inside the models. When comparing Seq2Seq and Attention-Seq2Seq, relative gain of applied attention module to the overall model in terms of MDS was 2.1%, while it became 3.6% considering the PDS metric.

Practically, it is reasonable to make a trade-off between the relevance and diversity. The PDS is more suitable for choosing the systems with stringent diversity requirement, and the MDS is a softer metric, which should be taken into consideration when measuring the diversity improvements by integrating some new modules into NRG models.

Moreover, it can be observed that the relevance oriented metric MaxBLEU gets improvement along

with the increasing of the diversity oriented PDS and MDS. This phenomenon indicates a relationship between relevance and diversity against that in some of text generation tasks (e.g., image caption (Yao et al., 2017)). Since there are generally many references for a given query, the relevance and diversity are possible to be improved simultaneously for the response generation task (Li et al., 2016a). And thus, the topic changing on the generated results is tolerable.

5.4 Human Correlation Analysis

To validate the correlations between human ratings and the proposed metrics, we further invite 9 annotators with rich movie knowledge to judge the relevance and diversity of the generated responses from benchmark methods. Each baseline model generate 10 responses for each query in the test dataset. The annotators are first asked to judge whether a generated response is relevant to the query (labeled with 1) or not (labeled with 0). After that, the annotators estimate the diversity of relevant responses of each query with a scale of 1 to 3. The final Fleiss Kappa (Fleiss, 1971) score is 0.46, which denotes moderate agreement of the annotators.

Model	Spearman	p-value	Pearson	p-value
MaxBLEU	0.31	0.022	0.29	0.036
MDS	0.36	0.041	0.33	0.028
PDS	0.39	0.038	0.35	0.040

Table 6: Correlation between the proposed metrics and human judgments for the Reddit dataset.

The Pearson and Spearman correlation between the human evaluations and each metric are given in Table 6. It can be observed that the proposed metrics correlate with human judgments moderately with $p - value < 0.05$, which is quite different from the correlation test in Liu et al. (2016). This can be attributed to the fact that there are multiple references for each query in our test dataset. Although the proposed metrics are derived from the word-overlap based BLEU scores, expanding references of each query makes such scores much more reasonable for evaluating the relevance and diversity of generated responses.

6 Conclusion and Future Work

In this paper, we have proposed the Large Scale Domain-Specific Conversational Corpus (LSDSCC), collected from the movie discuss threads in the Reddit community, for training and testing the Neural Response Generation (NRG) models. In addition, necessary data cleansing and pruning works are done to remove noises in the utterances. Moreover, we employ volunteers to annotate a diverse query-responses testing set, with reference groups taken into consideration for objectively quantifying the diversity of generated results. On the basis of the testing set, we propose two evaluative diversity metrics (mean diversity score and probabilistic diversity score) calculated according to the standard MaxBLEU score.

Furthermore, we investigate the performance of popular Seq2Seq based models with various diversity promotion strategies, and the score of them are collected to validate the effectiveness of the proposed metrics. The proposed dataset and evaluation metrics are expected to be used for the effective training and reasonable testing of NRG models.

In the future studies, we would explore the possibility of promoting diversity on the learning procedure, by directly optimizing diversity loss in the cost function. Besides, injecting external information during response's generation would be another challenging work.

Abstract

Coding EMRs with diagnosis and procedure codes is an indispensable task for billing, secondary data analyses, and monitoring health trends. Both speed and accuracy of coding are critical. While coding errors could lead to more patient-side financial burden and misinterpretation of a patient's well-being, timely coding is also needed to avoid backlogs and additional costs for the healthcare facility. In this paper, we present a new neural network architecture that combines ideas from few-shot learning matching networks, multi-label loss functions, and convolutional neural networks for text classification to significantly outperform other state-of-the-art models. Our evaluations are conducted using a well known de-identified EMR dataset (MIMIC) with a variety of multi-label performance measures.

1 Introduction

Electronic medical record (EMR) coding is the process of extracting diagnosis and procedure codes from the digital record (the EMR) pertaining to a patient's visit. The digital record is mostly composed of multiple textual narratives (e.g., discharge summaries, pathology reports, progress notes) authored by healthcare professionals, typically doctors, nurses, and lab technicians. Hospitals heavily invest in training and retaining professional EMR coders to manually annotate all patient visits by reviewing EMRs. Proprietary commercial software tools often termed as computer-assisted coding (CAC) systems are already in use in many healthcare facilities and were found to be helpful in increasing medical coder productivity (Dougherty et al., 2013). Thus progress in automated EMR coding methods is expected to directly impact real world operations.

In the US, the diagnosis and procedure codes used in EMR coding are from the International Classification of Diseases (ICD) terminology (specifically the ICD-10-CM variant) as required by the Health Insurance Portability and Accountability Act (HIPPA). ICD codes facilitate billing activities, retrospective epidemiological studies, and also enable researchers to aggregate health statistics and monitor health trends. To code EMRs effectively, medical coders are expected to have thorough knowledge of ICD-10-CM and follow a complex set of guidelines to code EMRs. For example, if a coder accidentally uses the code "heart failure" (ICD-10-CM code I50) instead of "acute systolic (congestive) heart failure" (ICD-10-CM code I50.21), then the patient may be charged substantially more[1] causing significant unfair burden. Therefore, it is important for coders to have better tools at their disposal to find the most appropriate codes. Additionally, if coders become more efficient, hospitals may hire fewer coders to reduce their operating costs. Thus automated coding methods are expected to help with expedited coding, cost savings, and error control.

In this paper, we treat medical coding of EMR narratives as a multi-label text classification problem. Multi-label classification (MLC) is a machine learning task that assigns a set of labels (typically from a fixed terminology) to an instance. MLC is different from multi-class problems, which assign a single label to each example from a set of labels. Compared to general multi-label problems, EMR coding has three distinct challenges. First, with thousands of ICD codes, the label space is large and the label distribution is extremely unbalanced – most codes occur very infrequently with a few codes occurring several orders of magnitude more than others. Second and more importantly, a patient may have a large number of diagnoses and procedures.

Proceedings of NAACL-HLT 2018, pages 2081–2091
New Orleans, Louisiana, June 1 - 6, 2018.

On average, coders annotate an EMR with more than 20 such codes and hence predicting the top one or two codes is not sufficient for EMR coding. Third, EMR narratives may be very long (e.g., discharge summaries may have over 1000 words), which may result in a needle in a haystack situation when attempting to seek evidence for particular codes.

Recent advances in *extreme multi-label classification* have proven to work well for large label spaces. Many of these methods (Yu et al., 2014; Bhatia et al., 2015; Liu et al., 2017) focus on creating efficient multi-label models that can handle 10^4 to 10^6 labels. While these models perform well in large label spaces, they don't necessarily focus on improving prediction of infrequent labels. Typically, they optimize for the top 1, 3, or 5 ranked labels by focusing on the P@1, P@3, and P@5 evaluation measures. The labels ranked at the top usually occur frequently in the dataset and it is not obvious how to handle infrequent labels. One solution would be to ignore the rare labels. However, when the majority of medical codes are infrequent, this solution is unsatisfactory.

While neural networks have shown great promise for text classification (Kim, 2014; Yang et al., 2016; Johnson and Zhang, 2017), the label imbalances associated with EMR coding hinder their performance. Imagine if a dataset contains only one training example for every class leading to *one-shot learning*, a subtask of *few-shot learning*. How can we classify a new instance? A trivial solution would be to use a non-parametric 1-NN (1 nearest neighbor) classifier. 1-NN does not require learning any label specific parameters and we only need to define features to represent our data and a distance metric. Unfortunately, defining good features and picking the best distance metric is nontrivial. Instead of manually defining the feature set and distance metric, neural network training procedures have been developed to learn them automatically (Koch et al., 2015). For example, matching networks (Vinyals et al., 2016) can automatically learn discriminative feature representations and a useful distance metric. Therefore, using a 1-NN prediction method, matching networks work well for infrequent labels. However, researchers typically evaluate matching networks on multi-class problems without label imbalance. For EMR coding with extreme label imbalance with several labels occurring thousands of times, traditional parametric neural networks (Kim, 2014) should work very well on the frequent labels. In this paper, we introduce a new variant of matching networks (Vinyals et al., 2016; Snell et al., 2017) to address the EMR coding problem. Specifically, we combine the non-parametric idea of k-NN and matching networks with traditional neural network text classification methods to handle both frequent and infrequent labels encountered in EMR coding.

Overall, we make the following contributions in this paper:

- We propose a novel semi-parametric neural matching network for diagnosis/procedure code prediction from EMR narratives. Our architecture employs ideas from matching networks (Vinyals et al., 2016), multiple attention (Lin et al., 2017), multi-label loss functions (Nam et al., 2014a), and convolutional neural networks (CNNs) for text classification (Kim, 2014) to produce a state-of-the-art EMR coding model.
- We evaluate our model on publicly available EMR datasets to ensure reproducibility and benchmarking; we also compare against prior state-of-the-art methods in EMR coding and demonstrate robustness across multiple standard evaluation measures.
- We analyze and measure how each component of our model affects the performance using ablation experiments.

2 Related Work

In this section we cover recent methodologies that are either relevant to our approach and problem or form the main ingredients of our contribution.

2.1 Extreme Multi-label Classification

Current methods for extreme MLC fall into two categories: embedding and tree-based methods. Embedding-based methods aim to reduce the training complexity. They effectively reduce the label space by assuming the training label matrix is low rank. Intuitively, rather than learning independent classifiers for each label (binary relevance) (Tsoumakas et al., 2010), classifiers are learned in a reduced label space $\hat{L} \ll L$ where L is the total number of labels. Likewise, a projection matrix is learned to convert predictions from the reduced label space back to the original label space. In general, embedding methods vary

based on how they reduce the label space and how the projection operation is optimized. Tai and Lin (2012) use principal component analysis (PCA) to reduce the label space. Low-rank Empirical risk minimization for Multi-Label Learning (LEML) (Yu et al., 2014) jointly optimizes the label space reduction and the projection processes. RobustXML (Xu et al., 2016) is similar to LEML but it treats infrequent labels as outliers and models them separately. Liu et al. (2017) employ neural networks for extreme multi-label problems using a funnel-like architecture that reduces the label vector dimensionality. Tree-based multi-label methods work by recursively splitting the feature space. These methods usually differ based on the node splitting criterion. FastXML (Prabhu and Varma, 2014) partitions the feature space using the nDCG measure as the splitting criterion. PfastreXML (Jain et al., 2016) improves on FastXML by using a propensity scored nDCG splitting criterion and re-ranking the predicted labels to optimize various ranking measures.

2.2 Memory Augmented Neural Networks

Memory networks (Weston et al., 2014) have access to external memory, typically consisting of information the model may use to make predictions. Intuitively, informative memories concerning a given instance are found by the memory network to improve its predictive power. Kamra et al. (2017) use memory networks to fix issues of catastrophic forgetting. They show that external memory can be used to learn new tasks without forgetting previous tasks. Memory networks are now applied to a wide variety of natural language processing tasks, including question answering and language modeling (Sukhbaatar et al., 2015; Bordes et al., 2015; Miller et al., 2016).

Matching networks (Vinyals et al., 2016; Snell et al., 2017) have recently been developed for few/one-shot learning problems. We can interpret matching networks as a key-value memory network (Miller et al., 2016). The "keys" are training instances, while the "values" are the labels associated with each training example. Intuitively, the concept is similar to a hashmap. The model will search for the most similar training instance to find its respective "value". Also, matching networks can be interpreted as a k-NN based model that automatically learns an informative distance metric. Finally, Altae-Tran et al. (2017) used matching networks for drug discovery, a problem where data is limited.

2.3 Diagnosis Code Prediction

The 2007 shared task on coding radiology reports (Pestian et al., 2007) was the first effort that popularized automated EMR coding. Traditionally, linear methods have been used for diagnosis code prediction. Perotte et al. (2013) developed a hierarchical support vector machine (SVM) model that takes advantage of the ICD-9-CM hierarchy. In our prior work, we train a linear model for every label (Rios and Kavuluru, 2013) and re-rank the labels using a learning-to-rank procedure (Kavuluru et al., 2015). Zhang et al. (2017) supplement the diagnosis code training data with data from PubMed (biomedical article corpus and search system) to train linear models using both the original training data and the PubMed data.

Recent advances in neural networks have also been put to use for EMR coding: Baumel et al. (2018) trained a CNN with multiple sigmoid outputs using binary cross-entropy. Duarte et al. (2017) use hierarchical recurrent neural networks (RNNs) to annotate death reports with ICD-10 codes. Vani et al. (2017) introduced grounded RNNs for EMR coding. They found that iteratively updating their predictions at each time step significantly improved the performance. Finally, similar to our work, memory networks (Prakash et al., 2017) have recently been used for diagnosis coding. However, we would like to note two significant differences between the memory network from Prakash et al. (2017) and our model. First, they don't use a matching network and their memories rely on extracting information about each label from Wikipedia. In contrast, our model does not use any auxiliary information. Second, they only evaluate on the 50 most frequent labels, while we evaluate on all the labels in the dataset.

3 Our Architecture

An overview of our model is shown in Figure 1. Our model architecture has two main components.

1. We augment a CNN with external memory over a support set S, which consists of a small subset of the training dataset. The model searches the support set to find similar examples with respect to the input instance. We make use of the homophily assumption that similar instances in the support set are coded

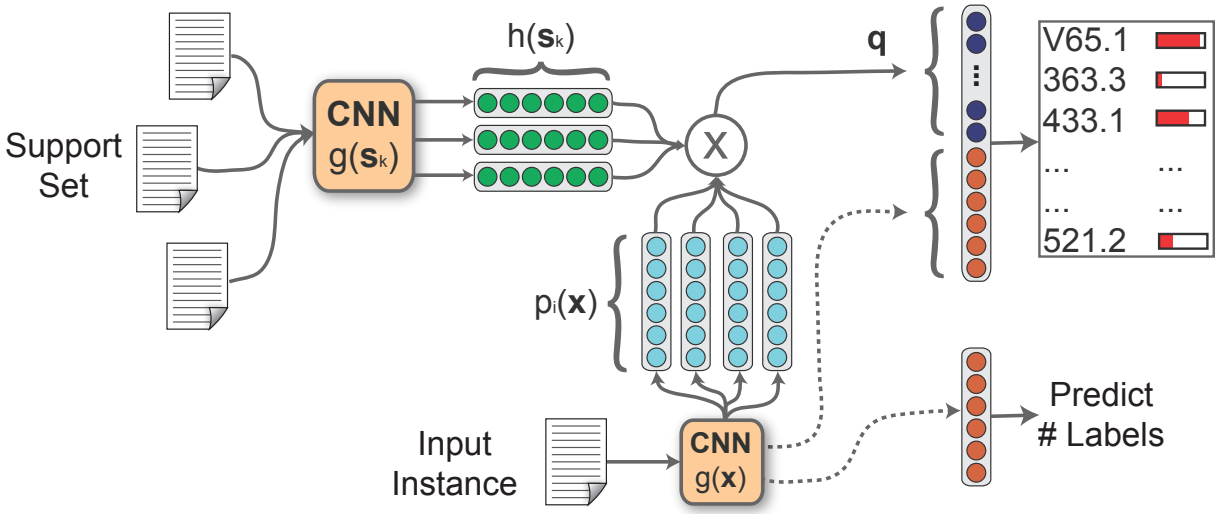

Figure 1: The matching CNN architecture. For each input instance, $\mathbf{x}$, we search a support set using different representations of $\mathbf{x}$ and use the similar support instances and auxiliary features to the output layer.

with similar labels. Therefore, we use the related support set examples as auxiliary features. The similar instances are chosen automatically by combining ideas from metric learning and neural attention. We emphasize that unlike in a traditional k-NN setup, we do NOT explicitly use the labels of the support set instances. The support set essentially enriches and complements the features derived from the input instance.

2. Rather than predicting labels by thresholding, we rank them and select the top k labels specific to each instance where k is predicted using an additional output unit (termed MetaLabeler). We train the MetaLabeler along with the classification loss using a multi-task training scheme.

Before we go into more specific details of our architecture, we introduce some notation. Let X represent the set of all training documents and $\mathbf{x}$ be an instance of X. Likewise, let S represent the set of support instances and s be an instance of S. We let L be the total number of unique labels. Our full model is described in following subsections.

3.1 Convolutional Neural Networks

We use a CNN to encode each document following what is now a fairly standard approach consisting of an embedding layer, a convolution layer, a max-pooling layer, and an output layer (Collobert et al., 2011; Kim, 2014). However, in our architecture, the CNN additionally aids in getting intermediate representations for the multi-head matching network component (Section 3.2).

Intuitively, CNNs make use of the sequential nature of text, where a non-linear function is applied to *region vectors* formed from vectors of words in short adjacent word sequences. Formally, we represent each document as a sequence of word vectors, $[\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_n]$, where $\mathbf{w}_i \in \mathbb{R}^d$ represents the vector of the i-th word in the document. The region vectors are formed by concatenating each window of s words, $\mathbf{w}_{i-s+1}|| \ldots ||\mathbf{w}_i$, into a local region vector $\mathbf{c}_j \in \mathbb{R}^{sd}$. Next, $\mathbf{c}_j$ is passed to a non-linear function

$$\hat{\mathbf{c}}_j = ReLU(\mathbf{W}\,\mathbf{c}_j + \mathbf{b}),$$

where $\mathbf{W} \in \mathbb{R}^{v \times sd}$, $\mathbf{b} \in \mathbb{R}^v$, and ReLU is a rectified linear unit (Glorot et al., 2011; Nair and Hinton, 2010). Each row of $\mathbf{W}$ represents a convolutional filter; so v is the total number of filters.

After processing each successive region vector, we obtain a document representation $\mathbf{D} = [\hat{\mathbf{c}}_1, \hat{\mathbf{c}}_2, \ldots, \hat{\mathbf{c}}_{n+s-1}]$ by concatenating each $\hat{\mathbf{c}}_j$ forming a matrix $\mathbf{D} \in \mathbb{R}^{v \times (n+s-1)}$. Each row of $\mathbf{D}$ is referred to as a *feature map*, formed by different convolutional filters. Unfortunately, this representation is dependent on the length of the document and we cannot pass it to an output layer. We use max-over-time pooling to create a fixed size vector

$$g(\mathbf{s}) = [\hat{c}^1_{max}, \hat{c}^2_{max}, \ldots, \hat{c}^q_{max}],$$

where $\hat{c}^j_{max} = \max(\hat{c}^j_1, \hat{c}^j_2, \ldots, \hat{c}^j_{n+s-1})$.

3.2 Multi-Head Matching Network

Using the support set and the input instance, our goal is to estimate $P(\mathbf{y}|\mathbf{x}, S)$. The support set S is chosen based on nearest neighbors and its selection process is discussed in Section 3.4. Among instances in S, our model finds informative support instances with respect to $\mathbf{x}$ and creates a feature vector using them. This feature vector is combined with the input instance to make predictions.

First, each support instance $\mathbf{s}_k \in S$ is projected into the support space using a simple single-layer feed forward NN as

$$h(g(\mathbf{s}_k)) = ReLU(\mathbf{W}_s\, g(\mathbf{s}_k) + \mathbf{b}_s),$$

where $\mathbf{W}_s \in \mathbb{R}^{z \times v}$ and $\mathbf{b}_s \in \mathbb{R}^z$. Likewise, we project each input instance $\mathbf{x}$ into the input space using a different feed forward neural network,

$$p_i(g(\mathbf{x})) = ReLU(\mathbf{W}^i_\alpha\, g(\mathbf{x}) + \mathbf{b}^i_\alpha),$$

where $\mathbf{W}^i_\alpha \in \mathbb{R}^{z \times v}$ and $\mathbf{b}^i_\alpha \in \mathbb{R}^z$. Compared to the support set neural network where we use only a single network, for the input instance we have u projection neural networks. This means we have u versions of $\mathbf{x}$, an idea that is similar to self-attention (Lin et al., 2017), where the model learns multiple representations of an instance. Here each $p_i(g(\mathbf{x}))$ represents a single "head" or representation of the input $\mathbf{x}$. Using different weight matrices, $[\mathbf{W}^1_\alpha, \ldots, \mathbf{W}^u_\alpha]$ and $[\mathbf{b}^1_\alpha, \ldots, \mathbf{b}^u_\alpha]$, we create different representations of $\mathbf{x}$ (multiple heads). For both the input multi-heads and the support instance projection, we note that the same CNN is used (also indicated in Figure 1) whose output is subject to the feed forward neural nets outlined thus far in this section.

Rather than searching for a single informative support instance, we search for multiple relevant support instances. For each of the u input instance representations, we calculate a normalized attention score

$$A_{i,k} = \frac{\exp(-d(p_i(g(\mathbf{x})),\, h(g(\mathbf{s}_k))))}{\sum_{\mathbf{s}_{k'} \in S} \left[\exp(-d(p_i(g(\mathbf{x})),\, h(g(\mathbf{s}_{k'}))))\right]}$$

where $A_{i,k}$ represents the score of the k-th support example with respect to the i-th input representation $p_i(g(\mathbf{x}))$ and

$$d(\mathbf{x}_i, \mathbf{x}_j) = \|\mathbf{x}_i - \mathbf{x}_j\|_2^2,$$

is the square of the Euclidean distance between the input and support representations.

Next, the normalized scores are aggregated into a matrix $\mathbf{A} \in \mathbb{R}^{u \times |S|}$. Then, we create a feature vector

$$\mathbf{q} = vec(\mathbf{A}\,\mathbf{S}) \tag{1}$$

where $\mathbf{q} \in \mathbb{R}^{uz}$, vec is the matrix vectorization operator, and $\mathbf{S} \in \mathbb{R}^{|S| \times z}$ is the support instance CNN feature matrix whose i-th row is $h(g(\mathbf{s}_i))$ for $i = 1, \ldots, |S|$. Intuitively, multiple weighted averages of the support instances are created, one for each of the u input representations. The final feature vector,

$$\mathbf{h} = \mathbf{q}\,||\,g(\mathbf{x}), \tag{2}$$

is formed by concatenating the CNN representation of the input instance $\mathbf{x}$ and the support set feature vector $\mathbf{q}$.

Finally, the output layer for L labels involves computing

$$\hat{\mathbf{y}} = P(\mathbf{y}|\mathbf{x}, S) = \sigma(\mathbf{W}_c\,\mathbf{h} + \mathbf{b}_c) \tag{3}$$

where $\mathbf{W}_c \in \mathbb{R}^{L \times (uz+v)}$, $\mathbf{b}_c \in \mathbb{R}^L$, and σ is the sigmoid function. Because we use a sigmoid activation function, each label prediction ($\hat{y}_i$) is in the range from 0 to 1.

3.3 MetaLabeler

The easiest method to convert $\hat{\mathbf{y}}$ into label predictions is to simply threshold each element at 0.5. However, most large-scale multi-label problems are highly imbalanced. When training using binary cross-entropy, the threshold 0.5 is optimized for accuracy. Therefore, our predictions will be biased towards 0. A simple way to fix this problem is to optimize the threshold value for each label. Unfortunately, searching for the optimal threshold of each label is computational expensive in large label spaces. Here we train a regression based output layer

$$\hat{r} = ReLU(\mathbf{W}_r\, g(\mathbf{x}) + b_r)$$

where $\hat{r}$ estimates the number of labels $\mathbf{x}$ should be annotated with. At test time, we rank each label by its score in $\hat{\mathbf{y}}$. Next, $\hat{r}$ is rounded to the nearest integer and we predict the top $\hat{r}$ ranked labels.

3.4 Training

To train our model, we need to define two loss functions. First, following recent working on multi-label classification with neural net-

works (Nam et al., 2014b), we train using a multi-label cross-entropy loss. The loss is defined as

$$\mathcal{L}_c = \sum_{i=1}^{L} \big[-y_i \log(\hat{y}_i) - (1 - y_i) \log(1 - \hat{y}_i) \big],$$

which sums the binary cross-entropy loss for each label. The second loss is used to train the MetaLabeler for which we use the mean squared error

$$\mathcal{L}_{\mathbf{r}} = \|\mathbf{r} - \hat{\mathbf{r}}\|_2^2$$

where $\mathbf{r}$ is the vector of correct numbers of labels and $\hat{\mathbf{r}}$ is our estimate. We train these two losses using a multi-task learning paradigm (Collobert et al., 2011).

Similar to previous work with matching networks (Vinyals et al., 2016; Snell et al., 2017), "episode" or mini-batch construction can have an impact on performance. In the multi-label setting, episode construction is non-trivial. We propose a simple strategy for choosing the support set S which we find works well in practice. First, at the beginning of the training process we loop over all training examples and store $g(\mathbf{x})$ for every training instance. We will refer to this set of vectors as T. Next, for every step of the training process (for every mini-batch M), we search $T \setminus M$ to find the e nearest neighbors (using Euclidean distance) per instance to form our support set S. Likewise, we add e random examples from $T \setminus M$ to the support set. Therefore, our support set S contains up to $|M|e + e$ instances. The purpose of the random examples is to ensure the distance metric learned during training (captured by improving representations of documents as influenced by all network parameters) is robust to noisy examples.

3.5 Matching Network Interpretation

If we do not use the support set label vectors, then what is our network learning? To answer this question we directly compare the matching network formulation to our method. Matching networks can be expressed as

$$\hat{\mathbf{y}} = \sum_{\mathbf{s}_k \in S} a(\mathbf{x}, \mathbf{s}_k)\, \mathbf{y}_{\mathbf{s}_k}$$

where $a(,)$ is the attention/distance learned between two instances, k indexes each support instance, and $\mathbf{y}_k$ is a one-hot encoded vector. $a(,)$ is equivalent to $A_{1,k}$ assuming we use a single head. Traditional matching networks use one-hot encoded vectors because they are evaluated on multi-class problems. EMR coding is a multi-label problem. Hence, $\mathbf{y}_k$ is a multi-hot encoded vector. Moreover, with thousands of labels, it is unlikely even for neighboring instance pairs to share many labels; this problem is not encountered in the multi-class setting. We overcome this issue by learning new output label vectors for each support set instance. Assuming a single head, our method can be re-written as

$$\hat{\mathbf{y}} = \sigma(\mathbf{W}_c^1\, g(\mathbf{x}) + \mathbf{b}_c + \sum_{\mathbf{s}_k \in S} a(\mathbf{x}, \mathbf{s}_k)\, \tilde{\mathbf{y}}_{\mathbf{s}_k}), \quad (4)$$

where $\tilde{\mathbf{y}_k}$ is the learned label vector for support instance s. Next, we define $\tilde{\mathbf{y}_k}$, the learned support set vectors, as

$$\tilde{\mathbf{y}}_{\mathbf{s}_k} = \mathbf{W}_c^2\, h(g(\mathbf{s}_k)) \quad (5)$$

where both $\mathbf{W}_c^1$ and $\mathbf{W}_c^2$ are submatrices of $\mathbf{W}_c$. Using this reformulation, we can now see that our method's main components (equations (1)-(3)) are equivalent to this more explicit matching network formulation (equations (4)–(5)). Intuitively, our method combines a traditional output layer – the first half of equation 4 – with a matching network where the support set label vectors are learned to better match the labels of their nearest neighbors.

4 Experiments

In this section we compare our work with prior state-of-the-art medical coding methods. In Section 4.1 we discuss the two publicly available datasets we use. Next, Section 4.2 describes the implementation details of our model. We summarize the various baselines and models we compare against in Section 4.3. The evaluation metrics are described in Section 4.4. Finally, we discuss how our method performs in Section 4.5.

4.1 Datasets

EMR data is generally not available for public use especially if it involves textual notes. Therefore, we focus on the publicly available Medical Information Mart for Intensive Care (MIMIC) datasets for benchmarking purposes. We evaluate using two versions of MIMIC: MIMIC II (Lee et al., 2011) and MIMIC III (Johnson et al., 2016), where the former is a relatively smaller and older dataset

	# Train	# Test	# Labels	LC	AI/L
MIMIC II	18822	2282	7042	36.7	118.8
MIMIC III	37016	2755	6932	13.6	80.8

Table 1: This table presents the number of training examples (# Train), the number of test examples (# Test), label cardinality (LC), and the average number of instances per label (AI/L) for the MIMIC II and MIMIC III datasets.

and the latter is the most recent version. Following prior work (Perotte et al., 2013; Vani et al., 2017), we use the free text discharge summaries in MIMIC to predict the ICD-9-CM[2] codes. The dataset statistics are shown in Table 1.

For comparison purposes, we use the same MIMIC II train/test splits as Perotte et al. (2013). Specifically, we use discharge reports collected from 2001 to 2008 from the intensive care unit (ICU) of the Beth Israel Deaconess Medical Center. Following Perotte et al. (2013), the labels for each discharge summary are extended using the parent of each label in label set. The parents are based on the ICD-9-CM hierarchy. We use the hierarchical label expansion to maximize the prior work we can compare against.

The MIMIC III dataset has been extended to include health records of patients admitted to the Beth Israel Deaconess Medical Center from 2001 to 2012 and hence provides a test bed for more advanced learning methods. Unfortunately, it does not have a standard train/test split to compare against prior work given we believe we are the first to look at it for this purpose. Hence, we use both MIMIC II and MIMIC III for comparison purposes. Furthermore, we do not use the hierarchical label expansion on the MIMIC III dataset.

Before we present our results, we discuss an essential distinction between the MIMIC II and MIMIC III datasets. Particularly, we are interested in the differences concerning label imbalance. From Table 1, we find that MIMIC III has almost twice as many examples compared to MIMIC II in the dataset. However, MIMIC II on average has more instances per label. Thus, although MIMIC III has more examples, each label is used fewer times on average compared to MIMIC II. The reason for this is because of how the label sets for each instance were extended using the ICD-9 hierarchy in MIMIC II.

[2]In 2015, a federal mandate was issued that requires the use of ICD-10 instead of ICD-9. However because of this recent change, ICD-10 training data is limited. Therefore, we use publicly available ICD-9 datasets for evaluation.

4.2 Implementation Details

Preprocessing: Each discharge summary was tokenized using a simple regex tokenization scheme (\w\w+). Also, each word/token that occurs less than five times in the training dataset was replaced with the *UNK* token.

Model Details: For our CNN, we used convolution filters of size 3, 4 and 5 with 300 filters for each filter size. We used 300 dimensional skip-gram (Mikolov et al., 2013) word embeddings pre-trained on PubMed. The Adam optimizer (Kingma and Ba, 2015) was used for training with the learning rate 0.0001. The mini-batch size was set to 4, e – the number of nearest neighbors per instance – was set to 16, and the number of heads (u) is set to 8. Our code is available at: `https://github.com/bionlproc/med-match-cnn`

4.3 Baseline Methods

In this paper, we focused on comparing our method to state-of-the-art methods for diagnosis code prediction such as grounded recurrent neural networks (Vani et al., 2017) (GRNN) and multi-label CNNs (Baumel et al., 2018). We also compare against traditional binary relevance methods where independent binary classifiers (L1-regularized linear models) are trained for each label. Next, we compare against hierarchical SVM (Perotte et al., 2013), which incorporates the ICD-9-CM label hierarchy. Finally, we also report the results of the traditional matching network with one modification: We train the matching network with the multi-label loss presented in Section 3.4 and threshold using the MetaLabeler described in Section 3.3.

We also present two versions of our model: *Match-CNN* and *Match-CNN Ens*. Match-CNN is the multi-head matching network introduced in Section 3. Match-CNN Ens is an ensemble that averages three Match-CNN models, each initialized using a different random seed.

4.4 Evaluation Metrics

We evaluate our method using a wide variety of standard multi-label evaluation metrics. We use the popular micro and macro averaged F1 measures to assess how our model (with the MetaL-

abeler) performs when thresholding predictions. For problems with large labels spaces that suffer from significant imbalances in label distributions, the default threshold of 0.5 generally performs poorly (hence our use of MetaLabeler). To remove the thresholding effect bias, we also report different versions of the area under the precision-recall (PR) and receiver operating characteristic (ROC) curves. Finally, in a real-world setting, our system would not be expected to replace medical coders. We would expect medical coders to use our system to become more efficient in coding EMRs. Therefore, we would rank the labels based on model confidence and medical coders would choose the correct labels from the top few. To understand if our system would be useful in a real-world setting, we evaluate with precision at k (P@k) and recall at k (R@k). Having high P@k and R@k are critical to effectively encourage the human coders to use and benefit from the system.

4.5 Results

We show experimental results on MIMIC II in Table 2. Overall, our method improves on prior work across a variety of metrics. With respect to micro F1, we improve upon GRNN-128 by over 1%. Also, while macro-F1 is still low in general, we also improve macro F1 compared to state-of-the-art neural methods by more than 1%. In general, both micro and macro F1 are highly dependent on the thresholding methodology. Rather than thresholding at 0.5, we rank the labels and pick the top k based on a trained regression output layer. Can we do better than using a MetaLabeler? To measure this, we look at the areas under PR/ROC curves. Regarding micro and macro PR-AUC, we improve on prior work by $\approx 2.5\%$. This suggests that via better thresholding, the chances of improving both micro and macro F1 are higher for Match-CNN compared to other methods. Finally, we are also interested in metrics that evaluate how this model would be used in practice. We perform comparably with prior work on P@k. We show strong improvements in R@k with over a 4% improvement in R@40 compared to grounded RNNs and over 1% improvement when compared with Baumel et al. (2018). Our method also outperforms matching networks across every evaluation measure.

We present MIMIC III results in Table 3. We reiterate that MIMIC III does not have a standard train/test split. Hence we compare our model to our implementations of methods from prior ef-

	F1		P@k		R@k		AUC (PR)	
	Micro	Macro	8	40	8	40	Micro	Macro

Table 4: Ablation results for the MIMIC III dataset.

forts. For MIMIC III also we show improvements in multiple evaluation metrics. Interestingly, our method performs much better than the standard CNN on MIMIC III, compared to the relative performances of the two methods on MIMIC II. Match-CNN improves on CNN in R@40 by almost 5% on the MIMIC III dataset. The gain in R@40 is more than the 1% improvement found on MIMIC II. We hypothesize that the improvements on MIMIC III are because the label imbalance found in MIMIC III is higher than MIMIC II. Increased label imbalances mean more labels occur less often. Therefore, we believe our model works better with less training examples per label compared to the standard CNN model.

In Table 4 we analyze each component of our model using an ablation analysis on the MIMIC III dataset. First, we find that removing the matching component significantly effects our performance by reducing micro PR-AUC by almost 5%. Regarding micro and macro F1, we also notice that the MetaLabeler heuristic substantially improves on default thresholding (0.5). Finally, we see that the multi-head matching component provides reasonable improvements to our model across multiple evaluation measures. For example, P@8 and P@40 decrease by around 1% when we use attention with a single input representation.

5 Conclusion

In this paper, we introduce a semi-parametric multi-head matching network with a specific application to EMR coding. We find that by combining the non-parametric properties of matching networks with a traditional classification output layer, we improve metrics for both frequent and infrequent labels in the dataset. In the future, we plan to investigate three limitations of our current model.

1. We currently use a naive approach to choose the support set. We believe that improving the support set sampling method could substantially improve performance.

2. We hypothesize that a more sophisticated thresholding method could have a significant impact on the micro and macro F1 measures. As we show in Table 4, MetaLabeler outperforms naive thresholding strategies. However, given our method shows non-trivial gains in PR-AUC compared to micro/macro F1, we believe better thresholding strategies are a worthy avenue to seek improvements.

3. Both the MIMIC II and MIMIC III datasets have around 7000 labels but ICD-9-CM contains over 16000 labels and ICD-10-CM has nearly 70,000 labels. In future work, we believe significant attention should be given to zero-shot learning applied to EMR coding. To predict labels that have never occurred in the training dataset, we think it is vital to take advantage of the ICD hierarchy. Baker and Korhonen (2017) improve neural network training by incorporating hierarchical label information to create better weight initializations. However, this does not help with respect to zero-shot learning. If we can better incorporate expert knowledge about the label space, we may be able to infer labels we have not seen before.

Acknowledgments

Thanks to anonymous reviewers for their thorough reviews and constructive criticism that helped improve the clarity of the paper (especially leading to the addition of Section 3.5 in the revision). This research is supported by the U.S. National Library of Medicine through grant R21LM012274. We also gratefully acknowledge the support of the NVIDIA Corporation for its donation of the Titan X Pascal GPU used for this research.

Factors Influencing the Surprising Instability of Word Embeddings

Laura Wendlandt, Jonathan K. Kummerfeld and **Rada Mihalcea**
Computer Science & Engineering
University of Michigan, Ann Arbor
{wenlaura,jkummerf,mihalcea}@umich.edu

Abstract

Despite the recent popularity of word embedding methods, there is only a small body of work exploring the limitations of these representations. In this paper, we consider one aspect of embedding spaces, namely their stability. We show that even relatively high frequency words (100-200 occurrences) are often unstable. We provide empirical evidence for how various factors contribute to the stability of word embeddings, and we analyze the effects of stability on downstream tasks.

1 Introduction

Word embeddings are low-dimensional, dense vector representations that capture semantic properties of words. Recently, they have gained tremendous popularity in Natural Language Processing (NLP) and have been used in tasks as diverse as text similarity (Kenter and De Rijke, 2015), part-of-speech tagging (Tsvetkov et al., 2016), sentiment analysis (Faruqui et al., 2015), and machine translation (Mikolov et al., 2013a). Although word embeddings are widely used across NLP, their stability has not yet been fully evaluated and understood. In this paper, we explore the factors that play a role in the stability of word embeddings, including properties of the data, properties of the algorithm, and properties of the words. We find that word embeddings exhibit substantial instabilities, which can have implications for downstream tasks.

Using the overlap between nearest neighbors in an embedding space as a measure of stability (see section 3 below for more information), we observe that many common embedding spaces have large amounts of instability. For example, Figure 1 shows the instability of the embeddings obtained by training *word2vec* on the Penn Treebank (PTB) (Marcus et al., 1993). As expected, lower frequency words have lower stability and higher frequency words have higher stability. What is surprising however about this graph is the medium-frequency words, which show huge variance in stability. This cannot be explained by frequency, so there must be other factors contributing to their instability.

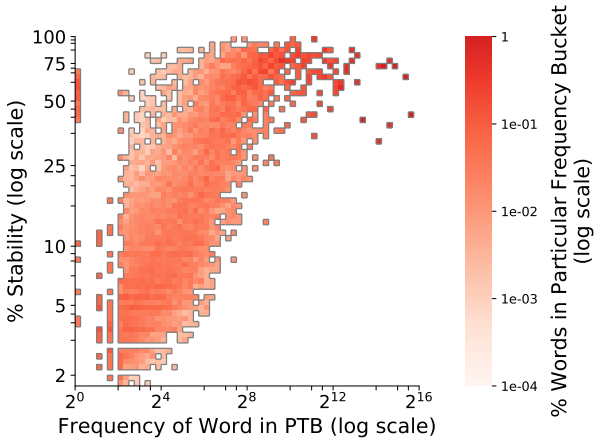

Figure 1: Stability of *word2vec* as a property of frequency in the PTB. Stability is measured across ten randomized embedding spaces trained on the training portion of the PTB (determined using language modeling splits (Mikolov et al., 2010)). Each word is placed in a frequency bucket (x-axis), and each column (frequency bucket) is normalized.

In the following experiments, we explore which factors affect stability, as well as how this stability affects downstream tasks that word embeddings are commonly used for. To our knowledge, this is the first study comprehensively examining the factors behind instability.

2 Related Work

There has been much recent interest in the applications of word embeddings, as well as a small, but growing, amount of work analyzing the properties of word embeddings.

Here, we explore three different embedding methods: PPMI (Bullinaria and Levy, 2007),

Proceedings of NAACL-HLT 2018, pages 2092–2102
New Orleans, Louisiana, June 1 - 6, 2018.

word2vec (Mikolov et al., 2013b), and GloVe (Pennington et al., 2014). Various aspects of the embedding spaces produced by these algorithms have been previously studied. Particularly, the effect of parameter choices has a large impact on how all three of these algorithms behave (Levy et al., 2015). Further work shows that the parameters of the embedding algorithm *word2vec* influence the geometry of word vectors and their context vectors (Mimno and Thompson, 2017). These parameters can be optimized; Hellrich and Hahn (2016) posit optimal parameters for negative sampling and the number of epochs to train for. They also demonstrate that in addition to parameter settings, word properties, such as word ambiguity, affect embedding quality.

In addition to exploring word and algorithmic parameters, concurrent work by Antoniak and Mimno (2018) evaluates how document properties affect the stability of word embeddings. We also explore the stability of embeddings, but focus on a broader range of factors, and consider the effect of stability on downstream tasks. In contrast, Antoniak and Mimno focus on using word embeddings to analyze language (e.g., Garg et al., 2018), rather than to perform tasks.

At a higher level of granularity, Tan et al. (2015) analyze word embedding spaces by comparing two spaces. They do this by linearly transforming one space into another space, and they show that words have different usage properties in different domains (in their case, Twitter and Wikipedia).

Finally, embeddings can be analyzed using second-order properties of embeddings (e.g., how a word relates to the words around it). Newman-Griffis and Fosler-Lussier (2017) validate the usefulness of second-order properties, by demonstrating that embeddings based on second-order properties perform as well as the typical first-order embeddings. Here, we use second-order properties of embeddings to quantify stability.

3 Defining Stability

We define *stability* as the percent overlap between nearest neighbors in an embedding space.[1] Given a word W and two embedding spaces A and B, take the ten nearest neighbors of W in both A and B. Let the stability of W be the percent overlap between these two lists of nearest neighbors. 100% stability indicates perfect agreement between the two embedding spaces, while 0% stability indicates complete disagreement. In order to find the ten nearest neighbors of a word W in an embedding space A, we measure distance between words using cosine similarity.[2] This definition of stability can be generalized to more than two embedding spaces by considering the average overlap between two sets of embedding spaces. Let X and Y be two sets of embedding spaces. Then, for every pair of embedding spaces (x, y), where $x \in X$ and $y \in Y$, take the ten nearest neighbors of W in both x and y and calculate percent overlap. Let the stability be the average percent overlap over every pair of embedding spaces (x, y).

Table 1: Top ten most similar words for the word *international* in three randomly intialized *word2vec* models trained on the NYT Arts Domain. Words in all three lists are in bold; words in only two of the lists are italicized.

Consider an example using this metric. Table 1 shows the top ten nearest neighbors for the word *international* in three randomly initialized *word2vec* embedding spaces trained on the NYT Arts domain (see Section 4.3 for a description of this corpus). These models share some similar words, such as *metropolitan* and *national*, but there are also many differences. On average, each pair of models has four out of ten words in common, so the stability of *international* across these three models is 40%.

The idea of evaluating ten best options is also found in other tasks, like lexical substitution (e.g., McCarthy and Navigli, 2007) and word associa-

[1] This metric is concurrently explored in work by Antoniak and Mimno (2018).

[2] We found comparable results for other distance metrics, such as l^1 norm, l^2 norm, and l^∞ norm, but we report results from cosine similarity to be consistent with other word embedding research.

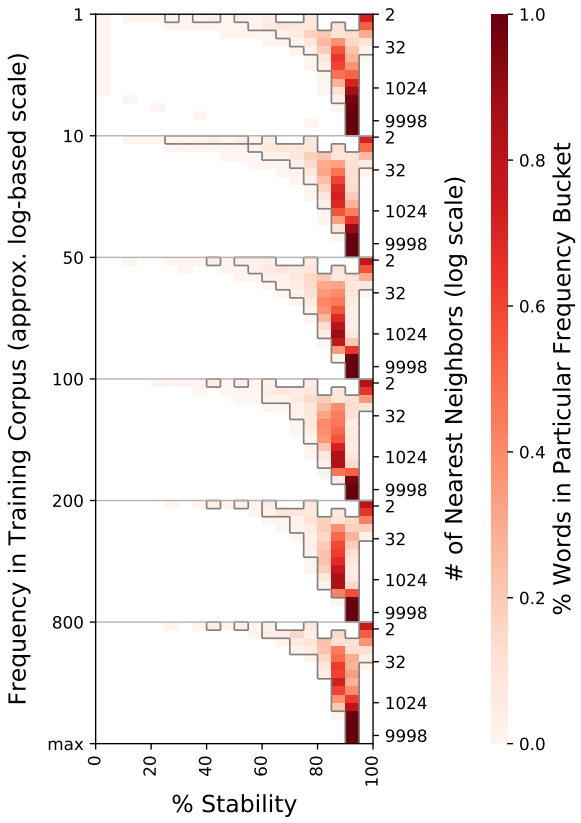

Figure 2: Stability of GloVe on the PTB. Stability is measured across ten randomized embedding spaces trained on the training data of the PTB (determined using language modeling splits (Mikolov et al., 2010)). Each word is placed in a frequency bucket (left y-axis) and stability is determined using a varying number of nearest neighbors for each frequency bucket (right y-axis). Each row is normalized, and boxes with more than 0.01 of the row's mass are outlined.

tion (e.g., Garimella et al., 2017), where the top ten results are considered in the final evaluation metric. To give some intuition for how changing the number of nearest neighbors affects our stability metric, consider Figure 2. This graph shows how the stability of GloVe changes with the frequency of the word and the number of neighbors used to calculate stability; please see the figure caption for a more detailed explanation of how this graph is structured. Within each frequency bucket, the stability is consistent across varying numbers of neighbors. Ten nearest neighbors performs approximately as well as a higher number of nearest neighbors (e.g., 100). We see this pattern for low frequency words as well as for high frequency words. Because the performance does not change substantially by increasing the number of nearest neighbors, it is computationally less intensive to use a small number of nearest neighbors. We choose ten nearest neighbors as our metric throughout the rest of the paper.

4 Factors Influencing Stability

As we saw in Figure 1, embeddings are sometimes surprisingly unstable. To understand the factors behind the (in)stability of word embeddings, we build a regression model that aims to predict the stability of a word given: (1) properties related to the word itself; (2) properties of the data used to train the embeddings; and (3) properties of the algorithm used to construct these embeddings. Using this regression model, we draw observations about factors that play a role in the stability of word embeddings.

4.1 Methodology

We use ridge regression to model these various factors (Hoerl and Kennard, 1970). Ridge regression regularizes the magnitude of the model weights, producing a more interpretable model than non-regularized linear regression. This regularization mitigates the effects of multicollinearity (when two features are highly correlated). Specifically, given N ground-truth data points with M extracted features per data point, let $\mathbf{x}_n \in \mathbb{R}^{1\times M}$ be the features for sample n and let $\mathbf{y} \in \mathbb{R}^{1\times N}$ be the set of labels. Then, ridge regression learns a set of weights $\mathbf{w} \in \mathbb{R}^{1\times M}$ by minimizing the least squares function with l^2 regularization, where λ is a regularization constant:

$$L(\mathbf{w}) = \frac{1}{2}\sum_{n=1}^{N}(\mathbf{y}_n - \mathbf{w}^\top \mathbf{x}_n)^2 + \frac{\lambda}{2}||\mathbf{w}||^2$$

We set $\lambda = 1$. In addition to ridge regression, we tried non-regularized linear regression. We obtained comparable results, but many of the weights were very large or very small, making them hard to interpret.

The goodness of fit of a regression model is measured using the coefficient of determination R^2. This measures how much variance in the dependent variable $\mathbf{y}$ is captured by the independent variables $\mathbf{x}$. A model that always predicts the expected value of $\mathbf{y}$, regardless of the input features, will receive an R^2 score of 0. The highest possible R^2 score is 1, and the R^2 score can be negative.

Given this model, we create training instances by observing the stability of a large number of

words across various combinations of two embedding spaces. Specifically, given a word W and two embedding spaces A and B, we encode properties of the *word* W, as well as properties of the *datasets* and the *algorithms* used to train the embedding spaces A and B. The target value associated with this features is the stability of the word W across embedding spaces A and B. We repeat this process for more than 2,500 words, several datasets, and three embedding algorithms.

Specifically, we consider all the words present in all seven of the data domains we are using (see Section 4.3), 2,521 words in total. Using the feature categories described below, we generate a feature vector for each unique word, dataset, algorithm, and dimension size, resulting in a total of 27,794,025 training instances. To get good average estimates for each embedding algorithm, we train each embedding space five times, randomized differently each time (this does not apply to PPMI, which has no random component). We then train a ridge regression model on these instances. The model is trained to predict the stability of word W across embedding spaces A and B (where A and B are not necessarily trained using the same algorithm, parameters, or training data). Because we are using this model to learn associations between certain features and stability, no test data is necessary. The emphasis is on the model itself, not on the model's performance on a specific task.

We describe next each of the three main categories of factors examined in the model. An example of these features is given in Table 2.

Table 2: Consider the word *international* in two embedding spaces. Suppose embedding space A is trained using *word2vec* (embedding dimension 100) on the NYT Arts domain, and embedding space B is trained using PPMI (embedding dimension 100) on Europarl. This table summarizes the resulting features for this word across the two embedding spaces.

4.2 Word Properties

We encode several features that capture attributes of the word W. First, we use the primary and secondary part-of-speech (POS) of the word. Both of these are represented as bags-of-words of all possible POS, and are determined by looking at the primary (most frequent) and secondary (second most frequent) POS of the word in the Brown corpus[3] (Francis and Kucera, 1979). If the word is not present in the Brown corpus, then all of these POS features are set to zero.

To get a coarse-grained representation of the polysemy of the word, we consider the number of different POS present. For a finer-grained representation, we use the number of different WordNet senses associated with the word (Miller, 1995; Fellbaum, 1998).

We also consider the number of syllables in a word, determined using the CMU Pronuncing Dictionary (Weide, 1998). If the word is not present in the dictionary, then this is set to zero.

4.3 Data Properties

Data features capture properties of the training data (and the word in relation to the training data). For this model, we gather data from two sources: New York Times (NYT) (Sandhaus, 2008) and Europarl (Koehn, 2005). Overall, we consider seven domains of data: (1) NYT - U.S., (2) NYT - New York and Region, (3) NYT - Business, (4) NYT - Arts, (5) NYT - Sports, (6) All of the data from

[3]Here, we use the universal tagset, which consists of twelve possible POS: adjective, adposition, adverb, conjunction, determiner / article, noun, numeral, particle, pronoun, verb, punctuation mark, and other (Petrov et al., 2012).

Dataset	Sentences	Vocab. Size	Num. Tokens / Vocab. Size
NYT US	13,923	5,787	64.37
NYT NY	36,792	11,182	80.41
NYT Business	21,048	7,212	75.96
NYT Arts	28,161	10,508	65.29
NYT Sports	21,610	5,967	77.85
All NYT	121,534	24,144	117.98
Europarl	2,297,621	43,888	1,394.28

Table 3: Dataset statistics.

domains 1-5 (denoted "All NYT"), and (7) All of English Europarl. Table 3 shows statistics about these datasets. The first five domains are chosen because they are the top five most common categories of news articles present in the NYT corpus. They are smaller than "All NYT" and Europarl, and they have a narrow topical focus. The "All NYT" domain is more diverse topically and larger than the first five domains. Finally, the Europarl domain is the largest domain, and it is focused on a single topic (European Parliamentary politics). These varying datasets allow us to consider how data-dependent properties affect stability.

We use several features related to domain. First, we consider the raw frequency of word W in both the domain of data used for embedding space A and the domain of data for space B. To make our regression model symmetric, we effectively encode three features: the higher raw frequency (between the two), the lower raw frequency, and the absolute difference in raw frequency.

We also consider the vocabulary size of each corpus (again, symmetrically) and the percent overlap between corpora vocabulary, as well as the domain of each of the two corpora, represented as a bag-of-words of domains. Finally, we consider whether the two corpora are from the same domain.

Our final data-level features explore the role of curriculum learning in stability. It has been posited that the order of the training data affects the performance of certain algorithms, and previous work has shown that for some neural network-based tasks, a good training data order (curriculum learning strategy) can improve performance (Bengio et al., 2009). Curriculum learning has been previously explored for *word2vec*, where it has been found that optimizing training data order can lead to small improvements on common NLP tasks (Tsvetkov et al., 2016). Of the embedding algorithms we consider, curriculum learning only affects *word2vec*. Because GloVe and PPMI use the data to learn a complete matrix before building embeddings, the order of the training data will not affect their performance. To measure the effects of training data order, we include as features the first appearance of word W in the dataset for embedding space A and the first appearance of W in the dataset for embedding space B (represented as percentages of the total number of training sentences)[4]. We further include the absolute difference between these percentages.

4.4 Algorithm Properties

In addition to word and data properties, we encode features about the embedding algorithms. These include the different algorithms being used, as well as the different parameter settings of these algorithms. Here, we consider three embedding algorithms, *word2vec*, GloVe, and PPMI. The choice of algorithm is represented in our feature vector as a bag-of-words.

PPMI creates embeddings by first building a positive pointwise mutual information word-context matrix, and then reducing the dimensionality of this matrix using SVD (Bullinaria and Levy, 2007). A more recent word embedding algorithm, *word2vec* (skip-gram model) (Mikolov et al., 2013b) uses a shallow neural network to learn word embeddings by predicting context words. Another recent method for creating word embeddings, GloVe, is based on factoring a matrix of ratios of co-occurrence probabilities (Pennington et al., 2014).

For each algorithm, we choose common parameter settings. For *word2vec*, two of the parameters that need to be chosen are window size and minimum count. Window size refers to the maximum distance between the current word and the predicted word (e.g., how many neighboring words to consider for each target word). Any word appearing less than the minimum count number of times in the corpus is discarded and not considered in the *word2vec* algorithm. For both of these features, we choose standard parameter settings, namely, a window size of 5 and a minimum count of 5. For GloVe, we also choose standard parameters. We

[4] All *word2vec* experiments reported here are run in a multi-core setting, which means that these percentages are approximate. However, comparable results were achieved using a single-core version of *word2vec*.

Feature	Weight

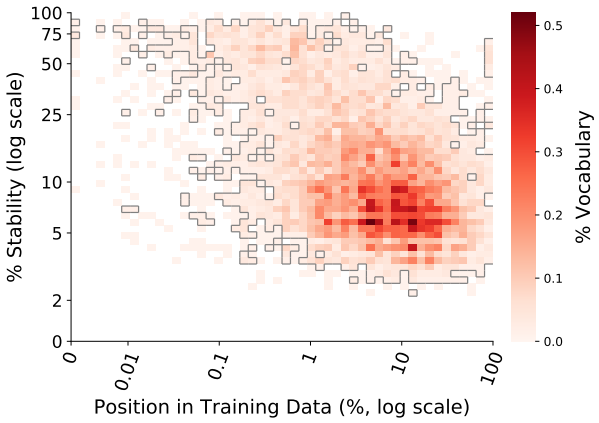
use 50 iterations of the algorithm for embedding dimensions less than 300, and 100 iterations for higher dimensions.

We also add a feature reflecting the embedding dimension, namely one of five embedding dimensions: 50, 100, 200, 400, or 800.

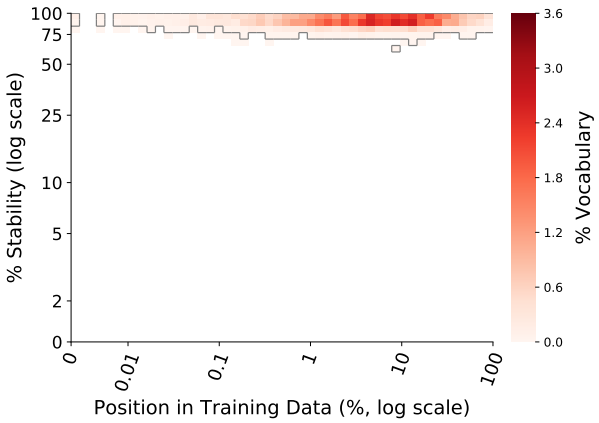
5 Lessons Learned: What Contributes to the Stability of an Embedding

Overall, the regression model achieves a coefficient of determination (R^2) score of 0.301 on the training data, which indicates that the regression has learned a linear model that reasonably fits the training data given. Using the regression model, we can analyze the weights corresponding to each of the features being considered, shown in Table 4. These weights are difficult to interpret, because features have different distributions and ranges. However, we make several general observations about the stability of word embeddings.

Observation 1. Curriculum learning is important. This is evident because the top two features (by magnitude) of the regression model capture where the word first appears in the training data. Figure 3 shows trends between training data position and stability in the PTB. This figure contrasts *word2vec* with GloVe (which is order invariant).



(a) *word2vec*



(b) GloVe

Figure 3: Stability of both *word2vec* and GloVe as properties of the starting word position in the training data of the PTB. Stability is measured across ten randomized embedding spaces trained on the training data of the PTB (determined using language modeling splits (Mikolov et al., 2010)). Boxes with more than 0.02% of the total vocabulary mass are outlined.

To further understand the effect of curriculum learning on the model, we train a regression model with all of the features except the curriculum learning features. This model achieves an R^2 score of 0.291 (compared to the full model's score of 0.301). This indicates that curriculum learning is a factor in stability.

Observation 2. POS is one of the biggest factors in stability. Table 4 shows that many of the top weights belong to POS-related features (both primary and secondary POS). Table 5 compares aver-

Primary POS	Avg. Stability
Numeral	47%
Verb	31%
Determiner	31%
Adjective	31%
Noun	30%
Adverb	29%
Pronoun	29%
Conjunction	28%
Particle	26%
Adposition	25%
Punctuation mark	22%

Table 5: Percent stability broken down by part-of-speech, ordered by decreasing stability.

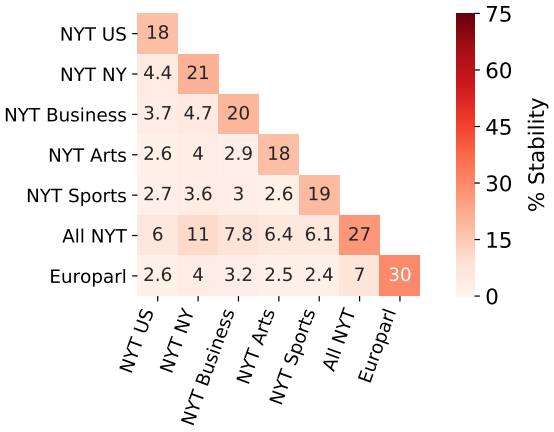


Figure 4: Percent stability broken down by domain.

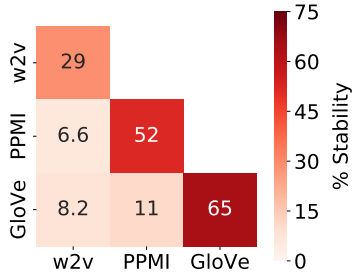

Figure 5: Percent stability broken down between algorithm (in-domain data only).

age stabilities for each primary POS. Here we see that the most stable POS are numerals, verbs, and determiners, while the least stable POS are punctuation marks, adpositions, and particles.

Observation 3. Stability within domains is greater than stability across domains. Table 4 shows that many of the top factors are domain-related. Figure 4 shows the results of the regression model broken down by domain. This figure shows the highest stabilities appearing on the diagonal of the matrix, where the two embedding spaces both belong to the same domain. The stabilities are substantially lower off the diagonal.

Figure 4 also shows that "All NYT" generalizes across the other NYT domains better than Europarl, but not as well as in-domain data ("All NYT" encompasses data from US, NY, Business, Arts, and Sports). This is true even though Europarl is much larger than "All NYT".

Observation 4. Overall, GloVe is the most stable embedding algorithm. This is particularly apparent when only in-domain data is considered, as in Figure 5. PPMI achieves similar stability, while *word2vec* lags considerably behind.

To further compare *word2vec* and GloVe, we look at how the stability of *word2vec* changes with the frequency of the word and the number of neighbors used to calculate stability. This is shown in Figure 6 and is directly comparable to Figure 2. Surprisingly, the stability of *word2vec* varies substantially with the frequency of the word. For lower-frequency words, as the number of nearest neighbors increases, the stability increases approximately exponentially. For high-frequency words, the lowest and highest number of nearest neighbors show the greatest stability. This is different than GloVe, where stability remains reasonably constant across word frequencies, as shown in Figure 2. The behavior we see here agrees with the conclusion of (Mimno and Thompson, 2017), who find that GloVe exhibits more well-behaved geometry than *word2vec*.

Observation 5. Frequency is not a major factor in stability. To better understand the role that frequency plays in stability, we run separate ablation experiments comparing regression models with frequency features to regression models without frequency features. Our current model (using raw frequency) achieves an R^2 score of 0.301. Comparably, a model using the same features, but with normalized instead of raw frequency, achieves a score of 0.303. Removing frequency from either regression model gives a score of 0.301. This indicates that frequency is not a major factor in stability, though normalized frequency is a larger factor than raw frequency.

Finally, we look at regression models using only frequency features. A model using only raw frequency features has an R^2 score of 0.008, while

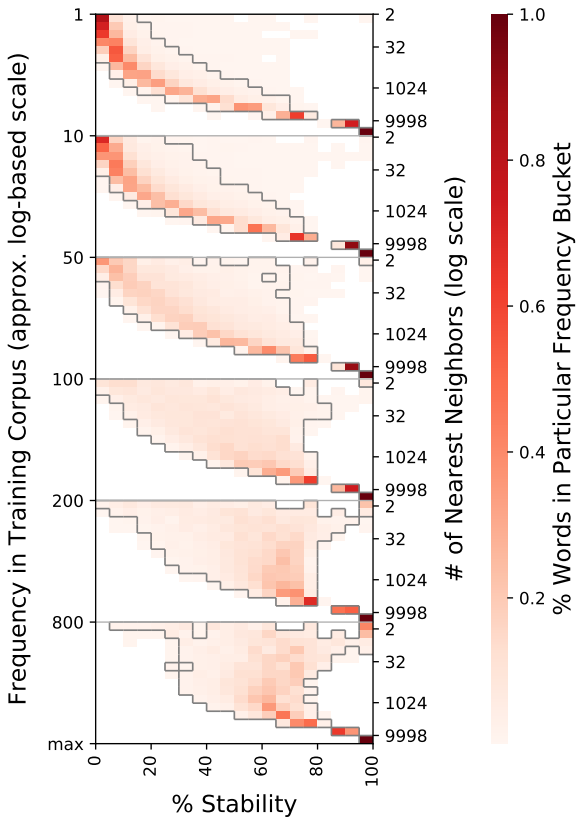

Figure 6: Stability of *word2vec* on the PTB. Stability is measured across ten randomized embedding spaces trained on the training data of the PTB (determined using language modeling splits (Mikolov et al., 2010)). Each word is placed in a frequency bucket (left y-axis) and stability is determined using a varying number of nearest neighbors for each frequency bucket (right y-axis). Each row is normalized, and boxes with more than 0.01 of the row's mass are outlined.

a model with only normalized frequency features has an R^2 score of 0.0059. This indicates that while frequency is not a major factor in stability, it is also not negligible. As we pointed out in the introduction, frequency does correlate with stability (Figure 1). However, in the presence of all of these other features, frequency becomes a minor factor.

6 Impact of Stability on Downstream Tasks

Word embeddings are used extensively as the first stage of neural networks throughout NLP. Typically, embeddings are initalized based on a vector trained with *word2vec* or GloVe and then further modified as part of training for the target task. We study two downstream tasks to see whether stability impacts performance.

Since we are interested in seeing the impact of

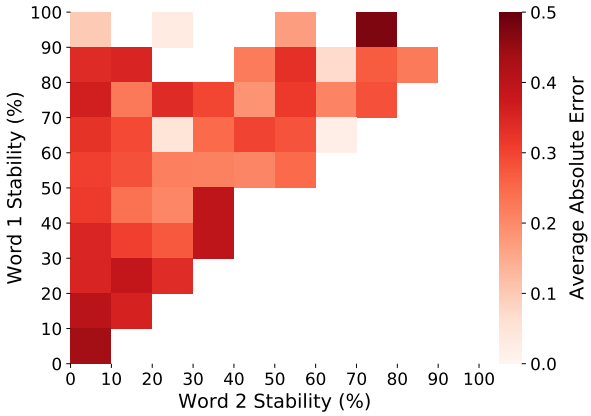

Figure 7: Absolute error for word similarity.

word vector stability, we choose tasks that have an intuitive evaluation at the word level: word similarity and POS tagging.

6.1 Word Similarity

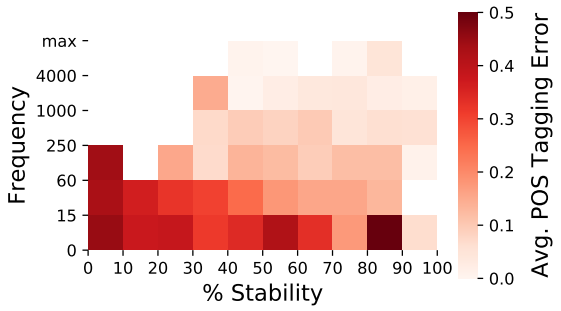
To model word similarity, we use 300-dimensional *word2vec* embedding spaces trained on the PTB. For each pair of words, we take the cosine similarity between those words averaged over ten randomly initialized embedding spaces.

We consider three datasets for evaluating word similarity: WS353 (353 pairs) (Finkelstein et al., 2001), MTurk287 (287 pairs) (Radinsky et al., 2011), and MTurk771 (771 pairs) (Halawi et al., 2012). For each dataset, we normalize the similarity to be in the range $[0, 1]$, and we take the absolute difference between our predicted value and the ground-truth value. Figure 7 shows the results broken down by stability of the two words (we always consider Word 1 to be the more stable word in the pair). Word similarity pairs where one of the words is not present in the PTB are omitted.

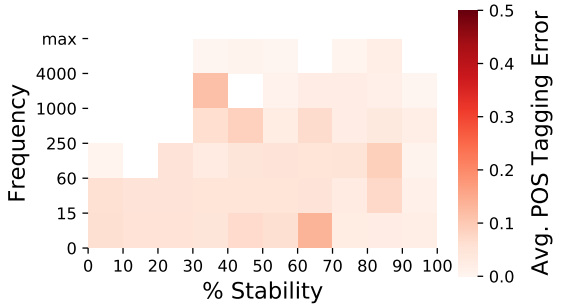
We find that these word similarity datasets do not contain a balanced distribution of words with respect to stability; there are substantially more unstable words than there are stable words. However, we still see a slight trend: As the combined stability of the two words increases, the average absolute error decreases, as reflected by the lighter color of the cells in Figure 7 while moving away from the (0,0) data point.

6.2 Part-of-Speech Tagging

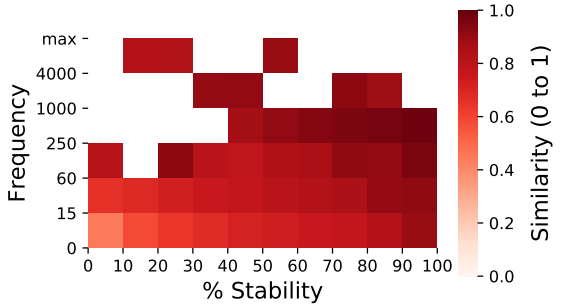
Part-of-speech (POS) tagging is a substantially more complicated task than word similarity. We use a bidirectional LSTM implemented using DyNet (Neubig et al., 2017). We train nine sets of



(a) POS error probability with fixed vectors.



(b) POS error probability when vectors may shift in training.



(c) Cosine similarity between original word vectors and shifted word vectors.

Figure 8: Results for POS tagging. (a) and (b) show average POS tagging error divided by the number of tokens (darker is more errors) while either keeping word vectors fixed or not during training. (c) shows word vector shift, measured as cosine similarity between initial and final vectors. In all graphs, words are bucketed by frequency and stability.

128-dimensional word embeddings with *word2vec* using different random seeds. The LSTM has a single layer and 50-dimensional hidden vectors. Outputs are passed through a *tanh* layer before classification. To train, we use SGD with a learning rate of 0.1, an input noise rate of 0.1, and recurrent dropout of 0.4.

This simple model is not state-of-the-art, scoring 95.5% on the development set, but the word vectors are a central part of the model, providing a clear signal of their impact. For each word, we group tokens based on stability and frequency. Figure 8 shows the results.[5] Fixing the word vectors provides a clearer pattern in the results, but also leads to much worse performance: 85.0% on the development set. Based on these results, it seems that training appears to compensate for stability. This hypothesis is supported by Figure 8c, which shows the similarity between the original word vectors and the shifted word vectors produced by the training. In general, lower stability words are shifted more during training.

Understanding how the LSTM is changing the input embeddings is useful information for tasks with limited data, and it could allow us to improve embeddings and LSTM training for these low-resource tasks.

7 Conclusion and Recommendations

Word embeddings are surprisingly variable, even for relatively high frequency words. Using a regression model, we show that domain and part-of-speech are key factors of instability. Downstream experiments show that stability impacts tasks using embedding-based features, though allowing embeddings to shift during training can reduce this effect. In order to use the most stable embedding spaces for future tasks, we recommend either using GloVe or learning a good curriculum for *word2vec* training data. We also recommend using in-domain embeddings whenever possible.

The code used in the experiments described in this paper is publicly available from `http://lit.eecs.umich.edu/downloads.html`.

Acknowledgments

We would like to thank Ben King and David Jurgens for helpful discussions about this paper, as well as our anonymous reviewers for useful feedback. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the NSF or MIDAS.

[5] The unusual dark spot that occurs at medium-high stability and low frequency is caused primarily by words that have a substantially different POS distribution in the test data than in the training data.

{qi_liu, yue_zhang}@sutd.edu.sg

Abstract

We investigate the task of mining relevant stocks given a topic of concern on emerging capital markets, for which there is lack of structural understanding. Deep learning is leveraged to mine evidences from large scale textual data, which contain valuable market information. In particular, distributed word similarities trained over large scale raw texts are taken as a basis of relevance measuring, and deep reinforcement learning is leveraged to learn a strategy of topic expansion, given a small amount of manually labeled data from financial analysts. Results on two Chinese stock market datasets show that our method outperforms a strong baseline using information retrieval techniques.

1 Introduction

Stock prices are affected by events. For example, recent announcement of a state plan to build a new economic region, Xiong'an near Beijing, by the Chinese government has led to the rise of hundreds of stocks, which can directly or indirectly benefit from the plan. As a second example, the winning of a lawsuit against IP (Intellectual Property) breach can strengthen investors' confidence on technological and entertainment companies. We refer to the topics or themes of such events (e.g. Xiong'an and IP) as *concepts* and their relevant stocks as *concept stocks*. Given a news event, it can be highly useful for investors to find a list of relevant concept stocks for making investment decisions.

For popular concepts, lists of relevant concept stocks can be found from analyst reports from financial websites. On the other hand, concepts are dynamic and flexible. In addition, insights can be relatively scarce for emerging capital markets, such as the Chinese market, which had been closed to foreign investments before 2015. It is therefore a challenging research question how to automatically find out potentially relevant stocks given a topic of interest, from a large market of multi-thousand equities.

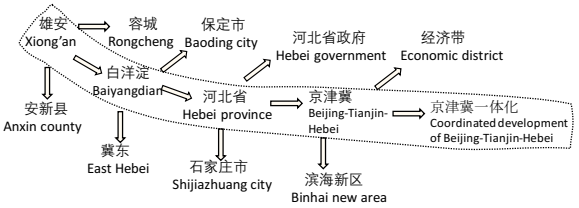

Figure 1: Concept relatedness. $A \Rightarrow B$ indicates that B is one of the 3 most related concepts to A.

Intuitively, evidences between concepts and stocks exist in text documents over the Internet. For example, news articles report events and companies involved. In addition, company filings such as annual/quarter reports contain factual knowledge about stocks, which can also be useful background information. For example, knowing that a company invests heavily on research is useful for correlating the company with IP-protection laws. Such evidence-mining process can involve multiple steps. As shown in Figure 1, starting from concept, Xiong'an, one might learn that the new economical region is located in the Baiyangdian area, which is further located in Hebei province. By further reading, one can infer that the new economic region is related with the coordinated development plan for the Beijing-Tianjin-Hebei region, and therefore benefit a wider range of stocks.

Based on the intuition above, we build a neural model for mining evidences for concept stock recommendation. The basis of our model is distributed similarities between concepts and stocks, obtained from embeddings trained over large-scale raw documents. Embedding similarities encode correlations from direct narrative evidence within context windows. To further include a multi-step

Proceedings of NAACL-HLT 2018, pages 2103–2112
New Orleans, Louisiana, June 1 - 6, 2018.

evidence mining, we build an iterative model for *concept expansion*, augmenting a given concept by iteratively adding more relevant concepts from background documents. As demonstrated in Figure 1, this process can be ambiguous, since there can be multiple directions for further reading given a set of concepts. We leverage a small amount of manually labeled data, downloaded from financial analysis websites, for guiding evidence mining.

In particular, we take a reinforcement learning method, which regards the evidence mining process as a decision process. The starting point is a given input concept, such as Xiong'an or Electronic Vehicle. At each step, a decision is made to stop further reading, or to continue adding related concepts to the set of concepts being considered. Existing concepts can also be removed from further consideration. Documents that discuss each concept are used to support the decision. After the process stops, relevant stocks to the set of concepts are recommended. The decision process is guided using a neural network model structure, trained with a loss function over the quality of the finally recommended stocks.

Results on two Chinese datasets show that our method outperforms a strong ranking-based baseline, which utilizes only direct evidences. Our method can be easily adapted for other markets given the availability of a small amount of training data. Our code is released[1].

2 Related Work

Our work is related to information retrieval and query expansion, where a concept can be regarded as a query and relevant stocks can be regarded as retrieved results. We rely on external evidence for correlating concepts and stocks.

Ranking is an important problem in information retrieval. We focus on ranking using neural models here. One line of work (Shen et al., 2014a,b) models queries and documents using convolutional neural network and ranks the documents pair-wise or list-wise. Another related method (Cao et al., 2015) adopts recursive neural networks to rank sentences for multi-document summarization. These methods requires massive annotated data, which is expensive to obtain for concept stock recommendation.

Query Expansion: One line of work (Cao et al., 2008; Preston and Colman, 2000) utilizes a feedback-based relevance model to expand queries. Another line applies language modeling to estimate conditional probabilities of concepts given a query, and expands the query with the most probable concepts (Bai et al., 2005; Carpineto and Romano, 2012). Recently, word embeddings are adopted for query expansion (Kuzi et al., 2016; Diaz et al., 2016). Our framework belongs to this line of work with a difference that we use reinforcement learning to dynamically expand queries instead of following handcrafted rules such as using k-nearest neighbors.

Reinforcement Learning: Our work aligns with existing work using reinforcement learning to collect evidences. Narasimhan et al. (2016) utilize external evidence to improve information extraction. While the work requires handcrafted features, our model uses dense embedding features. Athukorala et al. (2016) devise an interactive search engine balancing exploration and exploitation. Their work relies on user interaction to make decisions. In contrast, our work does not rely on active feedback, which can be expensive to obtain under our settings. Rodrigo and Cho (2017) introduce a query reformulation system based on reinforcement learning that rewrites a long and complex query to maximize the number of relevant documents returned. Differently, we do not assume complex queries and focus on recommending relevant stocks in our system. Zhong et al. (2017) solves a different problem, i.e. translating natural language questions to corresponding SQL queries.

3 Problem Definition

Our task is to find stocks relevant to a concept according to a variety of data sources, such as news, tweets and company files. Formally, given a concept c, a set of m stocks $\{o_i\}_{i=1}^{m}$ and n data sources $\{S_i\}_{i=1}^{n}$, where each S_i is a set of documents $\{D_j^i\}_{j=1}^{|S_i|}$ and each D_j^i is a sequence of words $w_1, w_2 ... w_{|D_j^i|}$, we assume the relevant stocks of the concept are revealed in the data sources (e.g. we discover PetroChina as a concept stock of 'petroleum' from the document 'PetroChina acquires Keppel's entire stake in Singapore Petroleum') and the task is to automatically discover these relations and select a subset of stocks as c's concept stocks based on the data sources $\{S_i\}_{i=1}^{n}$.

(a) Ranking Baseline (b) Reinforcement Learning for Query Expansion

Figure 2: Concept Stock Recommendation Models

4 Representation

Motivated by the success of embedding-based models (Mikolov et al., 2013; Pennington et al., 2014) in capturing semantic regularities, we use embeddings to represent concepts, stocks and documents.

In particular, we adopt Chinese word segmentation (Yang et al., 2017) to obtain words from documents. Doc2Vec (Le and Mikolov, 2014) is then used on the documents of each data source S_i to obtain a local word embedding matrix E^i and a local document embedding matrix F^i, where each column of E^i (F^i) corresponds to a word (document) vector representation of S_i. In particular, we use embeddings, E^i_c and E^i_o as the local concept representation of c and the local stock representation of o in data source S_i, respectively. Furthermore, we obtain a global word embedding matrix E by averaging the local embedding matrices, $E^1 ... E^n$, where E_c and E_o are regarded as the global concept representation of c and the global stock representation of o, respectively.

We propose a ranking baseline and a reinforcement learning model for query expansion based on these representations.

5 Ranking Baseline

Inspired by Shen et al. (2014a; 2014b), our ranking baseline discriminatively projects the representations of concepts and evidences of stocks into a semantic space for measuring their relevances.

Mining Evidences: Formally, given a concept c and a stock o, we consult the data sources, retrieving the set of documents $\{D^i_{c,o}\}$ most relevant to (c, o) from each data source S_i as evidences.

To obtain evidences, we use c's local embedding E^i_c and o's local embedding E^i_o for representing the stock-concept pair (c, o). Cosine similarities are calculated between $E^i_c + E^i_o$ and each column of F^i for measuring the semantic relatedness of each document to (c, o). Suppose that the columns are normalized, the scores are calculated as:

$$score(\{D^i_j\}_{j=1}^{|S_i|}) = (F^i)^T(E^i_c + E^i_o) \quad (1)$$

q (q is set as 5 empirically) documents $\{D^i_{c,o}\}$ with the maximum scores are selected as evidences from each S_i. When $|F^i|$ is large, we use approximate k-nearest-neighbor algorithms, namely Locality Sensitive Hashing (Datar et al., 2004), to improve efficiency.

Learning to Rank o Given c: The overall framework for measuring relevances is shown in Figure 2 (a). Given a concept c and stock o, for each data source S_i, the local stock representation E^i_o and the local document representations of the q most relevant documents, denoted as $\{F^i_{c,o}\}$, are sequentially fed into Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to acquire a semantic representation of the evidences.

A bidirectional extension (Graves and Schmidhuber, 2005) is applied to capture semantics both left-to-right and right-to-left. As a result, two sequences of hidden states are obtained, i.e. $\overrightarrow{h}_1, \overrightarrow{h}_2 ... \overrightarrow{h}_{q+1}$ and $\overleftarrow{h}_1, \overleftarrow{h}_2 ... \overleftarrow{h}_{q+1}$. We concatenate $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ at each time step to obtain the final hidden states $h_1, h_2 ... h_{q+1}$.

Average pooling (Boureau et al., 2010) is applied on the hidden states $h_1, h_2 ... h_{q+1}$ to obtain

evidence representation $I^i_{c,o}$,

$$I^i_{c,o} = \frac{\sum_{t=1}^{q+1} h_t}{q+1} \quad (2)$$

We concatenate all $I^i_{c,o}$ with the global concept representation of c (i.e. the average of local representations, $E^1_c ... E^n_c$) and feed the result to a softmax layer to obtain the probability of a stock o being c's concept stock, denoted as $p(o|c)$. Given a concept c, all stocks are ranked by the probabilities.

Given a set of gold-standard concept stock data, supervised learning is conducted to learn $p(o|c)$. The loss function is defined as:

$$E_{(c,o,y)}[-log\, p(o|c)^y - log\, (1-p(o|c))^{(1-y)}] \quad (3)$$

Here y is 1 when o is a concept stock of c, and 0 otherwise. Equation 3 maximizes $p(o|c)$ $(1 - p(o|c))$ when $y = 1$ $(y = 0)$. AdaGrad (Duchi et al., 2011) is applied to update parameters.

6 Recommendation via Query Expansion

The ranking baseline can require large amounts of annotated data to deliver satisfying performance (Shen et al., 2014a,b), which can be costly. In addition, the algorithm has to deal with highly imbalanced datasets, since there are thousands of stocks in a stock market, but only a few are related to a concept c, which greatly harms the performance of discriminatively trained algorithms (Wu and Chang, 2003).

We take a different approach, utilizing the same data sources and representations as the ranking baseline. To better leverage a small amount of supervision data, we apply reinforcement learning to expand the query concept c, consulting supporting evidences from the data sources $\{S_i\}_{i=1}^m$. We leverage embedding similarities as a basis for concept-stock relatedness. The advantage is that embeddings can be trained over large scale raw texts unsupervisedly, without the need for manually labeled stock lists.

6.1 Direct Semantic Relatedness

Embeddings represent similarities between concepts and stocks if they co-exist literally in a context window during embedding training. As a result, irrelevant (relevant) stocks are less (more) similar to the concept c, since they infrequently (frequently) co-occur, which alleviates the problem brought by imbalanced datasets in that irrelevant stocks can be spotted at ease.

Global representations of c and o is utilized to obtain a direct relevance score $\hat{f}(c, o)$:

$$\hat{f}(c, o) = E_c \cdot E_o, \quad (4)$$

where $\cdot$ denotes the dot product operation. The stocks are ranked by $\hat{f}(c, o)$ and concept stocks are these with the maximum cosine similarities.

6.2 Indirect Semantic Relatedness by Query Expansion

While $\hat{f}(c, o)$ measures direct relevance between c and o in embedding contexts, we want to find those o' that are indirectly relevant to c by reasoning as shown in Figure 1. Query expansion (Kuzi et al., 2016; Diaz et al., 2016) is used to this end. One naive baseline is expanding the concept c with its k-nearest-neighbor concepts, denoted as $[c_e]$, from global matrix E measured by cosine similarity. Relevance between the expanded concepts $[c, [c_e]]$ and o is calculated as:

$$\begin{aligned}\hat{f}([c, [c_e]], o) &= E_{[c,[c_e]]} \cdot E_o \\ &= (E_c + \sum_{c_e \in [c_e]} E_{c_e}) \cdot E_o \end{aligned} \quad (5)$$

We define $E_{[c,[c_e]]}$ as the addition of E_c and each E_{c_e}. The baseline is relatively inflexible since a fixed number of k expansion concepts are selected for all c. In contrast, the reasoning procedures shown in Figure 1 can take an arbitrary number of steps. Besides, the naive baseline does not incorporate supervision, thus being unable to decide whether the selected concepts are beneficial for concept stock recommendation.

We use reinforcement learning to tackle this issue, directly learning how to expand queries from a few labeled cases. Given c, our method works iteratively, expanding the concept until it expects further expansions are not desired. For each candidate concept to expand c, a decision is made by the model on whether it will improve, worsen or have no effect on recommendation accuracies.

Based on these, we model query expansion with a Markov Decision Process (MDP) to discriminatively select expansion concepts for c to maximize recommendation accuracies, while requiring much less training data compared to the ranking baseline.

The overall framework is shown in Figure 2 (b). Formally, a MDP is a list $[Z, A, T, R]$, where $Z = \{z\}$ is a set of states, $A = \{a\}$ is a set of actions, $T(z, a)$ is a transition function, which determines the next state $z' = T(z, a)$ after performing action a on z, and R is a reward function. We describe each in detail below:

States: Each state z is a list of lists:

$$z = [[c, [c_e]], [v^1, \{F^1_{context}\}]...[v^n, \{F^n_{context}\}]], \quad (6)$$

where $[c, [c_e]]$ consists of the input concept c and its expansion concept list $[c_e]$ so far. In the start state, $[c_e]$ is empty, and thus $[c, [c_e]] = [c, [\,]]$. $[v^i, \{F^i_{context}\}]$ consists of a new candidate concept v^i and its supporting evidences $\{F^i_{context}\}$. Since globally trained embeddings underperform locally trained embeddings (Diaz et al., 2016) for query expansion, we use local embeddings E^i to suggest candidate concepts v^i, instead of using global embedding E. v^i is obtained by finding the most similar concept of $[c, [c_e]]$ from local embeddings E^i. $\{F^i_{context}\}$ is the document representations of the q most relevant documents to $([c, [c_e]], v^i)$ as evidences. Formally, $\{F^i_{context}\}$ is the document representations of the q documents with the maximum scores, $score'(\{D^i_j\}^{|S_i|}_{j=1}) = (F^i)^T(E^i_{[c,[c_e]]} + E^i_{v^i})$. As a result, at each state, we have n candidate concepts $v^1...v^n$. The neural agent chooses at most one concept to be added to $[c_e]$ based on the evidences.

Action: The agent can take four types of actions. (1) Add one of n candidate concepts to $[c_e]$ (2) Reject all n candidate concepts. (3) Remove the last added concept from $[c_e]$ (4) Stop the process.

State Transition: After taking an action a on a state z, a new state z' is yielded by the transition function $T(z, a)$. If one of the candidate concepts v^i is chosen, v^i is added to $[c_e]$. In addition, the new state z' is obtained by updating $[v^1, \{F^1_{context}\}]...[v^n, \{F^n_{context}\}]$ by finding the most similar concepts of the new $[c, [c_e]']$ and their supporting evidences among the local embeddings. If action (2) is chosen, $[c, [c_e]]$ remains, while the $v^1...v^n$ is replaced with the second most similar concepts of $[c, [c_e]]$ among the local embeddings, and the process repeats until action (1), (3) or (4) is chosen. If (3) is chosen, the last added concept is removed from $[c_e]$, and $[v^1, \{F^1_{context}\}]...[v^n, \{F^n_{context}\}]$ are updated according to the new $[c, [c_e]']$. If (4) is chosen, the query expansion process finishes. The final $[c, [c_e]]$ is the result of query expansion.

Neural Agent: Given a state z, the neural agent chooses one action to take among the four types of actions. To this end, $[c, [c_e]]$ and each $[v^i, \{F^i_{context}\}]$ are fed into separate Bi-LSTM to obtain a concept representation and candidate concept representations, respectively. We further concatenate these representations and use a linear layer to obtain Q-values $Q(z, a; \theta)$ for each action a (Sutton and Barto, 1998). Note that we do not use softmax to normalize the Q-values since Q-value is the expectation of discounted sums of rewards by definition instead of probabilities. The action with the maximum Q-value is chosen.

Reward: A reward r is associated at each step specified by the reward function R, which evaluates the goodness of action a on state z. We use the difference of mean average precision (MAP) (Christopher et al., 2008) before and after an action a as the reward function:

$$R(z, a, z') = MAP(z') - MAP(z), \quad (7)$$

where MAP is defined as:

$$MAP(z) = \frac{1}{|\omega(c)|} \sum_{o \in \omega(c)} Precision@rank(o; z, E) \quad (8)$$

and

$$Precision@K = \frac{\sum_{o' \in \omega(c)} \mathbb{1}(rank(o'; z, E) \leq K)}{K} \quad (9)$$

$\omega(c)$ is the set of concept stocks of the concept c in training data. $rank(o; z, E)$ is the rank of the stock o, which is calculated by utilizing $[c, [c_e]]$ of z and global embedding E to rank all stocks using Equation 5. $\mathbb{1}$ is the indicator function. Therefore, MAP measures the goodness of the ranking, which is large if the stocks in $\omega(c)$ are ranked higher compared to the others. Reward r is positive if $[c, [c_e]']$ of z' can rank stocks better compared to $[c, [c_e]]$ of z and negative otherwise.

We choose MAP based on two reasons: (1) MAP provides a measure of quality, which has been shown to have good discrimination and stability. Besides, MAP is roughly the average area under the precision-recall curve for a set of queries (Christopher et al., 2008). Thus, optimizing MAP can indirectly improve both precision and recall. (2) MAP provides smoother scores than other metrics such as Precision@K and Recall@K.

In summary, at each step, the MDP framework chooses an action a based on a state z, obtaining a

new state z' and a reward r, which forms a sample, (z, a, z', r). The process repeats until action (4) is chosen.

6.3 Learning

We adopt Q-learning (Sutton and Barto, 1998) to optimize the neural agent, which uses a function $Q(z, a)$ to represent Q-values and the recursive Bellman equation to perform Q-value iteration, when observing a new sample (z, a, z', r). Since the state space Z can be extremely large in practice, we represent the Q-value function $Q(z, a)$ with a neural agent shown in Figure 2 (b) named the action network parametrized by θ (Mnih et al., 2015). The deep Q-learning method has the ability to capture nonlinear features and achieve better performance compared with traditional methods (Narasimhan et al., 2015). Formally,

$$Q(z, a) = Q(z, a; \theta) \tag{10}$$

To improve learning stability, sample reward estimates are obtained from a separate target network with the same architecture as the action network (Mnih et al., 2015), parametrized by θ_{target}. Formally, the sample reward estimate of (z, a, z', r) is:

$$y' = \begin{cases} r & if\ a = action(4) \\ r + \gamma \max_{a_{new} \in A} Q(z', a_{new}; \theta_{target}) & otherwise \end{cases} \tag{11}$$

Note that if the action (4) is taken, $y' = r$ since the process stops at state z and no further action will be taken so that the sum of rewards is r.

To learn the model parameters θ, the action network outputs $Q(z, a; \theta)$ should be close to sample estimates obtained from target network. Thus, we introduce an experience memory M to save history samples and select a mini-batch of samples according to a uniform distribution. We use the mean square error as the loss function:

$$E_{(z,a,z',r) \sim U(M)}[(Q(z, a; \theta) - y')^2] \tag{12}$$

The training phase is shown in Algorithm 1. In lines 8-12, we use ϵ-greedy exploration, which encourages the agent to explore unknown state space (Sutton and Barto, 1998).

7 Experiments

7.1 Datasets

We construct two datasets from the Chinese websites, Jinrongjie[2] and Tonghuashun[3], respectively, which are two mass medias for China stock markets. These two websites periodically publish their concept stock lists, which are manually collected and analyzed by their financial professionals. We observe high quote change correlations of the stocks of each concept c and their lists are commonly used by investors to select stocks, which confirms the credibility of these datasets. The Jinrongjie dataset consists of 206 concepts and each concept has an average of 25.4 manually suggested concept stocks. For the Tonghuashun dataset, there are 900 concepts and 15.6 manually suggested concept stocks on average.

There are two main stock exchanges in China, the Shanghai Stock Exchange[4] and the Shenzhen Stock Exchange[5]. We crawled stock lists from their official websites, with 3326 stocks in total.

We utilize four public data sources, S_1 to S_4, the statistics of which are shown in Table 1.

Table 1: Data Source statistics

S_1: *News* is crawled from Sina Finance News[6], which originates from 2009 to 2017.

S_2: *Reports* consists of annual and quarterly company reports crawled from Sina Finance[7].

S_3: *Wikipedia* includes relevant wikipedia pages of the concepts and stocks, if any, which can provide some background knowledge.

S_4: *Search Engine* includes open-domain information for the concepts and stocks obtained using Bing API [8]. We adopt search engine results for representing heterogeneous web texts. The top-ranked webpages are crawled.

Given the Jinrongjie and Tonghuashun datasets, we randomly select 70%, 10% and 20% of the concepts as training, development and testing sets, respectively.

7.2 Baselines and Parameter Settings

We compare our method with four baselines:

Search is a naive information retrieval baseline, which sends the concept c and each stock o to an inverted index and obtains a list of top-k ranked documents ($k = 5$ in experiments) by a fixed ranking metric, Ocapi BM25 (Robertson et al., 2009). The stocks are ranked by the average of top-k documents' BM25 scores.

Rank is our ranking baseline. Five top-ranked documents from each source are fed into the model. All 3326 stocks are ranked for each concept.

Semantics ranks the stocks using Equation 4, which is the naive semantic relatedness $\hat{f}(c, o)$.

Semantics+ extends **Semantics** by including 8 most similar words to expand original concepts.

Semantics++ extends **Semantics** by including the most similar words with similarities larger than 0.65 to expand original concepts. On average, 6.3 concepts are included.

Table 2: Concept stock recommendation results on Jinrongjie and Tonghuashun. $*$ denotes statistical significance using Wilcoxon signed rank test ($p < 0.05$)

For our model, denoted as **RL**, we set the window size as 80, the embedding size as 300 and the vocabulary size as $100,000$ in view of the large variety of phrases after word segmentation to train Doc2Vec. Also, the experience memory size is set to $50,000$ and older training samples are abandoned. The ϵ value is set as 1 at the start and gradually decreases to 0.1 after 3000 annealing steps. We perform a training phase after every 3 decision steps. The mini-batch size is set to 50. Dropout is applied to avoid overfitting and the dropout rate is 0.5. We set the learning rate for AdaGrad as 0.01. Gradient clipping (Pascanu et al., 2013) is adopted to prevent gradient exploding and vanishing during training process.

7.3 Recommendation Accuracies

We use four metrics, mean average precision (MAP), precision at 5 and 10 ($P@5$, $P@10$) and recall at 30 ($R@30$) to evaluate the algorithms. The results are shown in Table 2.

From Table 2, the first observation is that **RL** outperforms the baselines on both datasets, which demonstrates the effectiveness of combining semantic relatedness with query expansion based on reinforcement learning. The baseline **Rank** achieves the second best results. The large gap between **RL** and **Rank** indicates that **RL** is much easier to train compared to **Rank** on small data.

Second, we observe that **Semantics+** improves over **Semantics**, which shows that query expansion has the potentials to alleviate concept ambiguities and benefit concept stock recommendation. **Semantics++** can outperform **Semantics+** by considering semantic similarities. Also, compared to

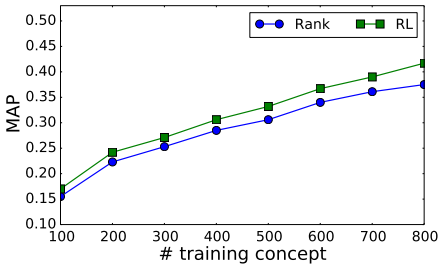

Figure 3: Learning Curve

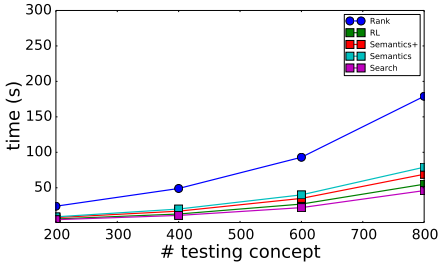

Figure 4: Efficiency

RL, we conclude that query expansion based on reinforcement learning could better utilize training data and significantly outperform naive query expansion methods.

The last observation is that **Search** performs the worst among the methods. This sheds light on the limitations of traditional search models and confirms the effectiveness of semantic modeling by word embedding and neural models.

7.4 Influence of Size of Training Data

We increase the amount of training concepts and study whether **RL** is easier to train than **Rank**. The results on Tonghuashun is shown in Figure 3 (similar patterns are demonstrated using Jinrongjie). With more training concepts, the MAPs of both methods increase. However, **RL** consistently outperforms **Rank** and the margin becomes larger. Thusly, we conclude that **RL** requires less data than **Rank** to achieve similar performance.

7.5 Efficiency Comparison

Figure 4 shows the efficiency of all algorithms on testing data. The three unsupervised algorithm **Search**, **Semantics** and **Semantics+** are more efficient compared to the supervised algorithm, **Rank** and **RL**. **RL** is more efficient compared to **Rank**, since **Rank** has to rank every stock to obtain concept stocks.

中字头 (Sino)

Table 3: Example concept stocks, where ~~stock~~ indicates a incorrectly recognized concept stock.

7.6 Case Study

Data Sources Effectiveness: To study the effectiveness of data sources, we count how many concepts are chosen from each data source during query expansion. For the Tonghuashun test data (similar tendencies are observed for Jinrongjie), 761, 689, 199, 344 concepts are selected for S_1-S_4, respectively. Accumulated rewards of these concepts for S_1-S_4 are 76.13, 61.32, 7.49 and 14.10, respectively. We conclude that *News* and *Reports* are relatively more effective for improving recommendation accuracies.

Recommended Stocks: To obtain a better understanding of our method, we examine the symbols of the top-5 selected stocks of concepts and some examples are shown in Table 3.

We notice that **RL** can effectively extend concepts with relevant concepts. For example, the algorithm extends 中字头 (Sino) with 中国 (China) and 国企 (State-owned enterprises), 特斯拉 (Tesla) with 入华 (into China), 电动车 (Electric cars) and 马斯克 (Musk) and 智能物流 (Intelligent Logistics) with 物流 (Logistics), CSN (China Smart Logistic Network), 仓储 (Warehousing) and 配送 (Delivery), which results in more accurate concept stocks.

For 特斯拉 (Tesla), **RL** made two mistakes due to rumor and ambiguity. For example, 上海临港SHLG is chosen because of rumors that Tesla will establish a new factory there. 万向钱潮WXQC is mistakenly chosen because 万向钱潮WXQC is called China's Tesla in some news due to its investments in electric cars. In contract, **Semantics+** and **Rank** are limited by lack of su-

pervision and highly unbalanced datasets, respectively. For example, **Rank** mistakenly chooses 美菱电器MLDQ in that it confuses 智能家电 (Smart Appliances) with 智能物流 (Intelligent Logistics). We conclude that **RL** is capable of expanding concepts with relevant concepts that helps find more revelant stocks.

Conclusion

We have investigated a reinforcement learning method to automatically mine evidences from large-scale text data for measuring the correlation between a concept and a list of stocks. Compared to standard information retrieval methods, our method leverages a small amount of training data for obtaining a flexible strategy of query expansion, thus being able to disambiguate contexts in exploration. Results on two Chinese datasets show that our method is highly competitive for our task, thus providing a tool for investors to gain understandings of emerging markets.

Abstract

The long short-term memory (LSTM) language model (LM) has been widely investigated for automatic speech recognition (ASR) and natural language processing (NLP). Although excellent performance is obtained for large vocabulary tasks, tremendous memory consumption prohibits the use of LSTM LMs in low-resource devices. The memory consumption mainly comes from the word embedding layer. In this paper, a novel binarized LSTM LM is proposed to address the problem. Words are encoded into binary vectors and other LSTM parameters are further binarized to achieve high memory compression. This is the first effort to investigate binary LSTMs for large vocabulary language modeling. Experiments on both English and Chinese LM and ASR tasks showed that binarization can achieve a compression ratio of 11.3 without any loss of LM and ASR performance and a compression ratio of 31.6 with acceptable minor performance degradation.

1 Introduction

Language models (LMs) play an important role in natural language processing (NLP) tasks. N-gram language models used to be the most popular language models. Considering the previous N-1 words, N-gram language models predict the next word. However, this leads to the loss of long-term dependencies. The sample space size increases exponentially as N grows, which induces data sparseness (Cao and Yu, 2017).

Neural network (NN) based models were first introduced into language modeling in 2003 (Bengio et al., 2003). Given contexts with a fixed size, the model can calculate the probability distribution of the next word. However, the problem of long-term dependencies still remained, because the context window is fixed. Currently, recurrent neural network (RNN) based models are widely used on natural language processing (NLP) tasks for excellent performance (Mikolov et al., 2010). Recurrent structures in neural networks can solve the problem of long-term dependencies to a great extent. Some gate based structures, such as long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent unit (GRU) (Chung et al., 2014) improve the recurrent structures and achieve state-of-the-art performance on most NLP tasks.

However, neural network models occupy tremendous memory space so that it is almost impossible to put the models into low-resource devices. In practice, the vocabulary is usually very large. So the memory consumption mainly comes from the embedding layers. And, the word embedding parameters are floating point values, which adds to the memory consumption.

The first contribution in this paper is that a novel language model, the binarized embedding language model (BELM) is proposed to reduce the memory consumption. Words are represented in the form of binarized vectors. Thus, the consumption of memory space is significantly reduced. Another contribution in the paper is that we binarize the LSTM language model combined with the binarized embeddings to further compress the parameter space. All the parameters in the LSTM language model are binarized.

Experiments are conducted in language modeling and automatic speech recognition (ASR) rescoring tasks. Our model performs well without any loss of performance at a compression ratio of 11.3 and still has acceptable results with only a minor loss of performance even at a compression ratio of 31.6. Investigations are also made to evaluate whether the binarized embeddings lose information. Experiments are conducted on word

New Orleans, Louisiana, June 1 - 6, 2018.

similarity tasks. The results show the binarized embeddings generated by our models still perform well on the two datasets.

The rest of the paper is organized as follows, section 2 is the related work. Section 3 explains the proposed language model and section 4 shows the experimental setup and results. Finally, conclusions will be given in section 5 and we describe future work in section 6.

2 Related Work

Nowadays, with the development of deep learning, neural networks have yielded good results in many areas. However, neural networks may require tremendous memory space, making it difficult to run such models on low-resource devices. Thus, it is necessary to compress neural networks.

In recent years, many methods of compressing neural networks have been proposed. Pruning (Han et al., 2015) reduces the number of parameters of the neural network by removing all connections with the weights below a threshold. Quantization (Han et al., 2015) clusters weights to several clusters. A few bits are used to represent the neurons and to index a few float values.

Binarization is also a method to compress neural networks. BNNs(Courbariaux et al., 2016) are binarized deep neural networks. The weights and activations are constrained to 1 or -1. BNNs can drastically reduce memory size and replace most arithmetic operations with bit-wise operations. Different from pruning and quantization, binarization does not necessarily require pre-training and can achieve a great compression ratio. Many binarization methods have been proposed (Courbariaux et al., 2015, 2016; Rastegari et al., 2016; Xiang et al., 2017). However, only a few (Hou et al., 2016; Edel and Köppe, 2016) are related to recurrent neural network. (Hou et al., 2016) implements a character level binarized language model with a vocabulary size of 87. However, they did not do a comprehensive study on binarized large vocabulary LSTM language models.

3 Binarized Language Model

3.1 LSTM Language Model

The RNN language model is proposed to deal with sequential data. Due to the vanishing and exploding gradients problem, it is difficult for a RNN language model to learn long-term dependencies. The LSTM, which strengthens the recurrent neural model with a gating mechanism, tackles this problem and is widely used in natural language processing tasks.

The goal of a language model is to compute the probability of a sentence $(x_1, \ldots, x_N)$. A typical method is to decompose this probability word by word.

$$P(x_1, ..., x_N) = \prod_{t=1}^{N} P(x_t | x_1, ..., x_{t-1}) \quad (1)$$

(Hochreiter and Schmidhuber, 1997) proposed a Long Short-Term Memory Network, which can be used for sequence processing tasks. Consider an one-layer LSTM network, where N is the length of the sentence, and x_t is the input at the t-th moment. y_t is the output at the t-th moment, which is equal to x_{t+1} in a language model. Denote $\boldsymbol{h_t}$ and $\boldsymbol{c_t}$ as the hidden vector and the cell vector at the t-th moment, which is used for representing the history of $(x_1, ..., x_{t-1})$. $\boldsymbol{h_0}$ and $\boldsymbol{c_0}$ are initialized with zero. Given x_t, $\boldsymbol{h_{t-1}}$ and $\boldsymbol{c_{t-1}}$, the model calculates the probability of outputting y_t.

The first step of an LSTM language model is to extract the representation $\boldsymbol{e_t}$ of the input x_t from the embeddings $\mathbf{W_e}$. Since x_t is a one-hot vector, this operation can be implemented by indexing rather than multiplication.

$$\boldsymbol{e_t} = \mathbf{W_e} \boldsymbol{x_t} \quad (2)$$

After that, $\boldsymbol{e_t}$, along with $\boldsymbol{h_{t-1}}$ and $\boldsymbol{c_{t-1}}$ are fed into the LSTM cell. The hidden vector $\boldsymbol{h_t}$ and the cell vector $\boldsymbol{c_t}$ can be computed according to:

$$\begin{aligned}
\boldsymbol{f_t} &= \text{sigmoid}\left(\mathbf{W_f}\left\{\boldsymbol{h_{t-1}}, \boldsymbol{e_t}\right\} + \boldsymbol{b_f}\right) \\
\boldsymbol{i_t} &= \text{sigmoid}\left(\mathbf{W_i}\left\{\boldsymbol{h_{t-1}}, \boldsymbol{e_t}\right\} + \boldsymbol{b_i}\right) \\
\boldsymbol{o_t} &= \text{sigmoid}\left(\mathbf{W_o}\left\{\boldsymbol{h_{t-1}}, \boldsymbol{e_t}\right\} + \boldsymbol{b_o}\right) \\
\hat{\boldsymbol{c}}_{\boldsymbol{t}} &= \tanh\left(\mathbf{W_{\hat{c}}}\left\{\boldsymbol{h_{t-1}}, \boldsymbol{e_t}\right\} + \boldsymbol{b_{\hat{c}}}\right) \\
\boldsymbol{c_t} &= \boldsymbol{f_t} \cdot \boldsymbol{c_{t-1}} + \boldsymbol{i_t} \cdot \hat{\boldsymbol{c}}_{\boldsymbol{t}} \\
\boldsymbol{h_t} &= \boldsymbol{o_t} \cdot \tanh\left(\boldsymbol{c_t}\right)
\end{aligned} \quad (3)$$

The word probability distribution at the t-th moment can be calculated by:

$$P(y_t | x_1, ..., x_t) = \boldsymbol{p_t} = \text{softmax}(\mathbf{W_y} \boldsymbol{h_t}) \quad (4)$$

The probability of taking y_t as the output at the t-th moment is:

$$p_{y_t} = \boldsymbol{p_t} \times \boldsymbol{y_t} \quad (5)$$

3.2 Binarized Embedding Language Model

The binarized embedding language model (BELM) is a novel LSTM language model with binarized input embeddings and output embeddings. For a one-layer LSTM language model with a vocabulary size of V, embedding and hidden layer size of H. The size in bytes of the input embeddings, the output embeddings, and the LSTM cells are $4VH$, $4VH$ and $32H^2 + 16H$. When V is much larger than H, which is often the case for language models, the parameters of the input embeddings and the output embeddings occupy most of the space. If the embeddings of the input layer and the output layer are binarized, the input layer and the output layer will only take $1/32$ of the original memory consumption, which can greatly reduce the memory consumption of running neural language model.

It is important to find good binary embeddings. Directly binarizing well-trained word embeddings cannot yield good binarized representations. Instead, we train good binary embeddings from scratch. The training approach is similar to the methods proposed in (Courbariaux et al., 2016; Rastegari et al., 2016). At run-time, the input embedding and the output embedding are binarized matrices. However, at train-time, float versions of the embeddings, which are used for calculating the binarized version of embeddings, are still maintained. In the propagation step, a deterministic function sign is used to binarize the float versions of the embeddings. In the back-propagation step, the float versions of the embeddings are updated according to the gradient of the binarized embedding.

$$w^b = \text{sign}\,(w) = \begin{cases} +1 & if\ w > 0, \\ -1 & otherwise. \end{cases} \tag{6}$$

The derivative of the sign function is zero almost everywhere, and it is impossible to back-propagate through this function. As introduced in (Hubara et al., 2016), a straight-through estimator is used to get the gradient. Assume the gradient of the binarized weight $\frac{\partial C}{\partial \mathbf{W^b}}$ has been obtained, the gradient of the float version of the weight is:

$$\frac{\partial C}{\partial \mathbf{W}} = \frac{\partial C}{\partial \mathbf{W^b}} \tag{7}$$

A typical weight initialization method initializes each neuron's weights randomly from the Gaussian distribution $N(0, \sqrt{1/H})$. This initialization approach can maximize the gradients and mitigate the vanishing gradients problem. From this perspective, 1 or -1 is too large. So, in practice, we binarize the embeddings to a smaller scale. Although the weight is binarized to a floating point number, the matrix can also be saved one bit per neuron, as long as the fixed float value is memorized separately.

$$\text{binarize}\,(w) = \begin{cases} +\sqrt{1/H} & if\ w > 0, \\ -\sqrt{1/H} & otherwise. \end{cases} \tag{8}$$

Since directly binarizing the input embeddings $\mathbf{W_e}$ and the output embeddings $\mathbf{W_y}$ will limit the scale of the embeddings, additional linear layers (without activation) are added behind the input embedding layer and in front of the output embedding layer to enhance the model. Denote $\mathbf{W_e^b}$ and $\mathbf{W_y^b}$ as the binarized weights corresponding to $\mathbf{W_e}$ and $\mathbf{W_y}$. Denote $\mathbf{W_{T_e}}$ and $\boldsymbol{b_{T_e}}$, $\mathbf{W_{T_y}}$ and $\boldsymbol{b_{T_y}}$ as the weights and the biases of the first and the second linear layer. The input of the LSTM $\boldsymbol{e_t}$ and the word probability $\boldsymbol{p_t}$ of the binarized embedding language model are calculated according to:

$$\begin{aligned} \boldsymbol{e_t} &= \mathbf{W_{T_e}}\left(\mathbf{W_e^b}\boldsymbol{x_t}\right) + \boldsymbol{b_{T_e}} \\ \boldsymbol{p_t} &= \text{softmax}\left(\mathbf{W_y^b}\left(\mathbf{W_{T_y}}\boldsymbol{h_t} + \boldsymbol{b_{T_y}}\right)\right) \end{aligned} \tag{9}$$

The additional linear layer before the output embedding layer is very important for the binarized embedding language model, especially for low dimensional models. Removing this layer will result in an obvious decrease in performance.

3.3 Binarized LSTM Language Model

Subsection 3.2 explains how to binarize the embedding layer, but the LSTM network can also be binarized. In a binarized LSTM language model, all the matrices in the parameters are binarized, which can save much more memory space. Implementing the binarized linear layer is important for designing a binarized LSTM language model (BLLM). In a binarized linear layer, there are three parameters, $\mathbf{W}$, $\boldsymbol{\gamma}$ and $\boldsymbol{b}$. $\mathbf{W}$ is a matrix, $\boldsymbol{\gamma}$ and $\boldsymbol{b}$ are vectors. The matrix $\mathbf{W}$, which takes up most of the space in a linear layer, is binarized. $\boldsymbol{\gamma}$ and $\boldsymbol{b}$ remain floating point values. b is the bias of the linear layer, and $\boldsymbol{\gamma}$ is introduced to fix the scale problem of the binary matrix.

The forward- and back-propagation algorithms are shown in Algorithm 1 and Algorithm 2. The structure of this linear layer is very similar to the structure of batch normalization (Ioffe and Szegedy, 2015), except the output of each dimension over the mini-batches is not normalized. Batch normalization is hard to apply to a recurrent neural network, due to the dependency over entire sequences. However, the structure of the batch normalization is quite useful. Since binarizing W would fix the scale of the weight, additional freedom is needed to overcome this issue. The shift operation can rescale the output to a reasonable range.

Algorithm 1 The propagation of linear layer

Input: input $\boldsymbol{x}$, weights $\mathbf{W}$, $\boldsymbol{\gamma}$ and $\boldsymbol{b}$

Output: output $\boldsymbol{y}$

1: $\mathbf{W^b} = \text{binarize}\left(\mathbf{W}\right)$
2: $\boldsymbol{s} = \mathbf{W^b}\boldsymbol{x}$
3: $\boldsymbol{y} = \boldsymbol{s} \cdot \exp\left(\boldsymbol{\gamma}\right) + \boldsymbol{b}$

Algorithm 2 The back-propagation of linear layer

Input: input $\boldsymbol{x}$, weights $\mathbf{W}$, $\boldsymbol{\gamma}$ and $\boldsymbol{b}$, binarized weight $\mathbf{W^b}$, temporary value $\boldsymbol{s}$ (calculated in the propagation period), the gradient of the output $\frac{\partial C}{\partial \boldsymbol{y}}$, learning rate η, binary weight range α

Output: the gradient of the input $\frac{\partial C}{\partial \boldsymbol{x}}$, the gradient of the weight $\frac{\partial C}{\partial \mathbf{W}}$, $\frac{\partial C}{\partial \boldsymbol{\gamma}}$, $\frac{\partial C}{\partial \boldsymbol{b}}$, update the weights

1: $\frac{\partial C}{\partial \boldsymbol{b}} = \frac{\partial C}{\partial \boldsymbol{y}}$
2: $\frac{\partial C}{\partial \boldsymbol{\gamma}} = \frac{\partial C}{\partial \boldsymbol{y}} \cdot \boldsymbol{s} \cdot \exp\left(\boldsymbol{\gamma}\right)$
3: $\frac{\partial C}{\partial \boldsymbol{s}} = \frac{\partial C}{\partial \boldsymbol{y}} \cdot \exp\left(\boldsymbol{\gamma}\right)$, $\frac{\partial C}{\partial \mathbf{W^b}} = \frac{\partial C}{\partial \boldsymbol{s}}\boldsymbol{x}$, $\frac{\partial C}{\partial \mathbf{W}} = \frac{\partial C}{\partial \mathbf{W^b}}$
4: $\frac{\partial C}{\partial \boldsymbol{x}} = \frac{\partial C}{\partial \boldsymbol{s}}\mathbf{W^b}$
5: update $\mathbf{W}$, $\boldsymbol{\gamma}$, $\boldsymbol{b}$ according to $\frac{\partial C}{\partial \mathbf{W}}$, $\frac{\partial C}{\partial \boldsymbol{\gamma}}$, $\frac{\partial C}{\partial \boldsymbol{b}}$ with learning rate η.
6: $\text{clamp}(\mathbf{W}, -\alpha, \alpha)$
7: **return** $\frac{\partial C}{\partial x}$

The structure of the input embeddings and the output embeddings of the binarized LSTM language model is similar to the binarized embedding language model. The embeddings are binarized and additional linear layers are added after the input embedding layer and in front of the output embedding layer. However, the additional linear layers are also binarized according to Algorithm 1 and Algorithm 2.

3.4 Memory Reduction

Denote the size of the vocabulary as V, and the size of the embedding and hidden layer as H. The memory consumptions of a one-layer LSTM language model, BELM and BLLM are listed in Table 1.

Model	Memory (bytes)
LSTM	$8VH + 32H^2 + 16H$
BELM	$0.25VH + 40H^2 + 24H$
BLLM	$0.25VH + 1.25H^2 + 48H$

Table 1: Memory Requirements

For a language model, the vocabulary size is usually much larger than the hidden layer size. The main memory consumption comes from the embedding layers, which require $8VH$ bytes for an LSTM language model. Binarized embeddings can reduce this term to $0.25VH$ bytes. Further compression of the LSTM can drop the coefficient of H^2 from 32 to 1.25.

4 Experiments

4.1 Experimental Setup

Our model is evaluated on the English Penn TreeBank (PTB) (Marcus et al., 1993), Chinese short message (SMS) and SWB-Fisher (SWB). The Penn TreeBank corpus is a famous English dataset, with a vocabulary size of 10K and 4.8% words out of vocabulary (OOV), which is widely used to evaluate the performance of a language model. The training set contains approximately 42K sentences with 887K words. The Chinese SMS corpus is collected from short messages. The corpus has a vocabulary size of about 40K. The training set contains 380K sentences with 1931K words. The SWB-Fisher corpus is an English corpus containing approximately 2.5M sentences with 24.9M words. The corpus has a vocabulary size of about 30K. hub5e is the dataset for the SWB ASR task.

We also evaluate the word embeddings produced by our models on two word similarity datasets. The models are trained on the Text8 corpus to extract the word embeddings. The Text8 corpus is published by Google and collected from Wikipedia. Text8 contains about 17M words with a vocabulary size of about 47k. The WordSimilarity-353(WS-353) Test Collection contains two sets of English word pairs along with

human-assigned similarity judgments. The collection can be used to train and test computer algorithms implementing semantic similarity measures. A combined set (combined) is provided that contains a list of all 353 words, along with their mean similarity scores. (Finkelstein et al., 2001) The MEN dataset consists of 3,000 word pairs, randomly selected from words that occur at least 700 times in the freely available ukWaC and Wackypedia corpora combined (size: 1.9B and 820M tokens, respectively) and at least 50 times (as tags) in the open-sourced subset of the ESP game dataset. In order to avoid picking unrelated pairs only, the pairs are sampled so that they represent a balanced range of relatedness levels according to a text-based semantic score (Bruni et al., 2014).

First, we conduct experiments on the PTB, SWB and Text8 corpora respectively to evaluate language modeling performance. We use perplexity (PPL) as the metric to evaluate models of different sizes. Then, the models are evaluated on ASR rescoring tasks. Rescoring the 100-best sentences generated by the weighted finite state transducer (WFST), the model is evaluated by word error rate (WER). Finally, we conduct experiments on word similarity tasks to evaluate whether the word embeddings produced by our models lose any information.

4.2 Experiments in Language Modeling

For traditional RNN based language models, the memory consumption mainly comes from the embedding layers (both input and output layers). However, when the hidden layer size grows, the memory consumption of the RNN module also becomes larger. So the total memory usage relates to both the vocabulary size and hidden layer size, as mentioned in section 3.4.

Experiments are conducted in language modeling to evaluate the model on the PTB, SWB, and SMS corpora respectively. In language modeling tasks, we regularize the networks using dropout(Zaremba et al., 2014). We use stochastic gradient descent (SGD) for optimization. The batch size is set to 64. For the PTB corpus, the dropout rate is tuned for different training settings. For the SWB corpus, we do not use dropout technique. For the SMS corpus, the dropout rate is set to 0.25. We train models of different sizes on the three corpora and record the memory usage of the trained models. The initial learning rate is set to 1.0 for all settings. Since PTB is a relatively small dataset and the convergence rates of the BELM and the BLLM are slower than LSTM language model, we reduce the learning rate by half every three epochs if the perplexity on the validation set is not reduced. For the other experiments, the learning rate is always reduced by half every epoch if the perplexity on the validation set is not reduced. As introduced in section 3, the bias of the output embedding layer is omitted. Adding bias term in the output embedding layer leads to small performance degradation in the BELM and the BLLM model, although it leads to a small improvement in the LSTM model. This phenomenon may be related to optimization problems.

	Hidden size	**LSTM**	**BELM**	**BLLM**
Memory	500	48.0M	11.3M	1.6M
PPL		91.8	**88.0**	95.2
Memory	1000	112.0M	42.5M	3.8M
PPL		89.4	**85.7**	94.9

Table 2: Performances on the English PTB corpus

	Hidden size	**LSTM**	**BELM**	**BLLM**
Memory	500	129.1M	13.8M	4.1M
PPL		**57.6**	58.4	60.4
Memory	1000	274.2M	47.6M	8.9M
PPL		56.1	**55.6**	56.2

Table 3: Performance on the English SWB corpus

	Hidden size	**LSTM**	**BELM**	**BLLM**
Memory	500	170.8M	15.1M	5.4M
PPL		90.0	**89.8**	96.8
Memory	1000	357.6M	50.2M	11.5M
PPL		89.5	**87.8**	94.3

Table 4: Performance on the Chinese SMS corpus

Because the total memory usage relates to both the vocabulary size and hidden layer size, the memory reduction on various corpora is quite different. For our BELM model, the floating point embedding parameters are replaced by single bits, which could significantly reduce the memory usage. On the PTB corpus, the BELM models even

outperform the baseline LSTM LM. The small model (500 LSTM units) has a relative PPL improvement of 4.1% and achieves a compression ratio of 4.3 and the large model (1000 LSTM units) also has a relative PPL improvement of 4.1% and achieves a compression ratio of 2.6. On the SWB corpus, the BELM models still perform well compared with the baseline model and achieve compression ratios of 9.4 and 5.8 respectively for the small and large models. On the SMS corpus, the BELMs model also gains relative PPL improvements of 0.2% and 1.9%, and achieves compression ratios of 11.3 and 7.1 respectively. In summary, the BELM model performs as well as the baseline model both on English and Chinese corpora, and reduces the memory consumption to a large extent.

The BLLM model, however, does not outperform the baseline model, but still has acceptable results with a minor loss of performance. Since both the LSTM model and the embeddings are binarized, the total compression ratio is quite significant. The average compression ratio is about 32.0, so the memory consumption of the language model is significantly reduced.

We also study the performance of pruning the LSTM language model. We prune each parameter matrix and the embedding layers with various pruning rates respectively, and fine-tune the model with various dropout rates. In our experiments, pruning 75% parameter nodes hardly affects the performance. However, if we try pruning more parameter nodes, the perplexity increases rapidly. For example, for the English PTB dataset, when we prune 95% parameter nodes of the embedding layers of an LSTM language model (500 LSTM units), the perpexity will increase from 91.8 to 112.3. When we prune 95% parameter nodes of an LSTM language model (500 LSTM units), the perplexity will increase from 91.8 to 132.3. Therefore, the effect of pruning is not as good as binarization for the language modeling task.

Binarization can be considered as a special case of quantization, which quantizes the parameters to pairs of opposite numbers. So, compared to normal quantization, binarization can achieve a better compression ratio. In addition, for binarization, we do not need to determine the position of each unique values in advance. Therefore, binarization is more flexible than quantization.

We then study the effect of extra binary linear layers in the BLLM. The additional binary linear layer after the input embedding layer and the additional binary linear layer in front of the output embedding layer are removed respectively in this experiment. We use well-trained embeddings to initialize the corresponding embedding layers and do the binarization using the method proposed in (Rastegari et al., 2016) when the additional binary linear layer is removed. The perplexities are listed in Table 5. No-i means no additional binary linear layer after the input embedding layer. No-o means no additional binary linear layer in front of the output embedding layer. No-io means no additional binary linear layers. The experiment is conducted on the PTB corpus.

	Hidden size	**BLLM**	**BLLM no-i**	**BLLM no-o**	**BLLM no-io**
PPL	500	95.2	95.2	101.7	100.3
PPL	1000	94.9	94.5	96.7	96.3

Table 5: Performances on the English PTB corpus

If the additional binary linear layer after the input embedding layer is removed, the performance does not drop, and even becomes better when the hidden layer size is 1000. Although the additional binary layer after the input embedding layer is removed, the float version of the input embeddings of BLLM no-i is initialized with well-trained embeddings, while the BLLM is not initialized with the well-trained embeddings. We think initialization is the reason why the BLLM no-i performs comparatively to the BLLM. We also observe a PPL increase of 1-2 points for BLLM no-i if the input embeddings are not pre-trained (not listed in the table). This phenomenon prompts us to pre-train embeddings, which we leave to future work. Once the additional binary linear layer in front of the output embedding layer is removed, the performance degradation is serious. This shows that the output embeddings of the language model should not be directly binarized; the additional binary linear layer should be inserted to enhance the model's capacity, especially for low dimensional models.

4.3 Experiments on ASR Rescoring Tasks

Experiments are conducted on the ASR rescoring task to evaluate the model on the hub5e and SMS corpora. Hub5e is a test dataset of the SWB corpus which we use for ASR rescoring tasks. For the hub5e dateset, A VDCNN (Qian et al., 2016)

(very deep CNN) model on the 300-hour task is applied as the acoustic model. For the Chinese SMS dataset, the acoustic model is a CD-DNN-HMM model. The weighted finite state transducer (WFST) is produced with a 4-gram language model. Then our language models are utilized to rescore the 100-best candidates. The models are evaluated by the metric of word error rate (WER).

Model	Hidden size	hub5e	SMS
LSTM	500	8.7	10.5
BELM		**8.5**	**10.3**
BLLM		8.7	10.8
LSTM	1000	8.5	10.4
BELM		8.5	**10.2**
BLLM		**8.4**	10.3

Table 6: Performances on ASR rescoring tasks

Table 6 shows the results on ASR rescoring tasks. The BELM model and BLLM model perform well both on the English and Chinese datasets. The BELM model achieves an absolute 0.2% WER improvement compared with the baseline model in three of the experiments. The BLLM model also has good results, even though it performs not so well in language modeling. The results show that our language models work well on ASR rescoring tasks even with much less memory consumption.

4.4 Investigation of Binarized Embeddings

The experiments above show the good performances of our models. We also want to investigate whether the binarized embeddings lose any information. So, the embeddings are evaluated on two word similarity tasks. Experiments are conducted on the WS-353 and MEN tasks. We have trained the baseline LSTM model, the BELM model and BLLM model of a medium size on the Text8 corpus. We binarize the embeddings of the trained baseline LSTM model to investigate whether there is any loss of information by the simple binarization method (labeled LSTM-bin in the table below). For each dimension, we calculate the mean and set the value to 1 if it is bigger than the mean, otherwise, we set it to -1.

The embedding size and the hidden layer size are set to 500. We use stochastic gradient descent (SGD) to optimize our models. We use cosine distance to evaluate the similarity of the word pairs. Spearman's rank correlation coefficient is calculated to evaluate the correlation between the two scores given by our models and domain experts.

Model	PPL
LSTM	166.0
BELM	164.7
BLLM	172.3

Table 7: Language modeling performance on the Text8 corpus

Model	WS-353	MEN
LSTM	53.1	46.3
LSTM-bin	25.5	19.4
BELM	49.1	47.0
BLLM	**56.0**	**52.2**

Table 8: Performances on the word similarity tasks

Table 7 shows our models perform well in language modeling on the Text8 corpus. Table 8 summarizes the performance of the word embeddings in the similarity tasks. The embeddings generated by the simple binarization method perform obviously worse than the other embeddings, which indicates that much information is lost. The BELM model outperforms the baseline model on the MEN task, although it doesnt perform as well as the baseline model on the WS-353 task. However, the MEN dataset contains many more word pairs, which makes the results on this dataset more convincing. The BLLM model significantly outperforms the baseline model on the two tasks. The results indicate that the binarized embeddings of the BLLM do not lose any semantic information although the parameters are represented only by -1 and 1.

We suspect that binarization plays a role in regularization and produces more robust vectors. We also give an example visualization of some word vectors. The dimension of the embeddings of the BLLM is reduced by TSNE (Maaten and Hinton, 2008). The words which are the closest to **father** (according to the cosine distance of word vectors) are shown in Figure 1.

In this figure, **mother** and **parents** are the closest words to **father**, which is quite understandable. The words **husband**, **wife**, **grandfather** and **grandmother** also gather together and most words in the figure are related to **father**, indicat-

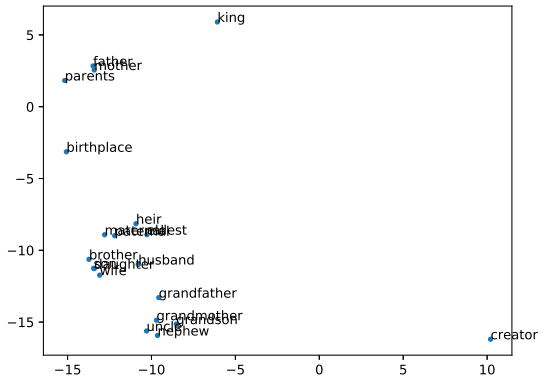

Figure 1: Visualization of the Binarized Embeddings

ing the embeddings indeed carry semantic information.

5 Conclusion

In this paper, a novel language model, the binarized embedding language model (BELM) is proposed to solve the problem that NN based language models occupy tremendous space. For traditional RNN based language models, the memory consumption mainly comes from the embedding layers (both input and output layers). However, when the hidden layer size grows, the memory consumption of the RNN module also becomes larger. So, the total memory usage relates to both the vocabulary size and hidden layer size. In the BELM model, words are represented in the form of binarized vectors, which only contain parameters of -1 or 1. For further compression, we binarize the long short-term memory language model combined with the binarized embeddings. Thus, the total memory usage can be significantly reduced. Experiments are conducted on language modeling and ASR rescoring tasks on various corpora. The results show that the BELM model performs well without any loss of performances at compression ratios of 2.6 to 11.3, depending on the hidden and vocabulary size. The BLLM model compresses the model parameters almost thirty-two times with a slight loss of performance. We also evaluate the embeddings on word similarity tasks. The results show the binarized embeddings even perform much better than the baseline embeddings.

6 Future Work

In the future, we will study how to improve the performance of the BLLM model. And, we will research methods to accelerate the training and reduce the memory consumption during training.

Abstract

Emotion recognition in conversations is crucial for the development of empathetic machines. Present methods mostly ignore the role of inter-speaker dependency relations while classifying emotions in conversations. In this paper, we address recognizing utterance-level emotions in dyadic conversational videos. We propose a deep neural framework, termed conversational memory network, which leverages contextual information from the conversation history. The framework takes a multimodal approach comprising audio, visual and textual features with gated recurrent units to model past utterances of each speaker into memories. Such memories are then merged using attention-based hops to capture inter-speaker dependencies. Experiments show an accuracy improvement of $3-4\%$ over the state of the art.

1 Introduction

Development of machines with emotional intelligence has been a long-standing goal of AI. With the increasing infusion of interactive systems in our lives, the need for empathetic machines with emotional understanding is paramount. Previous research in affective computing has looked at dialogues as an essential basis to learn emotional dynamics (Sidnell and Stivers, 2012; Poria et al., 2017a; Zhou et al., 2017).

Since the advent of Web 2.0, dialogue videos have proliferated across the internet through platforms like movies, webinars, and video chats. Emotion detection from such resources can benefit numerous fields like counseling (De Choudhury et al., 2013), public opinion mining (Cambria et al., 2017), financial forecasting (Xing et al., 2018), and intelligent systems such as smart homes and chatbots (Young et al., 2018).

In this paper, we analyze emotion detection in videos of dyadic conversations. A dyadic conversation is a form of a dialogue between two entities. We propose a conversational memory network (CMN), which uses a multimodal approach for emotion detection in utterances (a unit of speech bound by breathes or pauses) of such conversational videos.

Emotional dynamics in a conversation is known to be driven by two prime factors: self and inter-speaker emotional influence (Morris and Keltner, 2000; Liu and Maitlis, 2014). Self-influence relates to the concept of *emotional inertia*, i.e., the degree to which a person's feelings carry over from one moment to another (Koval and Kuppens, 2012). Inter-speaker emotional influence is another trait where the other person acts as an influencer in the speaker's emotional state. Conversely, speakers also tend to mirror emotions of their counterparts (Navarretta et al., 2016). Figure 1 provides an example from the dataset showing the presence of these two traits in a dialogue.

Existing works in the literature do not capitalize on these two factors. Context-free systems infer emotions based only on the current utterance in the conversation (Bertero et al., 2016). Whereas, state-of-the-art context-based networks like Poria et al., 2017b, use long short-term memory (LSTM) networks to model speaker-based context that suffers from incapability of long-range summarization and unweighted influence from context, leading to model bias.

Our proposed CMN incorporates these factors by using emotional context information present in the conversation history. It improves speaker-based emotion modeling by using memory networks which are efficient in capturing long-term

Proceedings of NAACL-HLT 2018, pages 2122–2132
New Orleans, Louisiana, June 1 - 6, 2018.

dependencies and summarizing task-specific details using attention models (Weston et al., 2014; Graves et al., 2014; Young et al., 2017).

Specifically, the memory cells of CMN are continuous vectors that store the context information found in the utterance histories. CMN also models interplay of these memories to capture inter-speaker dependencies.

CMN first extracts multimodal features (audio, visual, and text) for all utterances in a video. In order to detect the emotion of a particular utterance, say u_i, it gathers its histories by collecting previous utterances within a context window. Separate histories are created for both speakers. These histories are then modeled into memory cells using gated recurrent units (GRUs).

After that, CMN reads both the speaker's memories and employs attention mechanism on them, in order to find the most useful historical utterances to classify u_i. The memories are then merged with u_i using an addition operation weighted by the attention scores. This is done to model inter-speaker influences and dynamics. The whole cycle is repeated for multiple hops and finally, this merged representation of utterance u_i is used to classify its emotion category.

The contributions of this paper can be summarized as follows:

1. We propose an architecture, termed CMN, for emotion detection in a dyadic conversation that considers utterance histories of both the speaker to model emotional dynamics. The architecture is extensible to multi-speaker conversations in formats such as textual dialogues or conversational videos.

2. When applied to videos, we adopt a multimodal approach to extract diverse features from utterances. It also makes our model robust to missing information.

3. CMN provides a significant increase in accuracy of 3 – 4% over previous state-of-the-art networks. One variant called CMN$_{self}$ which does not consider the inter-speaker relation in emotion detection also outperforms the state of the art by a significant margin.

The remainder of the paper is organized as follows: Section 2 provides a brief literature review; Section 3 formalizes the problem statement; Section 4 describes the proposed method in detail; experimental results are covered in Section 5; finally, Section 6 provides concluding remarks.

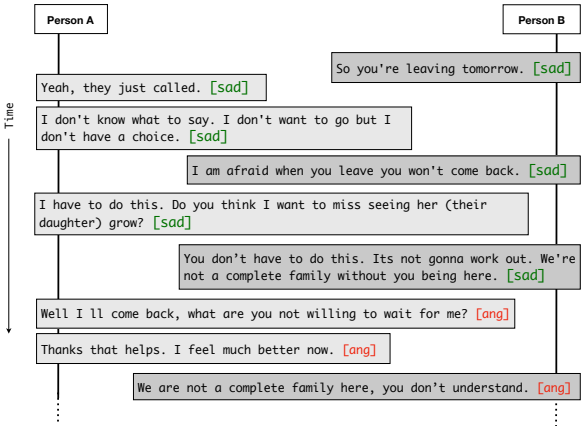

Figure 1: An abridged dialogue from the dataset. Person A (wife) is leaving B (husband) for a work assignment. Initially both A and B are emotionally driven by their own *emotional inertia*. In the end, *emotional influence* can be seen when B, despite being sad, reacts angrily to A's angry statement.

2 Related Works

Over the years, emotion recognition as an area of research has seen contributions from researchers across varied fields like signal processing, machine learning, cognitive and social psychology, natural language processing, etc. (Picard, 2010). Ekman, 1993, provided initial findings that related facial expressions as universal indicators of emotions. Datcu and Rothkrantz, 2008, 2011, showed the importance of acoustic cues in affect modeling.

A large section of researchers approaches emotion recognition from a multimodal learning perspective. Hence, many works used visual and audio features together for detecting affect (Busso et al., 2004; Castellano et al., 2008; Ranganathan et al., 2016). An in-depth review of the literature in these systems is provided by D'mello and Kory, 2015. Our work, which performs context-sensitive recognition (Wöllmer et al., 2010) uses three modalities: audio, visual and text. Recently, this combination of modalities has provided the best performance in affect recognition systems (Poria et al., 2017b; Wang et al., 2017; Tzirakis et al., 2017), thus motivating the use of a multimodal approach.

Previous works have focused on conversations as a resourceful event for emotion analysis. Rususvuori, 2013, provides an in-depth analysis on how emotions affect social interactions and conversations. In fact, significant works have attributed emotional dynamics as an interactive phe-

nomenon, rather than being within-person and one-directional (Richards et al., 2003; Hareli and Rafaeli, 2008). Such emotional dynamics are modeled by observing transition properties. Yang et al., 2011, study patterns for emotion transitions and show the evidence of emotional inertia. Xiaolan et al., 2013, use finite state machines to model transitions using stimuli and personality characteristics. Our work also tries to model emotional transitions using multimodal features. Unlike these works, however, we use memory networks to achieve the same.

The use of memory networks have been instrumental in the progress of multiple research problems, e.g., question-answering (Weston et al., 2014; Sukhbaatar et al., 2015; Kumar et al., 2016), machine translation (Bahdanau et al., 2014), speech recognition (Graves et al., 2014), and commonsense reasoning (Cambria et al., 2018). The repeated read and write to their memory cells is often coupled with attention modules, thus allowing it to filter only relevant memories.

Our model is loosely inspired from Sukhbaatar et al., 2015. Unlike their model, which directly encodes sentences into memories, we perform temporal sequence processing on our utterance histories using GRUs. We also extend their architecture to handle two speakers while keeping the possibility to add more. Finally, our model is different in the fact that we use multimodal features for input and processing.

3 Task Definition

Our goal is to infer the emotion of utterances present in a dyadic conversation. Let us define a dyadic conversation to be an asynchronous exchange of utterances between two persons P_a and P_b. Both the speakers speak a sequence of utterances U_a and U_b, respectively. Here, $U_\lambda = (s^1_\lambda, s^2_\lambda, ..., s^{l_\lambda}_\lambda)$ is ordered temporally, where s^i_λ is the i^{th} utterance by P_λ and l_λ is the total number of utterances spoken by person $P_\lambda,\ \lambda \in \{a, b\}$. Overall, the utterances by both speakers can be linearly ordered based on temporal occurrence as $(u_1, u_2, ...u_{l_a+l_b})$, where, $u_j \in U_a$ or U_b.

Our model takes as input an utterance u_i whose emotion category (Section 5.1) needs to be classified. To get its history, preceding K utterances of each person are separately collected as $hist_a$ and $hist_b$. Here, K serves as the length of the context window for history of u_i. Thus, for $\lambda \in \{a, b\}$:

$$hist_\lambda = \{u_j \mid u_j \in U_\lambda,\ j < i\}\ ,\ \mid hist_\lambda \mid \leq K \quad (1)$$

$hist_\lambda$ is also ordered temporally. At the beginning of the conversation, histories would have lesser than K utterances, i.e., $\mid hist_\lambda \mid < K$.

In the remaining sections, for brevity, we explain the processes using a subscript λ which can instantiate to either a or b, i.e., $\lambda \in \{a, b\}$.

4 Approach

We start by detailing the multimodal feature extraction scheme for all utterances followed by the mechanism to model emotional context using memory networks.

4.1 Multimodal Feature Extraction

The first phase of CMN is to extract multimodal features of all utterances in the conversations. The dyadic conversations are present in the form of videos. Each utterance of a particular conversation is thus a small segment of the full video. For each utterance, we extract features for the modes: audio, visual and text. The process of feature extraction for each mode is described below.

4.1.1 Textual Features Extraction

We extract features from the transcript of an utterance video using convolutional neural networks (CNNs). CNNs are effective in learning high level abstract representations of sentences from constituting words or n-grams (Kalchbrenner et al., 2014). To get our sentence representation, we use a simple CNN with one convolutional layer followed by max-pooling (Kim, 2014; Poria et al., 2016).

Specifically, the convolution layer consists filters of sizes $3, 4$ and 5 with 50 feature maps each. Max-pooling is employed on these feature maps with a pooling window of size 2. Finally, a fully connected layer is used with 100 neurons. The activations of this layer form our sentence representation t_u.

4.1.2 Audio Feature Extraction

To extract audio features we use openSMILE (Eyben et al., 2010). It is an open-source software which provides high dimensional audio vectors. These vectors comprise of features like loudness, Mel-spectra, MFCC, pitch, etc. Audio features play a significant role in providing information on the emotional state of a speaker (Song et al., 2004).

In fact, the literature shows that there exists a high correlation between many statistical measures of speech with speakers' emotion. For example, high pitch and fast speaking rate often denote anger while sadness associates low standard deviation of pitch and slow speech rate (Dellaert et al., 1996; Amir, 1998). In this work, we use the *IS13_ComParE*[1] config file which extracts a total of 6373 features for each utterance video. Z-standardization is performed for voice normalization and dimension of the audio vector is reduced to 100 using a fully-connected neural layer. This provides the final audio feature vector a_u.

4.1.3 Visual Feature Extraction

Facial expressions and visual surrounding provide rich emotional indicators. We use a 3D-CNN to capture these details from the utterance video. Apart from the benefits of extracting relevant features from each image frame, 3D-CNN also extracts spatiotemporal features across frames (Tran et al., 2015). This leads to the identification of emotional expressions like a smile or frown.

The working of a 3D-CNN is identical to its 2D counterpart with an input being a video v of dimension: $(3, f, h, w)$. Here, 3 represents the RGB channels and f, h, w are the number of frames, height, and width of each frame, respectively. For the convolution operation, a 3D filter f_l of dimension $(f_m, 3, f_d, f_h, f_w)$ is used where, $f_{[m/d/h/f]}$ represents number of feature maps, depth, height and width of the filter, respectively. Max-pooling is applied to the output of this convolution across a 3D sliding window of dimension (m_p, m_p, m_p).

In our model, we use 128 feature maps for 3D filters of size 5. For pooling, we set m_p to be 3 whose output is fed to a fully connected layer with 100 neurons. All the values are decided using hyperparameter tuning (see Section 5). For the input utterance, the activations of this layer form the video representation v_u.

Fusion: We perform feature level fusion to map the individual modalities to a joint space. This is done through a simple feature concatenation. Thus, the extracted features t_u, a_u and v_u are joined to form the utterance representation $u = [t_u; a_u; v_u]$ of dimension $d_{in} = 300$. This multimodal representation is generated for all utterances in a conversation.

[1] http://audeering.com/technology/opensmile

Literature consists of numerous fusion techniques for multimodal data (Atrey et al., 2010; Zadeh et al., 2017; Poria et al., 2017c). Exploring these on CMN, however, is beyond the scope of this paper and left as a future work.

4.2 Conversational Memory Network

For classifying the emotion of an utterance u_i, its corresponding histories ($hist_a$ and $hist_b$) are taken. Each history $hist_\lambda$ contains the preceding K utterances by person P_λ (see Section 3). Here, both u_i and utterances in the histories are represented using their multimodal feature vectors of dimension $\mathcal{R}^{d_{in}}$ (Figure 2).

The histories are first modeled into memory cells using GRUs. This provides the memories with context information summarized by the GRU. We call this step as memory representation. Following cognitive evidence of self-emotional dynamics, we model separate memory cells for each person. Thus, identical but separate computations are performed on both histories. From these memories, content relevant to utterance u_i is then filtered out using attention mechanism over multiple input/output hops. At each hop, both memories are accumulated and merged with u_i to model inter-speaker emotional dynamics. First, we describe our model as a single layer memory network which runs one hop operation on the memories.

4.2.1 Single Layer

Here, we explain the representation scheme of the memories for both histories and the input/output operations on them along with attention mechanism. The memory representation for each history is generated using a GRU for modeling emotion transitions. First, we define the GRU cell.

Gated Recurrent Unit: GRUs are a gating mechanism in recurrent neural networks introduced by (Cho et al., 2014). Similar to an LSTM (Hochreiter and Schmidhuber, 1997), GRU provides a simpler computation with similar performance. At any timestep t, it utilizes two gates r_t (*reset gate*) and z_t (*update gate*) to control the combination criteria with current input utterance u_t and previous hidden state s_{t-1}.

The new state s_t is computed as:

$$z_t = \sigma(V^z.u_t + W^z.s_{t-1} + b^z) \quad (2)$$

$$r_t = \sigma(V^r.u_t + W^r.s_{t-1} + b^r) \quad (3)$$

$$h_t = tanh(V^h.u_t + W^h.(s_{t-1} \otimes r_t) + b^h) \quad (4)$$

$$s_t = (1 - z_t) \otimes h_t + z_t \otimes s_{t-1} \quad (5)$$

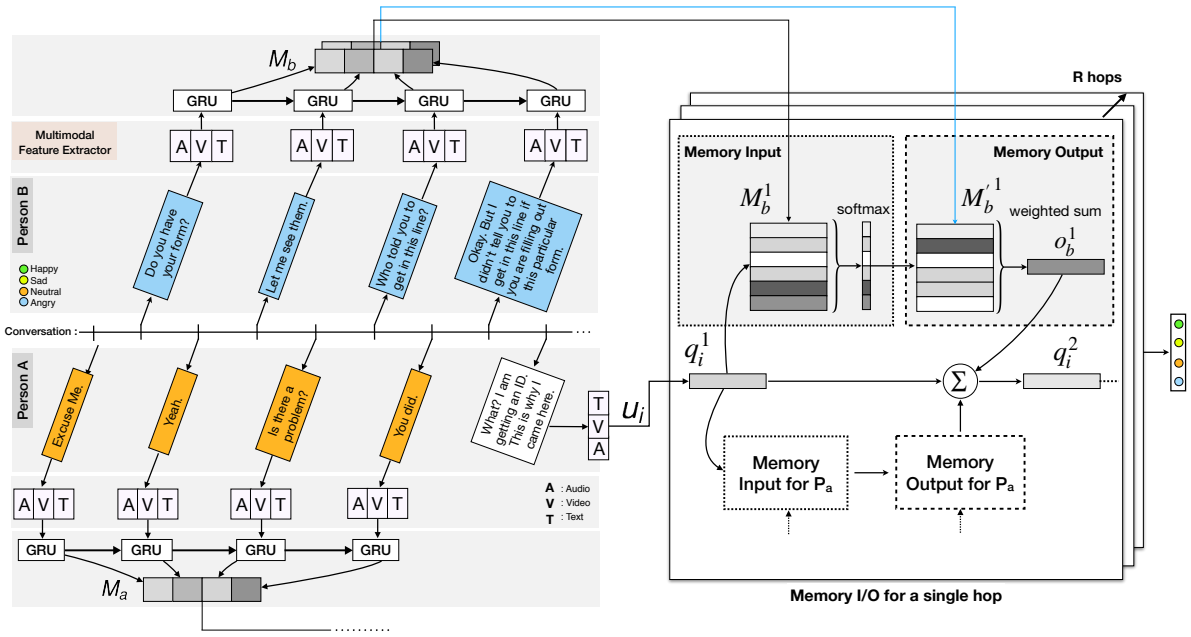

Figure 2: Overall architecture of proposed model: CMN. First, multimodal representations are extracted for each utterance and then the previous $K = 4$ utterances by both persons are used to model the histories using GRUs. For each person, $R+1$ different GRUs are used to represent $M_\lambda^{(r)}$ for all R hops. Then, attention based filtering using multiple memory hops is performed. Finally, Person A's utterance u_i is classified to predict its emotion category.

Here, V, W and b are parameter matrices and vector and $\otimes$ represents element-wise multiplication. The above equations can be summarized as: $s_t = GRU_\lambda(s_{t-1}, u_t)$.

Memory Representation: For each $\lambda \in \{a, b\}$, a memory representation $M_\lambda = [m_\lambda^1, ..., m_\lambda^K]$ for $hist_\lambda$ is generated using a GRU. To grasp the temporal context, the K utterances in $hist_\lambda$ are framed as a sequence (starting from the oldest one) and fed to the GRU$_\lambda$. At each timestep $t \in [1, K]$, the GRU$_\lambda$'s internal state s_t (equation 5) forms the t^{th} memory cell m_λ^t of memory representation M_λ.

Memory Input: This step takes the memory representation M_λ and performs an attention mechanism on it, resulting in an attention vector $p_\lambda \in \mathcal{R}^K$. First, the current utterance u_i is embedded into a vector q_i of dimension $\mathcal{R}^d$ using a projection matrix $B \in \mathcal{R}^{d \times d_{in}}$. To find the relevance of each memory m_λ^t's context with q_i, a match between both is computed.
We do this by taking an inner product as follows:

$$q_i = B.u_i \tag{6}$$

$$p_\lambda^t = softmax(q_i^T.m_\lambda^t) \tag{7}$$

Here, $softmax(x_i) = e^{x_i} / \sum_j e^{x_j}$ and attention vector $p_\lambda = \{p_\lambda^t\}$ is a probability distribution over the input memories $M_\lambda = \{m_\lambda^t\}$ for $t \in [1, K]$.

Memory Output: First a new set of memories are created using another GRU$_\lambda^{'}$ to get new memory representation $M_\lambda^{'} = \{(m_\lambda^t)^{'}\}$. An output representation $o_\lambda \in \mathcal{R}^d$ is then generated using the weighted sum of attention vector p_λ and new memory $M_\lambda^{'}$ as follows:

$$o_\lambda = \sum_t p_\lambda^t.(m_\lambda^t)^{'} = M_\lambda^{'}.p_\lambda \tag{8}$$

Thus, the output representation o_λ contains weighted contextual summary accumulated from the memory.

Final Prediction: To generate the predictions for the current utterance u_i, we combine the output representations of both persons: o_a and o_b with u_i's representation q_i and perform an affine transformation using matrix W_o. Softmax is applied to this final vector to get the emotion predictions,

$$\hat{y} = softmax(W_o.(q_i + o_a + o_b)) \tag{9}$$

Categorical cross-entropy is used as the loss:

$$Loss = \frac{-1}{N} \sum_{i=1}^{N} \sum_{j=1}^{C} y_{i,j} \; log_2(\hat{y}_{i,j}) \tag{10}$$

Here, N denotes total utterances across all videos and C is the number of emotion categories. y_i is the one-hot vector ground truth of i^{th} utterance from the training set and $\hat{y}_{i,j}$ is its predicted probability of belonging to class j.

4.2.2 Multiple Layers

Many recent works on memory networks adopt a multiple hop scheme in their network. This repeated input and output cycle on the memories along with a soft attention module, leads to a refined representation of the memories (Sukhbaatar et al., 2015; Kumar et al., 2016). Motivated by these works, we extend our model to perform R hops on the memories. This is done by stacking the single hop layers (Section 4.2.1) as follows:

- At a particular hop r, the output memory of the previous hop $M_\lambda^{'(r-1)}$ is used as the input memory of the current hop $M_\lambda^{(r)}$. Output memory of current r^{th} hop is generated using a new $GRU_\lambda^{(r)}$. This constraint of sharing parameters adjacently between layers is added for reduction in total parameters and ease of training.
- At every hop, the query utterance u_i's representation q_i is updated as:

$$q_i^{(r+1)} = q_i^{(r)} + o_a^{(r)} + o_b^{(r)} \quad (11)$$

  $o_\lambda^{(r)}$ is calculated as per equation 8 using $M_\lambda^{'(r)}$.
- After R hops, the final prediction is done using equation 9 as: $\hat{y} = softmax(W_o.(q_i^{(R+1)}))$. Algorithm 1 summarizes the overall CMN network.

5 Experiments

5.1 Dataset

We perform experiments on the IEMOCAP dataset[2] (Busso et al., 2008). It is a multimodal database of 10 speakers (5 male and 5 female) involved in two-way dyadic conversations. A pair of speakers is given multiple conversation scenarios which are grouped in a single session. All the conversations are segmented into utterances. Each utterance is annotated using the following emotion categories: anger, happiness, sadness, neutral, excitement, frustration, fear, surprise, and other. However, in our experiments, we consider the first four categories. This is done to compare our method with state-of-the-art frameworks (Poria et al., 2017b; Rozgic et al., 2012). The dataset provides rich video and audio samples for all the utterances along with transcriptions.

Apart from these emotional states, we also investigate the valence and arousal degrees of each utterance. IEMOCAP provides labels for both these attributes on a 5-point Likert scale. Following Aldeneh et al., 2017, we convert the attributes into 3 categories, namely, *low* ($\leq$ 2), *medium* ($>$ 2 and $<$ 4) and *high* ($\geq$ 4). The dataset configuration for the experiments is obtained from Poria et al. (2017b). The first 8 speakers (Session 1 - 4) compose the training fold while the last session is used as the testing fold. Overall, the training and testing set comprises of 4290 utterances (120 conversational videos) and 1208 utterances (31 conversational videos), respectively. There is no speaker overlap in the training and testing set to make the model person-independent.

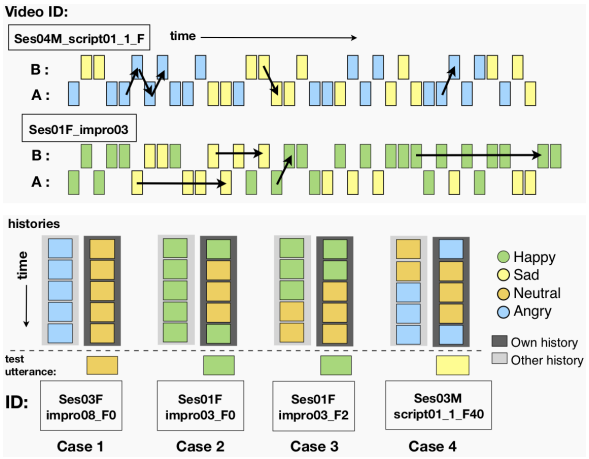

Figure 3: Each block represents an utterance and the blocks are ordered as per temporal occurrence. Color scheme identifies their corresponding emotions. The arrows denote emotional influence directions.

5.2 Emotional Influence Patterns

In this section, we perform dataset exploration to check the existence of emotional influences. Figure 3a) presents the emotion sequence of two videos

[2] http://sail.usc.edu/iemocap/

sampled from the dataset. Both videos show the presence of self and inter-speaker emotional influences. Visual exploration of videos from the dataset reveal significant existence of such instances in the conversations. To provide quantitative evidence of the emotional influence patterns, we curate a non exhaustive list of possible cases of influence. For all utterances in the dataset, we sample their histories by setting $K = 5$, i.e., five previous utterances (as per availability) from both speakers.

Cases 1 and 2 (Figure 3) represent scenarios when the emotion of current utterance is influenced by self or the other person respectively. In case 3, the utterance has relevant content in the histories that do not precede immediately. An effective attention mechanism provides the capability to capture this pattern. Finally case 4 presents the situation when the utterance is independent of the history. Such situations are indicative from the content of the utterance which often deviates from the previous topic of discussion or introduces a new information. Table 1 presents a statistical summary of these cases present in the dataset. From the table it can be seen that a large section of the dataset demonstrate these influence patterns. This provides motivation to explicitly model these patterns. We thus hypothesize that models that are able to capture these cases would have superior emotion inference capabilities.

This passive exploration is a label-based analysis which is performed as a sanity check. Needless to say, existence of some false positive patterns at the label level is imminent. On the other hand, our model CMN is content-based which enables it to mine intricate patterns from the utterance histories.

5.2.1 Training Details

We use 10% of the training set as a held-out validation set for hyperparameter tuning. To optimize the parameters, we use Stochastic Gradient Descent (SGD) optimizer, starting with an initial learning rate (lr) of 0.01. An annealing approach halves the lr every 20 epochs and termination is decided using an early-stop measure with a patience of 12 by monitoring the validation loss. Gradient clipping is used for regularization with a norm set to 40. Hyperparameters are decided using a Random Search (Bergstra and Bengio, 2012). Based on validation performance, context window length K is set to be 40 and the number of hops R is fixed at 3 hops. If K previous utterances are unavailable, then null utterances are added at the beginning of the history sequence. The dimension size of the memory cells d is set as 50.

	Case 1	*Case 2*	*Case 3*	*Case 4*
Percentage	63.77	40.44	30.97	16.24

Table 1: Percentage of occurrence of different cases in the dataset as mentioned in Section 5.2. All cases are analyzed with $K = 5$. Utterances whose history has atleast 3 similar emotion labels in either own history or the history of the other person, is counted in case 1 or 2, respectively. Case 3 is considered when the utterance's emotion is found in atleast 3 utterances which occur before the second past-utterance of each history. Case 4 is considered when no history has the emotion label of the current utterance.

5.2.2 Baselines

We compare CMN with the following baselines:

SVM-ensemble: A strong context-free benchmark model which uses similar multimodal approach on an ensemble of trees. Each node represents binary support vector machines (SVM) (Rozgic et al., 2012).

bc-LSTM: A bi-directional LSTM equipped with hierarchical fusion, proposed by Poria et al., 2017b. It is the present state-of-the-art method. The model uses context features from unimodal LSTMs and its concatenation is fed to a final LSTM for classification. For fair comparison in an end-to-end learning paradigm, we remove the penultimate SVM of this model. The model doesn't accommodate inter-speaker dependencies.

Memn2n: The original memory network as proposed by Sukhbaatar et al., 2015. Contrasting to CMN, the model generates the memory representations for each historical utterance using an embedding matrix B as used in equation 7, without sequential modeling. Thus for utterance u_i, both memories are created as M_λ using $\{m^t_\lambda = B.u_t \mid u_t \in hist_\lambda \text{ and } t \in [1, K]\}$ for $\lambda \in \{a, b\}$.

CMN$_{Self}$: In this baseline, we use only self history for classifying emotion of utterance u_i. Thus, if u_i is spoken by person P_a, then only $hist_a$ is considered. Clearly, this variant is also incapable of modeling inter-speaker dependencies.

CMN$_{NA}$: Single layer variant of the CMN with no attention module. Thus, its output o_λ (equation 8) is generated using a uniform probability distribution p_λ, i.e., $\{p^t_\lambda = \frac{1}{K}\}^K_{t=1}$.

5.3 Results

Table 2 presents the performances of CMN and its variants along with the state-of-the-art mod-

Models	hops	history	Emotion Categories					Valence		Arousal

[1](Rozgic et al., 2012), [2](Poria et al., 2017b). †: significantly better than bc-LSTM[1]

Table 2: Comparison of CMN and its variants with state-of-the-art models (Section 5.2.2). All results use multimodal features. We report scores using weighted accuracy (WAA) and unweighted recall (UAR). UAR is a popular metric that is used when dealing with imbalanced classes (Rosenberg, 2012). Results are an average of 10 runs with varied weight initializations. We assert significance when $p < 0.05$ under McNemar's test.

els. CMN succeeds over both neural (Poria et al., 2017b) and SVM-based (Rozgic et al., 2012) methods by 3.3% and 8.12%, respectively. Improvement in performance is seen for all emotions over the ensemble-SVM based method. A similar trend is seen with bc-LSTM (Poria et al., 2017b), where our model does explicitly well for the active emotions *happiness* and *anger*. This trend suggests that CMN is capable of capturing inter-speaker emotional influences which are often seen in the presence of such active emotions.

The importance of sequential processing of the histories using a recurrent neural network (in our case, a GRU) is evidenced by the poorer performance of Memn2n with respect to CMN. This suggests that gathering contexts temporally through sequential processing is indeed a superior method over non-temporal memory representations. CMN_{self} which uses only single history channel also provides lesser performance when compared to CMN. This signifies the role of inter-speaker influences that often moderate the emotions of the current utterance. Overall, predictions on valence and arousal levels also show similar results which reinforce our hypothesis of CMN's ability to model emotional dynamics.

Hyperparameters: Figure 4 provides a summary of the performance trend of our model for different values of the hyperparameters K (context window length) and Q (number of hops). In the first graph, as K increases, more past-utterances are provided to the model as memories. The performance maintains a positive correlation with K. This trend supplements our intuition that the historical context acts as an essential resource to model emotional dynamics. Given enough history, the performance saturates. The second graph shows that multiple hops on the histories indeed lead to an improvement in performance. The attention-based filtering in each hop provides a refined context representation of the histories. Models with hops in the range of 3 – 10 outperform the single layer variant. However, each added hop contributes a new set of parameters for memory representation, leading to an increase in total parameters of the model and making it susceptible to overfitting. This effect is evidenced in the figure where higher hops lead to a dip in performance.

Multimodality: Table 3 summarizes the performance of unimodal and multimodal variants of the baselines along with CMN. As seen in the table, text modality performes best out of the three. This is in contrast to Rozgic et al. 2012 where audio provides the best performance. A possible reason for

Models	*unimodal audio*	*unimodal visual*	*unimodal text*	*trimodal*
SVM-ensemble	60.8	51.5	48.5	69.5‡
bc-LSTM	62.2	56.1	72.5	74.3‡
Memn2n	63.0	61.8	72.6	75.0‡
CMN_{self}	63.1	62.5	73.0	76.5‡
CMN_{NA}	62.4	60.9	74.1	75.7

‡: significantly better than unimodals ($p < 0.05$)

Table 3: Comparison of CMN to all the baselines in different modalities. Weighted accuracy is used as the metric.

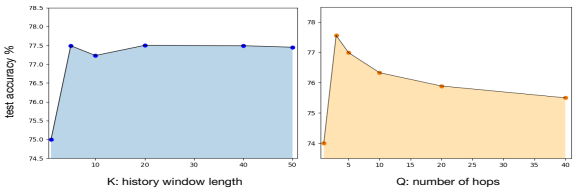

Figure 4: Performance trends of our model with different values of K (history length) and Q (number of hops). While K is varied, Q is set to be 3. Similarly, $K = 20$ when Q varies.

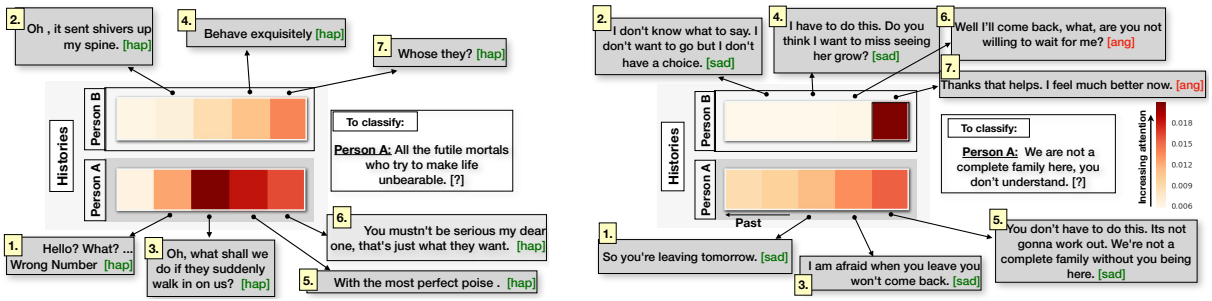

(a) Correct label: *happiness* (b) Correct label: *anger*

Figure 5: Average attention vectors across 3 hops for both memories for a given test utterance.

this shift is the improved representational scheme of the textual modality. Text tends to have lesser noisy signals as opposed to audio-visual sources, thus providing better features in the joint representation. Overall, multimodal systems outperform the unimodal variants justifying the design of CMN as a multimodal system.

Table 3 also showcases the superiority of CMN and its variants over bc-LSTM. The proposed model achieves better performance over the state of the art in all the unimodal and multimodal segments. This asserts the importance of the memory-network framework and its ability to effectively store context information.

Role of Attention: Attention module plays a vital role in memory refinement. This is also observed in Table 2, where CMN$_{NA}$ provides inferior performance over CMN. With the uniform weight, all the memory cells in both memories M_a and M_b equally contribute to the output representation. This incorporates irrelevant information from the perspective of emotional context.

Case Study: We perform qualitative visualization of the attention module by applying it on the testing set. Figure 5a represents a conversation where both the speakers are in an excited and jolly mood. Person A, in particular, drives the dialogue with less influence from Person B. To classify the test utterance of A, the attention module of CMN successfully focuses on the utterances $1, 3, 5$ which had triggered the speaker's positive mood in the video. This shows CMN's capacity to model speaker-based emotions. Also, at the textual level, utterances 3 and 6 do not seem to depict a happy mood. However, audio and visual sources provide contrasting evidence which helps CMN to correctly model them as utterances spoken with happiness. This shows the advantage of a multimodal system.

In Figure 5b we reiterate through the dialogue presented in Figure 1. As shown, Person A converses in a sad mood (utterances $1, 3, 5$ in Fig 5b), bounded by the grief of his wife's departure. But when he expresses his inhibitions, his wife B reacts in an angry and sarcastic manner (utterance 7). This ignites an emotional shift for A who then replies angrily. In this example, CMN is able to focus on utterance 7 spoken by B to anticipate A's test utterance to be an angry statement, thus showing its ability to model inter-speaker influences. However, there are cases where our model fails, e.g., in the absence of historical utterances as this forces attention to focus on null memories.

6 Conclusion

In this paper, we presented a deep neural framework that identifies emotions for utterances in dyadic conversational videos. Our results suggest that leveraging context information from utterance histories and representing them as memories indeed helps to better recognize emotions. Performing speaker-specific modeling and considering inter-speaker influences also helps in capturing emotional dynamics.

This work also showed the importance of attention mechanism in filtering relevant contextual information from utterance histories and, hence, paved the path to the development of more efficient and human-like dialogue systems.

Abstract

Spoken language understanding (SLU) is an essential component in conversational systems. Most SLU components treat each utterance independently, and then the following components aggregate the multi-turn information in the separate phases. In order to avoid error propagation and effectively utilize contexts, prior work leveraged history for contextual SLU. However, most previous models only paid attention to the related content in history utterances, ignoring their temporal information. In the dialogues, it is intuitive that the most recent utterances are more important than the least recent ones, in other words, time-aware attention should be in a decaying manner. Therefore, this paper designs and investigates various types of time-decay attention on the sentence-level and speaker-level, and further proposes a flexible universal time-decay attention mechanism. The experiments on the benchmark Dialogue State Tracking Challenge (DSTC4) dataset show that the proposed time-decay attention mechanisms significantly improve the state-of-the-art model for contextual understanding performance[1].

1 Introduction

Spoken dialogue systems that can help users to solve complex tasks such as booking a movie ticket have become an emerging research topic in artificial intelligence and natural language processing areas. With a well-designed dialogue system as an intelligent personal assistant, people can accomplish certain tasks more easily via natural language interactions. Today, there are several virtual intelligent assistants, such as Apple's Siri, Google's Home, Microsoft's Cortana, and Amazon's Echo. Recent advance of deep learning has inspired many applications of neural models to dialogue systems (Wen et al., 2017; Bordes et al., 2017; Dhingra et al., 2017; Li et al., 2017).

A key component of a dialogue system is a spoken language understanding (SLU) module—it parses user utterances into semantic frames that capture the core meaning (Tur and De Mori, 2011). A typical pipeline of SLU is to first decide the domain given the input utterance, and based on the domain, to predict the intent and to fill associated slots corresponding to a domain-specific semantic template, where each utterance is treated independently (Hakkani-Tür et al., 2016; Chen et al., 2016b,a; Wang et al., 2016). To overcome the error propagation and further improve understanding performance, the contextual information has been shown useful (Bhargava et al., 2013; Xu and Sarikaya, 2014; Chen et al., 2015; Sun et al., 2016). Prior work incorporated the dialogue history into the recurrent neural networks (RNN) for improving domain classification, intent prediction, and slot filling (Xu and Sarikaya, 2014; Shi et al., 2015; Weston et al., 2015; Chen et al., 2016c). Recently, Chi et al. (2017) and Zhang et al. (2018) demonstrated that modeling speaker role information can learn the notable variance in speaking habits during conversations in order to benefit understanding.

In addition, neural models incorporating attention mechanisms have had great successes in machine translation (Bahdanau et al., 2014), image captioning (Xu et al., 2015), and various tasks. Attentional models have been successful because they separate two different concerns: 1) deciding which input contexts are most relevant to the output and 2) actually predicting an output given the most relevant inputs. For example, the highlighted current utterance from the tourist, "*uh on august*", in the conversation of Figure 1 is to respond the question about WHEN, and the content-

aware contexts that can help current understanding are the first two utterances from the guide "*and you were saying that you wanted to come to singapore*" and "*un maybe can i have a little bit more details like uh when will you be coming*". Previous work proposed an end-to-end time-aware attention network to leverage both contextual and temporal information for spoken language understanding and achieved the significant improvement, showing that the temporal attention can guide the attention effectively (Chen et al., 2017). However, the time-aware attention function is an inflexible hand-crafted setting, which is a fixed function of time for assessing the attention.

This paper focuses on investigating various flexible time-aware attention mechanism in neural models with contextual information and speaker role modeling for language understanding. The contributions are three-fold:

- This paper investigates different time-aware attention mechanisms and provides guidance for the future research about designing the time-aware attention function.
- This paper proposes an end-to-end learnable universal time-decay mechanism with great flexibility of modeling temporal information for diverse dialogue contexts.
- The proposed model achieves the state-of-the-art understanding performance in the dialogue benchmark DSTC dataset.

2 The Proposed Framework

The model architecture is illustrated in Figure 2. First, the previous utterances are fed into the contextual model to encode into the history summary, and then the summary vector and the current utterance are integrated for helping understanding. The contextual model leverages the attention mechanisms highlighted in red, which implements different attention functions for sentence and speaker role levels. The whole model is trained in an end-to-end fashion, where the history summary vector and the attention weights are automatically learned based on the downstream SLU task. The objective of the proposed model is to optimize the conditional probability of the intents given the current utterance, $p(\hat{\mathbf{y}} \mid \mathbf{x})$, by minimizing the cross-entropy loss.

2.1 Speaker Role Contextual Language Understanding

Given the current utterance $\mathbf{x} = \{w_t\}_1^T$, the goal is to predict the user intents of $\mathbf{x}$, which includes the speech acts and associated attributes. We apply a bidirectional long short-term memory (BLSTM) model (Schuster and Paliwal, 1997) to history encoding in order to learn the probability distribution of the user intents.

$$\mathbf{v}_{\text{cur}} = \text{BLSTM}(\mathbf{x}, W_{\text{his}} \cdot \mathbf{v}_{\text{his}}), \quad (1)$$

$$\mathbf{o} = \texttt{sigmoid}(W_{\text{SLU}} \cdot \mathbf{v}_{\text{cur}}), \quad (2)$$

where W_{his} is a weight matrix and $\mathbf{v}_{\text{his}}$ is the history summary vector, $\mathbf{v}_{\text{cur}}$ is the context-aware vector of the current utterance encoded by the BLSTM, and $\mathbf{o}$ is the intent distribution. Note that this is a multi-label and multi-class classification, so the `sigmoid` function is employed for modeling the distribution after a dense layer. The user intent labels are decided based on whether the value is higher than a threshold tuned by the development set.

Considering that speaker role information is shown to be useful for better understanding in complex dialogues (Chi et al., 2017), we follow the prior work for utilizing the contexts from two roles to learn history summary representations, $\mathbf{v}_{\text{his}}$ in (1), in order to leverage the role-specific contextual information. Each role-dependent recurrent unit $\text{BLSTM}_{\text{role}_i}$ receives corresponding inputs, x_{t,role_i}, which includes multiple utterances u_i ($i = [1, ..., t-1]$) preceding the current utterance u_t from the specific role, role_i, and have been processed by an encoder model.

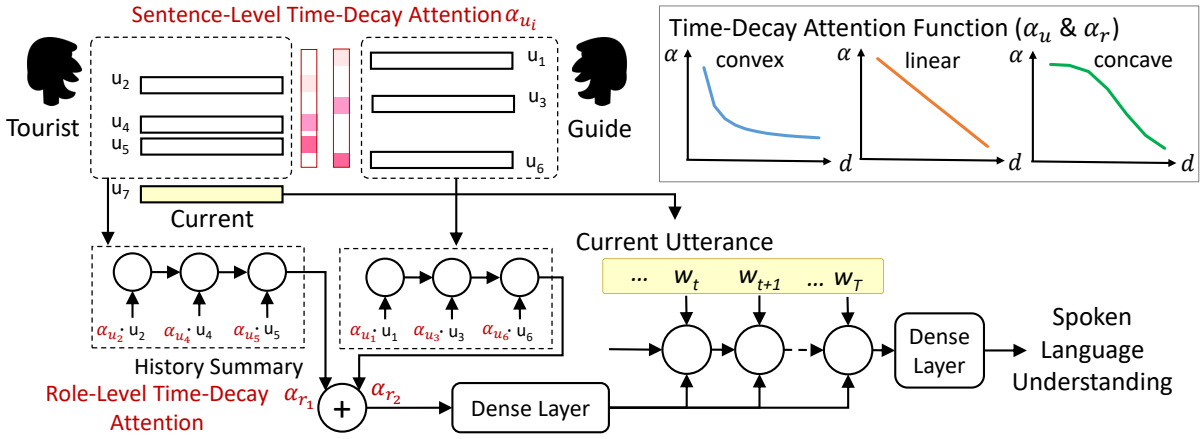

Figure 2: Illustration of the proposed time-aware attention contextual model with three types of time-decay attention functions.

$$\mathbf{v}_{\text{his}} = \sum_{\text{role}} \mathbf{v}_{\text{his,role}} = \sum_{\text{role}} \text{BLSTM}_{\text{role}}(x_{t,\text{role}}), \quad (3)$$

where $x_{t,\text{role}}$ are vectors after one-hot encoding that represent the annotated intent and the attribute features. Note that this model requires the ground truth annotations for history utterances for training and testing. Therefore, each role-based contextual module focuses on modeling role-dependent goals and speaking style, and $\mathbf{v}_{\text{cur}}$ from (1) would contain role-based contextual information.

2.2 Neural Attention Mechanism

One of the earliest work with a memory component applied to language processing is memory networks (Weston et al., 2015; Sukhbaatar et al., 2015), which encodes mentioned facts into vectors and stores them in the memory for question answering. The idea is to encode important knowledge and store it into memory for future usage with attention mechanisms. Attention mechanisms allow neural network models to selectively pay attention to specific parts. There are also various tasks showing the effectiveness of attention mechanisms (Xiong et al., 2016; Chen et al., 2016c). Recent work showed that two attention types (content-aware and time-aware) and two attention levels (sentence-level and role-level) significantly improve the understanding performance for complex dialogues. This paper focuses on expanding the time-aware attention based on the investigation of different time-decay functions, and further learning an universal time-decay function automatically. For time-aware attention mechanisms, we apply it using two levels, sentence-level and role-level structures, and Section 3 details the design and analysis of time-aware attention.

For the sentence-level attention, before feeding into the contextual module, each history vector is weighted by its time-aware attention α_{u_j} for replacing (3):

$$\mathbf{v}^U_{\text{his}} = \sum_{\text{role}} \text{BLSTM}_{\text{role}}(x_{t,\text{role}}, \{\alpha_{u_j} \mid u_j \in \text{role}\}).$$

For the role-level attention, a dialogue is disassembled from a different perspective on which speaker's information is more important (Chi et al., 2017). The role-level attention is to decide how much to address on different speaker roles' contexts ($\mathbf{v}_{\text{his,role}}$) in order to better understand the current utterance. The importance of a speaker given the contexts can be approximated to the maximum attention value among the speaker's utterances, $\alpha_{\text{role}} = \max \alpha_{u_j}$, where u_j includes all contextual utterances from the speaker. With the role-level attention, the sentence-level history from (3) can be rewritten into

$$\mathbf{v}^R_{\text{his}} = \sum_{\text{role}} \alpha_{\text{role}} \cdot \mathbf{v}_{\text{his,role}} \quad (4)$$

for combining role-dependent history vectors with their attention weights.

2.3 End-to-End Training

The objective is to optimize SLU performance, predicting multiple speech acts and attributes described in Section 2.1. In the proposed model,

all encoders, prediction models, and attention weights can be automatically learned in an end-to-end manner.

3 Time-Decay Attention Learning

The decaying function curves can be easily separated into three types: *convex*, *linear*, and *concave*, illustrated in the top-right part of Figure 2, and each type of time-decay functions expresses a time-aware perspective given dialogue contexts. Note that all attention weights will be normalized such that their summation is equal to 1.

3.1 Convex Time-Decay Attention

A *convex* curve also known as "concave upward", in a simple 2D Cartesian coordinate system (x, y), a convex curve $f(x)$ means when x goes greater, the slope $f'(x)$ is increasing. Intuitively, recent utterances contain more salient information, and the salience decreases very quickly when the distance increases; therefore we introduce the time-aware attention mechanism that computes attention weights according to the time of utterance occurrence explicitly. We first define the time difference between the current utterance and the preceding sentence u_i as $d(u_i)$, and then simply use its reciprocal to formulate a convex time-decay function:

$$\alpha_{u_i}^{\text{conv}} = \frac{1}{a \cdot d(u_i)^b}, \tag{5}$$

where a and b are scalar parameters.

The increasing slopes of the decay-curve assert that importance of utterances should be attenuated rapidly, and the importance of a earlier history sentence would be considerably compressed. Note that Chen et al. used a fixed convex time-decay function ($a = 1, b = 1$) (Chen et al., 2017).

3.2 Linear Time-Decay Attention

A *linearly* decaying time-aware attention function should also be taken into consideration. In a simple 2D Cartesian coordinate system (x, y), the slopes of a linear function remain consistent when x changes. That is, the importance of preceding utterances linearly declines as the distance between the previous utterance and the target utterance becomes larger.

$$\alpha_{u_i}^{\text{lin}} = \max(e \cdot d(u_i) + f, 0), \tag{6}$$

where e and f are the slope and the α-intercept of the linear function. Note that when the distance $d(u_i)$ is larger than $-\frac{f}{e}$, we assign the attention value as 0.

3.3 Concave Time-Decay Attention

A *concave* curve also called "concave downward", in contrast to convex curves, in a simple 2D Cartesian coordinate system (x, y), a concave curve $f(x)$ means that the slope $f'(x)$ is decreasing when x goes greater. Intuitively, the attention weight decreases relatively slow when the distance increases. To implement this idea, we design a $Butterworth\ filter$-like low-distance pass filter (Butterworth, 1930) that is similar to the concave time-decay function in the beginning of the curve.

$$\alpha_{u_i}^{\text{conc}} = \frac{1}{1 + (\frac{d(u_i)}{D_0})^n}, \tag{7}$$

where D_0 is the cut-off distance and n is the order of filter. The decreasing slopes of the decay-curve assert that the importance of utterances should weaken gradually, and the importance of a earlier history sentence would still be considerably compressed. Moreover, it is more likely to preserve the information in the multiple recent utterances instead of focusing only on the most recent one.

3.4 Universal Time-Decay Attention

As mentioned previously, there are three types of decaying curves: convex, linear, concave, each type represents a different perspective on dialogue contexts and models different contextual patterns. However, because the contextual patterns may be diverse, a single type of function could not fit the complex behavior well. Hence, we propose a flexible and universal time-decay attention function by composing three types of attentional curves:

$$\begin{aligned}\alpha_{u_i}^{\text{univ}} &= w_1 \cdot \alpha_{u_i}^{\text{conv}} + w_2 \cdot \alpha_{u_i}^{\text{lin}} + w_3 \cdot \alpha_{u_i}^{\text{conc}} \\ &= \frac{w_1}{a \cdot d(u_i)^b} + w_2(e \cdot d(u_i) + f) \\ &\quad + \frac{w_3}{1 + (\frac{d(u_i)}{D_0})^n},\end{aligned} \tag{8}$$

where w_i are the weights of time-decay attention functions. Because the framework can be trained in an end-to-end manner, all parameters (w_i, a, b, e, f, D_0, n) can be automatically learned to construct a flexible time-decay function. With the combination of different curves and the adjustable weights, the proposed universal time-decay attention function expresses the flexibility of not being

strictly decaying; that is, the model can automatically learn a properly oscillating curve in order to model the diverse and complex contextual patterns using the attention mechanism.

4 Experiments

To evaluate the proposed model, we conduct the language understanding experiments on human-human conversational data.

4.1 Setup

The experiments are conducted using the DSTC4 dataset, which consist of 35 dialogue sessions on touristic information for Singapore collected from Skype calls between 3 tour guides and 35 tourists, these 35 dialogs sum up to 31,034 utterances and 273,580 words (Kim et al., 2016). All recorded dialogues with the total length of 21 hours have been manually transcribed and annotated with speech acts and semantic labels at each turn level. The speaker information (guide and tourist) is also provided. Unlike previous DSTC series collected human-computer dialogues, human-human dialogues contain rich and complex human behaviors and bring much difficulty to all the tasks. Given the complex dialogue patterns and longer contexts, DSTC4 is a suitable benchmark dataset for evaluation. We randomly selected 28 dialogues as the training set, 5 dialogues as the testing set, and 2 dialogues as the validation set.

We choose the mini-batch *Adam* as the optimizer with the batch size of 256 examples. The size of each hidden recurrent layer is 128. We use pre-trained 200-dimensional word embeddings $GloVe$ (Pennington et al., 2014). We only apply 30 training epochs without any early stop approach. We focus on predicting multiple labels including intents and attributes, so the evaluation metric is an average F1 score for balancing recall and precision in each utterance. The experiments are shown in Table 1, where we report the average results over five runs. We include the best understanding performance (row (a)) from the participants of DSTC4 in IWSDS 2016 for reference (Kim et al., 2016). The one-tailed t-test is performed to validate the significance of improvement, and the numbers with markers indicate the significant improvement with $p < 0.05$.

4.2 Effectiveness of Time-Decay Attention

To evaluate the proposed time-decay attention, we compare the performance with the naïve LU model without any contextual information (row (b)), the contextual model without any attention mechanism (row (c)), and the one using the content-aware attention mechanism (row (d)), where the attention can be learned at sentence and role levels. The row (a) is the performance reported in the DSTC challenge[2]. It is intuitive that the model without considering contexts (row (b)) performs much worse than the contextual ones for dialogue modeling. The proposed time-aware results are shown in the rows (e)-(h), where the rows (e)-(f) use only the time-aware attention while the rows (g)-(h) model both content-aware and time-aware attention mechanisms together. It is obvious that almost all time-aware results are better than three baselines.

In order to investigate the performance of various time-decay attention functions, for each curve we apply two settings: 1) **Hand**: hand-crafted

[2]This experiment is not performed on the same setup as this paper, and the shown number is estimated for reference.

hyper-parameters (rows (e) and (g)) and 2) **E2E**: end-to-end training for parameters (rows (f) and (h)). In the hand-crafted setting, the hyper-parameters $a = 1, b = 1, e = -0.125, f = 1, D_0 = 5, n = 3$ are adopted[3]. Table 1 shows that among three types of the sentence-level time-decay attention, only the convex time-decay attention significantly outperforms the baselines, indicating that an unsuitable time-decay attention function is barely useful. For both settings, the convex functions perform best among the three types of time-decay functions. Also, the end-to-end trainable setting results in better performance for most cases.

For our proposed universal time-decay attention mechanism, the same settings are conducted: 1) composing fixed versions for three types of time-decay functions weighted by learned parameters w_i and 2) fully trainable parameters for all time-decay functions. These two settings provide different levels of flexibility in fitting dialogue contextual attention, and the experimental results show that two settings both outperform all other time-decay attention functions.

For sentence-level attention, the end-to-end trainable universal time-decay attention achieves best performance (rows (f) and (h)), where the flexible time-aware attention (rows (f) and (h)) obtains 2.9% relative improvement compared to the model without the attention mechanism (row (c)) and the model using content-aware attention only (row (d)). For role-level attention, all types of time-decay functions significantly improve the results. The probably reason may be that modeling temporal importance for each sentence is more difficult and less accurate, and speaker roles in the dialogues provide informative cues for the model to connect the temporal importance from the same speakers together; therefore, the conversational patterns can be considered to additionally improve the understanding results. The further analysis is discussed in Section 4.3. Similarly, the best results are also from the end-to-end trainable universal time-decay function.

The significant improvement achieved by the universal functions indicates that our model can effectively learn a suitable attention function through this flexible setting and derive a proper curve to fit the temporal tendency to help the model preserve the essence and drop unimportant parts in the dialogue contexts. To further investigate what the universal time-decay attention learns, we inspect the learned weights w_i and find that the convex attention function almost dominates the whole function. In other words, our model automatically learns that the convex time-decay attention is more suitable for modeling contexts from the dialogue data than the other two types. Therefore, we can conclude that in complex dialogues, the recent utterances contain majority of salient information for spoken language understanding, where the attention decay trend follows a convex curve.

We analyze the content-aware attention impact by comparing the results between time-aware only (rows (e)-(f)) and content and time-aware jointly (rows (g)-(h)). The content-aware attention (row (d)) fails to focus on the important contexts for improving understanding performance in the complex dialogues and even performs slightly worse than the contextual model without attention (row (c)). Without a delicately-designed attention mechanism, it is not guaranteed that incorporating an additional content-aware attention would bring better performance and the experimental results show that a simple and coarse content-aware attention barely provides any usable information given the complex dialogues. Therefore, we focus on whether our time-aware attention mechanisms can compensate the poor attention learned from the content-aware model. In other words, we are not going to verify whether our time-aware attention mechanisms could collaborate with the content-aware attention mechanism, instead, we focus on examining how much our proposed time-aware attention could mitigate the detriment of the content-aware attention. By comparing the results between time-aware only (rows (e)-(f)) and content and time-aware jointly (rows (g)-(h)), we find that our universal time-decay attention keeps the improvement without too much performance drop by involving the learned temporal attention. Namely, our proposed attention mechanism can capture temporal information precisely, and it therefore can counteract the harmful impact of inaccurate content-aware attention.

4.3 Effectiveness of Role-Level Attention

For role-level attention, Table 1 shows that all results with various time-decay attention mecha-

[3]The chosen parameters are based on the domain knowledge about dialogue properties.

LU Model	Context Length 3	5	7
No Attention Contextual	74.75	74.69 (-)	74.52 (-)
Content-Aware Contextual	74.04	73.90 (-)	73.69 (-)
Time-Aware (Hand)	76.05	76.34 (+)	76.41 (+)
Time-Aware (E2E)	76.26	76.43 (+)	76.67 (+)
Content+Time (Hand)	75.16	75.27 (+)	75.48 (+)
Content+Time (E2E)	75.82	75.92 (+)	75.83 (-)

Table 2: The sentence-level performance reported on F1 of the proposed universal time-decay attention under different context length settings (%). The symbols '+' and '-' indicate the performance trends.

Parameter	Time-Aware (E2E Trainable) Sentence	Role
w_1	0.758	1.078
w_2	0.544	-0.378
w_3	-0.302	0.300
a	0.888	0.841
b	0.969	1.084
e	-0.320	-0.129
f	0.640	0.993
D_0	4.873	4.980
n	2.977	2.755

Table 3: The converged values of end-to-end trainable parameters from the proposed universal time-decay attention models. The values are averaged over five runs.

nisms are better than the one with only content-aware attention (row (d)). However, linear and concave time-decay functions do not provide additional improvement when we model the attention at the sentence level. The probable reason may be that it is difficult to model attention for individual sentences given the unsuitable time-decay functions. That is, if designs of attention functions are unsuitable for dialogue contexts, the encoded sentence embeddings would be weighted by improper attention values. On the other hand, for role-level attention, each speaker role is assigned an attention value to represent their importance in the conversational interactions. Previous work (Chi et al., 2017; Chen et al., 2017) also demonstrated the effectiveness of considering speaker interactions for better understanding performance. By introducing role-level attention, the sentence-level attentional weights can be smoothed to avoid inappropriate values. Surprisingly, even though learning sentence-level temporal attention is difficult, our proposed universal time-decay attention can achieve similar performance for sentence-level and role-level attention (76.67% and 76.75% from the row (f)), further demonstrating the strong adaptability of fitting diverse dialogue contexts and the capability of capturing salient information.

4.4 Robustness to Context Lengths

It is intuitive that longer context brings richer information; however, it may obstruct the attention learning and result in poor performance because more information should be modeled and accurate estimation is not trivial. Because when modeling dialogues, we have no idea about how many contexts are enough for better understanding, the robustness to varying context lengths is important for the contextual model design. Here, we compare the results using different context lengths (3, 5, 7) for detailed analysis in Table 2, where the number is for each speaker. The models without attention and the content-aware models become slightly worse with increasing context lengths. However, our proposed universal time-decay attention model mostly achieves better performance when including longer contexts, demonstrating not only the flexibility of adapting diverse contextual patterns but also the robustness to varying context lengths.

4.5 Universal Time-Decay Attention Analysis

This paper proposes a flexible time-decay attention mechanism by composing three types of time-aware attention functions in different decaying tendencies, where each decaying curves reflect a specific perspectives on distribution over salient information in dialogue contexts. The proposed universal time-decay attention shows great capability of modeling diverse dialogue patterns in the experiments and therefore proves that our proposed method is a general design of time-decay attention. In our design, we endow the attention function with flexibility by employing many trainable parameters and hence it can automatically learn a properly decaying curve for fitting the dialogue contexts better.

To further analyze the combination of different time-decay attention functions, we inspect the converged values of the trainable parameters from the proposed universal time-decay attention models in Table 3. Under the end-to-end trainable setting, the initialization of the trainable parameters are the same as the hand-crafted ones ($w_i = 1, a = 1, b = 1, e = -0.125, f = 1, D_0 = 5, n = 3$). In the experiments, the models automatically figure out that convex time-decay attention function should have a higher weight than others for both

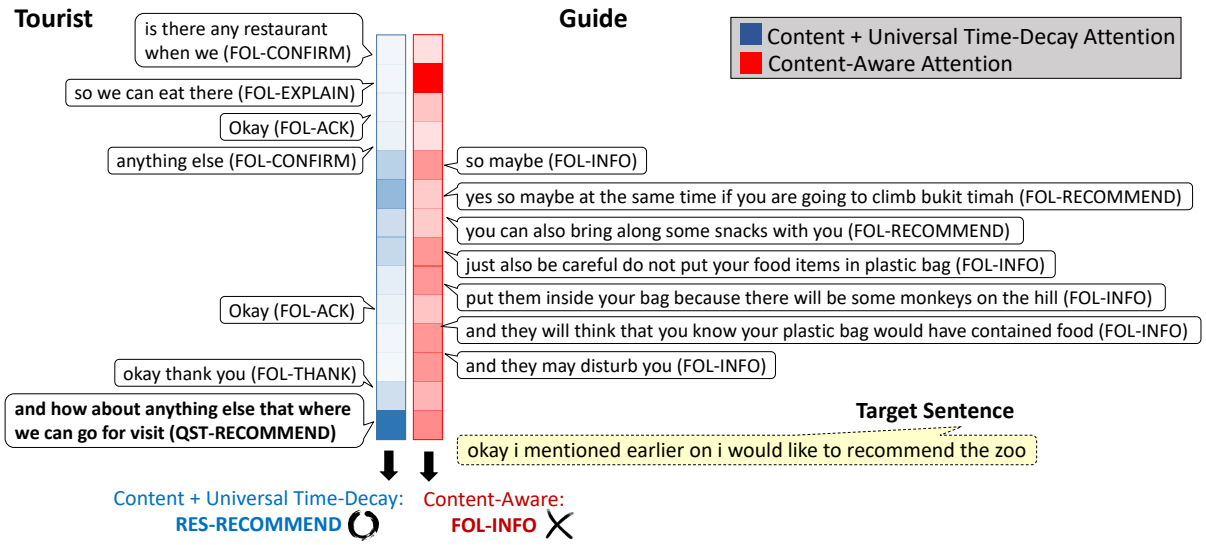

Figure 3: The visualization of the attention weights enhanced by the proposed time-decay function compared with the weights learned by the content-aware attention model.

sentence-level or role-level models ($w_1 > w_2$ and $w_1 > w_3$). Namely, in dialogue contexts, the recent utterances contain most information related to the current utterance, which is aligned with our intuition.

4.6 Qualitative Analysis

From the above experiments, the proposed time-decay attention mechanisms significantly improve the performance on both sentence and role levels. To further understand how the time-decay attention changes the content-aware attention, we dig deeper into the learned attentional values for sentences and illustrate the visualization in Figure 3. The figure shows a partial dialogue between the tourist (left) and the guide (right), where the color shades indicate the learned attention intensities of sentences. It can be found that the learned content-aware attention (red; row (c)) focuses on the incorrect sentence ("*so we can eat there*" (FOL-EXPLAIN)) and hence predicts the wrong label, FOL-INFO. The reason may be that with a coarse and simple design of content-aware attention mechanism, the attention function may not provide additional benefit for improvement. By additionally leveraging our proposed universal time-decay attention methods, the result (blue; row (g)) shows that the adjusted attention pays the highest attention on the most recent utterance and thereby predicts the correct intent, RES-RECOMMEND. It can be found that our proposed time-decay attention can effectively turn the attention to the correct contexts in order to correctly predict the dialogue act and attribute. Therefore, the proposed attention mechanisms are demonstrated to be effective for improving understanding performance in such complex human-human conversations.

5 Conclusion

This paper designs and investigates various time-decay attention functions based on an end-to-end contextual language understanding model, where different perspectives on dialogue contexts are analyzed and a flexible and universal time-decay attention mechanism is proposed. The experiments on a benchmark human-human dialogue dataset show that the understanding performance can be boosted by simply introducing the proposed time-decay attention mechanisms for guiding the model to focus on the salient contexts following a convex curve. Moreover, the proposed universal time-decay mechanisms are easily extensible to multi-party conversations and showing the potential of leveraging temporal information in NLP tasks of dialogues.

Towards understanding text factors in oral reading

Anastassia Loukina, Van Rynald T. Liceralde, Beata Beigman Klebanov

Princeton, NJ, USA
{aloukina,vliceralde,bbeigmanklebanov}@ets.org

Abstract

Using a case study, we show that variation in oral reading rate across passages for professional narrators is consistent across readers and much of it can be explained using features of the texts being read. While text complexity is a poor predictor of the reading rate, a substantial share of variability can be explained by timing and story-based factors with performance reaching r=0.75 for unseen passages and narrator.

1 Introduction

Listening to and performing oral reading are activities that permeate daily life, from parents reading aloud to young children, through reading instruction in elementary school, to audiobook narrations increasingly chosen by adults as the form of book-reading that fits in a busy schedule. Oral reading is also used in assessment of language skills for children and language learners, and in professions such as teaching and news broadcasting.

Reading rate is a common metric used to control or evaluate oral reading. It is usually computed as a number of words read per minute, and is used in many applications. For example, research in second language acquisition has considered both optimal reading rates for listening materials aimed at English language learners and reading rates that ensure the highest comprehensibility of accented speech (Munro and Derwing, 1998). Speech rate is a standard feature in systems for automated scoring of second language proficiency (Higgins et al., 2011) including read aloud tasks (Zechner et al., 2012; Evanini et al., 2015). Reading rate is also one of the main measures used to assess the fluency of oral reading (Hasbrouck and Tindal, 2006).

The assumption underlying these uses is that reading rate is a property of the reader (or controlled by the reader). However, variation in reading rate across different passages for the same readers has also been reported (Foulke, 1968; Tauroza and Allison, 1990; Ardoin et al., 2005; Compton et al., 2004; Beigman Klebanov et al., 2017).

Improving the understanding of the properties of oral reading, such as reading rate, is thus an important theoretical goal. We also have a specific practical reason to study text-based variation in reading rate. We are developing an intervention for improving literacy that would encourage sustained reading by having the student read aloud multiple passages from an engaging novel-length book, taking turns with others. While it is technically easy to compute reading rate by timing the readers, if a reader's rate across different texts is not stable given his current reading skill, it is not clear that tracking the rate over time would yield a valid measurement of improvement in skill. However, if such variation is systematically dependent on the text being read, rather than a random or idiosyncratic fluctuation, we might be able to adjust the measurement to account for text effect.

In order to inform both the theoretical and the applied goals, we address the following research questions in this paper:

1. Is reading rate constant for a given reader across various texts?

2. If not, do different readers show similar patterns of variation across texts, or is variation idiosyncratic?

3. If variation exists and is systematic across readers, can we identify the properties of texts that impact reading rate?

In this paper, we study reading rates in two professional narrations of the same book-length text. By using professional narrations we are able to

Proceedings of NAACL-HLT 2018, pages 2143–2154
New Orleans, Louisiana, June 1 - 6, 2018.

eliminate other factors that might cause variation in reading rate, such as reader fatigue or disfluencies. While these would play a role in a practical application, we seek first to answer the research questions in a setup that allows focusing on the relationship between reading rate and the passage being read, controlling for other factors.

2 Related work

2.1 Passage effects in reading

Passage effects in reading have been addressed most directly in the context of assessment of reading. Since the intention is to measure the student's reading ability, any difference in performance that is not due to reading ability confounds the measurement. In particular, since comprehension complexity of a passage is known to impact reading comprehension, it seems reasonable to assume that it would also impact other aspects of reading skill, including oral reading fluency. In fact, this assumption underlies text selection for tests of oral reading fluency such as DIBELS (Good and Kaminski, 2002) that rely on readability to select comparable passages (Francis et al., 2008).

Yet research also suggests that controlling for readability does not entirely solve the problem of text-based variation in reading fluency. Ardoin et al. (2005) examined readability formulas for their ability to predict fluency and generally found only low-to-moderate correlations ($r<0.5$). Researchers also observed that fluency measurements for the same students varied across texts even for passages of comparable readability (Ardoin et al., 2005; Compton et al., 2004; Petscher and Kim, 2011; Francis et al., 2008).

Moreover, Francis et al. (2008) found that while actual fluency scores vary across different readability-controlled passages, the relative ranking of students is only minimally different when estimated using different passages, suggesting that variation in fluency has some consistency across readers; results to a similar effect were reported by Beigman Klebanov et al. (2017).

Oral reading fluency is commonly measured using words correct per minute – a combination of reading accuracy and reading rate. It is thus not clear whether the observations above pertain more to the accuracy aspect of oral reading (not considered in the current paper) or to reading rate, although Beigman Klebanov et al. (2017) noted that consistent variation across students was observed both for reading rate and for reading fluency.

To summarize, it appears that while readability could explain some of the variation in oral reading performance, there are also indicators that it is not sufficient on its own to effectively control for variation in oral reading performance caused by the properties of the passage being read.

2.2 Factors that affect duration of segments and pauses

2.2.1 Sentence-level timing

Since oral reading involves saying the text aloud, the durations of individual segments, words and phrases as well as location and duration of silent pauses are subject to constraints that have been extensively studied in literature on phonetic timing; see White (2014); Hirschberg (2002) for a review.

Thus it has been long known that different segments have different intrinsic durations which account for a lot of variation in segmental durations (Peterson and Lehiste, 1960; Klatt, 1976; van Santen, 1992): for example, high vowels tend to be shorter than low vowels. At the syllable level, in many languages vowels tend to be shorter when followed by a voiceless consonant than when followed by a voiced consonant (House and Fairbanks, 1953; Crystal and House, 1988) while consonants within a consonant cluster tend to be shorter than single consonants (Klatt, 1976).

Further constraints are at play at word, phrase and sentence level. White (2014) summarizes these as "domain-head" and "domain-edge" lengthening effects. "Domain-head" lengthening refers to lengthening of salient elements such as syllables bearing lexical stress, words in prominent positions (Peterson and Lehiste, 1960; Crystal and House, 1988; van Santen, 1992). "Domain-edge" effects include lengthening of segments in word-initial position or sentence-final lengthening (Turk and Shattuck-Hufnagel, 2000, 2007).

Finally, these domain-head and domain-edge lengthening effects do not apply uniformly: some segments and some positions are more resistant to lengthening than others (Peterson and Lehiste, 1960; Klatt, 1976; van Santen, 1992; White, 2014). The magnitude of lengthening also depends on the number of elements within each domain: in monosyllabic words, the stressed syllable receives all of the prosodic lengthening, but in disyllabic and trisyllabic words, some of the

lengthening spreads to the unstressed syllables and lengthening of the stressed syllable is attenuated (Turk and Shattuck-Hufnagel, 2000; White and Turk, 2010).

In addition to segmental lengthening, phrase and sentence boundaries are often associated with some amount of pause. The location and duration of sentence-internal pauses depends both on syntactic structure and the number of syllables in each adjacent unit: sentence-internal pauses associated with punctuation or major syntactic boundaries tend to be longer than other sentence-internal pauses, with sentence-final pauses being the longest (Pfitzinger and Reichel, 2006; Burrows et al., 2005; Bailly and Gouvernayre, 2012).

2.2.2 Content and duration

Beyond domain-head and domain-edge effects, duration of segments and pauses is also affected by other aspects of text content. Frequent words tend to have shorter duration than phonologically similar less frequent words. Words that are more predictable in a given context tend to be shorter than words with higher information load and repeated words are pronounced shorter than the first mention (see Zhao and Jurafsky (2009); Bell et al. (2009) for reviews). Note that these effects persist after one controls for "domain-head" effects described in the previous section (Bell et al., 2009).

Further factors come into play in the context of story-telling where the speaker is either reading or narrating a well-rehearsed story. Montaño and Alías (2017) review approaches used to characterize story-telling speech.

Several studies observed that the duration of pauses between sentences and paragraphs in a longer story is not uniform. In their analysis of pausing in book reading, Bailly and Gouvernayre (2012) reported that pauses between paragraphs were longer than pauses between sentences. They also found that the thematic relationships between sentences affect breathing patterns although these were not immediately related to pause duration.

Reading rate has also been shown to depend on the emotional state of the speaker, whether genuine or performed as part of a dramatic reading: for example, actors tend to speak slower when expressing anger, fear or sorrow (Williams and Stevens (1972), see Scherer (2003) for a comprehensive review). Doukhan et al. (2011) analyzed pause distribution in a corpus of tales and reported "speakers' expressive reinterpretation of sentence syntactic structure" which they attributed to expressiveness of the reader.

There is also evidence that prosody may be affected by the narrative structure. Theune et al. (2006) observed in an informal analysis that Dutch actors narrating fairy-tales reduced their speech tempo when approaching the story climax. They also noticed an increase in duration in some words that indicated extreme value of a property. Doukhan et al. (2011) analyzed prosody in a corpus of French tales using Propp's morphology of Folktale (Propp, 1968). They found that narrative structures had a significant effect on various prosodic properties. For duration, epilogues were associated with lower articulation rate (syllables/min without pauses) while refrains had the lowest pausing time percentage. Finally, several studies found that impersonation by narrator of different characters leads to clear differences in pitch, intensity and spectral quality (Doukhan et al., 2011; Wang et al., 2006).

In short, previous research suggests that multiple factors may affect phone and pause duration in a reading of a story: from the phonetic properties of individual segments to where the passages falls within the narrative structure. However, most of these studies considered durations of individual segments, words, or pauses. It is not clear which of these effects will still persist when durations are averaged over a longer text as is the case for reading rate computation. In fact, studies in phonetics talk about "emergent speech rate" that can be relatively consistent over long stretches of speech (White, 2014). Furthermore, pause duration is likely to have a substantial effect on the reading rate (Kendall, 2013) yet previous research on pausing in story-telling suggests that this can be highly idiosyncratic.

3 Data

3.1 Text

We use the "Harry Potter and the Sorcerer's Stone" by J.K. Rowling (Rowling, 2015) as the case study for this paper. The book consists of 79,508 words spread across 17 chapters. We divided the text into 313 non-overlapping passages of about 250 words each (mean = 249 words; range: 190-309).[1] Boundaries of passages were set to be the starts

[1] This is roughly the intended length of a reading turn in the turn-taking reading intervention described in the Introduction.

and ends of paragraphs, where the end of a passage consists of a paragraph whose addition brings the passage closer to 250 words than without adding the paragraph. When generating passages, we took into account chapter boundaries so that no passage spanned two chapters: the word-count for passage generation was always re-set from the beginning of the chapter and any short fragments left at the end of a chapter were not included in the analysis. We randomly assigned 156 passages to the training set and 157 passages to the test set.

3.2 Audio

We used data from two narrators. The first dataset, hereafter referred to as JD, comes from a narration by the actor Jim Dale published as an audio-book (Rowling and Dale, 2016). The book is released as 17 .mp3 files with one file per chapter.

The second dataset comes from the audio-book with a female narrator, provided to us by Learning Ally.[2] We will refer to it as LA. These recordings are created by volunteers and are made available on subscription-basis to students diagnosed with disabilities that impact their ability to read print-based materials. Learning Ally recordings are subject to quality control similar to that of commercial audio-books.[3]

3.3 Calculating reading rate

We used forced alignment to automatically align the audio for JD narration for each chapter with the book text and establish the passage boundaries. We used the Kaldi toolkit (Povey et al., 2011) and publicly available acoustic models trained on the LibriSpeech corpus (Panayotov et al., 2015). The forced alignment was spot-checked manually for accuracy and found to be very accurate. The LA audio was already aligned with the book text.

The LA recordings were split across multiple audio files. To avoid any artifacts of the recording process, we only used the passages where the whole audio was in the same file. Out of the original 314 passages, 270 passages (86%) satisfied this condition, of these 134 in the training set and 136 in the test set. We used these matching training and testing passages for both narrators, in order to facilitate comparisons.

[2] https://www.learningally.org/

[3] We cannot use another well-known commercially available narration, by Stephen Fry, since he narrates the British version of the book.

For both narrators we used the time stamps for the beginning of the first word in the passage and the end of the last word in the passage to compute the total duration of the passage, which was then divided by the number of words in the passage to yield the reading rate (words per minute, WPM).

4 RQ1: Is reading rate constant?

To answer our first question, we looked at the distribution of the reading rate across the passages in the training set.

The distribution of WPM for both narrators was close to normal. JD: mean = 164.01; SD = 12.66; min = 129.2; max = 197.7. LA: mean = 125.12; SD = 11.4; min = 86.8; max = 156.9. Based on discussions in the literature regarding syllables per second being a more stable measure of reading rate than WPM (Tauroza and Allison, 1990; Griffiths, 1991; Munro and Derwing, 1998), we calculated rate in syllables per second, and observed a similar pattern of variation (JD: mean = 3.52, SD = 0.30, LA: mean = 2.72, SD = 0.27). We also found that WPM and syllables per second were highly correlated, for each of the narrators ($r \geq 0.9$). We therefore continue with WPM, as this is the commonly used measure in the reading assessment context. The distribution of WPM for each of the narrators is shown in Figure **??**.

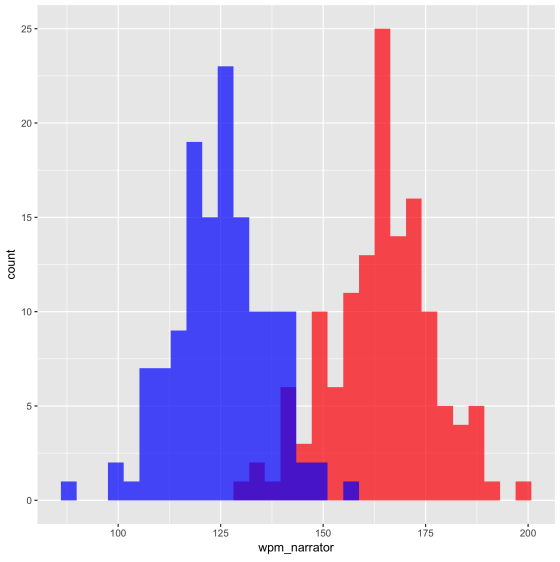

Figure 1: Distribution of WPM for LA (blue) and JD (red).

The answer to RQ1 is that while there is clearly a sense in which one narrator generally reads slower than the other, it is not the case that a narra-

tor keeps the same rate of reading across different passages.

5 RQ2: Is variation in reading rate correlated across the two narrators?

We next compared the reading rates of the two narrators on the 134 training set passages. We found them to be highly correlated: Pearson's r = .81. This suggests that a substantial share of the variation across passages is systematic rather than idiosyncratic. We therefore proceed to the next question – what factors can explain this variation?

6 RQ3: What textual factors explain variation in reading rate?

6.1 Method

We use a standard model building approach to answer RQ3. We used the train partition with JD's WPM (hereafter JD-train) to identify possible textual features as well as the best learner to combine these features. We then trained separate models on the training data for the two narrators. We evaluated the two models on: (a) different passages from the test partition as read by the same narrator; (b) same passages as used for model training but read by a different narrator; (c) different passages (test partition) read by a different narrator.

6.2 Baseline: text complexity

We used text complexity as our baseline, following the practice in the reading assessment community. While we do not expect either of the narrators to experience any reading comprehension difficulties, one might reasonably assume that a skilled narrator would slow down on fragments which are harder for the listener to comprehend.

We used TextEvaluator,[4] a state-of-the-art measure of comprehension complexity of a text (Napolitano et al., 2015; Sheehan et al., 2014, 2013; Nelson et al., 2012).[5] TextEvaluator extracts a range of linguistic features and uses them to compute a complexity score on the scale of 100–2000. TextEvaluator computes three complexity scores based on the models optimized for literary, informational and mixed texts. We used the literary metric. The average complexity score for passages in the training set was 613.1, with a large variation across passages: min=240, max=1,019, SD=154.75. In other words, the selected book offers its readers much variety in the configurations of textual features across its different passages.

6.3 Features

We used the passage text to extract 107 features that capture different factors that might affect durations in oral reading. These could be grouped into four categories.

6.3.1 Sentence-level timing factors

We hypothesized that the timing effects described in section 2.2.1 are likely to be the source of at least some variation in reading rates across the text. Due to the complexity of these effects, building an accurate model that would predict segmental durations based on the text is not a trivial task.

This problem has been extensively discussed in literature on modeling prosody for text-to-speech synthesis systems (TTS) which generally combined the insights from the phonetic studies with statistical learning in order to establish the optimal duration for each segment and pause in synthesized audio. Therefore rather than attempting to build our own model, we synthesized the audio for each passage using Apple's built-in TTS engine (OS X 10.11.6). We used the male Alex voice which in terms of overall quality and default speaking rate appeared closest to JD. According to Capes et al. (2017), linguistic features used for training this system include segment identity and segmental context, stress, part-of-speech context, prominence[6], sentence type and initial/final positional features for syllable, word, phrase and sentence;[7] in other words, features directly related to timing factors discussed in 2.2.1.

We used the generated audio to compute the WPM for each passage. The mean reading rate of TTS was close to that of JD: 157.1 vs. 164.0. There was variation across passages with WPM varying from 129.2 to 197.7 (SD = 9.13).

6.3.2 Lexical, syntactic, and discourse features

Next, we considered lexico-syntactic properties of the passages. Some of these (lexical fre-

[4] https://textevaluator.ets.org/

[5] TextEvaluator appears in the Nelson et al. (2012) benchmark as SourceRater.

[6] See for example (Hirschberg, 1993) for features used to establish prominence

[7] Note that Capes et al. (2017) describe a different engine from the one used in this study, however as noted in the paper it shares the front-end for linguistic feature extraction with other Mac OS TTS systems. The same features are also described in (Zen et al., 2009).

quency, emotion, arousal) may be associated with local changes in segment and pause durations (see 2.2.2). Many of the features are used as low-level features in readability estimation (Graesser et al., 2004; Sheehan et al., 2014), and are thus likely to capture facets of a reader's experience when reading the text.

These included: (1) Vocabulary features capturing presence as well as average score along some meaning dimension, such as concreteness, imageability, emotion, arousal, motion, academic register (Coltheart, 1981; Warriner et al., 2013; Coxhead, 2000); (2) Morphological features (e.g., count of nominalizations, count of syllables); (3) Distributional features such as average word frequency; (4) Syntactic features such as counts of different part-of-speech, as well as features based on specific constructions (relative clauses, preposed clauses etc.); (5) Discourse features that deal with paragraphing (e.g., word count of the longest paragraph, average paragraph length in sentences) and overall cohesion (e.g., average lexical overlap across adjacent sentences).

6.3.3 Story-related features

Considering previous work on prosody in storytelling, we also built features that relate to the overall story development. These included: (1) The number of occurrences of names of the main characters and other proper nouns important to the plot (*Harry*, *Hermione*, *Weasley*, *Dumbledore*, *Ollivander*, *Quidditch*), under the assumption that there might be systematic ways in which the narrators act out certain kinds of people (older vs younger, for example), as well as events that could indicate a fast-paced event, such as a commentated game of Quidditch; (2) The order in which the passage appears in the book (as a numeric continuous variable); (3) Plot arc as estimated by `syuzhet` package (Jockers, 2015). This package uses sentiment analysis to attempt to reveal the latent structure of the narrative. We used the default sentiment lexicon developed by the Nebraska Literary Lab supplied with the package.

6.3.4 Performance-related features

Finally we considered typographic features that provide clues to how the text should be performed when read aloud. These included exclamation marks (!), ellipses (...), words printed in all capitals and indications that a character stutters.

6.4 Learner

We used 3-fold cross-validation on JD-train to compare performance of 9 regressors available via `SKLL`[8] package including Random Forest, SVR and various regularized linear models. We used grid-search with 3-fold cross-validation within each fold to fine-tune the parameters for all learners. We found that Lasso regression achieved the highest average performance and therefore used it as the learner for subsequent evaluations.

6.5 Results

Table 1 shows the performance of all models on the four datasets in our study. Since we are interested in explaining variation across passages rather than predicting the actual reading rate of a given narrator for a given passage, we use Pearson's r as our evaluation metric, as it would capture the extent to which the predicted and the observed values deviate similarly from their respective means, and thus would not be affected by differences in absolute values between the two narrators.

Dataset	Baseline	M_{JD}	M_{LA}
JD-train	0.38	-	0.71
LA-train	0.40	0.80	-
JD-test	0.37	0.74	0.74
LA-test	0.45	0.75	0.80

Table 1: Performance (Pearson's r) of models trained using Lasso regression on JD-train (M_{JD}) or LA-train (M_{LA}). The models are evaluated on unseen data: different passages read by the same narrator, same passages read by a different narrator and different passages read by different narrator. The table also shows the correlations with baseline (text complexity score).

The correlations between the baseline (estimates of comprehension complexity) and WPM of the two narrators were r=0.37–0.45. We also note that the direction of the correlation was opposite to our expectation: more complex passages were in fact read faster.

Our models substantially outperformed the baseline with r increasing from 0.4 to 0.7–0.8. In other words, the final models explain much of the variability in reading rates. Furthermore, this level of performance holds for predicting variation in reading rate for a set of unseen passages

[8]We used v1.3 from https://github.com/EducationalTestingService/skll.

read by a different narrator (M_{LA} on JD-test and M_{JD} on LA-test), suggesting fairly strong generalization. Results also suggest that the prediction is somewhat easier for LA than for JD, in that evaluations on the former are in the 0.75–0.80 range, and for the latter – in the 0.71–0.74 range, no matter which narrator supplied the training data. This could be due to Jim Dale's narration being more theatrical/artistic, hence somewhat more idiosyncratic.

We used 3-fold cross-validation on JD-train and LA-train to further consider how much of the variation can be explained by different groups of features discussed in Section 6.3. The results are shown in Table 2. For both narrators, models based on all groups of features outperformed models based on individual groups of features, but all groups of features were effective in explaining at least some variance in reading rate across passages. Timing as modeled by TTS was the highest performing feature followed by lexico-syntactic features and story-based features.

Dataset	JD-train	LA-train
Baseline	0.37	0.39
All features	0.69	0.77
Sentence-level timing	0.63	0.75
Lexical/syntactic/discourse	0.55	0.65
Story-related	0.47	0.47
Performance-related	0.35	0.35

Table 2: Performance of the four groups of features described in Section 6.3 on the training passages for each of the narrators. The table shows average Pearson's r for 3-fold cross-validation on JD-train and LA-train. All models use Lasso regression.

To summarize, we found text complexity to be a poor predictor of passage-to-passage variability in reading rates of adult narrators. These findings are consistent with recent work in the oral reading fluency community which found variation in children's reading fluency across passages after controlling for grade level (see Section 2.1).

We found that textual factors that explain a substantial share of passage-to-passage variability in reading rates include sentence-level timing factors such as distribution of segments, stressed syllables, sentences, and pauses as well as features related to passage vocabulary and syntax, story and performance. Given the good generalization of our results to both a new narrator and to new passages, we believe they hold promise for explaining some of the unaccounted-for variation in reading rates observed in the oral reading fluency studies; more research is necessary to explore this direction.

7 Discussion

Out of 107 original features, 17 features had nonzero coefficients in M_{JD} and 14 in M_{LA}, with 6 features in the overlap: timing, ellipsis, number of verbs in past tense, preposition count, *Weasley*, and *Dumbledore*. Additional features selected in only one of the two models included various vocabulary features (such as age of acquisition, imageability for M_{JD}), syntax (average word count before main verb, contractions for M_{JD}), discourse (average lexical overlap in adjacent sentences), as well as story features (`syuzhet` and *Dudley* for M_{LA}, *Ollivander*, *quidditch* for M_{JD}).

Some of these features lend themselves to an easy explanation. Thus in our study, a strong predictor of narrator slowdown was occurrence of ellipsis (...), a mark of hesitation or thoughtfulness; these were not modeled as such by TTS.

Similarly, the positive weight alloted to the average lexical overlap in adjacent sentences is consistent with the expectation that repeat instances would be read faster.

Effective character features included *Ollivander* and *Dumbledore*; mentions of both of these indicate a slowdown in narration. One possible explanation is that passages with multiple mentions of these characters are likely to be those where they speak. Both of these characters are elderly; acting them out could yield a slower rate of speech.[9]

In other cases the interpretation of the feature was less straightforward. Thus the feature with the second highest coefficient after timing for both narrators was that which counted occurrences of members of the *Weasley* family. Why?

Figure 1 plots standardized reading rates of JD (blue), LA (orange), and TTS (black) as a function of the location in the book. It is clear from the plot that in addition to passage-by-passage variation there is a global pattern in narrator WPM: the narrators slow down over the first few chapters,

[9]Barbara Roseblatt, an audiobook narration coach, explicitly advises to slow down when reading the contribution of the old character in a coversation with a young one: https://www.youtube.com/watch?v=MVmywsM9-h4, 5:17. Jim Dale himself describes his image of Dumbledore as *hesitant, wheezy old man*: https://www.youtube.com/watch?v=whzhEIB9Qkg: 2:45.

then speed up, and slow down again in the last third. It is also apparent that the TTS curve is flatter, suggesting that some of the slowdown and especially the speedup are not due to sentence-level timing factors.

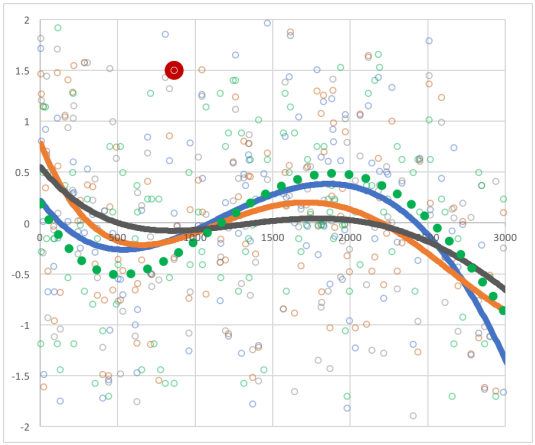

Figure 2: Standardized reading rates of JD (blue), LA (orange), TTS (black) as a function of the location of the passage in the novel. Trend lines are 4th degree polynomial approximations. The y-axis shows standardized readings rates (JD, LA, TTS). The large red dot and the green dotted line will be explained later in the text.

This book-level trend can help explain the strong performance of *Weasley*. This feature covers a number of characters that are prominent in the magic world as experienced by Harry (Ron, his brothers, sister, mother); they play no role at all in the first part of the story that is based in the Muggle world. The large red dot in Figure 1 indicates the first passage with a non-zero count for *Weasley*. This is very close to the onset of the speedup that is not captured by TTS. Apparently, the speedup coincides with an important plot transition (see Behr (2005) on plot transitions in Harry Potter), which is, in turn, indicated by a character mention pattern.

Next, we looked closely at one of the vocabulary features, specifically, imageability, calculated as the number of word tokens in a passage that belong to the MRC Imageability list (Coltheart, 1981). This feature has a partial correlation of -0.186 with JD controlling for TTS. In an attempt to identify the subset of the 1,194 words on the list that drive the correlation, we removed stopwords, all words that appeared in only one training passage, as well as short words (2-3 letters) and long words (7 letters or more). The partial correlation remained virtually the same (-0.178, $p < 0.05$).

These manipulations left us with 573 non-stop reasonably frequent 4-6 letter words. These words tend to name common everyday objects and properties (henceforth, **everyday** list), such as body parts (*knee, skin, neck, hair, nose, face, teeth*), colors (*blue, gray, green, white, black, orange, yellow*), family (*aunt, uncle, mother, father, sister, wife*), elements (*fire, water, wind, rain*) and materials (*silver, gold, stone, metal, glass, paper, silk*), eating (*cake, wine, dinner, hungry, eating*), common properties of objects (*warm, cold, broad, narrow, soft, hard, tall, short, long, clean, dirty*) and humans (*kind, evil, rude, polite, eager, proud, stupid, famous*), standard house interior (*chair, table, mirror, door, wall, room, clock*), feelings and emotions (*fear, hurt, hate, pain, anger, gloom, tired, panic, safe, boring, afraid, relief*), as well as numbers (*first, nine, half, dozen*), directional (*inside, back, front, behind, bottom*) and time expressions (*soon, hour, late, week, month, early, minute, moment*). These words "carry" the story, so to speak, in that on average about one third of all nonstop words in each passage belong to this list, albeit with substantial variation (min = 0.20; max = 0.49).

If the effect of the feature was simply due to higher incidence of the short high frequency everyday words, we would expect a *positive* correlation with the reading rate; in fact, the correlation is negative, suggesting that perhaps the feature is useful as an indirect indicator of something else, rather than for the phonological properties of the words on the list.

Variation across passages in the use of everyday words appears non-random. In particular, the first third of the book averages 41.4 matches per passages; the rest of the book averages 37.3. Given the above observations with *Weasley*, this is easy to explain in reference to the story line – the first part of the book mainly happens in Muggle ("normal") world, while the rest of the book happens in an alternative world of Hogwarts that is familiar enough (and so references to human feelings, bodies, and character still draw on the culturally familiar stock) yet different enough to drive a 10% average decline in the use of stock vocabulary, where special foods, special money units, the special game of quidditch, special subjects on the school's curriculum remain off the common list.

Since overlap with the everyday list has a negative correlation with reading rate, we flip the sign

of the standardized everyday token counts, and overlay the plot with that of reading rates; see the green dotted line in Figure 1. It is apparent that the global pattern of JD WPM is closely traced by the feature, especially in the middle area where JD is speeding up and then slowing down again.

The observed global slowdown, speedup, and slowdown appear to align with the traditional three-part narrative structure (exposition, complication, and resolution) (Chandler and Munday, 2016). One of our features (`syuzhet`) was based on the plot arc. While this feature was selected in one of the models, its partial correlation with JD after controlling for TTS was not significant. Our results suggest that important plot transitions can sometimes be captured indirectly by tracing patterns of word usage for other specific classes of words such as characters or everyday words and that for skilled readers these transitions can be associated with systematic changes in reading rate.

8 Conclusions

The main contributions of this paper are as follows. First, we demonstrate using a case study that variation in reading rate across passages for professional narrators is consistent across readers and much of it can be explained using features of the texts being read. These findings suggest that it is possible to estimate the expected variation in durations of oral reading across texts. In the assessment context, this has a potential of providing a powerful control mechanism for selecting comparable passages for parallel forms of a test of oral reading; in a context when one cannot adjust the materials (such as a reading intervention using a particular book), it might be possible to adjust the measurement of reading rate to compensate for the effects of the text on the observed performance.

Secondly, we found that timing is a very powerful feature, yet not a perfect predictor of reading rate (the two narrators are still highly correlated controlling for timing, partial r=0.64). This opens up a possibility for a sophisticated assessment of oral reading using both TTS and human benchmark to separate reading that adheres to basic timing constraints of English speech (which constitutes a demonstrably big part of fluent reading) from a more nuanced expressive reading that TTS is not currently doing, but good human readers are. Thus beyond assessment context, our findings can also inform work on text-to-speech synthesis for book-length texts.

Extending and validating the results reported here using additional types of text and separating the effect of text factors on the two components of reading rate, articulation rate and pausing, is an important next step to get a more comprehensive picture of the impact of text on oral reading.

Acknowledgments

We thank John Sabatini and Tenaha O'Reilly for many comments and suggestions that inspired this work; Binod Gyawali and Patrick Lange for preprocessing the book; Diane Napolitano for help with extracting TextEvaluator features; Learning Ally for allowing us to use their version of the narration; Nitin Madnani, Michael Flor, Keelan Evanini, and three anonymous NAACL reviewers for their comments and suggestions.

Abstract

Contextual influences on language often exhibit substantial cross-lingual regularities; for example, we are more verbose in situations that require finer distinctions. However, these regularities are sometimes obscured by semantic and syntactic differences. Using a newly-collected dataset of color reference games in Mandarin Chinese (which we release to the public), we confirm that a variety of constructions display the same sensitivity to contextual difficulty in Chinese and English. We then show that a neural speaker agent trained on bilingual data with a simple multitask learning approach displays more human-like patterns of context dependence and is more pragmatically informative than its monolingual Chinese counterpart. Moreover, this is not at the expense of language-specific semantic understanding: the resulting speaker model learns the different basic color term systems of English and Chinese (with noteworthy cross-lingual influences), and it can identify synonyms between the two languages using vector analogy operations on its output layer, despite having no exposure to parallel data.

1 Introduction

In grounded communication tasks, speakers face pressures in choosing referential expressions that distinguish their targets from others in the context, leading to many kinds of pragmatic meaning enrichment. For example, the harder a target is to identify, the more the speaker will feel the need to refer implicitly and explicitly to alternatives to draw subtle contrasts (Zipf, 1949; Horn, 1984; Levinson, 2000). However, the ways in which these contrasts are expressed depend heavily on language-specific syntax and semantics.

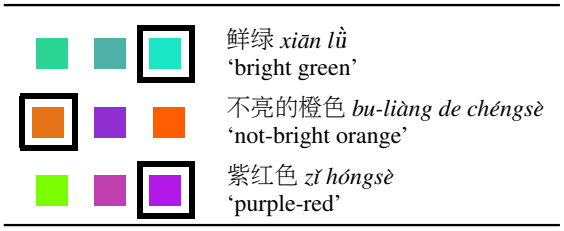

Figure 1: Reference game contexts and utterances from our Chinese corpus. The boxed color is the target. Some color terms show differences between Chinese and English, such as 绿 *lǜ* 'green' in the first example for a color that might be referred to with 'blue' or 'aqua' in English.

In this paper, we seek to develop a model of contextual language production that captures language-specific syntax and semantics while also exhibiting responsiveness to contextual differences. We focus on a color reference game (Rosenberg and Cohen, 1964; Dale and Reiter, 1995; Krahmer and van Deemter, 2012) played in both English and Mandarin Chinese. A reference game (Figure 1) involves two agents, one designated the "speaker" and the other the "listener". The speaker and listener are shown the same set of k colors $C = \{c_1, \ldots, c_k\}$ (in our experiments, $k = 3$), and one of these colors c_t is indicated secretly to the speaker as the "target". Both players share the same goal: that the listener correctly guesses the target color. The speaker may communicate with the listener in free-form natural-language dialogue to achieve this goal. Thus, a model of the speaker must process representations of the colors in the context and produce an utterance to distinguish the target color from the others. We evaluate a sequence-to-sequence speaker

Proceedings of NAACL-HLT 2018, pages 2155–2165
New Orleans, Louisiana, June 1 - 6, 2018.

agent based on that of Monroe et al. (2017), who also collected the English data we use; our Chinese data are new and were collected according to the same protocols.

While English and Chinese both use fairly similar syntax for color descriptions, our reference game is designed to elicit constructions that make reference to the context, and these constructions—particularly comparatives and negation—differ morpho-syntactically and pragmatically between the two languages. Additionally, Chinese is considered to have a smaller number of basic color terms (Berlin and Kay, 1969), which predicts markedness of more specific descriptions.

Our primary goal is to examine the effects of *bilingual* training: building one speaker trained on both English and Chinese data with a shared vocabulary, so that it can produce utterances in either language. The reference game setting offers an objective measure of success on the grounded language task, namely, the speaker's ability to guide the listener to the target. We use this to address the tricky problem of speaker evaluation. Specifically, we use the speaker model and an application of Bayes' rule to infer the most likely target color given a human utterance, and we report the accuracy of that process at identifying the target color. We refer to this metric as *pragmatic informativeness* because it requires not only accuracy but also effectiveness at meeting the players' shared goal (Grice, 1975). A more formal definition and a discussion of alternatives are given in Section 4.1.

We show that a bilingually-trained model produces distributions over Chinese utterances that have higher pragmatic informativeness than a monolingual model. An analysis of the learned word embeddings reveals that the bilingual model learns color synonyms between the two languages without being directly exposed to labeled pairs. However, using a context-independent color term elicitation task from Berlin and Kay (1969) on our models, we show that the learned lexical meanings are largely faithful to each language's basic color system, with only minor cross-lingual influences. This suggests that the improvements due to adding English data are not primarily due to better representations of the input colors or lexical semantics alone. The bilingual model does better resemble human patterns of utterance length as a function of contextual difficulty, suggesting the pragmatic level as one possible area of cross-lingual generalization.

2 Data collection

We adapted the open-source reference game framework of Hawkins (2015) to Chinese and followed the data collection protocols of Monroe et al. (2017) as closely as possible, in the hope that this can be the first step in a broader multilingual color reference project. We recruit pairs of players on Amazon Mechanical Turk in real time, randomly assigning one the role of the speaker and the other the listener. Players are self-reported Chinese speakers, but they must pass a series of Chinese comprehension questions in order to proceed, with instructions in a format preventing copy-and-paste translation. The speaker and listener are placed in a game environment in which they both see the three colors of the context and a chatbox. The speaker sends messages through the chatbox to describe the target to the listener, who then attempts to click on the target. This ends the round, and three new colors are generated for the next. Both players can send messages through the chatbox at any time. After filtering out extremely long messages (number of tokens greater than 4σ above the mean), spam games,[1] and players who self-reported confusion about the game, we have a new corpus of 5,774 Chinese messages in color reference games, which we will release publicly. Data management information is given in Appendix B.

As in Monroe et al. (2017), the contexts are divided into three groups of roughly equal size: in the *far* condition (1,421 contexts), all the colors are at least a threshold distance θ from each other; in the *split* condition (1,412 contexts), the target and one distractor are less than θ from each other, with the other distractor at least θ away from both; and in the *close* condition (1,425 contexts), all colors are within θ from each other. We set $\theta = 20$ by the CIEDE2000 color-difference formula (Sharma et al., 2005), with all colors different by at least 5.

3 Human data analysis

As we mentioned earlier, our main goal with this work is to investigate the effects of bilingual training on pragmatic language use. We first examine the similarities and differences in pragmatic be-

[1] Some players found they could advance through rounds by sending duplicate messages. Games were considered spam if the game contained 25 or more duplicates.

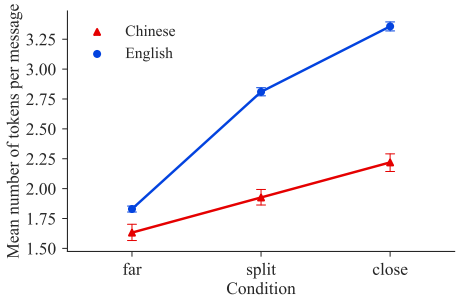

Figure 2: Comparison of mean length of messages in English and Chinese. The *split* and *close* conditions have more similar context colors (Section 2).

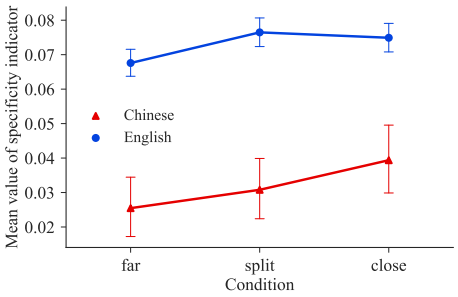

Figure 3: Comparison of WordNet specificity in Chinese and English.

haviors between the English and Chinese corpora we use. The picture that emerges accords well with our expectations about pragmatics: the broad patterns are aligned across the two languages, with the observed differences mostly tracing to the details of their lexicons and constructions.

3.1 Message length

We expect message length to correlate with the difficulty of the context: as the target becomes harder to distinguish from the distractors, the speaker will produce more complex messages, and length is a rough indicator of such complexity. To test this hypothesis, we used the Natural Language Toolkit (NLTK; Bird et al. 2009) and Jieba (Junyi, 2015) to tokenize English and Chinese messages, respectively, and counted the number of tokens in both languages as a measure of message length. The results (Figure 2) confirm that in both languages, players become more verbose in more difficult conditions.[2]

3.2 Specificity

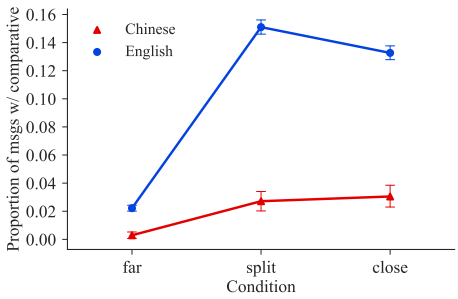
In the *split* and *far* conditions, the speaker must make fine-grained distinctions. A broad color term like *red* will not suffice if there are two reds, but more specific terms like *maroon* might identify the target. Thus, we expect specificity to increase as the difficulty of the context does. To assess this, we use WordNet (Fellbaum, 1998) to transform adjectives into derivationally-related noun forms, filter for nouns with *color* in their hypernym paths, and mark a message as "specific" if it contains at least one word with a hypernym depth greater than 7.

For Chinese, we translate to English via Google Translate, then measure the translated word using WordNet. It should be noted that this method has the drawback of obscuring differences between the two languages' color systems, as well as the potential for introducing noise due to errors in automatic translation. Though Mandarin variations of WordNet exist, we chose this translation method to standardize hypernym paths for both languages. Differences in ontology decisions between lexical resources prevent straightforward cross-lingual comparisons of hypernym depths, while automatic translation to a common language ensures the resulting hypernym paths are directly comparable.

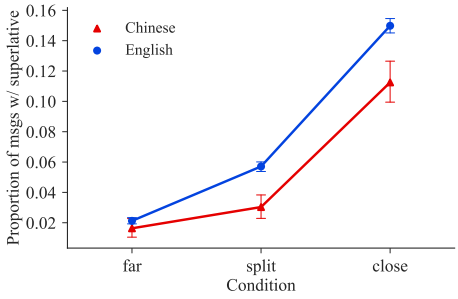
Figure 3 summarizes the results of this measurement. In general, the usage of high-specificity color words increases in more difficult conditions, as expected. However, we see that Chinese speakers use them significantly less than English speakers. Instead, Chinese speakers use nominal modifiers, such as 草 *cǎo* 'grass' and 海 *hǎi* 'ocean', which do not contain "color" in their hypernym paths and are thus not marked as high-specificity. To quantify this observation, we annotated random samples of 200 messages from each language for whether they contained nominal color descriptions, and found that 3.5% of the English messages contain such nominals versus 13.5% of the Chinese messages.

The use of nominal modifiers as opposed to adjectives ('dark orange', 'dull brown') is arguably expected given the claims of Berlin and Kay (1969) and others that Chinese has fewer basic color terms than English, thus requiring more visually evocative modifiers to clarify distinctions between similar hues. (This isn't a complete explanation, since Chinese is rich in narrow but rare

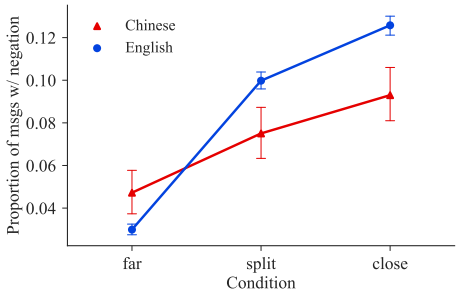
[2] We do not believe that the overall drop in message length from English to Chinese reflects a fundamental difference between the languages; this has a few possible explanations, from Chinese messages taking the form of "sentence segments" (Wang and Qin, 2010) to differences in tokenization.



(a) Usage of comparative adjectives in Chinese and English.



(b) Usage of superlative adjectives in Chinese and English.



(c) Usage of negation in Chinese and English.

Figure 4: Comparison of usage of comparatives, superlatives, and negation in English and Chinese.

non-basic color terms. For the cases where Chinese has an appropriate narrow color term, it is possible that speakers make a pragmatic decision to avoid obscure vocabulary in favor of more familiar nouns.)

3.3 Comparatives, superlatives, and negation

To detect comparative and superlative adjectives in English, we use NLTK POS-tagging, which outputs JJR and RBR for comparatives, and JJS and RBS for superlatives. In Chinese, we look for the tokens 更 *gèng* 'more' and 比 *bǐ* 'comparatively' to detect comparatives and 最 *zuì* 'most' to detect superlatives. We detect negation by tokenizing messages with NLTK and Jieba and then looking for the tokens *not* and *n't* in English and corresponding 不 *bù* and 没 *méi* in Chinese.

These statistics are shown in Figure 4. Both languages exhibit similar trends for superlative adjectives. In English, comparatives are used most frequently in the *split* condition and second most frequently in the *close* condition, while in Chinese, they occur at around the same rate in the *split* and *close* conditions. The literature is not conclusive about the source of these differences. Xia (2014) argues that complex attributives are rarely used and sound "syntactically deviant or Europeanized" (Zhu, 1982; Xie, 2001) in Chinese, citing the left-branching nature of the language as restricting attributives in length and complexity. There are also conflicting theories on the markedness of gradable adjectives in Chinese (Grano, 2012; Ito, 2008); such markedness may contribute to the frequency at which comparative forms are used.

We also see that both languages follow the same general trend of using negation more frequently as the condition becomes more difficult.

4 Models

We build and evaluate three artificial agents on this reference game task, two trained on monolingual descriptions (one for each language) and one on bilingual descriptions. We base these models on the basic speaker architecture from Monroe et al. (2017). The monolingual speakers represent the context by passing all the context colors as input to a long short-term memory (LSTM) sequence encoder, then concatenating this representation with a word vector for each previous output token as the input to an LSTM decoder that produces a color description token-by-token. This defines a distribution over descriptions u conditioned on the target and context, $S(u \mid c_t, C)$.

To accommodate bilingual training with this architecture, we expand the vocabulary to include English and Chinese words, and we add a flag ℓ to the input specifying whether the model's output should be in English ($\ell = 0$) or Chinese ($\ell = 1$):

$$S(u \mid \ell, c_t, C) = \prod_{i=1}^{|u|} s(u_i \mid u_{1..i-1}, \ell, c_t, C)$$

The flag ℓ is embedded as a single additional dimension that is concatenated alongside the context and input (previous token) vectors for the encoder. See Appendix A for additional training details.

4.1 Pragmatic informativeness

As mentioned in Section 1, we evaluate the two models on a measure of *pragmatic informative-*

ness: how well does the model represent a human speaker, such that a generative model of a listener can be built from it to interpret utterances? Formally, for a speaker $S(u \mid \ell, c_t, C)$ and an example consisting of an utterance, language identifier, and color context (u, ℓ, C), we identify the t^* that maximizes the probability of u according to S:

$$t^* = \arg\max_t S(u \mid c_t, C)$$

That is, L uses a noisy-channel model with a uniform prior over target colors and S as a generation model to infer the most likely target color given the input utterance. The pragmatic informativeness of a speaker is the proportion of target colors in a test set correctly identified by t^*.

One drawback of this metric is it does not evaluate how faithful the model is to the overall distribution of human utterances, only the relative conditional likelihoods of human utterances for different target colors. In practice, since the agents are trained to minimize log likelihood, we do not observe our agents frequently producing wildly unhumanlike utterances; however, this is a caveat to keep in mind for evaluating agents that do not naturally approximate a language model.

The understanding model implied in this metric is equivalent to a version of the Rational Speech Acts model of pragmatic language understanding (Frank and Goodman, 2012; Goodman and Frank, 2016), or the *pragmatic posterior* of the Rational Observer model (McMahan and Stone, 2015). An important difference between our speaker model and those in the work cited above is that our speaker model is a neural network that makes a combined judgment of applicability (semantic appropriateness) and availability (utterance prior), instead of modeling the two components separately. However, we stop short of directly predicting the referent of an expression discriminatively, as is done by e.g. Kennington and Schlangen (2015), so as to require a model that is usable as a speaker.

A related metric is *communicative success* as defined by Golland et al. (2010), which judges the speaker by the accuracy of a human listener when given model-produced utterances. Our pragmatic informativeness metric instead gives a model-derived listener human utterances and assesses its accuracy at identifying colors. Pragmatic informativeness has the advantage of not requiring additional expensive human labeling in response to model outputs; it can be assessed on an existing collection of human utterances, and can therefore be considered an automatic metric.

4.2 A note on perplexity

Perplexity is a common intrinsic evaluation metric for generation models.[3] However, for comparing monolingual and bilingual models, we found perplexity to be unhelpful, owing largely to its vocabulary-dependent definition. Specifically, if we fix the vocabulary in advance to include tokens from both languages, then the monolingual model performs unreasonably poorly, and bilingual training helps immensely. However, this is an unfair comparison: the monolingual model's high perplexity is dominated by low probabilities assigned to rare tokens in the opposite-language data that it did not see. Thus, perplexity ceases to be a measure of language modeling ability and assumes the role of a proxy for the out-of-vocabulary rate.

On the other hand, if we define the output vocabulary to be the set of tokens seen at least n times in training ($n = 1$ and 2 are common), then monolingual training yields better perplexity than bilingual training, but mainly because including opposite-language training data forces the bilingual model to predict more rare words that would otherwise be replaced with ⟨unk⟩.[4] This produces the counterintuitive result that perplexity initially goes *up* (gets worse) when increasing the amount of training data. (As a pathological case, with no training data, a model can get a perfect perplexity of 1 by predicting ⟨unk⟩ for every token.)

5 Experimental results and analysis

Pragmatic informativeness of the models on English and Chinese data is shown in Table 1. The main result is that training a bilingual model helps compared to a Chinese monolingual one; however, the benefit is asymmetrical, as training on monolingual English data is superior for English data to training on a mix of Chinese and English. All differences in Table 1 are significant at $p < 0.001$

[3] Two other intrinsic metrics, word error rate (WER) and BLEU (Papineni et al., 2002), were at or worse than chance despite qualitatively adequate speaker outputs, due to high diversity in valid outputs for similar contexts. This problem is common in dialogue tasks, for which BLEU is known to be an ineffective speaker evaluation metric (Liu et al., 2016).

[4] The rare words that make this difference are primarily the small number of English words that were used by the Chinese-language participants; no Chinese words were observed in the English data from Monroe et al. (2017)

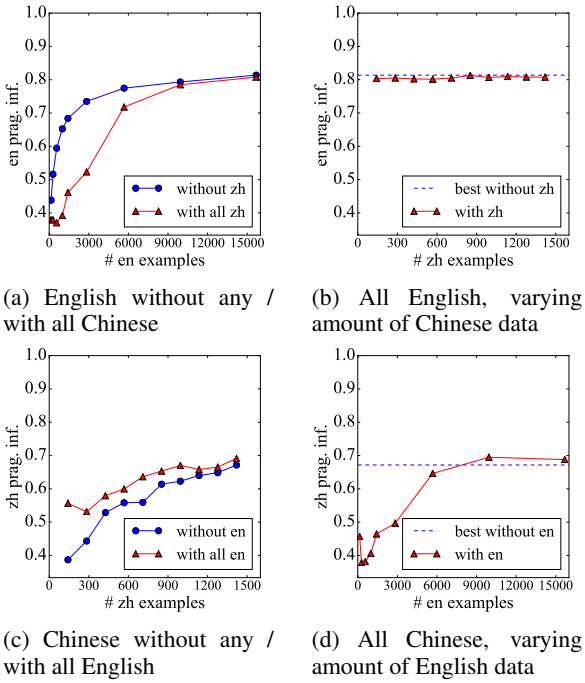
(approximate permutation test, 10,000 samples; Padó, 2006), except for the decrease on the English dev set, which is significant at $p < 0.05$.

An important difference between our corpora is that the English dataset is an order of magnitude larger than the Chinese. Intuitively, we expect adding more training data on the same task will improve the model, regardless of language. However, we find that the effect of dataset size is not so straightforward. In fact, the differences in training set size convey a non-linear benefit. Figure 5 shows the pragmatic informativeness of the monolingual and bilingual speakers on the development set as a function of dataset size (number of English and Chinese utterances). The blue curves (circles) in the plots on the left, Figure 5a and Figure 5c, are standard learning curves for the monolingual models, and their parallel red curves (triangles) show the pragmatic informativeness of the bilingual model with the same amount of in-language data plus all available data in the opposite language. The plots on the right, Figure 5b and Figure 5d, show the effect of gradually adding opposite-language data to the bilingual model starting with all of the in-language data.

Overall, we see that adding all English data consistently helps the Chinese monolingual model, whereas adding all Chinese data consistently hurts the English monolingual model (though with diminishing effects as the amount of English data increases). Adding small amounts of English data—especially amounts comparable to the size of the Chinese dataset—*decreases* accuracy of the Chinese model dramatically. This suggests an interaction between the total amount of data and the effect of bilingual training: a model trained on a moderately small number of in-language examples can benefit from a much larger training set in another language, but combining data in two languages is detrimental when both datasets are very small and has very little effect when the in-



(a) English without any / with all Chinese

language training set is large. This implies a benefit primarily in low-resource settings, which agrees with the findings of Johnson et al. (2016) using a similar architecture for machine translation.

5.1 Bilingual lexicon induction

To get a better understanding of the influence of the bilingual training on the model's lexical representations in the two languages, we extracted the weights of the final softmax layer of the bilingual speaker model and used them to induce a bilingual lexicon with a word vector analogy task. For two pairs of lexical translations, 蓝色 *lánsè* → "blue" and "red" → 红 *hóng*, we took the difference between the source language word vector and the target language word vector. To "translate" a word, we added this "translation vector" to the word vector for the source word, and found the word in the opposite language with the largest inner product to the resulting vector. The results are presented in Table 2. We identified the 10 most frequent color-related words in each language to translate. (In other words, we did not use this process to find translations of function words like "the" or the Chinese nominalization/genitive particle 的 *de*, but we show proposed translations that were not color-related, such as 灰 *huī* being translated as the English comparative ending "-er".)

zh	en	en	zh
绿色 ‘green’	**green**	green	**绿 ‘green’**

亮 ‘bright’	**bright**	pink	**粉色 ‘pink’**
灰 ‘grey’	-er	grey	**灰 ‘grey’**
蓝 ‘blue’	*teal*	dark	**暗 ‘dark’**
绿 ‘green’	**green**	gray	**灰 ‘grey’**
紫 ‘purple’	**purple**	yellow	**黄色 ‘yellow’**
草 ‘grass’	*green*	light	最 ‘most’

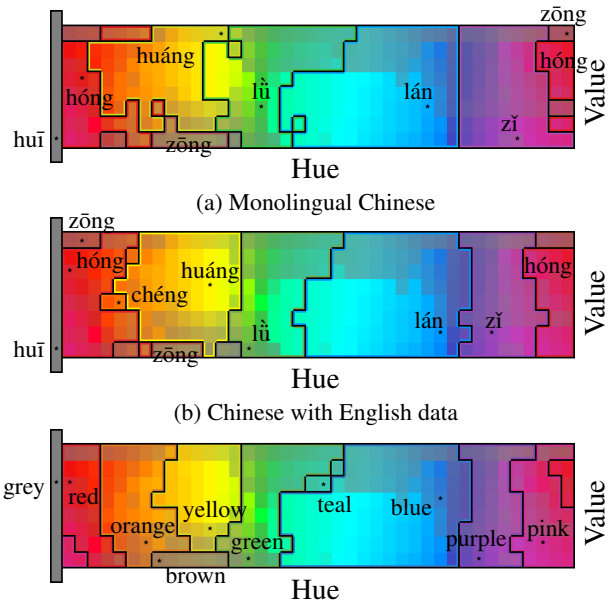
Table 2: Bilingual lexicon induction from Chinese to English (first two columns) and vice versa (last two). Correct translations in **bold**, semantically close words in *italic*.

The majority of common color words are translated correctly by this simple method, showing that the vectors in the softmax layer do express a linear correspondence between the representation of synonyms in the two languages.

5.2 Color term semantics

The above experiment suggests that the bilingual model has learned word semantics in ways that discover translation pairs. However, we wish to know whether bilingual training has resulted in changes to the model's output distribution reflecting differences in the two languages' color systems. To evaluate this, we performed an experiment similar to the basic color term elicitations in the World Color Survey (WCS; Berlin and Kay, 1969) on our models. For each of the 330 colors in the original WCS, we presented that color to our monolingual and bilingual models and recorded the most likely color description according to the conditional language model. Our models require a three-color context to produce a description; as an approximation to eliciting context-insensitive color terms, we gave the model ten contexts with randomly generated (uniform in H, S, and V) distractor colors and averaged the language model probabilities. We also identified, for each color term produced as the most likely description of one or more colors, the color that resulted in the highest probability of producing that term.

The results are in Figure 6. The charts use the layout of the WCS stimulus, in which the two axes represent dimensions of color variation similar to hue and lightness. Each region represents a set of colors that the model labeled with the same color term, and a star marks the color that resulted in the highest probability of producing that term. The Chinese terms, except for 红 *hóng*, are abbreviated by deleting the final morpheme 色 *sè* ‘color’.



(a) Monolingual Chinese

(b) Chinese with English data

(c) Monolingual English

Figure 6: Color term lexica: colors in the World Color Survey palette grouped by highest-probability description, averaged over 10 randomly-generated pairs of distractor colors. The color that results in the highest probability of each description is marked with a star. English influences on the bilingual model include the appearance of 橙色 *chéngsè* ‘orange’ and narrowing of 黄色 *huángsè* ‘yellow’ and 绿色 *lǜsè* ‘green’.

The charts agree with Berlin and Kay (1969) on most of the differences between the two languages: *orange* and *pink* have clear regions of dominance in English, whereas in the Mandarin monolingual model *pink* is subsumed by 红 *hóng* ‘red’, and *orange* is subsumed by 黄色 *huángsè* ‘yellow’. Our models produce three colors not in the six-color system[5] identified by Berlin and Kay for Mandarin: 灰色 *huīsè* ‘grey’, 紫色 *zǐsè* ‘purple’, and 棕色 *zōngsè* ‘brown’. We do not specifically claim these should be considered *basic* color terms, since Berlin and Kay give a theoretical definition of “basic color term” that is not rigorously captured by our model. In particular, they explicitly exclude 灰色 *huīsè* from the set of basic color terms, despite its frequency, because it has a mean-

[5]Notably absent are ‘black’ and ‘white’. The collection methodology of Monroe et al. (2017) restricted colors to a single lightness, so black and white are not in the data. For these charts, we replaced the World Color Survey swatches with the closest color used in our data collection.

ing that refers to an object ('ashes'). The other two may have been excluded for the same reason, or they may represent a change in the language or the influence of English on the participants' usage.[6]

A few differences between the monolingual and bilingual models can be characterized as an influence of one language's color system on the other. First, *teal* appears as a common description of a few color swatches from the English monolingual model, but the bilingual model, like the Chinese model, does not feature a common word for teal. Second, the Chinese monolingual model does not include a common word for orange, but the bilingual model identifies 橙色 *chéngsè* 'orange'. Finally, the English *green* is semantically narrower than the Chinese 绿色 *lǜsè*, and the Chinese bilingual model exhibits a corresponding narrowing of the range of 绿色 *lǜsè*.

Overall, however, the monolingual models capture largely accurate maps of each language's basic color system, and the bilingual model retains the major contrasts between them, rather than "averaging" between the two. This suggests that the bilingual model learns a representation of the input colors that encodes their categorization in both languages, and that for the most part these lexical semantic representations do not influence each other.

5.3 Comparing model and human utterances

One observation indicates that the improvements in the bilingually-trained model are primarily at the pragmatic (context-dependent) level of language production. Figure 7 reveals that the bilingually-trained model better captures the main pragmatic pattern we observe in the human data, that of increasing message length in harder conditions. In both languages, the monolingual model uses longer utterances in the easy *far* condition than human speakers do, whereas the bilingual model is significantly closer on that condition to the human statistics. We see similar results in the use of negations and comparatives; the use of superlatives is not substantially different between the monolingual and bilingual models.

We note that this result does not rule out several competing hypotheses. In particular, we do not exclude improvements in compositional semantics or syntax, nor do we distinguish improvements in specific linguistic areas from broader regularization effects of having additional data in general. Preliminary experiments involving augmentation of the data by duplicating and deleting constituents show no gains, suggesting that the improvement depends on certain kinds of regularities in the English data that are not provided by artificial manipulations. However, more investigation is needed to thoroughly assess the role of general-purpose regularization in our observations.

[6]MTurk's restriction to US workers makes English influence more likely than would otherwise be expected.

6 Related work

The method we use to build a bilingual model involves adding a single dimension to the previous-token vectors in the encoder representing the language (Section 4). In essence, the two languages have separate vocabulary representation at the input and output but shared hidden representations. Adding a hard constraint on the output vocabulary would make this equivalent to a simple form of multitask learning (Caruana, 1997; Collobert and Weston, 2008). However, allowing the model to use tokens from either language at any time is simpler and results in better modeling of mixed-language data, which is more common in non-English environments. In fact, our model occasionally ignores the flag and "code-switches" be-

tween the two languages within a single output, which is not possible in typical multitask architectures.

Using shared parameters for cross-lingual representation transfer has a large literature. Klementiev et al. (2012) and Hermann and Blunsom (2014) use multitask learning with multilingual document classification to build cross-lingual word vectors, and observe accurate lexical translations from linear vector analogy operations. They include predicting translations for words in parallel data as one of their tasks. Our translations from vector relationships (Section 5.1) derive their cross-lingual relationships from the non-linguistic input of our grounded task, without parallel data.

Huang et al. (2013) note gains in speech recognition from cross-lingual learning with shared parameters. In machine translation, Johnson et al. (2016) add the approach of setting the output language using a symbol in the input. Kaiser et al. (2017) extend this to image captioning, speech recognition, and parsing in one multitask system. Our work complements these efforts with an in-depth analysis of bilingual training on a grounded generation task and an exploration of the relationship between cross-lingual semantic differences and pragmatics. In general, we see grounding in non-linguistic input, including images and sensory input from real and simulated worlds, as an intriguing substitute for direct linguistic supervision in low-resource settings. We encourage evaluation of multitask and multilingual models on tasks that require reference to the context for effective language production and understanding.

7 Conclusion

In this paper, we studied the effects of training on bilingual data in a grounded language task. We show evidence that bilingual training can be helpful, but with a non-obvious effect of dataset size: accuracy as a function of opposite-language data follows a U-shaped curve. The resulting model is more human-like in measures of sensitivity to contextual difficulty (pragmatics), while exhibiting language-specific lexical learning in the form of vector relationships between lexical pairs and differences between the two languages in common color-term extensions (semantics).

It should be noted that color descriptions in English and Chinese are similar both in their syntax and in the way they divide up the semantic space. We might expect that for languages like Arabic and Spanish (with their different placement of modifiers), or Waorani and Pirahã (with their much smaller color term inventories), the introduction of English data could have detrimental effects that outweigh the language-general gains. An investigation across a broader range of languages is desirable.

Our contribution includes a new dataset of human utterances in a color reference game in Mandarin Chinese, which we release to the public[7] with our code and trained model parameters.[8]

A Model details

Hyperparameters for the two main models are given in Table 3. Both Chinese monolingual and bilingual model were tuned for perplexity on a held-out subset of the training set, by random search followed by a local search from the best candidate until no single parameter change produced a better result. However, the tuned settings for the Chinese monolingual model did not outperform the settings from Monroe et al. (2017) for the English model on the development set, so in our final experiments the monolingual models used the same parameters.

The vocabulary for each model consisted of all tokens that were seen at least twice in training; the bilingual model's vocabulary is larger than the union of the words in each monolingual model because some tokens occurred once in each language (largely meta-commentary—e.g., *dunno*, *HIT*, *xD*—and some English color word typos).

hyperparameter	mono.	biling.
optimizer	ADAM	RMSProp
learning rate	0.004	0.004
dropout	0.1	0.1
gradient clip norm	–	1
LSTM cell size	100	50
embedding size	100	100
initial forget bias	0	5
nonlinearity	tanh	sigmoid
vocabulary size	895 (en) 260 (zh)	1,326

Table 3: Values of hyperparameters optimized in tuning for the monolingual and bilingual models, plus vocabulary sizes.

B Data management

This work was done under Stanford IRB Protocol 17827, which has the title "Pragmatic enrichment and contextual inference". Data was only collected from workers who indicated their informed consent. Workers on Amazon Mechanical Turk were paid $2.00 to complete each game consisting of 50 dialogue contexts, plus a bonus of $0.01 for each target the listener correctly identified. All worker identifiers have been removed from data that is released; the only other information collected about the workers was their Chinese language proficiency.

Learning with Latent Language

Abstract

The named concepts and compositional operators present in natural language provide a rich source of information about the abstractions humans use to navigate the world. Can this linguistic background knowledge improve the generality and efficiency of learned classifiers and control policies? This paper aims to show that using the space of natural language strings as a *parameter* space is an effective way to capture natural task structure. In a pretraining phase, we learn a language interpretation model that transforms inputs (e.g. images) into outputs (e.g. labels) given natural language descriptions. To learn a new concept (e.g. a classifier), we search directly in the space of descriptions to minimize the interpreter's loss on training examples. Crucially, our models do not require language data to learn these concepts: language is used only in pretraining to impose structure on subsequent learning. Results on image classification, text editing, and reinforcement learning show that, in all settings, models with a linguistic parameterization outperform those without.[1]

1 Introduction

The structure of natural language reflects the structure of the world. For example, the fact that it is easy for humans to communicate the concept *left of the circle* but comparatively difficult to communicate *mean saturation of the first five pixels in the third column* reveals something about the abstractions we find useful for interpreting and navigating our environment (Gopnik and Meltzoff, 1987). In machine learning, efficient automatic discovery of reusable abstract structure remains a major challenge. This paper investigates whether

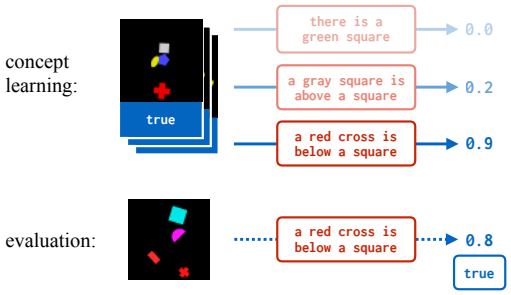

Figure 1: Example of our approach on a binary image classification task. We assume access to a pretrained language interpretation model that outputs the probability that an image matches a given description. To learn a new visual concept, we search in the space of natural language descriptions to maximize the interpretation model's score (top). The chosen description can be used with the interpretation model to classify new images (bottom). Figures best viewed in color.

background knowledge from language can provide a useful scaffold for acquiring it. We specifically propose to use language as a latent *parameter space* for few-shot learning problems of all kinds, including classification, transduction and policy search. We aim to show that this linguistic parameterization produces models that are both more accurate and more interpretable than direct approaches to few-shot learning.

Like many recent frameworks for multitask- and meta-learning, our approach consists of three phases: a pretraining phase, a concept-learning phase, and an evaluation phase. Here, the product of pretraining is a language interpretation model that maps from descriptions to predictors (e.g. image classifiers or reinforcement learners). Our thesis is that language learning is a powerful, general-purpose kind of pretraining, even for tasks that do not directly involve language.

New concepts are learned by searching directly in the space of natural language strings to mini-

New Orleans, Louisiana, June 1 - 6, 2018.

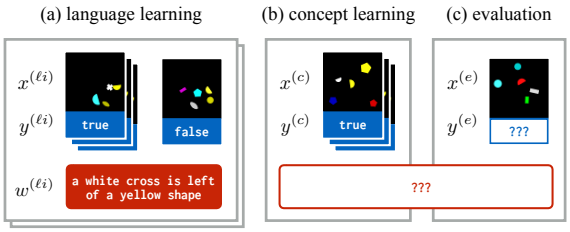

Figure 2: Formulation of the learning problem. Ultimately, we care about our model's ability to learn a concept from a small number of training examples (b) and successfully generalize it to held-out data (c). In this paper, concept learning is supported by a language learning phase (a) that makes use of natural language annotations on other learning problems. These annotations are not provided for the real target task in (b–c).

mize the loss incurred by the language interpretation model (Figure 1). Especially on tasks that require the learner to model high-level compositional structure shared by training examples, natural language hypotheses serve a threefold purpose: they make it easier to discover these compositional concepts, harder to overfit to few examples, and easier for humans to understand inferred patterns.

Our approach can be implemented using a standard kit of neural components, and is simple and general. In a variety of settings, we find that the structure imposed by a natural-language parameterization is helpful for efficient learning and exploration. The approach outperforms both multitask- and meta-learning approaches that map directly from training examples to outputs by way of a real-valued parameterization, as well as approaches that make use of natural language annotations as an additional supervisory signal rather than an explicit latent parameter. The natural language concept descriptions inferred by our approach often agree with human annotations when they are correct, and provide an interpretable debugging signal when incorrect. In short, by equipping models with the ability to "think out loud" when learning, they become both more comprehensible and more accurate.

2 Background

Suppose we wish to solve an image classification problem like the one shown in Figure 2b–c, mapping from images x to binary labels y. One straightforward way to do this is to solve a learning problem of the following form:

$$\arg\min_{\eta \in \mathbf{H}} \sum_{(x,y)} L(f(x;\eta), y)\,, \qquad (1)$$

where L is a loss function and f is a richly-parameterized class of models (e.g. convolutional networks) indexed by η (e.g. weight matrices) that map from images to labels. Given a new image x', $f(x';\eta)$ can be used to predict its label.

In the present work, we are particularly interested in *few-shot* learning problems where the number of (x, y) pairs is small—on the order of five or ten examples. Under these conditions, directly solving Equation 1 is a risky proposition—any model class powerful enough to capture the true relation between inputs and outputs is also likely to overfit. For few-shot learning to be successful, extra structure must be supplied to the learner. Existing approaches obtain this structure by either carefully structuring the hypothesis space or providing the learner with alternative training data. The approach we present in this paper combines elements of both, so we begin with a review of existing work.

(Inductive) **program synthesis** approaches (e.g. Gulwani, 2011) reduce the effective size of the hypothesis class $\mathbf{H}$ by moving the optimization problem out of the continuous space of weight vectors and into a discrete space of formal program descriptors (e.g. regular expressions or Prolog queries). Domain-specific structure like version space algebras (Lau et al., 2003) or type systems (Kitzelmann and Schmid, 2006) can be brought to bear on the search problem, and the bias inherent in the syntax of the formal language provides a strong prior. But while program synthesis techniques are powerful, they are also limited in their application: a human designer must hand-engineer the computational primitives necessary to compactly describe every learnable hypothesis. While reasonable for some applications (like string editing), this is challenging or impossible for others (like computer vision).

An alternative class of **multitask learning** approaches (Caruana, 1998) import the relevant structure from other learning problems rather than defining it manually (Figure 2a, top). Since we may not know *a priori* what set of learning problems we ultimately wish to evaluate on, it is useful to think of learning as taking places in three phases:

1. a **pretraining** (or "meta-training") phase that makes use of various different datasets i with examples $\{(x_1^{(\ell i)}, y_1^{(\ell i)}), \ldots, (x_n^{(\ell i)}, y_n^{(\ell i)})\}$ (Figure 2a)

2. a **concept-learning** phase in which the pretrained model is adapted to fit data $\{(x_1^{(c)}, y_1^{(c)}), \ldots, (x_n^{(c)}, y_n^{(c)})\}$ for a specific new task (Figure 2b)

3. an **evaluation** phase in which the learned concept is applied to a new input $x^{(e)}$ to predict $y^{(e)}$ (Figure 2c)

In these approaches, learning operates over two collections of parameters: shared parameters η and task-specific parameters θ. In pretraining, multitask approaches find:

$$\underset{\eta \in \mathbb{R}^a,\, \theta^{(\ell i)} \in \mathbb{R}^b}{\arg\min} \sum_{i,j} L\big(f(x_j^{(\ell i)};\, \eta,\, \theta^{(\ell i)}),\, y_j^{(\ell i)}\big)\,. \quad (2)$$

At concept learning time, they solve for:

$$\underset{\theta^{(c)} \in \mathbb{R}^b}{\arg\min} \sum_{j} L\big(f(x_j^{(c)};\, \eta,\, \theta^{(c)}),\, y_j^{(c)}\big) \quad (3)$$

on the new dataset, then make predictions for new inputs using $f(x^{(e)};\, \eta,\, \theta^{(c)})$.

Closely related **meta-learning** approaches (e.g. Schmidhuber, 1987; Santoro et al., 2016; Vinyals et al., 2016) make use of the same data, but collapse the inner optimization over $\theta^{(c)}$ and prediction of $y^{(e)}$ into a single learned model.

3 Learning with Language

In this work, we are interested in developing a learning method that enjoys the benefits of both approaches. In particular, we seek an intermediate language of task representations that, like in program synthesis, is both expressive and compact, but like in multitask approaches is learnable directly from training data without domain engineering. We propose to use natural language as this intermediate representation. We call our approach **learning with latent language** (L^3).

Natural language shares many structural advantages with the formal languages used in synthesis approaches: it is discrete, has a rich set of compositional operators, and comes equipped with a natural description length prior. But it also has a considerably more flexible semantics. And crucially, plentiful annotated data exists for *learning* this semantics: we cannot hand-write a computer program to recognize a *small dog*, but we can learn how to do it from image captions. More basically, the set of primitive operators available in language provides a strong prior about the kinds of abstractions that are useful for natural learning problems.

Concretely, we replace the pretraining phase above with a **language-learning** phase. We assume that at language-learning time we have access to natural-language **descriptions** $w^{(\ell i)}$ (Figure 2a, bottom). We use these w as *parameters*, in place of the task-specific parameters θ—that is, we learn a language **interpretation** model $f(x;\, \eta,\, w)$ that uses shared parameters η to turn a description w into a function from inputs to outputs. For the example in Figure 2, f might be an image rating model (Socher et al., 2014) that outputs a scalar judgment y of how well an image x matches a caption w.

Because these natural language parameters are observed at language-learning time, we need only learn the real-valued shared parameters η used for their interpretation (e.g. the weights of a neural network that implements the image rating model):

$$\underset{\eta \in \mathbb{R}^a}{\arg\min} \sum_{i,j} L\big(f(x_j^{(\ell i)};\, \eta,\, w^{(\ell i)}),\, y_j^{(\ell i)}\big)\,. \quad (4)$$

At concept-learning time, conversely, we solve only the part of the optimization problem over natural language strings:

$$\underset{w^{(c)} \in \Sigma^*}{\arg\min} \sum_{j} L\big(f(x_j^{(c)};\, \eta,\, w^{(c)}),\, y_j^{(c)}\big)\,. \quad (5)$$

This last step presents something of a challenge. When solving the corresponding optimization problem, synthesis techniques can exploit the algebraic structure of the formal language, while end-to-end learning approaches take advantage of differentiability. Here we can't do either—the language of strings is discrete, and any structure in the interpretation function is wrapped up inside the black box of f. Inspired by related techniques aimed at making synthesis more efficient (Devlin et al., 2017), we use learning to help us develop an effective optimization procedure for natural language parameters.

In particular, we simply use the language-learning datasets, consisting of pairs $(x_j^{(\ell i)}, y_j^{(\ell i)})$ and descriptions w_i, to fit a reverse **proposal** model, estimating:

$$\arg\max_\lambda \textstyle\sum_i \log q(w_i | x_1^{(\ell i)}, y_1^{(\ell i)}, \ldots, x_n^{(\ell i)}, y_n^{(\ell i)}; \lambda)$$

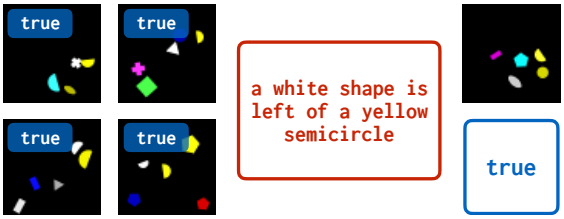

Figure 3: The few-shot image classification task. Learners are shown four positive examples of a visual concept (left) and must determine whether a fifth image matches the pattern (right). Natural language annotations are provided during language learning but must be inferred for concept learning.

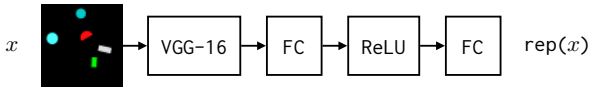
where q provides a (suitably normalized) approximation to the distribution of descriptions given task data. In the running example, this proposal distribution is essentially an image captioning model (Donahue et al., 2015). By sampling from q, we expect to obtain candidate descriptions that are likely to obtain small loss. But our ultimate inference criterion is still the true model f: at evaluation time we perform the minimization in Equation 5 by drawing a fixed number of samples, selecting the hypothesis $w^{(c)}$ that obtains the lowest loss, and using $f(x^{(e)}; \eta, w^{(c)})$ to make predictions.

What we have described so far is a generic procedure for equipping collections of related learning problems with a natural language hypothesis space. In Sections 4 and 5, we describe how this procedure can be turned into a concrete algorithm for supervised classification and sequence prediction. In Section 6, we describe how to extend these techniques to reinforcement learning.

4 Few-shot Classification

We begin by investigating whether natural language can be used to support high-dimensional few-shot classification. Our focus is on visual reasoning tasks like the one shown in Figure 3. In these problems, the learner is presented with four images, all positive examples of some visual concept like *a blue shape near a yellow triangle*, and must decide whether a fifth, held-out image matches the same concept. These kinds of reasoning problems have been well-studied in visual question answering settings (Johnson et al., 2017; Suhr et al., 2017). Our version of the problem, where the input and output feature no text data, but an explanation must be inferred, is similar to the visual reasoning problems proposed by Raven (1936) and Bongard (1968).

To apply the recipe in Section 2, we need to specify an implementation of the interpretation model f and the proposal model q. We begin by computing representations of input images x. We start with a pre-trained 16-layer VGGNet (Simonyan and Zisserman, 2014). Because spatial information is important for these tasks, we extract a feature representation from the final convolutional layer of the network. This initial featurization is passed through two fully-connected layers to form a final image representation, as follows:



We define interpretation and proposal models:[2]

$$f(x; w) = \sigma\big(\texttt{rnn-encode}(w)^\top \texttt{rep}(x)\big)$$
$$q(w \mid \{x_j\}) = \texttt{rnn-decode}\big(w \mid \tfrac{1}{n}\textstyle\sum_j \texttt{rep}(x_j)\big)$$

The interpretation model f outputs the probability that x is assigned a positive class label, and is trained to maximize log-likelihood. Because only positive examples are provided in each language learning set, the proposal model q can be defined in terms of inputs alone. Details regarding training hyperparameters, RNN implementations, etc. may be found in Appendix A.

Our evaluation aims to answer two questions. First, does the addition of language to the learning process provide any benefit over ordinary multitask or meta-learning? Second, is it specifically better to use language as a hypothesis space for concept learning rather than just an additional signal for pretraining? We use several baselines to answer these questions:

1. *Multitask*: a multitask baseline in which the definition of f above is replaced by $\sigma(\theta_i^\top \texttt{rep}(x))$ for task-specific parameters θ_i that are optimized during both pretraining and concept-learning.

2. *Meta*: a meta-learning baseline in which f is defined by $\sigma([\frac{1}{n}\sum_j \texttt{rep}(x_j)]^\top \texttt{rep}(x))$.[3]

[2] Suppressing shared parameters η and λ for clarity.

[3] Many state-of-the-art approaches to meta-learning for classification (e.g. Snell et al., 2017) are not well-defined for possibly-overlapping evaluation classes with only positive examples provideded. Here we have attempted to provide a robust implementation that is as close as possible to the other systems under evaluation.

3. *Meta+Joint*: as in *Meta*, but the pretraining objective includes an additional term for predicting q (discarded for concept learning).

We report results on a dataset derived from the ShapeWorld corpus of Kuhnle and Copestake (2017). In this dataset the held-out image matches the target concept 50% of the time. In the validation and test folds, half of learning problems feature a concept that also appears in the language learning set (but with different exemplar images), while the other half feature both new images and a new concept. Images contain two or three distractor shapes unrelated to the objects that define the target concept. Captions in this dataset were generated from DMRS representations using an HPS grammar (Copestake et al., 2016). (Our remaining experiments use human annotators.) The dataset contains a total of 9000 pretraining tasks and 1000 of each validation and test tasks. More dataset statistics are provided in Appendix B.

Results are shown in Table 1. It can be seen that L^3 provides consistent improvements over the baselines, and that these improvements are present both when identifying new instances of previously-learned concepts and when discovering new ones. Some example model predictions are shown in Figure 4. The model often succeeds in making correct predictions, even though its inferred descriptions rarely match the ground truth. Sometimes this is because of inherent ambiguity in the description language (Figure 4a), and sometimes because the model is able to rule out candidates on the basis of partial captions alone (Figure 4b, where it is sufficient to recognize that the target concept involves a *circle*). More examples are provided in Appendix C.

Model	Val (old)	Val (new)	Val	Test
Random	50	50	50	50
Multitask	64	49	57	59
Meta	63	62	62	64
Meta+Joint	63	69	66	64
L^3 (ours)	**70**	**72**	**71**	**70**
L^3 (oracle)	77	80	79	78

Table 1: Evaluation on image classification. *Val (old)* and *Val (new)* denote subsets of the validation set that contain respectively previously-used and novel visual concepts. L^3 consistently outperforms alternative learning methods based on multitask learning, meta-learning, and meta-learning jointly trained to predict descriptions (*Meta+Joint*). The last row shows results when the model is given a ground-truth concept description rather than having to infer it from examples.

5 Programming by Demonstration

Next we explore whether the same technique can be applied to tasks that involve more than binary similarity judgments. We focus on structured prediction: specifically a family of string processing tasks. In these tasks, the model is presented with examples of five strings transformed according to some rule; it must then apply an appropriate transformation to a sixth (Figure 5). Learning proceeds as in the previous section, with:

$$\texttt{rep}(x, y) = \texttt{rnn-encode}([x, y])$$
$$f(y \mid x; w) =$$
$$\quad \texttt{rnn-decode}\big(y \mid [\texttt{rnn-encode}(x), \texttt{rnn-encode}(w)]\big)$$
$$q(w \mid \{(x_j, y_j)\}) =$$
$$\quad \texttt{rnn-decode}\big(w \mid \tfrac{1}{n}\textstyle\sum_j \texttt{rep}(x_j, y_j)\big)$$

Baselines are analogous to those for classification.

While string editing tasks of the kind shown in Figure 5 are popular in both the programming by demonstration literature (Singh and Gulwani, 2012) and the semantic parsing literature (Kushman and Barzilay, 2013), we are unaware of any datasets that support both learning paradigms at the same time. We have thus created a new dataset of string editing tasks by (1) sampling random regular transducers, (2) applying these transducers to collections of dictionary words, and (3) showing the collected examples to Mechanical Turk users

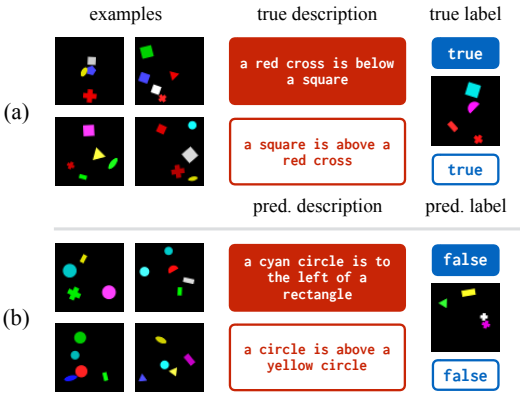


Figure 4: Example predictions for image classification. The model achieves high accuracy even though predicted descriptions rarely match the ground truth. High-level structure like the presence of certain shapes or spatial relations is consistently recovered.

Model	Val	Test
Identity	18	18
Multitask	54	50
Meta	66	62
Meta+Joint	63	59
L^3	**80**	**76**

Table 2: Results for string editing. The reported number is the percentage of cases in which the predicted string exactly matches the reference. L^3 is the best performing model; using language data for joint training rather than as a hypothesis space provides little benefit.

and asking them to provide a natural language explanation with their best guess about the underlying rule. The dataset thus features both multi-example learning problems, as well as structured and unstructured annotations for each target concept. There are 3000 tasks for language learning and 500 tasks for each of validation and testing (Appendix B). Annotations are included in the code release for this paper.

Results are shown in Table 2. In these experiments, all models that use descriptions have been trained on the natural language supplied by human annotators. While we did find that the Meta+Joint model converges considerably faster than all the others, its final performance is somewhat lower than the baseline Meta model. As before, L^3 outperforms alternative approaches for learning directly from examples with or without descriptions.

Because all of the transduction rules in this dataset were generated from known formal descriptors, these tasks provide an opportunity to perform additional analysis comparing natural language to more structured forms of annotation (since we have access to ground-truth regular expressions) and more conventional synthesis-based methods (since we have access to a ground-truth regular expression execution engine). We additionally investigate the effect of the number of

Figure 5: Example string editing task. Learners are presented with five examples of strings transformed according to some rule (left), and must apply an appropriate transformation to a sixth string (right). Language-learning annotations (center) may take the form of either natural language or regular expressions.

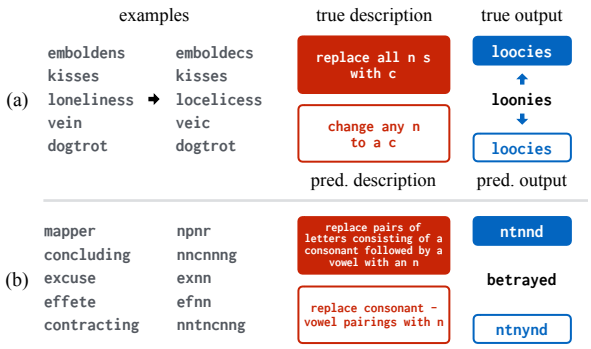

Figure 6: Example predictions for string editing.

samples drawn from the proposal model. These results are shown in Table 3.

A few interesting facts stand out. Under the ordinary evaluation condition (with no ground-truth annotations provided), language-learning with natural language data is actually better than language-learning with regular expressions. This might be because the extra diversity helps the model determine the relevant axes of variation and avoid overfitting to individual strings. Allowing the model to do its own inference is also better than providing ground-truth natural language descriptions, suggesting that it is actually better at generalizing from the relevant concepts than our human annotators (who occasionally write things like *I have no idea* for the inferred rule). Unsurprisingly, with ground truth REs (which unlike the human data are always correct) we can do better than any of the models that require inference. Coupling our inference procedure with an oracle RE evaluator, we essentially recover the synthesis-based approach of Devlin et al. (2017). Our findings are consistent with theirs: when an exact execution engine is available, there is no reason not to use it. But we can get almost 90% of the way there

Annotations	Samples		Oracle	
	1	100	Ann.	Eval.
None (Meta)	*66*	–	–	–
Natural language	66	*80*	75	–
Regular expressions	60	76	88	90

Table 3: Inference and representation experiments for string editing. Italicized numbers correspond to entries in Table 2. Allowing the model to use multiple samples rather than the 1-best decoder output substantially improves performance. The full model does better with inferred natural language descriptions than either regular expressions or ground-truth natural language.

with an execution model learned from scratch. Examples of model behavior are shown in Figure 6; more may be found in Appendix D.

6 Policy Search

The previous two sections examined supervised settings where the learning signal comes from few examples but is readily accessible. In this section, we move to a set of reinforcement learning problems, where the learning signal is instead sparse and time-consuming to obtain. We evaluate on a collection of 2-D treasure hunting tasks. These tasks require the agent to discover a rule that determines the location of buried treasure in a large collection of environments of the kind shown in Figure 7. To recover the treasure, the agent must navigate (while avoiding water) to its goal location, then perform a `DIG` action. At this point the episode ends; if the treasure is located in the agent's current position, it receives a reward, otherwise it does not. In every task, the treasure has consistently been buried at a fixed position relative to some landmark (in Figure 7 a heart). Both the offset and the identity of the target landmark are unknown to the agent, and the location of the landmark varies across maps. Indeed, there is nothing about the agent's observations or action space to suggest that landmarks and offsets are even the relevant axes of variation across tasks: only the language reveals this structure.

The interaction between language and learning in these tasks is rather different from the supervised settings. In the supervised case, language serves mostly as a guard against overfitting, and

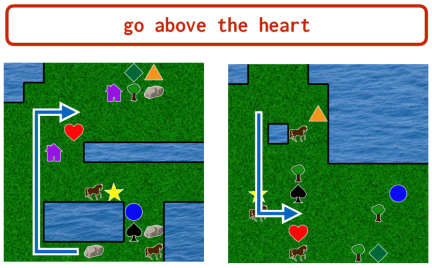

Figure 7: Example treasure hunting task: the agent is placed in a random environment and must collect a reward that has been hidden at a consistent offset with respect to some landmark. At language-learning time only, natural language instructions and expert policies are provided. The agent must both learn primitive navigation skills, like avoiding water, as well as the high-level structure of the reward functions for this domain.

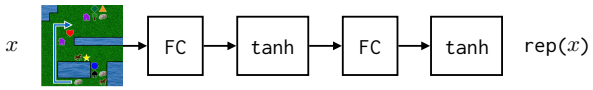
can be generated conditioned on a set of pre-provided concept-learning observations. Here, agents are free to interact with the environment as much as they need, but receive observations only during interaction. Thus our goal here will be to build agents that can *adapt quickly* to new environments, rather than requiring them to immediately perform well on held-out data.

Why should we expect L^3 to help in this setting? In reinforcement learning, we typically encourage our models to explore by injecting randomness into either the agent's action space or its underlying parameterization. But most random policies exhibit nonsensical behaviors; as a result, it is inefficient both to sample in the space of network weights and to perform policy optimization from a random starting point. Our hope is that when parameters are chosen from within a structured family, a stochastic search in this structured space will only ever consider behaviors corresponding to a reasonable final policy, and in this way discover good behavior faster than ordinary RL.

Here the interpretation model f describes a policy that chooses actions conditioned on the current environment state and a linguistic parameterization. As the agent initially has no observations at all, we simply design the proposal model to generate unconditional samples from a prior over descriptions. Taking x to be an agent's current observation of the environment state, we define a state representation network and models:



$$f(a \mid x; w) \propto \texttt{rnn-encode}(w)^\top W_a \, \texttt{rep}(x)$$
$$q(w) = \texttt{rnn-decode}(w)$$

This parameterization assumes a discrete action space, and assigns to each action a probability proportional to a bilinear function of the encoded description and world state. f is an instruction following model of a kind well-studied in natural language processing (Branavan et al., 2009); the proposal model allows it to generate its own instructions without external direction. To learn, we sample a fixed number of descriptions w from q. For each description, we sample multiple rollouts of the policy it induces to obtain an estimate of its average reward. Finally, we take the highest-scoring description and fine-tune its induced policy.

At language-learning time, we assume access to both natural language descriptions of these tar-

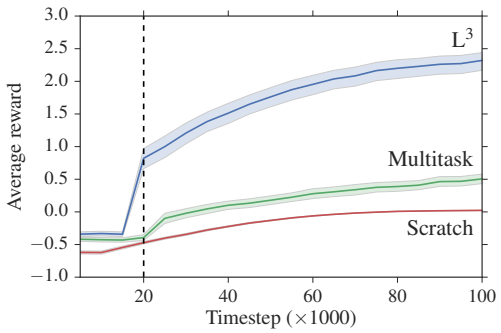


Figure 8: Treasure hunting reward obtained by each learning algorithm across multiple evaluation environments, after language learning has already taken place (bands show 95% confidence intervals for mean performance). *Multitask* learns an embedding for each task, while *Scratch* trains on every task individually. L^3 rapidly discovers high-scoring policies in most environments. Dashed line indicates the end of the concept-learning phase; subsequent performance comes from fine-tuning. The max reward for this task is 3.

get locations provided by human annotators, as well as expert policies for navigating to the location of the treasure. The multitask model we compare to replaces these descriptions with trainable task embeddings.[4] The learner is trained from task-specific expert policies using DAgger (Ross et al., 2011) during the language-learning phase, and adapts to individual environments using "vanilla" policy gradient (Williams, 1992) during the concept learning phase.

The environment implementation and linguistic annotations are in this case adapted from a natural language navigation dataset originally introduced by Janner et al. (2017). In our version of the problem (Figure 7), the agent begins each episode in a random position on a randomly-chosen map and must attempt to obtain the treasure. Relational concepts describing target locations are reused between language learning and concept-learning phases, but the environments themselves are distinct. For language learning the agent has access to 250 tasks, and is evaluated on an additional 50.

Averaged learning curves for held-out tasks are shown in Figure 8. As expected, reward for the L^3 model remains low during the initial exploration period, but once a description is chosen the score improves rapidly. Immediately L^3 achieves better reward than the multitask baseline, though it is not perfect; this suggests that the interpretation model is somewhat overfit to the pretraining environments. After fine-tuning even better results are rapidly obtained. Example rollouts are visualized in Appendix E. These results show that the model has used the structure provided by language to *learn* a better representation space for policies—one that facilitates sampling from a distribution over interesting and meaningful behaviors.

[4] In RL, the contribution of L^3 is orthogonal to that of meta-learning—one could use a technique like RL^2 (Duan et al., 2016) to generate candidate descriptions more efficiently, or MAML (Finn et al., 2017) rather than zero-shot reward as the training criterion for the interpretation model.

7 Other Related Work

This is the first approach we are aware of to frame a general learning problem as optimization over a space of natural language strings. However, many closely related ideas have been explored in the literature. String-valued latent variables are widely used in language processing tasks ranging from morphological analysis (Dreyer and Eisner, 2009) to sentence compression (Miao and Blunsom, 2016). Natural language annotations have been used in conjunction with training examples to guide the discovery of logical descriptions of concepts (Ling et al., 2017; Srivastava et al., 2017), and used as an auxiliary loss for training (Frome et al., 2013), analogously to the Meta+Joint baseline in this paper. Structured language-like annotations have been used to improve learning of generalizable structured policies (Oh et al., 2017; Andreas et al., 2017; Denil et al., 2017). Finally, natural language instructions available at *concept-learning* time (rather than language-learning time) have been used to provide side information to reinforcement learners about high-level strategy (Branavan et al., 2011), environments (Narasimhan et al., 2017) and exploration (Harrison et al., 2017).

8 Conclusion

We have presented an approach for learning in a space parameterized by natural language. Using simple models for representation and search in this space, we demonstrated that our approach outperforms standard baselines on classification, structured prediction and reinforcement learning tasks. We believe that these results suggest the following general conclusions:

Language encourages compositional generalization. Standard deep learning architectures are good at recognizing new instances of familiar

concepts, but not always at generalizing to new ones. By forcing decisions to pass through a linguistic bottleneck in which the underlying compositional structure of concepts is explicitly expressed, stronger generalization becomes possible.

Language simplifies structured exploration. Natural language scaffolding provides dramatic advantages in problems like reinforcement learning that require exploration: models with latent linguistic parameterizations can limit exploration to a class of behaviors that are likely *a priori* to be goal-directed and interpretable.

And generally, *language can help learning*. In multitask settings, it can even improve learning on tasks for which no language data is available at training or test time. While some of these advantages are also provided by techniques built on top of formal languages, natural language is at once more expressive and easier to obtain than formal supervision. We believe this work hints at broader opportunities for using naturally-occurring language data to improve machine learning for tasks of all kinds.

A Model and Training Details

In all models, RNN encoders and decoders use gated recurrent units (Cho et al., 2014).

Few-shot classification Models are trained with the ADAM optimizer (Kingma and Ba, 2015) with a step size of 0.0001 and batch size of 100. The number of pretraining iterations is tuned based on subsequent concept-learning performance on the development set. Neural network hidden states, task parameters, and word vectors are all of size 512. 10 hypotheses are sampled during for each evaluation task in the concept-learning phase.

Programming by demonstration Training as in the classification task, but with a step size of 0.001. Hidden states are of size 512, task parameters of size 128 and word vectors of size 32. 100 hypotheses are sampled for concept learning.

Policy search DAgger (Ross et al., 2011) is used for pre-training and vanilla policy gradient (Williams, 1992) for concept learning. Both learning algorithms use ADAM with a step size of 0.001 and a batch size of 5000 samples. For imitation learning, rollouts are obtained from the expert policy on a schedule with probability 0.95^t (for t the current epoch). For reinforcement learning, a discount of 0.9 is used. Because this dataset contains no development data, pretraining is run until performance on the pretraining tasks reaches a plateau. Hidden states and task embeddings are of size 64. 100 hypotheses are sampled for concept learning, and 1000 episodes (divided evenly among samples) are used to estimate hypothesis quality before fine-tuning.

B Dataset Information

ShapeWorld This is the only fully-synthetic dataset used in our experiments. Each scene features 4 or 5 non-overlapping entities. Descriptions refer to spatial relationships between pairs of entities identified by shape, color, or both. There are 8 colors and 8 shapes. The total vocabulary size is only 30 words, but the dataset contains 2643 distinct captions. Descriptions are on average 12.0 words long.

Regular expressions Annotations were collected from Mechanical Turk users. Each user was presented with the same task as the learner in this paper: they observed five strings being transformed, and had to predict how to transform a sixth. Only after they correctly generated the held-out word were they asked for a description of the rule. Workers were additionally presented with hints like "look at the beginning of the word" or "look at the vowels". Descriptions are automatically preprocessed to strip punctuation and ensure that every character literal appears as a single token.

The regular expression data has a vocabulary of 1015 rules and a total of 1986 distinct descriptions. Descriptions are on average 12.3 words in length but as long as 46 words in some cases.

Navigation The data used was obtained from Janner et al. (2017). We created our own variant of the dataset containing collections of related tasks. Beginning with the "local" tasks in the dataset, we generated alternative goal positions at fixed offsets from landmarks as described in the main section of this paper. Natural-language descriptions were selected for each task collection from the human annotations provided with the dataset. The vocabulary size is 74 and the number of distinct hints 446. The original action space for the environment is also modified slightly: rather than simply reaching the goal cell (achieved with reasonably high frequency by a policy that takes random moves), we require the agent to commit to an individual goal cell and end the episode with a special `DIG` action.

Data augmentation Due to their comparatively small size, a data augmentation scheme (Jia and Liang, 2016) is employed for the regular expression and navigation datasets. In particular, wherever a description contains a recognizable entity name (i.e. a character literal or a landmark name), a description template is extracted. These templates are then randomly swapped in at training time on other examples with the same high-level semantics. For example, the description *replace first b with e* is abstracted to *replace first CHAR1 with CHAR2*, and can subsequently be specialized to, e.g., *replace first c with d*. This templating is easy to implement because we have access to ground-truth structured concept representations at training time. If these were not available it would be straightforward to employ an automatic template induction system (Kwiatkowski et al., 2011) instead.

Object Counts! Bringing Explicit Detections Back into Image Captioning

Josiah Wang, Pranava Madhyastha and **Lucia Specia**
Department of Computer Science
University of Sheffield, UK
{j.k.wang, p.madhyastha, l.specia}@sheffield.ac.uk

Abstract

The use of explicit object detectors as an intermediate step to image captioning – which used to constitute an essential stage in early work – is often bypassed in the currently dominant end-to-end approaches, where the language model is conditioned directly on a mid-level image embedding. We argue that explicit detections provide rich semantic information, and can thus be used as an interpretable representation to better understand why end-to-end image captioning systems work well. We provide an in-depth analysis of end-to-end image captioning by exploring a variety of cues that can be derived from such object detections. Our study reveals that end-to-end image captioning systems rely on matching image representations to generate captions, and that encoding the frequency, size and position of objects are complementary and all play a role in forming a good image representation. It also reveals that different object categories contribute in different ways towards image captioning.

1 Introduction

Image captioning (IC), or image description generation, is the task of automatically generating a sentential textual description for a given image. Early work on IC tackled the task by first running object detectors on the image and then using the resulting explicit detections as input to generate a novel textual description, e.g. (Kulkarni et al., 2011; Yang et al., 2011). With the advent of sequence-to-sequence approaches to IC, e.g. (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015), coupled with the availability of large image description datasets, the performance of IC systems showed marked improvement, at least according to automatic evaluation metrics like Meteor (Denkowski and Lavie, 2014) and CIDEr (Vedantam et al., 2015).

The currently dominant neural-based IC systems are often trained end-to-end, using parallel (image, caption) datasets. Such systems are essentially sequential language models conditioned directly on some mid-level image features, such as an image embedding extracted from a pre-trained Convolutional Neural Network (CNN). Thus, they bypass the explicit detection phase of previous methods and instead generate captions *directly* from image features. Despite significant progress, it remains unclear why such systems work. A major problem with these IC systems is that they are less interpretable than conventional pipelined methods which use explicit detections.

We believe that it is timely to again start exploring the use of explicit object detections for image captioning. Explicit detections offer rich semantic information, which can be used to model the entities in the image as well as their interactions, and can be used to better understand image captioning.

Recent work (Yin and Ordonez, 2017) showed that conditioning an end-to-end IC model on visual representations that implicitly encode object details yields reasonably good captions. Nevertheless, it is still unclear *why* this works, and *what* aspects of the representation allow for such a good performance. In this paper, we study end-to-end IC in the context of explicit detections (Figure 1) by exploring a variety of cues that can be derived from such detections to determine *what* information from such representations helps image captioning, and *why*. To our best knowledge, our work is the first experimental analysis of end-to-end IC frameworks that uses object-level information that is highly interpretable as a tool for understanding such systems. Our main contributions are as follows:

1. We provide an in-depth analysis of the performance of end-to-end IC using a simple, yet effective 'bag of objects' representation that

Proceedings of NAACL-HLT 2018, pages 2180–2193
New Orleans, Louisiana, June 1 - 6, 2018.

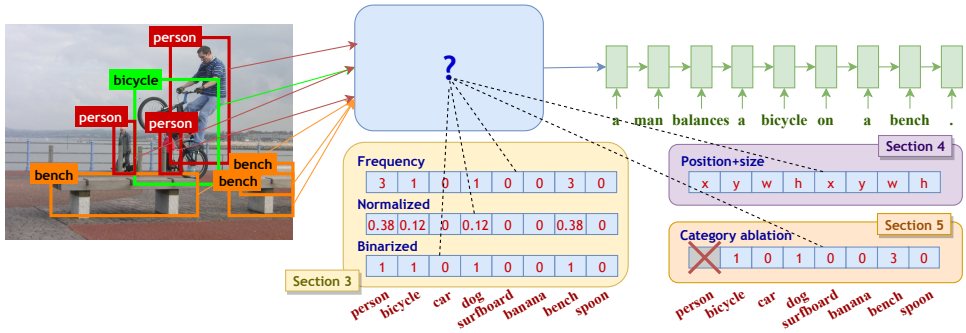

Figure 1: Using explicit detections as an intermediate step towards end-to-end image captioning. The question we investigate is what information can we extract from explicit detections that can be useful for image captioning.

is interpretable, and generates good captions despite being low-dimensional and highly sparse (Section 3).

2. We investigate whether other spatial cues can be used to provide information complementary to frequency counts (Section 3).
3. We study the effect of incorporating different spatial information of individual object instances from explicit detections (Section 4).
4. We analyze the contribution of the categories in representations for IC by ablating individual categories from them (Section 5).

Our hypothesis is that there are important components derived from explicit detections that can be used to effectively inform IC. Our study confirms our hypothesis, and that features such as the frequency, size and position of objects all play a role in forming a good image representation to match their corresponding representations in the training set. Our findings also show that different categories contribute differently to IC, and this partly depends on how likely they are to be mentioned in the caption given that they are depicted in the image. The results of our investigation will help further work towards more interpretable image captioning.

2 Related work

Early work on IC apply object detectors explicitly on an image as a first step to identify entities present in the image, and then use these detected objects as input to an image caption generator. The caption generator typically first performs content selection (selecting a subset of objects to be described) and generates an intermediate representation (e.g. semantic tuples or abstract trees), and then performs surface realization using rules, templates, n-grams or a maximum entropy language model. The main body of work uses object detectors for 20 pre-specified PASCAL VOC (Visual Object Classes) (Everingham et al., 2015) (Yang et al., 2011; Kulkarni et al., 2011; Li et al., 2011; Mitchell et al., 2012), builds a detector inferred from captions (Fang et al., 2015), or assumes gold standard annotations are available (Elliott and Keller, 2013; Yatskar et al., 2014).

Currently, deep learning end-to-end approaches dominate IC work (Donahue et al., 2015; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015). Such approaches do not use an explicit detection step, but instead use a 'global' image embedding as input (generally a CNN) and learn a language model (generally an LSTM) conditioned on this input. Thus, they are trained to learn image caption generation directly from a parallel image–caption dataset. The advantage is that no firm decisions need to be made about object categories. However, such approaches are hard to interpret and are dataset dependent (Vinyals et al., 2017).

Some recent work use object-level semantics for end-to-end IC (Gan et al., 2017; Wu et al., 2016; You et al., 2016). Such systems represent images as predictions of semantic concepts occurring in the image. These predictions, however, are at a global, *image* level ("does this image contain a chair?"), rather than at object *instance* level ("there is a big chair at position x"). In addition, most previous work regard surface-level terms extracted directly from captions as 'objects', while we use off-the-shelf predefined object categories which have a looser connection between the image and the caption (e.g. objects can be described in captions using different terms, depicted objects might not be mentioned in captions, and captions might mention objects that are not depicted).

Yin and Ordonez (2017) propose conditioning an end-to-end IC model on information derived from explicit detections. They implicitly encode the category label, position and size of object instances as an 'object-layout' LSTM and condition the language model on the final hidden state of this LSTM, and produce reasonably good image captions based only on those cues, without the direct use of images. Our work is different in that we feed information from explicit object detections *directly* to the language model in contrast to an object-layout LSTM which abstracts away such information, thereby retaining the *interpretability* of the input image representation. This gives us more control over the image representation which is simply encoded as a bag of categorical variables.

There is also recent work applying attention-based models (Xu et al., 2015) on explicit object proposals (Anderson et al., 2018; Li et al., 2017), which may capture object-level information from the attention mechanism. However, attention-based models require object information in the form of vectors, whereas our models use information of objects as categorical variables which allow for easy manipulation but are not compatible with the standard attention-based models. The model that we use, *under similar conditions* (i.e. under similar parametric settings), is comparable to the state-of-the-art models.

3 Bag of objects

We base our experiments on the MS COCO dataset (Lin et al., 2014). From our preliminary experiments, we found that a simple *bag of object categories* used as an image representation for end-to-end IC led to good scores according to automatic metrics, comparable to and perhaps even higher than those using CNN embeddings. This is surprising given that this bag of objects vector is *low-dimensional* (each element represents the frequency of one of 80 COCO categories) and *sparse* (mainly zeros, as only a few object categories tend to occur in a given image). In simple terms, it appears that the IC model can generate a reasonable caption by merely knowing what is in the image, e.g. that there are three *person*s, three *benches* and a *bicycle* in Figure 1.

This observation raises the following questions. What is it in this simple bag of objects representation that contributes to the surprisingly high performance on IC? Does it lie in the frequency counts? Or the choice of categories themselves? It is also worth noting that the image captions in COCO were crowd-sourced *independent* of the COCO object annotations, i.e. image captions were written based only on the image, without object-level annotations. The words used in the captions thus do not correspond directly to the 80 COCO categories (e.g. a *cup* may not be mentioned in a description even though it is present in the image, and vice versa, i.e. objects described in the caption may not correspond to any of the categories).

In order to shed some light into what makes bag of object categories representations work so well for IC, we first investigate whether the *frequency counts* is the main contributor. We then proceed to studying what else can be exploited from explicit object detections to improve on the bag of objects model, for example the size of object instances. We also perform an analysis on these representations to gain more insights into why the bag of objects model performs well.

3.1 Image captioning model

Our implementation is based on the end-to-end approach of Karpathy and Fei-Fei (2015). We use an LSTM (Hochreiter and Schmidhuber, 1997) language model as described in Zaremba et al. (2014). To condition the image information, we first perform a linear projection of the image representation followed by a non-linearity:

$$x = \sigma(W \cdot I_m) \tag{1}$$

where $I_m \in \mathcal{R}^d$ is the d-dimensional initial image representation, $W \in \mathcal{R}^{n \times d}$ is the linear transformation matrix, σ is the non-linearity. We use Exponential Linear Units (Clevert et al., 2016) as the non-linear activation in all our experiments. We initialize the LSTM-based caption generator with the projected image representation, x.

Training and inference. The caption generator is trained to generate sentences conditioned on x. We train the model by minimizing the cross-entropy, i.e. the sentence-level loss corresponds to the sum of the negative log likelihood of the correct word at each time step:

$$\Pr(S|x;\theta) = \sum_t \log(\Pr(w_t|w_{t-1}..w_0;x)) \tag{2}$$

where $\Pr(S|x;\theta)$ is the sentence-level loss con-

ditioned on the image feature x and $\Pr(w_t)$ is the probability of the word at time step t. This is trained with standard teacher forcing as described in Sutskever et al. (2014), where the correct word information is fed to the next state in the LSTM.

Inference is usually performed using approximate techniques like beam search and sampling methods. As we are mainly interested in studying different image representations, we focus on the language output that the models can most confidently produce. In order to isolate any other variables from the experiments, we generate captions using a greedy $\arg\max$ approach. We use a 2-layer LSTM with 128-dimensional word embeddings and 256-dimensional hidden dimensions. As training vocabulary we retain only words that appear at least twice. We provide details about hyperparameters and tuning in Appendix A.

3.2 Visual representations

The first part of our experiments studies the role of *frequency counts* of the 80-dimensional bag of objects representation. We explore the effects of using the following variants of the bag of objects representation: (i) **Frequency:** The number of instances per category; (ii) **Normalized:** The frequency counts normalized such that the vector sums to 1. This represents the *proportion* of object occurrences in the image; (iii) **Binarized:** An object category's entry is set to 1 if at least one instance of the category occurs, and 0 otherwise.

Berg et al. (2012) explore various factors that dictate what objects are mentioned in image descriptions, and found that object size and its position relative to the image centre are important. Inspired by these findings, we explore alternative representations based on these cues: (i) **Object size:** The area of the region provided by COCO, normalized by image size; we encode the largest object if multiple objects occur for the same category (max pooling). (ii) **Object distance:** The Euclidean distance from the object bounding box centre to the image centre, normalized by image size; we encode the object closest to the centre if multiple instances occur (min pooling). We also explore **concatenating** these features to study their complementarity.

Finally, we study the effects of **removing information** from the bag of objects representation. More specifically, we compare the results of retaining only a certain number of object instances in the *frequency*-based bag of objects representation, rather than representing an image with all objects present. We experiment with retaining only the frequency counts for one object category and 25%, 50%, and 75% of object categories; the remaining entries in the vector are set to zero. The object categories to be retained are selected, per image: (i) randomly; (ii) by the $N\%$ most frequent categories of the image; (iii) by the $N\%$ largest categories of the image; (iv) by the $N\%$ categories closest to the centre of the image.

We performed these evaluations based on (i) ground truth COCO annotations and (ii) the output of an off-the-shelf object detector (Redmon and Farhadi, 2017) trained on 80 COCO categories. With ground truth annotations we can isolate issues stemming from incorrect detections.

Representation	GT	Detect
CNN (ResNet-152 POOL5)	-	0.749
Frequency	0.807	0.752
Normalized	0.762	0.703
Binarized	0.751	0.703
Object min distance	0.759	0.691
Object max size	0.793	0.725
Obj max size + Obj min distance	0.799	0.743
Frequency + Obj min distance	0.830	0.769
Frequency + Obj max size	0.836	0.769
All three features	0.849	0.743

Table 1: CIDEr scores for image captioning using bag of objects variants as visual representations. We compare the results of using ground truth annotations (**GT**) and the output of a detector (**Detect**). As comparison we also provide, in the first row, the results of using a ResNet-152 POOL5 CNN image embedding with our implementation of an end-to-end IC system.

3.3 Experiments

We train our models on the full COCO training set, and use the standard, publicly available splits[1] of the validation set as in previous work (Karpathy and Fei-Fei, 2015) for validation and testing (5,000 images each). We use CIDEr (Vedantam et al., 2015) – the official metric for COCO – as our evaluation metrics for all experiments. For completeness, we present scores for other common IC metrics in Appendix B.

Table 1 shows the CIDEr scores of IC systems using variants of the bag of objects representation, for both ground truth annotations and

[1] http://cs.stanford.edu/people/karpathy/deepimagesent

Feature vs. Pooling	Min	Max	Mean
Obj. Size	0.748	0.793	0.789
Obj. Distance	0.759	0.768	0.740

Table 2: CIDEr scores for captioning comparing the use of min, max or average pooling of either object size or distance features, using ground truth annotations.

the output of an object detector. Compared to a pure CNN embedding (ResNet-152 POOL5), our object-based representations show higher (for ground truth annotations) or comparable CIDEr scores (for detectors). Our first observation is that frequency **counts** are essential to IC. Using normalized counts as a representation gives poorer results, which intuitively makes sense: An image with 20 cars and 10 people is significantly different from an image with two cars and one person. Using binarized counts (presence or absence) brings the score further down. This is to be expected: An image with one person is very different from one with 10 people.

Using spatial information (size or distance) also proved useful. Encoding the object size in place of frequency gave reasonably better results over using object distance from the image centre. We can conclude that the size and centrality of objects are important factors for captioning, with object size being more informative than position.

We also experimented with different methods for aggregating multiple instances of the same category, in addition to choosing the biggest instance and the instance closest to the image centre. For example, choosing the *smallest* instance (min pooling) or the instance *furthest* away from the image centre (max pooling), or just averaging them (mean pooling). Table 2 shows the results. For object size, the findings are as expected: Smaller object instances are less important for IC, although averaging them works comparably well. Surprisingly, in the case of distance, using the object *furthest* from the image centre actually gave slightly better results than the one closest. Further inspection revealed that aggregating instances is not effective in some cases. We found that the positional information (and interaction with other objects) captured by the object further away may sometimes represent the semantics of the image better than the object in the centre of the image. For example, in Figure 2, encoding only the position of the person in the middle will result in the

Obj. min distance:
• a man in a kitchen preparing food in a kitchen .
Obj. max distance:
• a group of people standing around a kitchen counter .

Figure 2: Example where encoding the distance of the object furthest away (solid green) is better than that of the one closest to the image centre (dashed red). The IC model assumes that only one person is in the middle in the former case, and infers that many people may be gathered around a table in the latter.

representation being similar to other images with only one person in the centre of the image (and also on a kitchen counter). Representing the person as the one furthest from the image will result in some inference (from training data) that there could be more than one person in the image sitting *around* the kitchen counter rather than a single person standing *at* the kitchen counter.

The combination of results (bottom row of Table 1) shows that the three features (frequency, object max size and min distance) are complementary, and that combining any pair gives better CIDEr scores than each alone. The combination of all three features produces the best results. These results are interesting, as adding spatial information of even just one object per category can produce a better score. This has, to our knowledge, not been previously demonstrated. The performance of using an explicit detector rather than ground truth annotations is poorer, as expected from noisy detections. However, the overall trend generally remains similar, except for the combination of all three features which gave poorer scores.

Finally, Figure 3 shows the results of partially removing or masking the information captured by the bag of object representation (frequency). As expected, IC performance degrades when less than 75% of information is retained. The performance of the system where the representation is reduced using frequency information suffers the most (even worst than removing categories randomly), suggesting that frequency does not correspond to an object category's importance, i.e. just because there is only one *person* in the image does

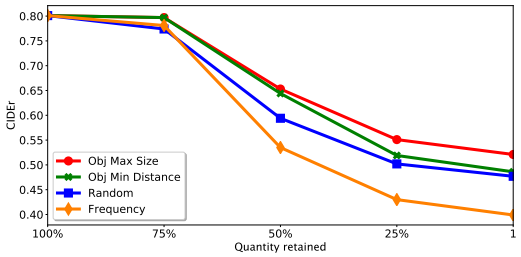

Figure 3: Change in CIDEr scores for image captioning by reducing the number of (ground truth) object instances in the image representation, based on different heuristics.

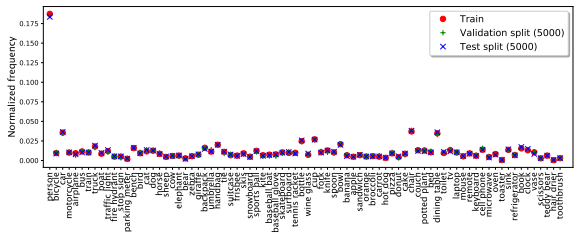

Figure 4: Object category distributions for COCO train, validation and test splits: normalized document frequency of each category. The distribution between the training and test sets are almost identical. A higher resolution version can be found in Appendix B.

not mean that it is less important than the ten *car*s depicted. On the other hand, object size correlates with object importance in IC, i.e. larger objects are more important than smaller objects for IC: The performance does not degrade as much as removing categories by their frequency in the image.

3.4 Analysis

We hypothesize that the bag of objects representation performs well because it serves as a good representation for the dataset and allows for better image matching. One observation is that the category distribution between the training and test sets are very similar (Figure 4), thus increasing the chance of the bag of objects representation producing a close match to one in the training set. From this observation, we posit that end-to-end IC models leverage COCO being repetitive to find similar matches for a test image to a combination of images in the training set. Further investigation on the category distribution (e.g. by splitting the dataset such that the test set contains unseen categories) is left for future work.

k-Nearest neighbour analysis. We further investigate our claim that end-to-end IC systems essentially perform complex image matching against the training set with the following experiment. The idea is that if the IC model performs some form of image matching and text retrieval from the training set, then the nearest neighbour (from training) of a test image should have a caption similar to the one generated by the model. However, the model does not always perform text retrieval as the LSTM is known to sometimes generate novel captions, possibly by aggregating or 'averaging' the captions of similar images and performing some factorization. We first generate captions for every training image using the bag of objects model (with ground truth frequency counts). We then compute the k-nearest training images for each given test image using both the bag of objects representation and its projection (Eq. 1). Finally, we compute the similarity score between the generated caption of the test image against all k-nearest captions. The similarity score measures how well a generated caption matches its nearest neighbour's captions. We expect the score to be high if the IC system generates an image similar to something 'summarized' from the training set.

Type	BLEU	Meteor	CIDEr	SPICE
Freq.	0.868	0.591	6.956	0.737
Proj.	0.912	0.634	7.651	0.799
Exact (2301)	1.000	1.000	10.000	1.000
Freq. (¬ Exact)	0.757	0.498	4.337	0.512
Proj. (¬ Exact)	0.837	0.560	5.638	0.628

Table 3: k-Nearest Neighbour (k=5) trial on the ground truth bag of objects (**Freq.**) and the projected bag of objects (**Proj.**) representations. The references are captions of 5-nearest images in each space. *Exact* represents a subset of 2301 samples where all the 5 neighbours have 0 distance (replicas) and ¬ represents nearest neighbours that are not replicas of the test image.

As reported in Table 3, overall the captions seem to closely match the captions of 5 nearest training images. Further analysis showed that 2301 out of 5000 captions had nearest images at a zero distance, i.e., the same exact representation was seen at least 5 times in training (note that CIDEr gives a score of 10 only if the test caption and *all* references are the same). We found that among the non-exact image matches, the projected image representation better captures candidates in the training set than bag of objects. Figure 5 shows the five nearest neighbours of an example non-exact match and their generated captions in the

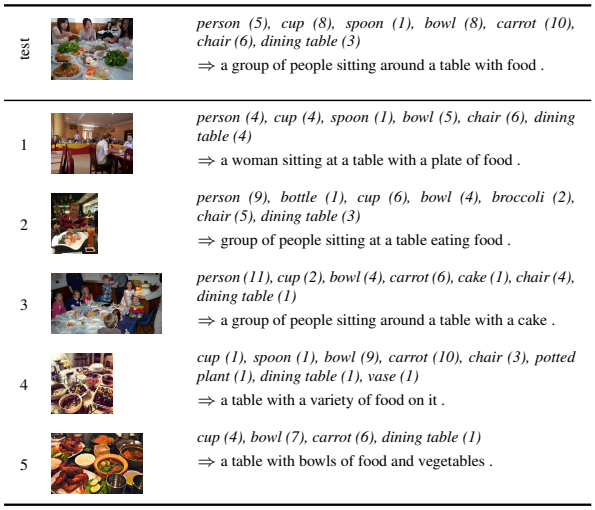

Figure 5: Five nearest neighbours from the training set in the projected space, for an example test image's (top row) original bag of objects representation that does not have an exact match in the training. For each image, we show the ground truth categories (and frequencies in parenthesis) and the generated caption. More examples can be found in Appendix D.

projection space. Note that the nearest neighbours are an approximation since we do not know the exact distance metric derived from the LSTM. We observe that the captions for unseen representations seem to be interpolated from multiple neighbouring points in the projection space, but further work is needed to analyze the hidden representations of the LSTM to understand the language model and to give firmer conclusions.

4 Spatial information on instances

Here we further explore the effect of incorporating spatial information of object detections for IC. More specifically, we enrich the representations by encoding positional and size information for more object instances, rather than restricting the encoding to only one instance per category which makes the representation less informative.

4.1 Spatial representation

We explore encoding **object instances and their spatial properties** as a fixed-size vector. In contrast to Section 3, we propose handling multiple instances of the same category by encoding spatial properties of *individual* instances rather than aggregating them as a single value. Each instance is represented as a tuple (x, y, w, h, a), where x and y are the coordinates of the centre of the bounding box and are normalized to the image width and height respectively, w and h are the width and height of the bounding box respectively, and a is the area covered by the object segment and normalized to the image size. Note that $w \times h \geq a$ (box encloses the segment). We assume that there are maximum 10 instances per vector, and instances of the same category are ordered by a (largest instance first). We encode each of the 80 categories as separate sets. Non-existent objects are represented with zeros. The dimension of the final vector is 4000 ($80 \times 10 \times 5$). We also perform a **feature ablation** experiment to isolate the contribution of different spatial components.

Feature set	Fixed	Tuned
Bag of objects	0.807	0.834
(x, y, w, h, a)	0.870	0.915
(x, y, w, h)	0.859	0.898
(x, y, a)	0.850	0.900
(w, h)	0.870	0.920
(a)	0.869	0.857
(x, y)	0.810	0.863
LSTM Yin and Ordonez (2017)†		0.922

Table 4: CIDEr scores for image captioning using representations encoding spatial information of instances derived from ground truth annotations, with either fixed hyperparameters (Section 3.1) or with hyperparameter tuning. † Results taken from (Yin and Ordonez, 2017).

4.2 Experiments

All experiments in this subsection use ground truth annotations – we expect the results of using an object detector to be slightly worse but in most cases follow a similar trend, as shown in the previous section. Table 4 shows the CIDEr scores using the same setup as Section 3, but using representations with spatial information about individual object instances. Encoding spatial information led to substantially better performance over bag of objects alone. Consistent with our previous observation, w and h (bounding box width and height) seems to be the most informative feature combination – it performs well even without positional information. Area (a) is less informative than the combination of w and h, possibly because it compresses width-height ratio information despite discarding noise from background regions. Positional information (x, y) does not seem to be as informative, consistent with observations from previous work (Wang and Gaizauskas, 2016).

The last column in Table 4 shows the CIDEr

Image ID: 378657

Objects in the image	*person*, *clock*
Representation	**Caption**
Frequency	a large clock tower with a large clock on it .
Object min distance	a clock tower with a large clock on it 's face .
Object max size	a man standing in front of a clock tower .
All three features	a clock tower with people standing in the middle of the water .
(x, y)	a large clock tower with a clock on the front .
(w, h)	a clock on a pole in front of a building
(a)	a large clock tower with people walking around it
(x, y, w, h, a)	a group of people standing around a clock tower .
CNN (ResNet-152)	a large building with a clock tower in the middle of it .
person removed	a clock tower with a weather vane on top of it .

Figure 6: Example captions with different models. The models with explicit object detection and additional spatial information ((x, y, w, h, a)) are more precise in most cases. The output of a standard ResNet-152 POOL5 is also shown, as well as that of the model where the most salient category – *person* – is removed from the feature vector. More example outputs are available in Appendix C.

scores when training the models by performing hyperparameter tuning during training. We note that the results with our simpler image representation are comparable to the ones reported in Yin and Ordonez (2017), which use more complex models to encode similar image information. Interestingly, we observe that positional information (x, y) work better than before tuning in this case.

Example outputs from the models in Sections 3 and 4 can be found in Figure 6.

5 Importance of different categories

In the previous sections, we explore IC based on explicit detections for 80 object categories. However, not all categories are made equal. Some categories could impact IC more than others (Berg et al., 2012). In this section we investigate ***which* categories are more important** for IC on the COCO dataset. Our **category ablation** experiment involves removing *one* category from the 80-dimensional bag of objects (ground truth frequency) representation at a time, resulting in 80 sets of 79D vectors without each ablated category.

We postulate that salient categories should lead to larger performance degradation than others. However, what makes a category 'salient' in general (*dog* vs. *cup*)? We hypothesize that it could be due to (i) how frequently it is depicted across images; (ii) how frequently it is mentioned in the captions when depicted in the image. To quantify these hypotheses, we **compute the rank correlation** between changes in CIDEr from removing the category and each of the statistic below:

- $f(v_c) = \sum_i^N 1(c \in C_i)$: frequency of the ablated category c being annotated among N images in the training set, where C_i is the set of all categories annotated in image i, and $1(x)$ is the indicator function.
- $p(t_c|v_c) \approx \frac{f(t_c,v_c)}{f(v_c)}$: proportion of ablated category being mentioned in any of the reference captions given that it is annotated in the image in the training set.

For determining whether a depicted category is mentioned in the caption, the matching method described in Ramisa et al. (2015) is used to increase recall by matching category labels with (i) the term themselves; (ii) the head noun for multiword expressions; (iii) WordNet synonyms and hyponyms. We treat these statistics as an approximation because of the potential noise from the matching process, although it is clean enough for our purposes.

We have also tried computing the correlation with $f(t_c)$ (frequency of the category being mentioned regardless of whether or not it is depicted). However, we found the word matching process too noisy as it is not constrained or grounded on the image (e.g. "hot dog" is matched to the *dog* category). Thus, we do not report the results for this.

5.1 Experiments

Figure 7 shows the result of the category ablation experiment. Categories like *train*, *sandwich*, *person* and *spoon* led to the largest drop in CIDEr scores. On the other end, categories like *surfboard*, *carrot* and *book* can be removed without negatively affecting the overall score.

By comparing the CIDEr score changes against the frequency counts of object annotations in the training set (top row), there does not seem to be a clear correlation between depiction frequency and CIDEr. Categories like *bear* are infrequent but led to a large drop in score; likewise, *chair* and *dining table* are frequent but do not affect the results

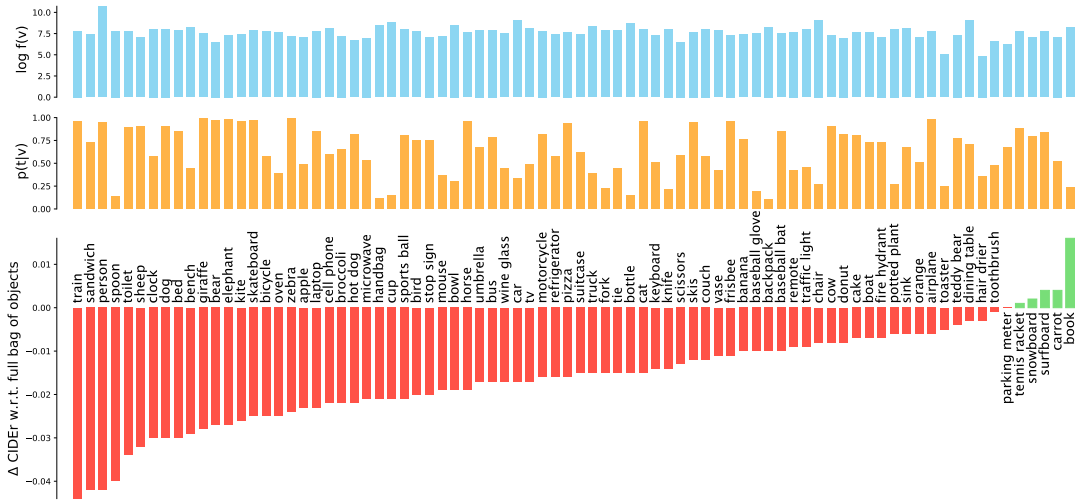

Figure 7: Difference in CIDEr scores when removing each category from the bag of objects representation (79 dimensions), compared to using the full 80D vector (bottom plot). See main text for details.

	Coefficient value (p-value)	
	$f(v_c)$	$p(t_c\|v_c)$
Spearman's ρ	0.137 (0.226)	0.227 (0.043)
Kendall's τ	0.093 (0.223)	0.153 (0.047)

Table 5: Correlation between changes in CIDEr score from category ablation and the frequency of depiction of the category ($f(v_c)$) against the probably of it being mentioned in the caption given depiction ($(p(t_c|v_c)$).

as negatively. In contrast, the frequency of a category being mentioned given that it is depicted is a better predictor for the changes in CIDEr scores in general (middle row). Animate objects seem to be important to IC and are often mentioned in captions (Berg et al., 2012). Interestingly, removing *spoon* greatly affects the results even though it is not frequent in captions.

Table 5 presents the rank correlation (Spearman's ρ and Kendall's τ, two-tailed test) between changes in CIDEr and the two heuristics. While both heuristics are positively correlated with the changes in CIDEr, we can conclude that the frequency of being mentioned (given that it is depicted) is better correlated with the score changes than the frequency of depiction. Of course, the categories are not mutually exclusive and object co-occurrence may also play a role. However, we leave this analysis for future work.

Figure 6 shows an example when the category *person* is removed from the feature vector. Here, the model does not generate any text related to *person*, as the training set contains images of clocks without people in it.

6 Conclusions

In this paper we investigated end-to-end image captioning by using highly interpretable representations derived from explicit object detections. We provided an in-depth analysis on the efficacy of a variety of cues derived from object detections for IC. We found that frequency counts, object size and position are informative and complementary. We also found that some categories have a bigger impact on IC than others. Our analysis showed that end-to-end IC systems are image matching systems that project image representations into a learned space and allow the LSTM to generate captions for images in that projected space.

Future work includes (i) investigating how object category information can be better used or expanded to improve IC; (ii) analyzing end-to-end IC systems by using interpretable representations that rely on other explicit detectors (e.g. actions, scenes, attributes). The use of such explicit information about object instances could help improve our understanding of image captioning.

A Hyperparmeter Settings

The hyperparameter settings for our model are as follows:

- **LSTM layers**: 2-Layer LSTM
- **Word Embedding Dimensionality**: 128
- **Hidden Layer Dimensionality**: 256
- **Maximum Epochs**: 50
- **Batch Size**: [50, 100]
- **LSTM dropout settings**: [0.2, 0.7]
- **Vocabulary threshold**: 2
- **Learning Rate**: [1e-4, 4e-4]
- **Optimiser**: Adam

For items in a range of values, we used grid search to tune the hyperparmeters.

B Full Experimental Results

Tables 6 and 7 show the results of several of our experiments with the most common metrics used in image captioning: BLEU, Meteor, ROUGE$_L$, CIDEr and SPICE.

Figure 8 gives a high resolution version of Figure 4, showing the similarity between train and test distributions in terms of object categories.

C Example captions for different models

Figure 9 shows example images from COCO and the output captions from different models. We compare the outputs of selected models from Sections 3 and 4, and a model where the *person* category is removed from the input vector (Section 5).

D Example nearest neighbours for test images

Figure 10 shows the five nearest neighbours in the training set of each non-replica example from the test set (where the exact ground truth frequency representation does not occur in training). See Section 3.4 for a more detailed description of the experiment.

Abstract

Multimodal machine learning algorithms aim to learn visual-textual correspondences. Previous work suggests that concepts with *concrete* visual manifestations may be easier to learn than concepts with abstract ones. We give an algorithm for automatically computing the visual concreteness of words and topics within multimodal datasets. We apply the approach in four settings, ranging from image captions to images/text scraped from historical books. In addition to enabling explorations of concepts in multimodal datasets, our concreteness scores predict the capacity of machine learning algorithms to learn textual/visual relationships. We find that 1) concrete concepts are indeed easier to learn; 2) the large number of algorithms we consider have similar failure cases; 3) the precise positive relationship between concreteness and performance varies between datasets. We conclude with recommendations for using concreteness scores to facilitate future multimodal research.

1 Introduction

Text and images are often used together to serve as a richer form of content. For example, news articles may be accompanied by photographs or infographics; images shared on social media are often coupled with descriptions or tags; and textbooks include illustrations, photos, and other visual elements. The ubiquity and diversity of such "text+image" material (henceforth referred to as *multimodal* content) suggest that, from the standpoint of sharing information, images and text are often natural complements.

Ideally, machine learning algorithms that incorporate information from both text and images should have a fuller perspective than those that consider either text or images in isolation. But Hill and Korhonen (2014b) observe that for their particular multimodal architecture, the level of *concreteness* of a concept being represented — intuitively, the idea of a *dog* is more concrete than that of *beauty* — affects whether multimodal or single-channel representations are more effective. In their case, concreteness was derived for 766 nouns and verbs from a fixed psycholinguistic database of human ratings.

In contrast, we introduce an adaptive algorithm for characterizing the visual concreteness of all the concepts indexed textually (e.g., "dog") in a given multimodal dataset. Our approach is to leverage the geometry of image/text space. Intuitively, a visually concrete concept is one associated with more locally similar sets of images; for example, images associated with "dog" will likely contain dogs, whereas images associated with "beautiful" may contain flowers, sunsets, weddings, or an abundance of other possibilities — see Fig. 1.

Allowing concreteness to be dataset-specific is an important innovation because concreteness is contextual. For example, in one dataset we work with, our method scores "London" as highly concrete because of a preponderance of iconic London images in it, such as Big Ben and double-decker buses; whereas for a separate dataset, "London" is used as a geotag for diverse images, so the same word scores as highly non-concrete.

In addition to being dataset-specific, our method readily scales, does not depend on an external search engine, and is compatible with both discrete and continuous textual concepts (e.g., topic distributions).

Dataset-specific visual concreteness scores enable a variety of purposes. In this paper, we

Proceedings of NAACL-HLT 2018, pages 2194–2205
New Orleans, Louisiana, June 1 - 6, 2018.

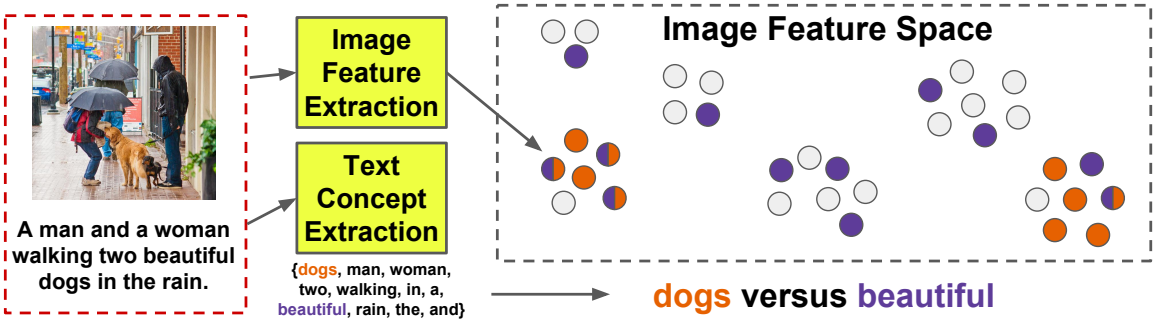

Figure 1: Demonstration of visual concreteness estimation on an example from the COCO dataset. The degree of visual clustering of textual concepts is measured using a nearest neighbor technique. The concreteness of "dogs" is greater than the concreteness of "beautiful" because images associated with "dogs" are packed tightly into two clusters, while images associated with "beautiful" are spread evenly.[1]

focus on using them to: 1) explore multimodal datasets; and 2) predict how easily concepts will be learned in a machine learning setting. We apply our method to four large multimodal datasets, ranging from image captions to image/text data scraped from Wikipedia,[2] to examine the relationship between concreteness scores and the performance of machine learning algorithms. Specifically, we consider the cross-modal retrieval problem, and examine a number of NLP, vision, and retrieval algorithms. Across all 320 significantly different experimental settings (= 4 datasets $\times$ 2 image-representation algorithms $\times$ 5 textual-representation algorithms $\times$ 4 text/image alignment algorithms $\times$ 2 feature pre-processing schemes), we find that more concrete instances are easier to retrieve, and that different algorithms have similar failure cases. Interestingly, the relationship between concreteness and retrievability varies significantly based on dataset: some datasets appear to have a linear relationship between the two, whereas others exhibit a concreteness threshold beyond which retrieval becomes much easier.

We believe that our work can have a positive impact on future multimodal research. §8 gives more detail, but in brief, we see implications in (1) evaluation — more credit should perhaps be assigned to performance on non-concrete concepts; (2) creating or augmenting multimodal datasets, where one might *a priori* consider the desired relative proportion of concrete vs. non-concrete concepts; and (3) *curriculum learning* (Bengio et al., 2009), where ordering of training examples could take concreteness levels into account.

2 Related Work

Applying machine learning to understand visual-textual relationships has enabled a number of new applications, e.g., better accessibility via automatic generation of alt text (Garcia et al., 2016), cheaper training-data acquisition for computer vision (Joulin et al., 2016; Veit et al., 2017), and cross-modal retrieval systems, e.g., Rasiwasia et al. (2010); Costa Pereira et al. (2014).

Multimodal datasets often have substantially differing characteristics, and are used for different tasks (Baltrušaitis et al., 2017). Some commonly used datasets couple images with a handful of unordered tags (Barnard et al., 2003; Cusano et al., 2004; Grangier and Bengio, 2008; Chen et al., 2013, inter alia) or short, literal natural language captions (Farhadi et al., 2010; Ordóñez et al., 2011; Kulkarni et al., 2013; Fang et al., 2015, inter alia). In other cross-modal retrieval settings, images are paired with long, only loosely thematically-related documents. (Khan et al., 2009; Socher and Fei-Fei, 2010; Jia et al., 2011; Zhuang et al., 2013, inter alia). We provide experimental results on both types of data.

Concreteness in datasets has been previously studied in either text-only cases (Turney et al., 2011; Hill et al., 2013) or by incorporating human judgments of perception into models (Silberer and Lapata, 2012; Hill and Korhonen, 2014a). Other work has quantified characteristics of concreteness in multimodal datasets (Young et al., 2014; Hill et al., 2014; Hill and Korhonen, 2014b; Kiela and Bottou, 2014; Jas and Parikh, 2015; Lazari-

[1] Image copyright information is provided in the supplementary material.

[2] We release our Wikipedia and British Library data at http://www.cs.cornell.edu/~jhessel/concreteness/concreteness.html

dou et al., 2015; Silberer et al., 2016; Lu et al., 2017; Bhaskar et al., 2017). Most related to our work is that of Kiela et al. (2014); the authors use Google image search to collect 50 images each for a variety of words and compute the average cosine similarity between vector representations of returned images. In contrast, our method can be tuned to specific datasets without reliance on an external search engine. Other algorithmic advantages of our method include that: it more readily scales than previous solutions, it makes relatively few assumptions regarding the distribution of images/text, it normalizes for word frequency in a principled fashion, and it can produce confidence intervals. Finally, the method we propose can be applied to both discrete and continuous concepts like topic distributions.

3 Quantifying Visual Concreteness

To compute visual concreteness scores, we adopt the same general approach as Kiela et al. (2014): for a fixed text concept (i.e., a word or topic), we measure the variance in the corresponding visual features. The method is summarized in Figure 1.

3.1 Concreteness of discrete words

We assume as input a multimodal dataset of n images represented in a space where nearest neighbors may be computed. Additionally, each image is associated with a set of discrete words/tags. We write w_v for the set of words/tags associated with image v, and V_w for the set of all images associated with a word w. For example, if the v^{th} image is of a dog playing frisbee, w_v might be $\{\text{frisbee}, \text{dog}, \text{in}, \text{park}\}$, and $v \in V_{\text{park}}$.

Our goal is to measure how "clustered" a word is in image feature space. Specifically, we ask: for each image $v \in V_w$, how often are v's nearest neighbors also associated with w? We thus compute the expected value of MNI_w^k, the number of mutually neighboring images of word w:

$$\mathbb{E}_{P_{data}}[\text{MNI}_w^k] = \frac{1}{|V_w|} \sum_{v \in V_w} |\text{NN}^k(v) \cap V_w| \,, \quad (1)$$

where $\text{NN}^k(v)$ denotes the set of v's k nearest neighbors in image space.

While Equation 1 measures clusteredness, it does not properly normalize for frequency. Consider a word like "and"; we expect it to have low concreteness, but its associated images will share neighbors simply because "and" is a frequent unigram. To correct for this, we compute the *concreteness* of a word as the ratio of $\mathbb{E}[\text{MNI}_w^k]$ under the true distribution of the image data to a random distribution of the image data:

$$\text{concreteness}(w) = \frac{\mathbb{E}_{P_{data}}[\text{MNI}_w^k]}{\mathbb{E}_{P_{random}}[\text{MNI}_w^k]} \quad (2)$$

While the denominator of this expression can be computed in closed form, we use $\mathbb{E}_{P_{random}}[\text{MNI}_w^k] \approx \frac{k|V_w|}{n}$; this approximation is faster to compute and is negligibly different from the true expectation in practice.

3.2 Extension to continuous topics

We extend the definition of concreteness to continuous concepts, so that our work applies also to topic model outputs; this extension is needed because the intersection in Equation 1 cannot be directly applied to real values. Assume we are given a set of topics T and an image-by-topic matrix $Y \in \mathbb{R}^{n \times |T|}$, where the v^{th} row[3] is a topic distribution for the text associated with image v, i.e., $Y_{ij} = P(\text{topic } j | \text{image } i)$. For each topic t, we compute the average topic weight for each image v's neighbors, and take a weighted average as:

$$\text{concreteness}(t) = \frac{k}{n} \cdot \frac{\sum_{v=1}^{n} [Y_{vt} \sum_{j \in \text{NN}^k(v)} Y_{jt}]}{\sum_{v=1}^{n} Y_{vt}} \quad (3)$$

Note that Equations 1 and 3 are computations of means. Therefore, confidence intervals can be computed in both cases either using a normality assumption or bootstrapping.

4 Datasets

We consider four datasets that span a variety of multimodal settings. Two are publicly available and widely used (COCO/Flickr); we collected and preprocessed the other two (Wiki/BL). The Wikipedia and British Library sets are available for download at `http://www.cs.cornell.edu/~jhessel/concreteness/concreteness.html`. Dataset statistics are given in Table 1, and summarized as follows:

Wikipedia (Wiki). We collected a dataset consisting of 192K articles from the English Wikipedia, along with the 549K images contained in those

[3] The construction is necessarily different for different types of datasets, as described in §4.

Figure 2: Examples of text and images from our new Wiki/BL datasets.

Table 1: Dataset statistics: total number of images, average text length in words, and size of the train/test splits we use in §6.

articles. Following Wilson's popularity filtering technique,[4] we selected this subset of Wikipedia by identifying articles that received at least 50 views on March 5th, 2016.[5] To our knowledge, the previous largest publicly available multimodal Wikipedia dataset comes from ImageCLEF's 2011 retrieval task (Popescu et al., 2010), which consists of 137K images associated with English articles.

Images often appear on multiple pages: an image of the Eiffel tower might appear on pages for Paris, for Gustave Eiffel, and for the tower itself.

Historical Books from British Library (BL). The British Library has released a set of digitized books (British Library Labs, 2016) consisting of 25M pages of OCRed text, alongside 500K+ images scraped from those pages of text. The release splits images into four categories; we ignore "bound covers" and "embellishments" and use images identified as "plates" and "medium sized." We associated images with all text within a 3-page window.

This raw data collection is noisy. Many books are not in English, some books contain far more images than others, and the images themselves are of varying size and rotation. To combat these issues we only keep books that have identifiably English text; for each cross-validation split in our machine-learning experiments (§6) we sample at most 10 images from each book; and we use *book-level* holdout so that no images/text in the test set are from books in the training set.

Captions and Tags. We also examine two popular existing datasets: Microsoft COCO (captions) (Lin et al., 2014) (**COCO**) and MIRFLICKR-1M (tags) (Huiskes et al., 2010) (**Flickr**). For COCO, we construct our own training/validation splits from the 123K images, each of which has 5 captions. For Flickr, as an initial preprocessing step we only consider the 7.3K tags that appear at least 200 times, and the 754K images that are associated with at least 3 of the 7.3K valid tags.

5 Validation of Concreteness Scoring

We apply our concreteness measure to the four datasets. For COCO and Flickr, we use unigrams as concepts, while for Wiki and BL, we extract 256-dimensional topic distributions using Latent Dirichlet Allocation (LDA) (Blei et al., 2003). For BL, topic distributions are derived from text in the aforementioned 3 page window; for Wiki, for each image, we compute the mean topic distribution of all articles that image appears in; for Flickr, we associate images with all of their tags; for COCO, we concatenate all captions for a given image. For computing concreteness scores for COCO/Flickr, we only consider unigrams associated with at least 100 images, so as to ensure the stability of MNI as defined in Equation 1.

We extract image features from the pre-softmax layer of a deep convolutional neural network, ResNet50 (He et al., 2016), pretrained for the ImageNet classification task (Deng et al., 2009); this method is known to be a strong baseline (Sharif Razavian et al., 2014).[6] For nearest neighbor search, we use the Annoy library,[7] which computes approximate kNN efficiently. We use $k = 50$ nearest neighbors, though the results presented are stable for reasonable choices of k, e.g., $k = 25, 100$.

5.1 Concreteness and human judgments

Following Kiela et al. (2014), we borrow a dataset of human judgments to validate our concreteness

[4] https://goo.gl/B11yyO

[5] The articles were extracted from an early March, 2016 data dump.

[6] We explore different image/text representations in later sections.

[7] github.com/spotify/annoy

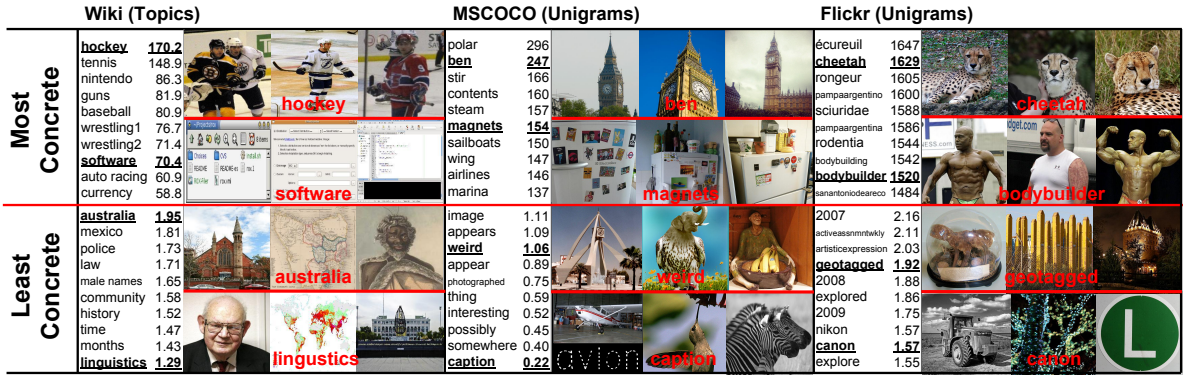

Figure 3: Examples of the most and least concrete words/topics from Wiki, COCO, and Flickr, along with example images associated with each **highlighted** word/topic.

computation method.[8] The concreteness of words is a topic of interest in psychology because concreteness relates to a variety of aspects of human behavior, e.g., language acquisition, memory, etc. Schwanenflugel and Shoben (1983); Paivio (1991); Walker and Hulme (1999); De Groot and Keijzer (2000).

We compare against the human-gathered unigram concreteness judgments provided in the USF Norms dataset (USF) (Nelson et al., 2004); for each unigram, raters provided judgments of its concreteness on a 1-7 scale. For Flickr/COCO, we compute Spearman correlation using these per-unigram scores (the vocabulary overlap between USF and Flickr/COCO is 1.3K/1.6K), and for Wiki/BL, we compute topic-level human judgment scores via a simple average amongst the top 100 most probable words in the topic.

As a null hypothesis, we consider the possibility that our concreteness measure is simply mirroring frequency information.[9] We measure frequency for each dataset by measuring how often a particular word/topic appears in it. A useful concreteness measure should correlate with USF more than a simple frequency baseline does.

For COCO/Flickr/Wiki, concreteness scores output by our method positively correlate with human judgments of concreteness more than frequency does (see Figure 4). For COCO, this pattern holds even when controlling for part-of-speech (not shown), whereas Flickr adjectives are not correlated with USF. For BL, neither frequency nor our concreteness scores are significantly correlated with USF. Thus, in three of our four datasets, our measure tends to predict human concreteness judgments better than frequency.

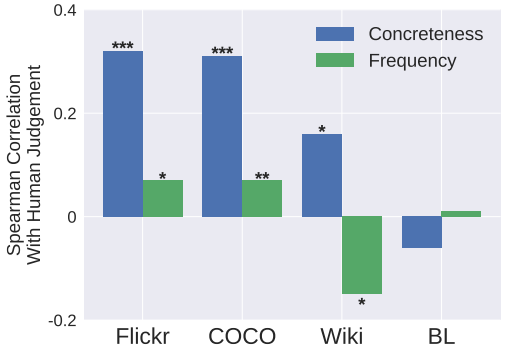

Figure 4: Spearman correlations between human judgment (USF) and our algorithm's outputs, and dataset frequency. In the case of Flickr/COCO/WIKI our concreteness scores correlate with human judgement to a greater extent than frequency. For BL, neither frequency nor our concreteness measure is correlated with human judgement. ***/**/* := $p < .001/.01/.05$

Concreteness and frequency. While concreteness measures correlate with human judgment better than frequency, we do expect *some* correlation between a word's frequency and its concreteness (Gorman, 1961). In all cases, we observe a moderate-to-strong positive correlation between infrequency and concreteness ($\rho_{wiki}, \rho_{coco}, \rho_{flickr}, \rho_{bl} = .06, .35, .40, .71$) indicating that rarer words/topics are more concrete, in general. However, the correlation is not perfect, and concreteness and frequency measure different

[8] Note that because concreteness of words/topics varies from dataset to dataset, we don't expect one set of human judgments to correlate perfectly with our concreteness scores. However, partial correlation with human judgment offers a common-sense "reality check."

[9] We return to this hypothesis in §6.1 as well; there, too, we find that concreteness and frequency capture different information.

properties of words.

5.2 Concreteness within datasets

Figure 3 gives examples from Wiki, COCO, and Flickr illustrating the concepts associated with the smallest and largest concreteness scores according to our method.[10] The scores often align with intuition, e.g., for Wiki, sports topics are often concrete, whereas country-based or abstract-idea-based topics are not.[11] For COCO, *polar* (because of polar bears) and *ben* (because of Big Ben) are concrete; whereas *somewhere* and *possibly* are associated with a wide variety of images.

Concreteness scores form a continuum, making explicit not only the extrema (as in Figure 3) but also the middle ground, e.g., in COCO, "wilderness" (rank 479) is more visually concrete than "outside" (rank 2012). Also, dataset-specific intricacies that are not obvious *a priori* are highlighted, e.g., in COCO, 150/151 references to "magnets" (rank 6) are in the visual context of a refrigerator (making "magnets" visually concrete) though the converse is not true, as both "refrigerator" (rank 329) and "fridge" (rank 272) often appear without magnets; 61 captions in COCO are exactly "There is no image here to provide a *caption* for," and this dataset error is made explicit through concreteness score computations.

5.3 Concreteness varies across datasets

To what extent are the concreteness scores dataset-specific? To investigate this question, we compute the correlation between Flickr and COCO unigram concreteness scores for 1129 overlapping terms. While the two are positively correlated ($\rho = .48, p < .01$) there are many exceptions that highlight the utility of computing dataset-independent scores. For instance, "London" is extremely concrete in COCO (rank 9) as compared to in Flickr (rank 1110). In COCO, images of London tend to be iconic (i.e., Big Ben, double decker buses); in contrast, "London" often serves as a geotag for a wider variety of images in Flickr. Conversely, "watch" in Flickr is concrete (rank 196) as it tends to refer to the timepiece, whereas "watch" is not concrete in COCO (rank 958) as it tends to refer to the verb; while these relationships are not obvious *a priori*, our concreteness method has helped to highlight these usage differences between the image tagging and captioning datasets.

6 Learning Image/Text Correspondences

Previous work suggests that incorporating visual features for less concrete concepts can be harmful in word similarity tasks (Hill and Korhonen, 2014b; Kiela et al., 2014; Kiela and Bottou, 2014; Hill et al., 2014). However, it is less clear if this intuition applies to more practical tasks (e.g., retrieval), or if this problem can be overcome simply by applying the "right" machine learning algorithm. We aim to tackle these questions in this section.

The learning task. The task we consider is the construction of a joint embedding of images and text into a shared vector space. Truly corresponding image/text pairs (e.g., if the text is a caption of that image) should be placed close together in the new space relative to image/text pairs that do not match. This task is a good representative of multimodal learning because computing a joint embedding of text and images is often a "first step" for downstream tasks, e.g., cross-modal retrieval (Rasiwasia et al., 2010), image tagging (Chen et al., 2013), and caption generation (Kiros et al., 2015).

Evaluations. Following previous work in cross-modal retrieval, we measure performance using the top-$k\%$ hit rate (also called recall-at-k-percent, $R@k\%$; higher is better). Cross-modal retrieval can be applied in either direction, i.e., searching for an image given a body of text, or vice-versa. We examine both the image-search-text and text-search-image cases. For simplicity, we average retrieval performance from both directions, producing a single metric;[12] higher is better.

Visual Representations. Echoing Wei et al. (2016), we find that features extracted from convolutional neural networks (CNNs) outperform classical computer vision descriptors (e.g., color histograms) for multimodal retrieval. We consider two different CNNs pretrained on different datasets: ResNet50 features trained on the ImageNet classification task (**RN-Imagenet**), and InceptionV3 (Szegedy et al., 2015) trained on the OpenImages (Krasin et al., 2017) image tagging task (**I3-OpenImages**).

[10] The BL results are less interpretable and are omitted for space reasons.

[11] Perhaps fittingly, the "linguistics" topic (top words: term, word, common, list, names, called, form, refer, meaning) is the least visually concrete of all 256 topics.

[12] Averaging is done for ease of presentation; the performance in both directions is similar. Among the parametric approaches (LS/DCCA/NS) across all datasets/NLP algorithms, the mean difference in performance between the directions is

	NP	LS	NS	DCCA

Figure 5: Concreteness scores versus retrievability (plotted) for each dataset, along with Recall at 1% (in tables, higher is better) for each algorithm combination. Tables give average retrieval performance over 10-fold cross-validation for each combination of NLP/alignment algorithm; the **best**, **second best**, and **third best** performing combinations are bolded and colored. The concreteness versus retrievability curves are plotted for the top-3 performing algorithms, though similar results hold for all algorithms. Our concreteness scores and performance are positively correlated, though the shape of the relationship between the two differs from dataset to dataset (note the differing scales of the y-axes). All results are for RN-ImageNet; the similar I3-OpenImages results are omitted for space reasons.

Text Representations. We consider sparse **unigram** and **tfidf** indicator vectors. In both cases, we limit the vocabulary size to 7.5K. We next consider latent-variable bag-of-words models, including LDA (Blei et al., 2003) (256 topics, trained with Mallet (McCallum, 2002)) a specialized biterm topic model (**BTM**) (Yan et al., 2013) for short texts (30 topics), and paragraph vectors (**PV**) (Le and Mikolov, 2014) (PV-DBOW version, 256 dimensions, trained with Gensim (Řehůřek and Sojka, 2010)).[13]

Alignment of Text and Images. We explore four algorithms for learning correspondences between image and text vectors. We first compare against Hodosh et al. (2013)'s nonparametric baseline (**NP**), which is akin to a nearest-neighbor search. This algorithm is related to the concreteness score algorithm we previously introduced in that it exploits the geometry of the image/text spaces using nearest-neighbor techniques. In general, performance metrics for this algorithm provide an estimate of how "easy" a particular task is in terms of the initial image/text representations.

We next map image features to text features via a simple linear transformation. Let (t_i, v_i) be a text/image pair in the dataset. We learn a linear transformation W that minimizes

$$\sum_i \|W f_{\text{image}}(v_i) - f_{\text{text}}(t_i)\|_2^2 + \lambda \|W\|_F \quad (4)$$

for feature extraction functions f_{image} and f_{text}, e.g., RN-ImageNet/LDA. It is possible to map images onto text as in Equation 4, or map text onto images in an analogous fashion. We find that the directionality of the mapping is important. We train models in both directions, and combine their best-performing results into a single least-squares (**LS**) model.

Next we consider Negative Sampling (**NS**), which balances two objectives: true image/text pairs should be close in the shared latent space, while randomly combined image/text pairs should be far apart. For a text/image pair (t_i, v_i), let $s(t_i, v_i)$ be the cosine similarity of the pair in the shared space. The loss for a single positive example (t_i, v_i) given a negative sample (t'_i, v'_i) is

$$h\big(s(t_i, v_i), s(t_i, v'_i)\big) + h\big(s(t_i, v_i), s(t'_i, v_i)\big) \quad (5)$$

for the hinge function $h(p, n) = \max\{0, \alpha - p + n\}$. Following Kiros et al. (2015) we set $\alpha = .2$.

1.7% (std. dev=2%).

[13] We also ran experiments encoding text using order-aware recurrent neural networks, but we did not observe significant performance differences. Those results are omitted for space reasons.

Finally, we consider Canonical Correlation Analysis (CCA), which projects image and text representations down to independent dimensions of high multimodal correlation. CCA-based methods are popular within the IR community for learning multimodal embeddings (Costa Pereira et al., 2014; Gong et al., 2014). We use Wang et al. (2015b)'s stochastic method for training deep CCA (Andrew et al., 2013) (**DCCA**), a method that is competitive with traditional kernel CCA (Wang et al., 2015a) but less memory-intensive to train.

Training details. LS, NS, and DCCA were implemented using Keras (Chollet et al., 2015).[14] In total, we examine all combinations of: four datasets, five NLP algorithms, two vision algorithms, four cross-modal alignment algorithms, and two feature preprocessing settings; each combination was run using 10-fold cross-validation.

Absolute retrieval quality. The tables in Figure 5 contain the retrieval results for RN-ImageNet image features across each dataset, alignment algorithm, and text representation scheme. We show results for $R@1\%$, but $R@5\%$ and $R@10\%$ are similar. I3-OpenImages image features underperform relative to RN-ImageNet and are omitted for space reasons, though the results are similar.

The BL corpus is the most difficult of the datasets we consider, yielding the lowest retrieval scores. The highly-curated COCO dataset appears to be the easiest, followed by Flickr and then Wikipedia. No single algorithm combination is "best" in all cases.

6.1 Concreteness scores and performance

We now examine the relationship between retrieval performance and concreteness scores. Because concreteness scores are on the word/topic level, we define a *retrievability* metric that summarizes an algorithm's performance on a given concept; for example, we might expect that retrievability(dog) is greater than retrievability(beautiful).

Borrowing the $R@1\%$ metric from the previous section, we let $\mathbb{I}[r_i < 1\%]$ be an indicator variable indicating that test instance i was retrieved correctly, i.e., $\mathbb{I}[r_i < 1\%]$ is 1 if the the average rank r_i of the image-search-text/text-search-image directions is better than 1%, and 0 otherwise. Let s_{ic} be the affinity of test instance i to concept c. In the case of topic distributions, s_{ic} is the proportion of topic c in instance i; in the case of unigrams, s_{ic} is the length-normalized count of unigram c on instance i. Retrievability is defined using a weighted average over test instances i as:

$$\text{retrievability}(c) = \frac{\sum_i s_{ic} \cdot \mathbb{I}[r_i < 1\%]}{\sum_i s_{ic}} \quad (6)$$

The retrievability of c will be higher if instances more associated with c are more easily retrieved by the algorithm.

Retrievability vs. Concreteness. The graphs in Figure 5 plot our concreteness scores versus retrievability of the top 3 performing NLP/alignment algorithm combinations for all 4 datasets. In all cases, there is a strong positive correlation between concreteness and retrievability, which provides evidence that more concrete concepts are easier to retrieve.

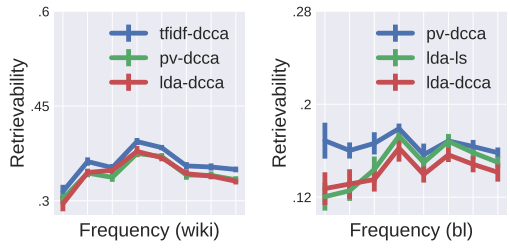
The shape of the concreteness-retrievability curve appears to vary between datasets more than between algorithms. In COCO, the relationship between the two appears to smoothly increase. In Wiki, on the other hand, there appears to be a concreteness threshold, beyond which retrieval becomes much easier.

There is little relationship between retrievability and frequency, further suggesting that our concreteness measure is not simply mirroring frequency. We re-made the plots in Figure 5, except we swapped the x-axis from concreteness to frequency; the resulting plots, given in Figure 6, are much flatter, indicating that retrievability and frequency are mostly uncorrelated. Additional regression analyses reveal that for the top-3 performing algorithms on Flickr/Wiki/BL/COCO, concreteness explains 33%/64%/11%/15% of the variance in retrievability, respectively. In contrast, for all datasets, frequency explained less than 1% of the variance in retrievability.

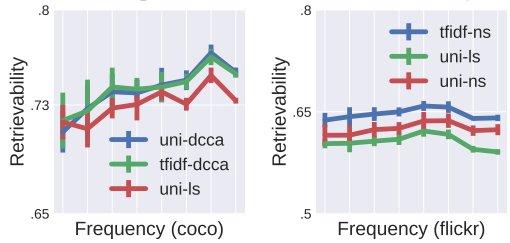
7 Beyond Cross-Modal Retrieval

Concreteness scores do more than just predict retrieval performance; they also predict the difficulty of image classification. Two popular shared tasks from the ImageNet 2015 competition published class-level errors of all entered systems. We used the unigram concreteness scores from

[14] We used Adam (Kingma and Ba, 2015), batch normalization (Ioffe and Szegedy, 2015), and ReLU activations. Regularization and architectures (e.g., number of layers in DCCA/NS, regularization parameter in LS) were chosen over a validation set separately for each cross-validation split. Training is stopped when retrieval metrics decline over the validation set. All models were trained twice, using both raw features and zero-mean/unit-variance features.



(a) Wikipedia (b) British Library



(c) COCO (d) Flickr

Figure 6: Correlation between word/topic frequency and retrievability for each of the four datasets. Compared to our concreteness measure (see Figure 5; note that the while x-axes are different, the y-axes are the same) frequency explains relatively little variance in retrievability.

Flickr/COCO computed in §3 to derive concreteness scores for the ImageNet classes.[15] We find that for both classification and localization, for all 10 top performing entries, and for both Flickr/COCO, there exists a moderate-to-strong Spearman correlation between concreteness and performance among the classes for which concreteness scores were available ($n_{\text{flickr}}, n_{\text{coco}} = 171, 288$; $.18 < \rho < .44$; $p < .003$ in all cases). This result suggests that concrete concepts may tend to be easier on tasks other than retrieval, as well.

8 Future Directions

At present, it remains unclear if abstract concepts should be viewed as noise to be discarded (as in Kiela et al. (2014)), or more difficult, but learnable, signal. Because large datasets (e.g., social media) increasingly mix modalities using ambiguous, abstract language, researchers will need to tackle this question going forward. We hope that visual concreteness scores can guide investigations of the trickiest aspects of multimodal tasks. Our work suggests the following future directions:

Evaluating algorithms: Because concreteness scores are able to predict performance prior to training, evaluations could be reported over concrete and abstract instances separately, as opposed to aggregating into a single performance metric. A new algorithm that consistently performs well on non-concrete concepts, even at the expense of performance on concrete concepts, would represent a significant advance in multimodal learning.

Designing datasets: When constructing a new multimodal dataset, or augmenting an existing one, concreteness scores can offer insights regarding how resources should be allocated. Most directly, these scores enable focusing on "concrete visual concepts" (Huiskes et al., 2010; Chen et al., 2015), by issuing image-search queries could be issued exclusively for concrete concepts during dataset construction. The opposite approach could also be employed, by prioritizing less concrete concepts.

Curriculum learning: During training, instances could be up/down-weighted in the training process in accordance with concreteness scores. It is not clear if placing more weight on the trickier cases (down-weighting concreteness), or giving up on the harder instances (up-weighting concreteness) would lead to better performance, or differing algorithm behavior.

[15] There are 1K classes in both ImageNet tasks, but we were only able to compute concreteness scores for a subset, due to vocabulary differences.

Speaker Naming in Movies

Mahmoud Azab, Mingzhe Wang, Max Smith, Noriyuki Kojima, Jia Deng, Rada Mihalcea

{mazab,mzwang,mxsmith,kojimano,jiadeng,mihalcea}@umich.edu

Abstract

We propose a new model for speaker naming in movies that leverages visual, textual, and acoustic modalities in an unified optimization framework. To evaluate the performance of our model, we introduce a new dataset consisting of six episodes of the Big Bang Theory TV show and eighteen full movies covering different genres. Our experiments show that our multimodal model significantly outperforms several competitive baselines on the average weighted F-score metric. To demonstrate the effectiveness of our framework, we design an end-to-end memory network model that leverages our speaker naming model and achieves state-of-the-art results on the subtitles task of the MovieQA 2017 Challenge.

1 Introduction

Identifying speakers and their names in movies, and videos in general, is a primary task for many video analysis problems, including automatic subtitle labeling (Hu et al., 2015), content-based video indexing and retrieval (Zhang et al., 2009), video summarization (Tapaswi et al., 2014), and video storyline understanding (Tapaswi et al., 2014). It is a very challenging task, as the visual appearance of the characters changes over the course of the movie due to several factors such as scale, clothing, illumination, and so forth (Arandjelovic and Zisserman, 2005; Everingham et al., 2006). The annotation of movie data with speakers' names can be helpful in a number of applications, such as movie question answering (Tapaswi et al., 2016), automatic identification of character relationships (Zhang et al., 2009), or automatic movie captioning (Hu et al., 2015).

Most previous studies relied primarily on visual information (Arandjelovic and Zisserman, 2005; Everingham et al., 2006), and aimed for the slightly different task of face track labeling;

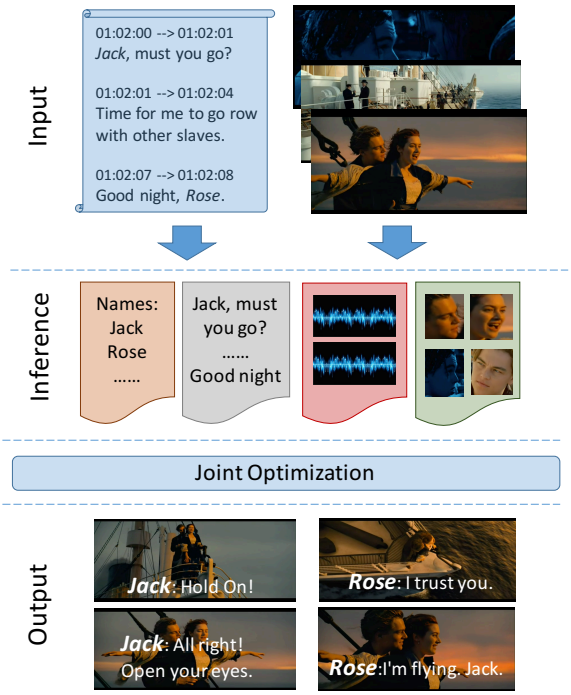

Figure 1: Overview of our approach for speaker naming.

speakers who did not appear in the video frame were not assigned any names, which is common in movies and TV shows. Other available sources of information such as scripts were only used to extract cues about the speakers' names to associate the faces in the videos with their corresponding character name (Everingham et al., 2006; Tapaswi et al., 2015; Bäuml et al., 2013; Sivic et al., 2009); however since scripts are not always available, the applicability of these methods is somehow limited.

Other studies focused on the problem of speaker recognition without naming, using the speech modality as a single source of information. While some of these studies attempted to incorporate the visual modality, their goal was to cluster the speech segments rather than name the speakers

Proceedings of NAACL-HLT 2018, pages 2206–2216
New Orleans, Louisiana, June 1 - 6, 2018.

(Erzin et al., 2005; Bost and Linares, 2014; Kapsouras et al., 2015; Bredin and Gelly, 2016; Hu et al., 2015; Ren et al., 2016). None of these studies used textual information (e.g., dialogue), which prevented them from identifying speaker names.

In our work, we address the task of speaker naming, and propose a new multimodal model that leverages in an unified framework of the visual, speech, and textual modalities that are naturally available while watching a movie. We do not assume the availability of a movie script or a cast list, which makes our model fully unsupervised and easily applicable to unseen movies.

The paper makes two main contributions. First, we introduce a new unsupervised system for speaker naming for movies and TV shows that exclusively depends on videos and subtitles, and relies on a novel unified optimization framework that fuses visual, textual, and acoustic modalities for speaker naming. Second, we construct and make available a dataset consisting of 24 movies with 31,019 turns manually annotated with character names. Additionally, we also evaluate the role of speaker naming when embedded in an end-to-end memory network model, achieving state-of-the-art performance results on the subtitles task of the MovieQA 2017 Challenge.

2 Related Work

The problem of speaker naming in movies has been explored by the computer vision and the speech communities. In the computer vision community, the speaker naming problem is usually considered as a face/person naming problem, in which names are assigned to their corresponding faces on the screen (Everingham et al., 2006; Cour et al., 2010; Bäuml et al., 2013; Haurilet et al., 2016; Tapaswi et al., 2015). On the other hand, the speech community considered the problem as a speaker identification problem, which focuses on recognizing and clustering speakers rather than naming them (Reynolds, 2002; Campbell, 1997). In this work, we aim to solve the problem of speaker naming in movies, in which we label each segment of the subtitles with its corresponding speaker name whether the speaker's face appeared on in the video or not.

Previous work can be furthered categorized according to the type of supervision used to build the character recognition and speaker recognition models: supervised vs. weakly supervised models. In the movie and television domains, utilizing scripts in addition to subtitles to obtain timestamped speaker information was also studied in (Everingham et al., 2006; Tapaswi et al., 2015; Bäuml et al., 2013; Sivic et al., 2009). Moreover, they utilized this information to resolve the ambiguity introduced by co-occurring faces in the same frame. Features were extracted through the period of speaking (detected via lip motion on each face). Then they assigned the face based on candidate names from the time-stamped script. Thus, these studies used speaker recognition as an essential step to construct cast-specific face classifiers. (Tapaswi et al., 2012) extended the face identification problem to include person tracking. They utilized available face recognition results to learn clothing models for characters to identify person tracks without faces.

In (Cour et al., 2010; Haurilet et al., 2016), the authors proposed a weakly supervised model depending on subtitles and a character list. They extracted textual cues from the dialog: first, second, and third person references, such as "I'm Jack", "Hey, Jack!", and "Jack left". Using a character list from IMDB, they mapped these references onto true names using minimum edit distance, and then they ascribed the references to face tracks. Other work removed the dependency on a true character list by determining all names through coreference resolution. However, this work also depended on the availability of scripts (Ramanathan et al., 2014). In our model, we removed the dependency on both the true cast list and the script, which makes it easier to apply our model to other movies and TV shows.

Recent work proposed a convolutional neural network (CNN) and Long Short-Term Memory (LSTM) based learning framework to automatically learn a function that combines both facial and acoustic features (Hu et al., 2015; Ren et al., 2016). Using these cues, they tried to learn matching face-audio pairs and non-matching face-audio pairs. They then trained a SVM classifier on the audio-video pairings to discriminate between the non-overlapping speakers. In order to train their models, they manually identified the leading characters in two TV shows, Friends and The Big Bang Theory (BBT), and collected their face tracks and corresponding audio segments using pre-annotated subtitles. Despite the very high performance reported in these studies, it is very hard to generalize their approach since it requires a lot

of training data.

On the other hand, talking faces have been used to improve speaker recognition and diarization in TV shows (Bredin and Gelly, 2016; Bost and Linares, 2014; Li et al., 2004). In the case of (Liu et al., 2008), they modeled the problem of speaker naming as facial recognition to identify speakers in news broadcasts. This work leveraged optical character recognition to read the broadcasters' names that were displayed on screen, requiring the faces to already be annotated.

3 Datasets

Our dataset consists of a mix of TV show episodes and full movies. For the TV show, we use six full episodes of season one of the BBT. The number of named characters in the BBT episodes varies between 5 to 8 characters per episode, and the background noise level is low. Additionally, we also acquired a set of eighteen full movies from different genres, to evaluate how our model works under different conditions. In this latter dataset, the number of named characters ranges between 6 and 37, and it has varied levels of background noise.

We manually annotated this dataset with the character name of each subtitle segment. To facilitate the annotation process, we built an interface that parses the movies subtitles files, collects the cast list from IMDB for each movie, and then shows one subtitle segment at a time along with the cast list so that the annotator can choose the correct character. Using this tool, human annotators watched the movies and assigned a speaker name to each subtitle segment. If a character name was not mentioned in the dialogue, the annotators labeled it as "unknown." To evaluate the quality of the annotations, five movies in our dataset were double annotated. The Cohen's Kappa inter-annotator agreement score for these five movies is 0.91, which shows a strong level of agreement.

To clean the data, we removed empty segments, as well as subtitle description parts written between brackets such as "[groaning]" and "[sniffing]". We also removed segments with two speakers at the same time. We intentionally avoided using any automatic means to split these segments, to preserve the high-quality of our gold standard.

Table 1 shows the statistics of the collected data. Overall, the dataset consists of 24 videos with a total duration of 40.28 hours, a net dialogue duration of 21.99 hours, and a total of 31,019 turns spoken by 463 different speakers. Four of the movies in this dataset are used as a development set to develop supplementary systems and to fine tune our model's parameters; the remaining movies are used for evaluation.

	Min	Max	Mean	σ
# characters/video	5	37	17.8	9.55
# Subtitle turns/video	488	2212	1302.4	563.06
# words/turn	1	28	8.02	4.157
subtitles duration (sec)	0.342	9.59	2.54	1.02

Table 1: Statistics on the annotated movie dataset.

4 Data Processing and Representations

We process the movies by extracting several textual, acoustic, and visual features.

4.1 Textual Features

We use the following representations for the textual content of the subtitles:

SkipThoughts uses a Recurrent Neural Network to capture the underlying semantic and syntactic properties, and map them to a vector representation (Kiros et al., 2015). We use their pretrained model to compute a 4,800 dimensional sentence representation for each line in the subtitles.[1]

TF-IDF is a traditional weighting scheme in information retrieval. We represent each subtitle as a vector of tf-idf weights, where the length of the vector (i.e., vocabulary size) and the idf scores are obtained from the movie including the subtitle.

4.2 Acoustic Features

For each movie in the dataset, we extract the audio from the center channel. The center channel is usually dedicated to the dialogue in movies, while the other audio channels carry the surrounding sounds from the environment and the musical background. Although doing this does not fully eliminate the noise in the audio signal, it still improves the speech-to-noise ratio of the signal. When a movie has stereo sound (left and right channels only), we down-mix both channels of the stereo stream into a mono channel.

In this work, we use the subtitles timestamps as an estimate of the boundaries that correspond to the uttered speech segments. Usually, each subtitle corresponds to a segment being said by a single speaker. We use the subtitle timestamps for segmentation so that we can avoid automatic speaker diarization errors and focus on the speaker naming problem.

[1] https://github.com/ryankiros/skip-thoughts

To represent the relevant acoustic information from each spoken segment, we use iVectors, which is the state-of-the-art unsupervised approach in speaker verification (Dehak et al., 2011). While other deep learning-based speaker embeddings models also exist, we do not have access to enough supervised data to build such models. We train unsupervised iVectors for each movie in the dataset, using the iVector extractor used in (Khorram et al., 2016). We extract iVectors of size 40 using a Gaussian Mixture Model-Universal Background Model (GMM-UBM) with 512 components. Each iVector corresponds to a speech segment uttered by a single speaker. We fine tune the size of the iVectors and the number of GMM-UBM components using the development dataset.

4.3 Visual Features

We detect faces in the movies every five frames using the recently proposed MTCNN (Zhang et al., 2016) model, which is pretrained for face detection and facial landmark alignment. Based on the results of face detection, we apply the forward and backward tracker with an implementation of the Dlib library (King, 2009; Danelljan et al., 2014) to extract face tracks from each video clip. We represent a face track using its best face in terms of detection score, and use the activations of the fc7 layer of pretrained VGG-Face (Parkhi et al., 2015) network as visual features.

We calculate the distance between the upper lip center and the lower lip center based on the 68-point facial landmark detection implemented in the Dlib library (King, 2009; Kazemi and Sullivan, 2014). This distance is normalized by the height of face bounding boxes and concatenated across frames to represent the amount of mouth opening. A human usually speaks with lips moving with a certain frequency (3.75 Hz to 7.5 Hz used in this work) (Tapaswi et al., 2015). We apply a band-pass filter to amplify the signal of true lip motion in these segments. The overall sum of lip motion is used as the score for the talking face.

5 Unified Optimization Framework

We tackle the problem of speaker naming as a transductive learning problem with constraints. In this approach, we want to use the sparse positive labels extracted from the dialogue and the underlying topological structure of the rest of the unlabeled data. We also incorporate multiple cues extracted from both textual and multimedia information. A unified learning framework is proposed to enable the joint optimization over the automatically labeled and unlabeled data, along with multiple semantic cues.

5.1 Character Identification and Extraction

In this work, we do not consider the set of character names as given because we want to build a model that can be generalized to unseen movies. This strict setting adds to the problem's complexity. To extract the list of characters from the subtitles, we use the Named Entity Recognizer (NER) in the Stanford CoreNLP toolkit (Manning et al., 2014). The output is a long list of person names that are mentioned in the dialogue. This list is prone to errors including, but not limited to, nouns that are misclassified by the NER as person's name such as "Dad" and "Aye", names that are irrelevant to the movie such as "Superman" or named animals, or uncaptured character names.

To clean the extracted names list of each movie, we cluster these names based on string minimum edit distance and their gender. From each cluster, we then pick a name to represent it based on its frequency in the dialogue. The result of this step consists of name clusters along with their distribution in the dialogue. The distribution of each cluster is the sum of all the counts of its members. To filter out irrelevant characters, we run a name reference classifier, which classifies each name into first, second or third person references. If a name was only mentioned as a third person throughout the whole movie, we discard it from the list of characters. We remove any name cluster that has a total count less than three, which takes care of the misclassified names' reference types.

5.2 Grammatical Cues

We use the subtitles to extract the name mentions in the dialogue. These mentions allow us to obtain cues about the speaker name and the absence or the presence of the mentioned character in the surrounding subtitles. Thus, they affect the probability that the mentioned character is the speaker or not. We follow the same name reference categories used in (Cour et al., 2010; Haurilet et al., 2016). We classify a name mention into: first (e.g., "I'm Sheldon"), second (e.g., "Oh, hi, Penny") or third person reference (e.g., "So how did it go with Leslie?"). The first person reference represents a positive constraint that allows us to label the corresponding iVector of the speaker and his face if

it exists during the segment duration. The second person reference represents a multi-instance constraint that suggests that the mentioned name is one of the characters that are present in the scene, which increases the probability of this character to be one of the speakers of the surrounding segments. On the other hand, the third person reference represents a negative constraint, as it suggests that the speaker does not exist in the scene, which lowers the character probability of the character being one of the speakers of the next or the previous subtitle segments.

To identify first, second and third person references, we train a linear support vector classifier. The first person, the second and third person classifier's training data are extracted and labeled from our development dataset, and fine tuned using 10-fold cross-validation. Table 2 shows the results of the classifier on the test data. The average number of first, second and third-person references in each movie are 14.63, 117.21, and 95.71, respectively.

	Precision	Recall	F1-Score
First Person	0.625	0.448	0.522
Second Person	0.844	0.863	0.853
Third Person	0.806	0.806	0.806
Average / Total	0.819	0.822	0.820

Table 2: Performance metrics of the reference classifier on the test data.

5.3 Unified Optimization Framework

Given a set of data points that consist of l labeled[2] and u unlabeled instances, we apply an optimization framework to infer the best prediction of speaker names. Suppose we have $l+u$ instances $X = \{x_1, x_2, ..., x_l, x_{l+1}, ..., x_{l+u}\}$ and K possible character names. We also get the dialogue-based positive labels y_i for instances x_i, where y_i is a k-dimension one-hot vector and $y_i^j = 1$ if x_i belongs to the class j, for every $1 \leq i \leq l$ and $1 \leq j \leq K$. To name each instance x_i, we want to predict another one-hot vector of naming scores $f(x_i)$ for each x_i, such that $\text{argmax}_j f^j(x_i) = z_i$ where z_i is the ground truth number of class for instance x_i.

To combine the positive labels and unlabeled data, we define the objective function for predictions f as follows:

$$L_{initial}(f) = \frac{1}{l}\sum_{i=1}^{l}||f(x_i) - y_i||^2 + \frac{1}{l+u}\sum_{i=1}^{l+u}\sum_{j=1}^{l+u} w_{ij}||f(x_i) - f(x_j)||^2 \quad (1)$$

Here w_{ij} is the similarity between x_i and x_j, which is calculated as the weighted sum of textual, acoustic and visual similarities. The inverse Euclidean distance is used as similarity function for each modality. The weights for different modalities are selected as hyperparameters and tuned on the development set. This objective leads to a convex loss function which is easier to optimize over feasible predictions.

Besides the positive labels obtained from first person name references, we also introduce other semantic constraints and cues to enhance the power of our proposed approach. We implement the following four types of constraints:

Multiple Instance Constraint. Although the second person references cannot directly provide positive constraints, they imply that the mentioned characters have high probabilities to be in this conversation. Following previous work (Cour et al., 2010), we incorporate the second person references as multiple instances constraints into our optimization: if x_i has a second person reference j, we encourage j to be assigned to its neighbors, i.e., its adjacent subtitles with similar timestamps. For the implementation, we simply include multiple instances constraints as a variant of positive labels with decreasing weights s, where $s = 1/(l-i)$ for each neighbor x_l.

Negative Constraint. For the third person references, the mentioned characters may not occur in the conversation and movies. So we treat them as negative constraints, which means they imply that the mentioned characters should not be assigned to corresponding instances. This constraint is formulated as follows:

$$L_{neg}(f) = \sum_{(i,j)\in N}[f^j(x_i)]^2 \quad (2)$$

where N is the set of negative constraints x_i doesn't belong class j.

Gender Constraint. We train a voice-based gender classifier by using the subtitles segments from the four movies in our development dataset (5,543

[2]Note that in our setup, all the labeled instances are obtained automatically, as described above.

segments of subtitles). We use the segments in which we know the speaker's name and manually obtain the ground truth gender label from IMDB. We extract the signal energy, 20 Mel-frequency cepstral coefficients (MFCCs) along with their first and second derivatives, in addition to time- and frequency-based absolute fundamental frequency (f0) statistics as features to represent each segment in the subtitles. The f0 statistics has been found to improve the automatic gender detection performance for short speech segments (Levitan et al., 2016), which fits our case since the median duration of the dialogue turns in our dataset is 2.6 seconds.

The MFCC features are extracted using a step size of 16 msec over a 64 msec window using the method from (Mathieu et al., 2010), while the f0 statistics are extracted using a step size of 25 msec over a 50 msec window as the default configuration in (Eyben et al., 2013). We then use these features to train a logistic regression classifier using the Scikit-learn library (Pedregosa et al., 2011). The average accuracy of the gender classifier on a 10-fold cross-validation is 0.8867.

Given the results for the gender classification of audio segments and character names, we define the gender loss to penalize inconsistency between the predicted gender and character names:

$$L_{gender}(f) = \sum_{(i,j)\in Q_1} P_{ga}(x_i)(1 - P_{gn}(j))f^j(x_i) + \sum_{(i,j)\in Q_2} (1 - P_{ga}(x_i))P_{gn}(j)f^j(x_i) \quad (3)$$

where $P_{ga(x_i)}$ is the probability for instance x_i to be a male, and $P_{gn(j)}$ is the probability for name j to be a male, and $Q_1 = \{(i,j)|P_{ga}(x_i) < 0.5, P_{gn}(j) > 0.5\}$, $Q_2 = \{(i,j)|P_{ga}(x_i) > 0.5, P_{gn}(j) < 0.5\}$.

Distribution Constraint. We automatically analyze the dialogue and extract the number of mentions of each character in the subtitles using Stanford CoreNLP and string matching to capture names that are missed by the named entity recognizer. We then filter the resulting counts by removing third person mention references of each name as we assume that this character does not appear in the surrounding frames. We use the results to estimate the distribution of the speaking characters and their importance in the movies. The main goal of this step is to construct a prior probability distribution for the speakers in each movie.

To encourage our predictions to be consistent with the dialogue-based priors, we penalize the square error between the distributions of predictions and name mentions priors in the following equation:

$$L_{dis}(f) = \sum_{j=1}^{K}(\sum(f^j(x_i)) - d_j)^2 \quad (4)$$

where d_j is the ratio of name j mentions in all subtitles.

Final Framework. Combining the loss in Eqn. 1 and multiple losses with different constraints, we obtain our unified optimization problem:

$$f^* = \arg\min_f \lambda_1 L_{initial}(f) + \lambda_2 L_{MI}(f) + \lambda_3 L_{neg}(f) + \lambda_4 L_{gender}(f) + \lambda_5 L_{dis}(f) \quad (5)$$

All of the λs are hyper-parameters to be tuned on development set. We also include the constraint that predictions for different character names must sum to 1. We solve this constrained optimization problem with projected gradient descent (PGD). Our optimization problem in Eqn. 5 is guaranteed to be a convex optimization problem and therefore projected gradient descent is guaranteed to stop with global optima. PGD usually converges after 800 iterations.

6 Evaluation

We model our task as a classification problem, and use the unified optimization framework described earlier to assign a character name to each subtitle.

Since our dataset is highly unbalanced, with a few main characters usually dominating the entire dataset, we adopt the weighted F-score as our evaluation metric, instead of using an accuracy metric or a micro-average F-score. This allows us to take into account that most of the characters have only a few spoken subtitle segments, while at the same time placing emphasis on the main characters. This leads sometimes to an average weighted F-score that is not between the average precision and recall.

One aspect that is important to note is that characters are often referred to using different names. For example, in the movie "The Devil's Advocate," the character Kevin Lomax is also referred to as Kevin or Kev. In more complicated situations, characters may even have multiple identities, such as the character Saul Bloom in the movie "Ocean's Eleven," who pretends to be another character named Lyman Zerga. Since our

goal is to assign names to speakers, and not necessarily solve this coreference problem, we consider the assignment of the subtitle segments to any of the speaker's aliases to be correct. Thus, during the evaluation, we map all the characters' aliases from our model's output to the names in the ground truth annotations. Our mapping does not include other referent nouns such as "Dad," "Buddy," etc.; if a segment gets assigned to any such terms, it is considered a misprediction.

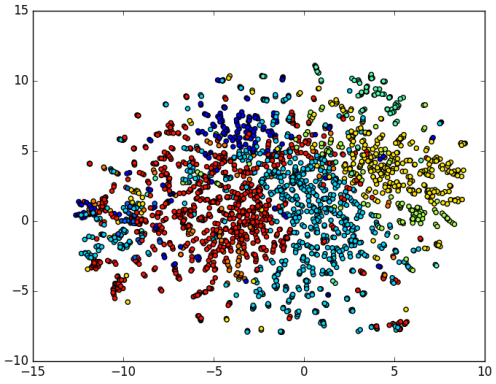
We compare our model against three baselines:

B1: Most-frequently mentioned character consists of selecting the most frequently mentioned character in the dialogue as the speaker for all the subtitles. Even though it is a simple baseline, it achieves an accuracy of 27.1%, since the leading characters tend to speak the most in the movies.

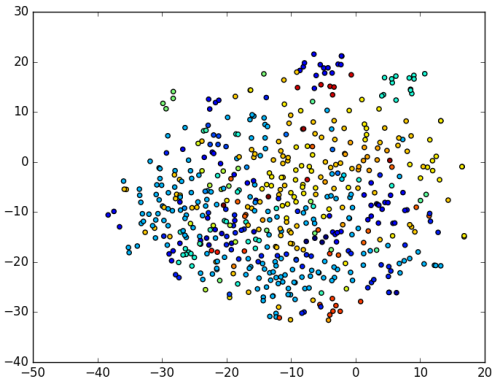
B2: Distribution-driven random assignment consists of randomly assigning character names according to a distribution that reflects their fraction of mentions in all the subtitles.

B3: Gender-based distribution-driven random assignment consists of selecting the speaker names based on the voice-based gender detection classifier. This baseline randomly selects the character name that matches the speaker's gender according to the distribution of mentions of the names in the matching gender category.

The results obtained with our proposed unified optimization framework and the three baselines are shown in Table 3. We also report the performance of the optimization framework using different combinations of the three modalities. The model that uses all three modalities achieves the best results, and outperforms the strongest baseline (B3) by more than 6% absolute in average



(a) The Big Bang Theory



(b) Titanic

Figure 2: For each speech segment, we applied t-SNE (Van Der Maaten, 2014) on their corresponding iVectors. The points with the same color represent instances with the same character name.

weighted F-score. It also significantly outperforms the usage of the visual and acoustic features combined, which have been frequently used together in previous work, suggesting the importance of textual features in this setting.

The ineffectiveness of the iVectors might be a result of the background noise and music, which are difficult to remove from the speech signal. Figure 2 shows the t-Distributed Stochastic Neighbor Embedding (t-SNE) (Van Der Maaten, 2014), which is a nonlinear dimensionality reduction technique that models points in such a way that similar vectors are modeled by nearby points and dissimilar objects are modeled by distant points, visualization of the iVectors over the whole BBT show and the movie "Titanic." In the BBT there is almost no musical background or background noise, while, Titanic has musical background in addition to the background noise such as the screams of the drowning people. From the graph,

the difference between the quality of the iVectors clusters on different noise-levels is clear.

Table 4 shows the effect of adding components of our loss function to the initial loss L_{init} function. The performance of the model using only L_{init} without the other parts is very low due to the sparsity of first person references and errors that the person reference classifier introduces.

	Precision	Recall	F-score
$L_{initial}$	0.0631	0.1576	0.0775
$L_{initial} + L_{gender}$	0.1160	0.1845	0.1210
$L_{initial} + L_{negative}$	0.0825	0.0746	0.0361
$L_{initial} + L_{distribution}$	0.1050	0.1570	0.0608
$L_{initial} + L_{MultipleInstance}$	0.3058	0.2941	0.2189

Table 4: Analysis of the effect of adding each component of the loss function to the initial loss.

In order to analyze the effect of the errors that several of the modules (e.g., gender and name reference classifiers) propagate into the system, we also test our framework by replacing each one of the components with its ground truth information. As seen in Table 5, the results obtained in this setting show significant improvement with the replacement of each component in our framework, which suggests that additional work on these components will have positive implications on the overall system.

	Precision	Recall	F-score
Our Model	0.3720	0.3108	0.2920
Voice Gender (VG)	0.4218	0.3449	0.3259
VG + Name Gender (NG)	0.4412	0.3790	0.3645
VG + NG + Name Ref	0.4403	0.3938	0.3748

7 Speaker Naming for Movie Understanding

Identifying speakers is a critical task for understanding the dialogue and storyline in movies. MovieQA is a challenging dataset for movie understanding. The dataset consists of 14,944 multiple choice questions about 408 movies. Each question has five answers and only one of them is correct. The dataset is divided into three splits: train, validation, and test according to the movie titles. Importantly, there are no overlapping movies between the splits. Table 6 shows examples of the question and answers in the MovieQA dataset.

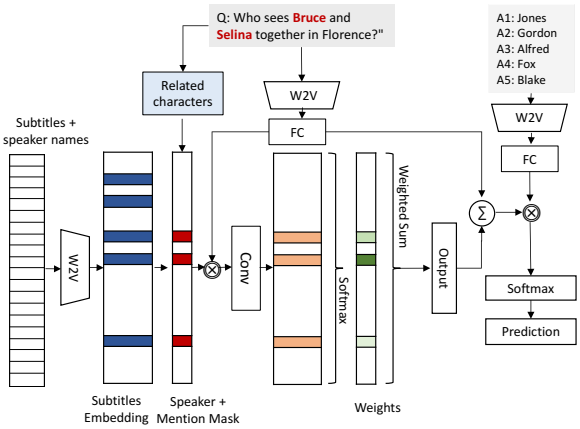

Figure 3: The diagram describing our Speaker-based Convolutional Memory Network (SC-MemN2N) model.

The MovieQA 2017 Challenge[3] consists of six different tasks according to the source of information used to answer the questions. Given that for many of the movies in the dataset the videos are not completely available, we develop our initial system so that it only relies on the subtitles; we thus participate in the challenge subtitles task, which includes the dialogue (without the speaker information) as the only source of information to answer questions.

To demonstrate the effectiveness of our speaker naming approach, we design a model based on an end-to-end memory network (Sukhbaatar et al., 2015), namely Speaker-based Convolutional Memory Network (SC-MemN2N), which relies on the MovieQA dataset, and integrates the speaker naming approach as a component in the network. Specifically, we use our speaker naming framework to infer the name of the speaker for each segment of the subtitles, and prepend the predicted speaker name to each turn in the subtitles.[4] To represent the movie subtitles, we represent each turn in the subtitles as the mean-pooling of a 300-dimension pretrained word2vec (Mikolov et al., 2013) representation of each word in the sentence. We similarly represent the input questions and their corresponding answers. Given a question, we use the SC-MemN2N memory to find an answer. For questions asking about specific characters, we keep the memory slots that have the characters in question as speakers or mentioned in, and mask out the rest of the memory slots. Figure

[4] We strictly follow the challenge rules, and only use text to infer the speaker names.

Movie	Question	Answers	
Fargo	What did Mike's wife, as he says, die from?	A1: She was killed	**A2: Breast cancer**
		A3: Leukemia	A4: Heart disease
		A5: Complications due to child birth	
Titanic	What does Rose ask Jack to do in her room?	A1: Sketch her in her best dress	A2: Sketch her nude
		A3: Take a picture of her nude	**A4: Paint her nude**
		A5: Take a picture of her in her best dress	

Table 6: Example of questions and answers from the MQA benchmark. The answers in bold are the correct answers to their corresponding question.

3 shows the architecture of our model.

Table 7 includes the results of our system on the validation and test sets, along with the best systems introduced in previous work, showing that our SC-MemN2N achieves the best performance. Furthermore, to measure the effectiveness of adding the speaker names and masking, we test our model after removing the names from the network (C-MemN2N). As seen from the results, the gain of SC-MemN2N is statistically significant[5] compared to a version of the system that does not include the speaker names (C-MemN2N). Figure 4 shows the performance of both C-MemN2N and SC-MemN2N models by question type. The results suggest that our speaker naming helps the model better distinguish between characters, and that prepending the speaker names to the subtitle segments improves the ability of the memory network to correctly identify the supporting facts from the story that answers a given question.

8 Conclusion

In this paper, we proposed a unified optimization framework for the task of speaker naming in movies. We addressed this task under a difficult setup, without a cast-list, without supervision from a script, and dealing with the complicated conditions of real movies. Our model includes textual, visual, and acoustic modalities, and incorporates several grammatical and acoustic constraints. Empirical experiments on a movie dataset demonstrated the effectiveness of our proposed method with respect to several competitive baselines. We also showed that an SC-MemN2N model that leverages our speaker naming model can achieve state-of-the-art results on the subtitles task of the MovieQA 2017 Challenge.

The dataset annotated with character names introduced in this paper is publicly available from `http://lit.eecs.umich.edu/downloads.html`.

Abstract

Visual Question Answering (VQA) is a well-known and challenging task that requires systems to jointly reason about natural language and vision. Deep learning models in various forms have been the standard for solving VQA. However, some of these VQA models are better at certain types of image-question pairs than other models. Ensembling VQA models intelligently to leverage their diverse expertise is, therefore, advantageous.

Stacking With Auxiliary Features (SWAF) is an intelligent ensembling technique which learns to combine the results of multiple models using features of the current problem as context. We propose four categories of auxiliary features for ensembling for VQA. Three out of the four categories of features can be inferred from an image-question pair and do not require querying the component models. The fourth category of auxiliary features uses model-specific explanations. In this paper, we describe how we use these various categories of auxiliary features to improve performance for VQA. Using SWAF to effectively ensemble three recent systems, we obtain a new state-of-the-art. Our work also highlights the advantages of explainable AI models.

1 Introduction

Visual Question Answering (VQA), the task of addressing open-ended questions about images (Malinowski and Fritz, 2014; Antol et al., 2015), has attracted significant attention in recent years (Andreas et al., 2016a; Goyal et al., 2016; Agrawal et al., 2016; Teney et al., 2017). Given an image and a natural language question about the image, the task is to provide an accurate natural language answer. VQA requires visual and linguistic comprehension, language grounding as well as common-sense knowledge. A variety of methods to address these challenges have been developed in recent years (Fukui et al., 2016; Xu and Saenko, 2016; Lu et al., 2016; Chen et al., 2015). The vision component of a typical VQA system extracts visual features using a deep convolutional neural network (CNN), and the linguistic component encodes the question into a semantic vector using a recurrent neural network (RNN). An answer is then generated conditioned on the visual features and the question vector.

Most VQA systems have a single underlying method that optimizes a specific loss function and do not leverage the advantage of using multiple diverse models. One recent ensembling approach to VQA (Fukui et al., 2016) combined multiple models that use multimodal compact bilinear pooling with attention and achieved state-of-the-art accuracy on the VQA 2016 challenge. However, their ensemble uses simple softmax averaging to combine outputs from multiple systems. Also, their model is pre-trained on the Visual Genome dataset (Krishna et al., 2017) and they concatenate learned word embeddings with pre-trained GloVe vectors (Pennington et al., 2014). Several other deep and non-deep learning approaches for solving VQA have also been proposed (Lu et al., 2016; Zhou et al., 2015; Noh et al., 2016). Although these models perform fairly well on certain image-question (IQ) pairs, they fail spectacularly on certain other IQ pairs. This led us to conclude that the various VQA models have learned to perform well on specific types of questions and images. Therefore, there is an opportunity to combine these models intelligently so as to leverage their diverse strengths.

Ensembling multiple systems is a well known standard approach to improving accuracy in machine learning (Dietterich, 2000). Stacking with Auxiliary Features (SWAF) (Rajani and Mooney, 2017) is a recent ensembling algorithm that learns to combine outputs of multiple systems using fea-

tures of the current problem as context. In this paper, we use SWAF to more effectively combine several VQA models. Traditional stacking (Wolpert, 1992) trains a supervised meta-classifier to appropriately combine multiple system outputs. SWAF further enables the stacker to exploit additional relevant knowledge of both the component systems and the problem by providing *auxiliary features* to the meta-classifier. Our approach extracts features from the IQ pair under consideration, as well as the component models and provides this information to the classifier. The meta-classifier then learns to predict whether a specific generated answer is correct or not.

Explanations attempt to justify a system's predicted output and provide context for their decision that may also help SWAF. We extract *visual* explanations from various deep learning models and use those as auxiliary features for SWAF. Our contributions can be summarized as follows: (a) developing novel auxiliary features that can be inferred from VQA questions and images; (b) extracting visual explanations from several component models for each IQ pair and using those to also generate auxiliary features; and (c) using SWAF to ensemble various VQA models and evaluating ablations of features while comparing our approach extensively to several individual as well as ensemble systems. By effectively ensembling three leading VQA systems with SWAF, we demonstrate state-of-the-art performance.

2 Background and Related Work

VQA is the task of answering a natural language question about the content of an image by returning an appropriate word or phrase. Figure 1 shows a sample of images and questions from the VQA 2016 challenge. The dataset consists of images taken from the MS COCO dataset (Lin et al., 2014) with three questions and answers per image obtained through Mechanical Turk (Antol et al., 2015). Table 1 summarizes the splits in the VQA dataset. Several deep learning models have been developed that combine a computer vision component with a linguistic component in order to solve the VQA challenge. Some of these models also use data-augmentation for pre-training. We discuss the VQA models we use in Section 5.

	Images	Questions
Training	82,783	248,349
Validation	40,504	121,512
Test	81,434	244,302

Table 1: VQA dataset splits.

Stacking With Auxiliary Features (SWAF) is an ensembling technique that combines outputs from multiple systems using their confidence scores and task-relevant features. It has previously been applied effectively to information extraction (Viswanathan et al., 2015), entity linking (Rajani and Mooney, 2016) and ImageNet object detection (Rajani and Mooney, 2017). To the best of our knowledge, there has been no prior work on stacking for VQA, and we are the first to show how model-specific explanations can serve as an auxiliary feature. The auxiliary features that we use are motivated by an analysis of the VQA dataset and also inspired by related work, such as using a Bayesian framework to predict the form of the answer from the question (Kafle and Kanan, 2016).

Deep learning models have been used widely on several vision and language problems. However, they frequently lack transparency and are unable to explain their decisions (Selvaraju et al., 2017). On the other hand, humans can justify their decisions with natural language as well as point to the visual evidence that supports their decision. There are several advantages of having AI systems that can generate explanations that support their predictions (Johns et al., 2015; Agrawal et al., 2016). These advantages have motivated recent work on explainable AI systems, particularly in computer vision (Antol et al., 2015; Goyal et al., 2016; Hendricks et al., 2016; Park et al., 2016). However, there has been no prior work on using explanations for ensembling multiple models or improving performance on a challenging task. In this

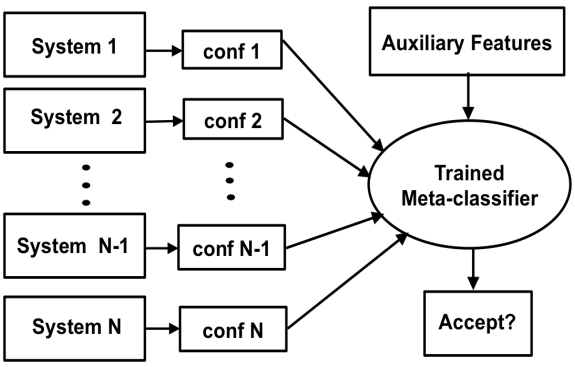

Figure 2: Ensemble Architecture using Stacking with Auxiliary Features. Given an input, the ensemble judges every possible question-answer pair produced by the component systems and determines the final output answer.

paper, we generate visual explanations for three different VQA models and use these explanations to develop auxiliary features that aid in effectively ensembling VQA systems.

3 Stacking With Auxiliary Features (SWAF) for VQA

In stacking, a meta-classifier is learned to combine the outputs of multiple underlying systems (Wolpert, 1992). The stacker learns a classification boundary based on the confidence scores provided by individual systems for each possible output. However, many times the scores produced by systems are not probabilities or not well calibrated and cannot be meaningfully compared. In such circumstances, it is beneficial to also have other reliable auxiliary features, as in the SWAF approach. SWAF provides the meta-classifier additional information, such as features of the current problem and provenance or explanation information about the output from individual systems. This allows SWAF to *learn* which systems do well on which types of problems and when to trust agreements between specific systems. The learned meta-classifier makes a binary decision whether or not to accept a particular output. Figure 2 gives an overview of the SWAF approach.

For stacking VQA systems, we first form unique question-answer pairs across all of the systems' outputs before passing them through the stacker. If a system generates a given output, then we use its probability estimate for that output, otherwise, the confidence is considered zero. If a question-answer pair is classified as correct by the stacker, and if there are other answers that are also classified as correct for the same question, the output with the highest meta-classifier confidence is chosen. For questions that do not have any answer classified as correct by the stacker, we choose the answer with lowest classifier confidence, which means it is least likely to be incorrect. The reason we do this is that the online VQA scorer expects an answer for each question in the test set and penalizes the model for every unanswered question.

The confidence scores along with other auxiliary features form the complete set of features used by the stacker. The auxiliary features are the backbone of the SWAF approach, enabling the stacker to intelligently learn to rely on systems' outputs conditioned on the supporting evidence. We use a total of four different categories of auxiliary features for VQA. Three of these types can be inferred directly from the image-question (IQ) pair and do not require querying the individual models. For the fourth category of auxiliary features, we generate *visual explanations* for the component models and use these to create the explanation auxiliary features. The first three categories of features are discussed below and the fourth category is discussed in the next section.

3.1 Question and Answer Types

Antol et al. (2015) analyzed the VQA data and found that most questions fall into several types based on the first few words (e.g. questions beginning with "What is...", "Is there...", "How many...", or "Does the..."). Using the validation data, we discover such lexical patterns to define a set of question types. The questions were tokenized and a question type was formed by adding one token at a time, up to a maximum of five, to the current substring. The question "What is the color of the vase?" has the following types: "What", "What is", "What is the", "What is the color", "What is the color of". The prefixes that contain at least 500 questions were then retained as types. We added a final type "other" for questions that do not fall into any of the predefined types, resulting in a total of 70 question types. A 70-bit vector is used to encode the question type as a set of auxiliary features.

The original analysis of VQA answers found that they are 38% "yes/no" type and 12% numbers.

There is clearly a pattern in the VQA answers as well and we use the questions to infer some of these patterns. We considered three answer types – "yes/no", "number", and "other". The answer-type auxiliary features are encoded using a one-hot vector. We classify all questions beginning with "Does","Is","Was","Are", and "Has" as "yes/no". Ones beginning with "How many", "What time", "What number" are assigned "number" type. These inferred answer types are not exhaustive but have good coverage. The intuition behind using the question and answer types as auxiliary features is that some VQA models are better than others at handling certain types of questions and/or answers. Making this information available at the time of classification aids the stacker in making a better decision.

3.2 Question Features

We also use a bag-of-words (BOW) representation of the question as auxiliary features. Words that occur at least five times in the validation set were included. The final sparse vector representing a question was normalized by the number of unique words in the question. In this way, we are able to embed the question into a single vector. Goyal et al. (2016) showed that attending to specific words in the question is important in VQA. Including a BOW for the question as auxiliary features equip the stacker to efficiently learn which words are important and can aid in classifying answers.

3.3 Image Features

We also used "deep visual features" of the image as additional auxiliary features. Specifically, we use the $4,096$ features from VGGNet's (Simonyan and Zisserman, 2015) $fc7$ layer . This creates an embedding of the image in a single vector which is then used by the stacker. Using such image features enables the stacker to learn to rely on systems that are good at identifying answers for particular types of images. Recall that the individual VQA models fuse an embedding of the image along with an embedding of the question. By using the question and image embeddings at the meta-classifier level, the stacker learns to discriminate between the component models based on a deeper representation of the IQ pair.

4 Using Explanations

Recently, there has been work on analyzing regions of an image that deep-learning models focus on when making decisions (Goyal et al., 2016; Hendricks et al., 2016; Park et al., 2016). This work shows that deep-learning models attend to relevant parts of the image when making a decision. For VQA, the parts of images that the models focus on can be thought of as *visual* explanations for answering the question. We use these visual explanations to construct auxiliary features for SWAF. The idea behind using explanation features is that they enable the stacker to learn to trust the agreement between systems when they also agree on the heat-map explanation by "looking" at the right region of the image when generating an answer.

4.1 Generating Explanations

We use the GradCAM algorithm (Selvaraju et al., 2017) to generate model-specific explanatory heat-maps for each IQ pair. This approach generates a class-discriminative localization-map for a given model based on its respective predicted output class in the following way. First, the gradient of the score y^c for the predicted class c is computed before the softmax layer with respect to the feature maps A^k of a convolutional layer. Then, the gradients flowing back are global average pooled to obtain the neuron importance weights.

$$w_k^c = \overbrace{\frac{1}{Z}\sum_i\sum_j}^{\text{global average pooling}} \underbrace{\frac{\partial y^c}{\partial A_{ij}^k}}_{\text{backprop gradients}}$$

The above weights capture the importance of a convolutional feature map k for the output class c, where Z is the total number of pixels in the feature map. A ReLU over the weighted combination of the feature maps results in the required localization-map for the output class as follows:

$$H^c = ReLU(\sum_k w_k^c A^k)$$

For each of the component VQA models, we generate the localization-map to be used as auxiliary features for ensembling. Figure 3 shows a sample of IQ pairs from the VQA dataset and their respective heat-maps generated for three VQA models.

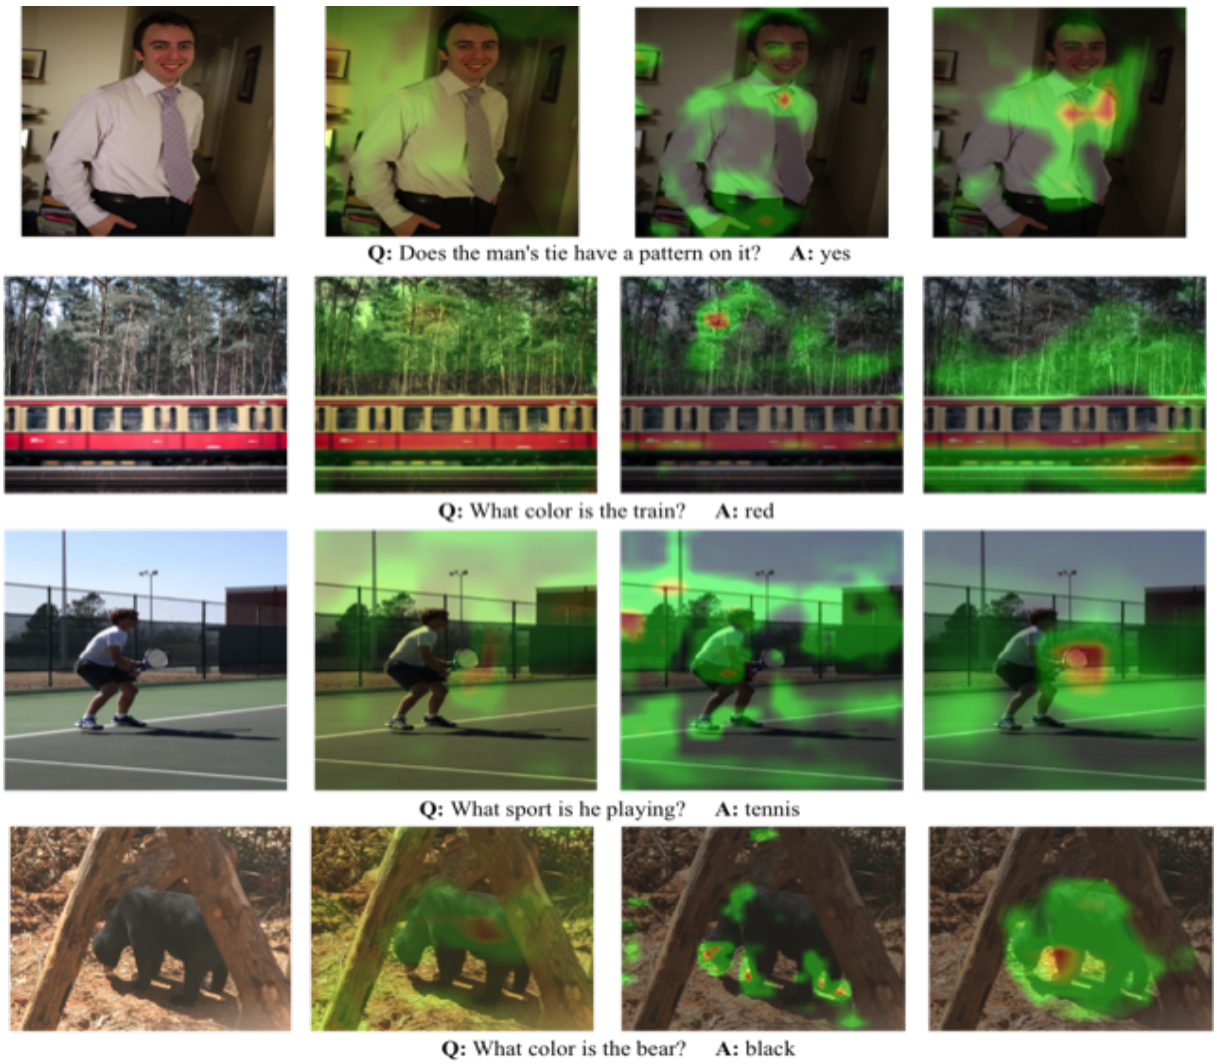

Figure 3: Each row from left to right shows an image-question pair from the VQA dataset along with localization-maps overlaid on the image generated by the LSTM, HieCoAtt and MCB models respectively. The answers shown are those predicted by our ensemble.

4.2 Explanation as Auxiliary Features

The localization-map generated by each VQA model serves as a visual explanation for the predicted output of that model. We compare agreement between the localization-maps of the individual models to generate auxiliary features for SWAF. We take the absolute gray-scale value of the localization-maps in of each model and compute their mean rank-correlation with the localization-map of every other model. We rank the pixels according to their spatial attention and then compute the correlation between the two ranked lists. The rank correlation protocol has been used in the past to compare machine-generated and human attention-maps as described by Das et al. (2016). We also experimented with using the Earth Mover's Distance (EMD) in place of the rank-order correlation metric, as discussed in Section 6. We compare the localization-maps of each pair of VQA models, generating $\binom{n}{2}$ "explanation agreement" auxiliary features for SWAF, where n is the total number of models.

5 Component VQA Systems

We use SWAF to combine three diverse VQA systems such that the final ensemble performs better than any individual component model even on questions with a low agreement. The three component models are trained on the VQA training set. Each of the three models is described below.

5.1 Long Short-Term Memory (LSTM)

The LSTM model (Antol et al., 2015) is one of the original baseline models used to establish a

benchmark for the VQA dataset. A VGGNet (Simonyan and Zisserman, 2015) is used to obtain embeddings for the image which is combined with an LSTM (Hochreiter and Schmidhuber, 1997) embedding of each question. An LSTM with two hidden layers is used to obtain a $2,048$-dimensional embedding of the question, followed by a fully-connected layer with *tanh* non-linearity to transform the embedding to $1,024$ dimensions. The l_2 normalized activations from the last hidden layer of VGGNet are used as a $4,096$ dimensional image embedding. The image embedding is first transformed to $1,024$ dimensions by a fully-connected layer with *tanh* nonlinearity to match the dimensionality of the LSTM embedding of the question. The transformed image and LSTM embeddings are then fused via element-wise multiplication.

5.2 Hierarchical Question-Image Co-Attention (HieCoAtt)

The idea behind the HieCoAtt model is that in addition to using visual attention to focus on where to look, it is equally important to model what words to attend to in the question (question-attention) (Lu et al., 2016). This model jointly reasons about the visual and language components using "co-attention". Question attention is modeled using a hierarchical architecture at word, phrase, and question levels.

HieCoAtt uses two types of co-attention – parallel and alternating. Parallel co-attention attends to the image and question simultaneously by calculating the similarity between image and question features at all pairs of image-locations and question-locations. Alternating co-attention sequentially alternates between generating image and question attention by attending to the image based on the question summary vector and then attending to the question based on the attended image features.

5.3 Multimodal Compact Bilinear pooling (MCB)

The MCB model combines the vision and language vector representations using an outer product instead of the traditional approach of using concatenation or element-wise product or sum of the two vectors (Fukui et al., 2016). Bilinear pooling computes the outer product between two vectors which, in contrast to the element-wise product, allows a multiplicative interaction between all elements of both vectors. To overcome the challenge of high dimensionality due to the outer product, the authors adopt the idea of using Multimodal Compact Bilinear pooling (MCB) (Gao et al., 2016) to efficiently and expressively combine multimodal features.

The MCB model extracts representations for the image using the 152-layer Residual Network (He et al., 2016) and an LSTM (Hochreiter and Schmidhuber, 1997) embedding of the question. The two vector are pooled using MCB and the answer is obtained by treating the problem as a multi-class classification problem with $3,000$ possible classes. The best MCB model is an ensemble of seven attention models and uses data-augmentation for pre-training along with pre-trained GloVe word embeddings. The best MCB model won the VQA 2016 challenge by obtaining the best performance on the test set.

6 Experimental Results and Discussion

We present experimental results on the VQA challenge using the SWAF approach and compare it to various baselines, individual and ensemble VQA models, as well as ablations of our SWAF algorithm on the standard VQA test set. In addition to the three data splits given in Table 1, the VQA challenge divides the test set into *test-dev* and *test-standard*. Evaluation on either split requires submitting the output to the competition's online server.[1] However, there are fewer restrictions on the number of submissions that can be made to the *test-dev* compared to the *test-standard*. The *test-dev* is a subset of the standard test set consisting of randomly selected $60,864$ (25%) questions. We use the *test-dev* set to tune the parameters of the meta-classifier. All the individual VQA models that we ensemble are trained only on the VQA training set and the SWAF meta-classifier is trained on the VQA validation set.

For the meta-classifier, we use a $L1$-regularized SVM classifier for generic stacking and stacking with only question/answer types as auxiliary features. For the question, image, and explanation features, we found that a neural network with two hidden layers works best. The first hidden layer is fully connected and the second has approximately half the number of neurons as the first layer. The question and image features are high-dimensional and therefore a neural network classifier worked

Table 2: Accuracy results on the VQA *test-standard* set. The first block shows performance of a VQA model that use external data for pre-training, the second block shows single system VQA models, the third block shows an ensemble VQA model that also uses external data for pre-training, and the fourth block shows ensemble VQA models.

well. We found that using late fusion (Karpathy et al., 2014) to combine the auxiliary features for the neural network classifier worked slightly better. We used Keras with Tensorflow back-end (Chollet, 2015) for implementing the network. We compare our approach to a voting baseline that returns the answer with maximum agreement, with ties broken in the favor of systems with higher confidence scores. We also compare against other state-of-the-art VQA systems not used in our ensemble: iBowIMG (Zhou et al., 2015), DPPNet (Noh et al., 2016) and the Neural Module Networks (NMNs) (Andreas et al., 2016b).

The iBowIMG concatenates the image features with the bag-of-word question embedding and feeds them into a softmax classifier to predict the answer, resulting in performance comparable to other models that use deep or recursive neural networks. The iBowIMG beats most VQA models considered in their paper. The DPPNet, on the other hand, learns a CNN with some parameters predicted from a separate parameter prediction network. Their parameter prediction network uses a Gated Recurrent Unit (GRU) to generate a question representation and maps the predicted weights to a CNN via hashing. The DPPNet uses external data (data-augmentation) in addition to the VQA dataset to pre-train the GRU. Another well-known VQA model is the Neural Module Network (NMN) that generates a neural network on the fly for each individual image and question. This is done through choosing from various sub-modules based on the question and composing these to generate the neural network, *e.g.*, the `find[x]` module outputs an attention map for detecting `x`. To arrange the modules, the question is first parsed into a symbolic expression and using these expressions, modules are composed into a sequence to answer the query. The whole system is trained end-to-end through backpropagation.

The VQA evaluation server, along with reporting accuracies on the full question set, also reports a break-down of accuracy across three answer categories. The image-question (IQ) pairs that have answer type as "yes/no", those that have "number" as their answer type and finally those that do not belong to either of the first two categories are classified as "other". Table 2 shows the full and category-wise accuracies. All scores for the stacking models were obtained using the VQA *test-standard* server. The table shows results for both single system and ensemble MCB models. We used the single system MCB model as a component in our ensemble. The ensemble MCB system, however, was the top-ranked system in the VQA 2016 challenge and it is pre-trained on the Visual Genome dataset (Krishna et al., 2017) as well as uses pre-trained GloVe vectors (Pennington et al., 2014). On the other hand, our ensemble system does not use any external data and consists

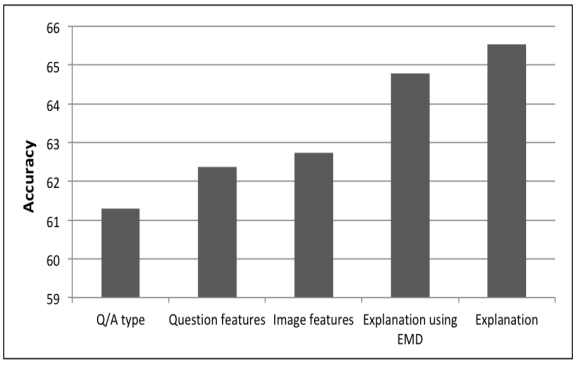

Figure 4: Results for auxiliary feature ablations on the VQA *test-dev* set. The `x-axis` indicates the feature set that was ablated from the final ensemble.

of only three component models.

The SWAF approach obtains a new state-of-the-art result on the VQA task. The vanilla stacking approach itself beats the best *individual* model and adding the auxiliary features further boosts the performance. Our SWAF model that uses all three sets of auxiliary features related to IQ pairs does particularly well on the more difficult "other" answer category, indicating that the auxiliary features provide crucial information at classification time. To further analyze the SWAF results, we performed experiments with ablations of the auxiliary features. Figure 4 shows the results on the *test-dev* set obtained when ablating each of the auxiliary feature sets. We observe that deleting the Q/A type decreased performance the most and deleting the explanation features decreased performance the least. This indicates that the Q/A type features are the most informative and the explanation features are the least informative for deciding the correct answer.

The voting baseline does not perform very well even though it is able to beat one of the component models. The SWAF ablation results clearly indicate that there is an advantage to using each type of auxiliary feature. Each of the auxiliary feature sets contributes to the final ensemble's performance, which is clear from Table 2. The voting and the "vanilla stacking" ensembles do not perform as well as SWAF. This leads us to conclude that the performance gain is actually obtained from using the auxiliary features.

In particular, using explanations generated by various deep learning models as auxiliary features improved performance. We observed that the localization-maps generated were fairly noisy, as is evident from Figure 3. Although the individual component systems agreed on an answer for many of the IQ pairs, the regions of the image they attend to varied significantly. However, the rank correlation metric in the auxiliary features made the localization-maps useful for ensembling. This is because, when training on the validation set, the stacker *learns* how to weight the auxiliary features, including those obtained using localization-maps. In this way, it learns to trust only the localization-maps that are actually useful. We also observed that there was a high positive correlation between the localization-maps generated by the HieCoAtt and MCB models, followed by the LSTM and MCB models, and then the LSTM and HieCoAtt models with several of the maps even negatively correlated between the last two models.

We also experimented with using Earth Mover's Distance (EMD) to compare heat-maps and found that it worked even better than rank-order correlation; however, it came at a cost of high computational complexity ($\mathcal{O}(n^3)$ vs. $\mathcal{O}(n)$). Figure 4 shows the difference in performance obtained when explanation features calculated using either EMD or rank-order correlation are ablated from the final ensemble. Clearly, using EMD to compare explanation maps has more impact on the system's accuracy. Consistent with previous findings (Bylinskii et al., 2018), our results confirm that EMD provides a finer-grained comparison between localization maps. Overall, our work shows that the utility of explanations is not limited to just developing human trust and making models more transparent. Explanations can also be used to improve performance on a challenging task.

7 Conclusions and Future Work

We have presented results for using stacking with auxiliary features (SWAF) to ensemble VQA systems. We proposed four different categories of auxiliary features, three of which can be inferred from an image-question pair. We showed that our model trained on these auxiliary features outperforms the individual component systems as well as other baselines to obtain a new state-of-the-art for VQA. For the fourth category of features, we have proposed and evaluated the novel idea of using explanations to improve ensembling of multiple systems. We demonstrated how visual explanations for VQA (represented as localization-maps) can be used to aid stacking with auxiliary

features. This approach effectively utilizes information on the degree to which systems agree on the *explanation* of their answers. We showed that the combination of all of these categories of auxiliary features, including explanation, gives the best results.

We believe that integrating explanation with ensembling has a two-fold advantage. First, as discussed in this paper, explanations can be used to improve the accuracy of an ensemble. Second, explanations from the component systems could be used to build an explanation for the overall ensemble. That is, by combining multiple component explanations, SWAF could also produce more comprehensible results. Therefore, in the future, we would like to focus on explaining the results of an ensemble. Another issue we plan to explore is using textual explanations (Park et al., 2016) for VQA. We believe that the words in the question to which a system attends can also be used to improve ensembling. Finally, we hope to apply our approach to additional problems beyond VQA.

Abstract

We introduce a new type of *deep contextualized* word representation that models both (1) complex characteristics of word use (e.g., syntax and semantics), and (2) how these uses vary across linguistic contexts (i.e., to model polysemy). Our word vectors are learned functions of the internal states of a deep bidirectional language model (biLM), which is pre-trained on a large text corpus. We show that these representations can be easily added to existing models and significantly improve the state of the art across six challenging NLP problems, including question answering, textual entailment and sentiment analysis. We also present an analysis showing that exposing the deep internals of the pre-trained network is crucial, allowing downstream models to mix different types of semi-supervision signals.

1 Introduction

Pre-trained word representations (Mikolov et al., 2013; Pennington et al., 2014) are a key component in many neural language understanding models. However, learning high quality representations can be challenging. They should ideally model both (1) complex characteristics of word use (e.g., syntax and semantics), and (2) how these uses vary across linguistic contexts (i.e., to model polysemy). In this paper, we introduce a new type of *deep contextualized* word representation that directly addresses both challenges, can be easily integrated into existing models, and significantly improves the state of the art in every considered case across a range of challenging language understanding problems.

Our representations differ from traditional word type embeddings in that each token is assigned a representation that is a function of the entire input sentence. We use vectors derived from a bidirectional LSTM that is trained with a coupled language model (LM) objective on a large text corpus. For this reason, we call them ELMo (Embeddings from Language Models) representations. Unlike previous approaches for learning contextualized word vectors (Peters et al., 2017; McCann et al., 2017), ELMo representations are deep, in the sense that they are a function of all of the internal layers of the biLM. More specifically, we learn a linear combination of the vectors stacked above each input word for each end task, which markedly improves performance over just using the top LSTM layer.

Combining the internal states in this manner allows for very rich word representations. Using intrinsic evaluations, we show that the higher-level LSTM states capture context-dependent aspects of word meaning (e.g., they can be used without modification to perform well on supervised word sense disambiguation tasks) while lower-level states model aspects of syntax (e.g., they can be used to do part-of-speech tagging). Simultaneously exposing all of these signals is highly beneficial, allowing the learned models select the types of semi-supervision that are most useful for each end task.

Extensive experiments demonstrate that ELMo representations work extremely well in practice. We first show that they can be easily added to existing models for six diverse and challenging language understanding problems, including textual entailment, question answering and sentiment analysis. The addition of ELMo representations alone significantly improves the state of the art in every case, including up to 20% relative error reductions. For tasks where direct comparisons are possible, ELMo outperforms CoVe (McCann et al., 2017), which computes contextualized representations using a neural machine translation encoder. Finally, an analysis of both ELMo and CoVe reveals that deep representations outperform

Proceedings of NAACL-HLT 2018, pages 2227–2237
New Orleans, Louisiana, June 1 - 6, 2018.

those derived from just the top layer of an LSTM. Our trained models and code are publicly available, and we expect that ELMo will provide similar gains for many other NLP problems.[1]

2 Related work

Due to their ability to capture syntactic and semantic information of words from large scale unlabeled text, pretrained word vectors (Turian et al., 2010; Mikolov et al., 2013; Pennington et al., 2014) are a standard component of most state-of-the-art NLP architectures, including for question answering (Liu et al., 2017), textual entailment (Chen et al., 2017) and semantic role labeling (He et al., 2017). However, these approaches for learning word vectors only allow a single context-independent representation for each word.

Previously proposed methods overcome some of the shortcomings of traditional word vectors by either enriching them with subword information (e.g., Wieting et al., 2016; Bojanowski et al., 2017) or learning separate vectors for each word sense (e.g., Neelakantan et al., 2014). Our approach also benefits from subword units through the use of character convolutions, and we seamlessly incorporate multi-sense information into downstream tasks without explicitly training to predict predefined sense classes.

Other recent work has also focused on learning context-dependent representations. `context2vec` (Melamud et al., 2016) uses a bidirectional Long Short Term Memory (LSTM; Hochreiter and Schmidhuber, 1997) to encode the context around a pivot word. Other approaches for learning contextual embeddings include the pivot word itself in the representation and are computed with the encoder of either a supervised neural machine translation (MT) system (CoVe; McCann et al., 2017) or an unsupervised language model (Peters et al., 2017). Both of these approaches benefit from large datasets, although the MT approach is limited by the size of parallel corpora. In this paper, we take full advantage of access to plentiful monolingual data, and train our biLM on a corpus with approximately 30 million sentences (Chelba et al., 2014). We also generalize these approaches to deep contextual representations, which we show work well across a broad range of diverse NLP tasks.

[1] `http://allennlp.org/elmo`

Previous work has also shown that different layers of deep biRNNs encode different types of information. For example, introducing multi-task syntactic supervision (e.g., part-of-speech tags) at the lower levels of a deep LSTM can improve overall performance of higher level tasks such as dependency parsing (Hashimoto et al., 2017) or CCG super tagging (Søgaard and Goldberg, 2016). In an RNN-based encoder-decoder machine translation system, Belinkov et al. (2017) showed that the representations learned at the first layer in a 2-layer LSTM encoder are better at predicting POS tags then second layer. Finally, the top layer of an LSTM for encoding word context (Melamud et al., 2016) has been shown to learn representations of word sense. We show that similar signals are also induced by the modified language model objective of our ELMo representations, and it can be very beneficial to learn models for downstream tasks that mix these different types of semi-supervision.

Dai and Le (2015) and Ramachandran et al. (2017) pretrain encoder-decoder pairs using language models and sequence autoencoders and then fine tune with task specific supervision. In contrast, after pretraining the biLM with unlabeled data, we fix the weights and add additional task-specific model capacity, allowing us to leverage large, rich and universal biLM representations for cases where downstream training data size dictates a smaller supervised model.

3 ELMo: Embeddings from Language Models

Unlike most widely used word embeddings (Pennington et al., 2014), ELMo word representations are functions of the entire input sentence, as described in this section. They are computed on top of two-layer biLMs with character convolutions (Sec. 3.1), as a linear function of the internal network states (Sec. 3.2). This setup allows us to do semi-supervised learning, where the biLM is pretrained at a large scale (Sec. 3.4) and easily incorporated into a wide range of existing neural NLP architectures (Sec. 3.3).

3.1 Bidirectional language models

Given a sequence of N tokens, $(t_1, t_2, ..., t_N)$, a forward language model computes the probability of the sequence by modeling the probability of to-

ken t_k given the history $(t_1, ..., t_{k-1})$:

$$p(t_1, t_2, \ldots, t_N) = \prod_{k=1}^{N} p(t_k \mid t_1, t_2, \ldots, t_{k-1}).$$

Recent state-of-the-art neural language models (Józefowicz et al., 2016; Melis et al., 2017; Merity et al., 2017) compute a context-independent token representation $\mathbf{x}_k^{LM}$ (via token embeddings or a CNN over characters) then pass it through L layers of forward LSTMs. At each position k, each LSTM layer outputs a context-dependent representation $\overrightarrow{\mathbf{h}}_{k,j}^{LM}$ where $j = 1, \ldots, L$. The top layer LSTM output, $\overrightarrow{\mathbf{h}}_{k,L}^{LM}$, is used to predict the next token t_{k+1} with a Softmax layer.

A backward LM is similar to a forward LM, except it runs over the sequence in reverse, predicting the previous token given the future context:

$$p(t_1, t_2, \ldots, t_N) = \prod_{k=1}^{N} p(t_k \mid t_{k+1}, t_{k+2}, \ldots, t_N).$$

It can be implemented in an analogous way to a forward LM, with each backward LSTM layer j in a L layer deep model producing representations $\overleftarrow{\mathbf{h}}_{k,j}^{LM}$ of t_k given $(t_{k+1}, \ldots, t_N)$.

A biLM combines both a forward and backward LM. Our formulation jointly maximizes the log likelihood of the forward and backward directions:

$$\sum_{k=1}^{N} \Big(\log p(t_k \mid t_1, \ldots, t_{k-1}; \Theta_x, \overrightarrow{\Theta}_{LSTM}, \Theta_s) + \log p(t_k \mid t_{k+1}, \ldots, t_N; \Theta_x, \overleftarrow{\Theta}_{LSTM}, \Theta_s) \Big).$$

We tie the parameters for both the token representation (Θ_x) and Softmax layer (Θ_s) in the forward and backward direction while maintaining separate parameters for the LSTMs in each direction. Overall, this formulation is similar to the approach of Peters et al. (2017), with the exception that we share some weights between directions instead of using completely independent parameters. In the next section, we depart from previous work by introducing a new approach for learning word representations that are a linear combination of the biLM layers.

3.2 ELMo

ELMo is a task specific combination of the intermediate layer representations in the biLM. For each token t_k, a L-layer biLM computes a set of $2L + 1$ representations

$$\begin{aligned} R_k &= \{\mathbf{x}_k^{LM}, \overrightarrow{\mathbf{h}}_{k,j}^{LM}, \overleftarrow{\mathbf{h}}_{k,j}^{LM} \mid j = 1, \ldots, L\} \\ &= \{\mathbf{h}_{k,j}^{LM} \mid j = 0, \ldots, L\}, \end{aligned}$$

where $\mathbf{h}_{k,0}^{LM}$ is the token layer and $\mathbf{h}_{k,j}^{LM} = [\overrightarrow{\mathbf{h}}_{k,j}^{LM}; \overleftarrow{\mathbf{h}}_{k,j}^{LM}]$, for each biLSTM layer.

For inclusion in a downstream model, ELMo collapses all layers in R into a single vector, $\mathbf{ELMo}_k = E(R_k; \mathbf{\Theta}_e)$. In the simplest case, ELMo just selects the top layer, $E(R_k) = \mathbf{h}_{k,L}^{LM}$, as in TagLM (Peters et al., 2017) and CoVe (McCann et al., 2017). More generally, we compute a task specific weighting of all biLM layers:

$$\mathbf{ELMo}_k^{task} = E(R_k; \Theta^{task}) = \gamma^{task} \sum_{j=0}^{L} s_j^{task} \mathbf{h}_{k,j}^{LM}. \quad (1)$$

In (1), $\mathbf{s}^{task}$ are softmax-normalized weights and the scalar parameter γ^{task} allows the task model to scale the entire ELMo vector. γ is of practical importance to aid the optimization process (see supplemental material for details). Considering that the activations of each biLM layer have a different distribution, in some cases it also helped to apply layer normalization (Ba et al., 2016) to each biLM layer before weighting.

3.3 Using biLMs for supervised NLP tasks

Given a pre-trained biLM and a supervised architecture for a target NLP task, it is a simple process to use the biLM to improve the task model. We simply run the biLM and record all of the layer representations for each word. Then, we let the end task model learn a linear combination of these representations, as described below.

First consider the lowest layers of the supervised model without the biLM. Most supervised NLP models share a common architecture at the lowest layers, allowing us to add ELMo in a consistent, unified manner. Given a sequence of tokens $(t_1, \ldots, t_N)$, it is standard to form a context-independent token representation $\mathbf{x}_k$ for each token position using pre-trained word embeddings and optionally character-based representations. Then, the model forms a context-sensitive representation $\mathbf{h}_k$, typically using either bidirectional RNNs, CNNs, or feed forward networks.

To add ELMo to the supervised model, we first freeze the weights of the biLM and then

concatenate the ELMo vector $\mathbf{ELMo}_k^{task}$ with $\mathbf{x}_k$ and pass the ELMo enhanced representation $[\mathbf{x}_k; \mathbf{ELMo}_k^{task}]$ into the task RNN. For some tasks (e.g., SNLI, SQuAD), we observe further improvements by also including ELMo at the output of the task RNN by introducing another set of output specific linear weights and replacing $\mathbf{h}_k$ with $[\mathbf{h}_k; \mathbf{ELMo}_k^{task}]$. As the remainder of the supervised model remains unchanged, these additions can happen within the context of more complex neural models. For example, see the SNLI experiments in Sec. 4 where a bi-attention layer follows the biLSTMs, or the coreference resolution experiments where a clustering model is layered on top of the biLSTMs.

Finally, we found it beneficial to add a moderate amount of dropout to ELMo (Srivastava et al., 2014) and in some cases to regularize the ELMo weights by adding $\lambda\|\mathbf{w}\|_2^2$ to the loss. This imposes an inductive bias on the ELMo weights to stay close to an average of all biLM layers.

3.4 Pre-trained bidirectional language model architecture

The pre-trained biLMs in this paper are similar to the architectures in Józefowicz et al. (2016) and Kim et al. (2015), but modified to support joint training of both directions and add a residual connection between LSTM layers. We focus on large scale biLMs in this work, as Peters et al. (2017) highlighted the importance of using biLMs over forward-only LMs and large scale training.

To balance overall language model perplexity with model size and computational requirements for downstream tasks while maintaining a purely character-based input representation, we halved all embedding and hidden dimensions from the single best model `CNN-BIG-LSTM` in Józefowicz et al. (2016). The final model uses $L = 2$ biLSTM layers with 4096 units and 512 dimension projections and a residual connection from the first to second layer. The context insensitive type representation uses 2048 character n-gram convolutional filters followed by two highway layers (Srivastava et al., 2015) and a linear projection down to a 512 representation. As a result, the biLM provides three layers of representations for each input token, including those outside the training set due to the purely character input. In contrast, traditional word embedding methods only provide one layer of representation for tokens in a fixed vocabulary.

After training for 10 epochs on the 1B Word Benchmark (Chelba et al., 2014), the average forward and backward perplexities is 39.7, compared to 30.0 for the forward `CNN-BIG-LSTM`. Generally, we found the forward and backward perplexities to be approximately equal, with the backward value slightly lower.

Once pretrained, the biLM can compute representations for any task. In some cases, fine tuning the biLM on domain specific data leads to significant drops in perplexity and an increase in downstream task performance. This can be seen as a type of domain transfer for the biLM. As a result, in most cases we used a fine-tuned biLM in the downstream task. See supplemental material for details.

4 Evaluation

Table 1 shows the performance of ELMo across a diverse set of six benchmark NLP tasks. In every task considered, simply adding ELMo establishes a new state-of-the-art result, with relative error reductions ranging from 6 - 20% over strong base models. This is a very general result across a diverse set model architectures and language understanding tasks. In the remainder of this section we provide high-level sketches of the individual task results; see the supplemental material for full experimental details.

Question answering The Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) contains 100K+ crowd sourced question-answer pairs where the answer is a span in a given Wikipedia paragraph. Our baseline model (Clark and Gardner, 2017) is an improved version of the Bidirectional Attention Flow model in Seo et al. (BiDAF; 2017). It adds a self-attention layer after the bidirectional attention component, simplifies some of the pooling operations and substitutes the LSTMs for gated recurrent units (GRUs; Cho et al., 2014). After adding ELMo to the baseline model, test set F_1 improved by 4.7% from 81.1% to 85.8%, a 24.9% relative error reduction over the baseline, and improving the overall single model state-of-the-art by 1.4%. A 11 member ensemble pushes F_1 to 87.4, the overall state-of-the-art at time of submission to the leaderboard.[2] The increase of 4.7% with ELMo is also significantly larger then the 1.8% improvement from adding CoVe to a baseline model (McCann et al., 2017).

[2] As of November 17, 2017.

TASK	PREVIOUS SOTA		OUR BASELINE	ELMO + BASELINE	INCREASE (ABSOLUTE/ RELATIVE)
SQuAD	Liu et al. (2017)	84.4	81.1	85.8	4.7 / 24.9%
SNLI	Chen et al. (2017)	88.6	88.0	88.7 ± 0.17	0.7 / 5.8%
SRL	He et al. (2017)	81.7	81.4	84.6	3.2 / 17.2%
Coref	Lee et al. (2017)	67.2	67.2	70.4	3.2 / 9.8%
NER	Peters et al. (2017)	91.93 ± 0.19	90.15	92.22 ± 0.10	2.06 / 21%
SST-5	McCann et al. (2017)	53.7	51.4	54.7 ± 0.5	3.3 / 6.8%

Table 1: Test set comparison of ELMo enhanced neural models with state-of-the-art single model baselines across six benchmark NLP tasks. The performance metric varies across tasks – accuracy for SNLI and SST-5; F_1 for SQuAD, SRL and NER; average F_1 for Coref. Due to the small test sizes for NER and SST-5, we report the mean and standard deviation across five runs with different random seeds. The "increase" column lists both the absolute and relative improvements over our baseline.

Textual entailment Textual entailment is the task of determining whether a "hypothesis" is true, given a "premise". The Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) provides approximately 550K hypothesis/premise pairs. Our baseline, the ESIM sequence model from Chen et al. (2017), uses a biLSTM to encode the premise and hypothesis, followed by a matrix attention layer, a local inference layer, another biLSTM inference composition layer, and finally a pooling operation before the output layer. Overall, adding ELMo to the ESIM model improves accuracy by an average of 0.7% across five random seeds. A five member ensemble pushes the overall accuracy to 89.3%, exceeding the previous ensemble best of 88.9% (Gong et al., 2018).

Semantic role labeling A semantic role labeling (SRL) system models the predicate-argument structure of a sentence, and is often described as answering "Who did what to whom". He et al. (2017) modeled SRL as a BIO tagging problem and used an 8-layer deep biLSTM with forward and backward directions interleaved, following Zhou and Xu (2015). As shown in Table 1, when adding ELMo to a re-implementation of He et al. (2017) the single model test set F_1 jumped 3.2% from 81.4% to 84.6% – a new state-of-the-art on the OntoNotes benchmark (Pradhan et al., 2013), even improving over the previous best ensemble result by 1.2%.

Coreference resolution Coreference resolution is the task of clustering mentions in text that refer to the same underlying real world entities. Our baseline model is the end-to-end span-based neural model of Lee et al. (2017). It uses a biLSTM and attention mechanism to first compute span representations and then applies a softmax mention ranking model to find coreference chains. In our experiments with the OntoNotes coreference annotations from the CoNLL 2012 shared task (Pradhan et al., 2012), adding ELMo improved the average F_1 by 3.2% from 67.2 to 70.4, establishing a new state of the art, again improving over the previous best ensemble result by 1.6% F_1.

Named entity extraction The CoNLL 2003 NER task (Sang and Meulder, 2003) consists of newswire from the Reuters RCV1 corpus tagged with four different entity types (`PER`, `LOC`, `ORG`, `MISC`). Following recent state-of-the-art systems (Lample et al., 2016; Peters et al., 2017), the baseline model uses pre-trained word embeddings, a character-based CNN representation, two biLSTM layers and a conditional random field (CRF) loss (Lafferty et al., 2001), similar to Collobert et al. (2011). As shown in Table 1, our ELMo enhanced biLSTM-CRF achieves 92.22% F_1 averaged over five runs. The key difference between our system and the previous state of the art from Peters et al. (2017) is that we allowed the task model to learn a weighted average of all biLM layers, whereas Peters et al. (2017) only use the top biLM layer. As shown in Sec. 5.1, using all layers instead of just the last layer improves performance across multiple tasks.

Sentiment analysis The fine-grained sentiment classification task in the Stanford Sentiment Treebank (SST-5; Socher et al., 2013) involves selecting one of five labels (from very negative to very positive) to describe a sentence from a movie review. The sentences contain diverse linguistic phenomena such as idioms and complex syntac-

Task	Baseline	Last Only	All layers	
			λ=1	λ=0.001
SQuAD	80.8	84.7	85.0	**85.2**
SNLI	88.1	89.1	89.3	**89.5**
SRL	81.6	84.1	84.6	**84.8**

Table 2: Development set performance for SQuAD, SNLI and SRL comparing using all layers of the biLM (with different choices of regularization strength λ) to just the top layer.

Task	Input Only	Input & Output	Output Only
SQuAD	85.1	**85.6**	84.8
SNLI	88.9	**89.5**	88.7
SRL	**84.7**	84.3	80.9

Table 3: Development set performance for SQuAD, SNLI and SRL when including ELMo at different locations in the supervised model.

tic constructions such as negations that are difficult for models to learn. Our baseline model is the biattentive classification network (BCN) from McCann et al. (2017), which also held the prior state-of-the-art result when augmented with CoVe embeddings. Replacing CoVe with ELMo in the BCN model results in a 1.0% absolute accuracy improvement over the state of the art.

5 Analysis

This section provides an ablation analysis to validate our chief claims and to elucidate some interesting aspects of ELMo representations. Sec. 5.1 shows that using deep contextual representations in downstream tasks improves performance over previous work that uses just the top layer, regardless of whether they are produced from a biLM or MT encoder, and that ELMo representations provide the best overall performance. Sec. 5.3 explores the different types of contextual information captured in biLMs and uses two intrinsic evaluations to show that syntactic information is better represented at lower layers while semantic information is captured a higher layers, consistent with MT encoders. It also shows that our biLM consistently provides richer representations then CoVe. Additionally, we analyze the sensitivity to where ELMo is included in the task model (Sec. 5.2), training set size (Sec. 5.4), and visualize the ELMo learned weights across the tasks (Sec. 5.5).

5.1 Alternate layer weighting schemes

There are many alternatives to Equation 1 for combining the biLM layers. Previous work on contextual representations used only the last layer, whether it be from a biLM (Peters et al., 2017) or an MT encoder (CoVe; McCann et al., 2017). The choice of the regularization parameter λ is also important, as large values such as $\lambda = 1$ effectively reduce the weighting function to a simple average over the layers, while smaller values (e.g., $\lambda = 0.001$) allow the layer weights to vary.

Table 2 compares these alternatives for SQuAD, SNLI and SRL. Including representations from all layers improves overall performance over just using the last layer, and including contextual representations from the last layer improves performance over the baseline. For example, in the case of SQuAD, using just the last biLM layer improves development F_1 by 3.9% over the baseline. Averaging all biLM layers instead of using just the last layer improves F_1 another 0.3% (comparing "Last Only" to λ=1 columns), and allowing the task model to learn individual layer weights improves F_1 another 0.2% (λ=1 vs. λ=0.001). A small λ is preferred in most cases with ELMo, although for NER, a task with a smaller training set, the results are insensitive to λ (not shown).

The overall trend is similar with CoVe but with smaller increases over the baseline. For SNLI, averaging all layers with λ=1 improves development accuracy from 88.2 to 88.7% over using just the last layer. SRL F_1 increased a marginal 0.1% to 82.2 for the λ=1 case compared to using the last layer only.

5.2 Where to include ELMo?

All of the task architectures in this paper include word embeddings only as input to the lowest layer biRNN. However, we find that including ELMo at the output of the biRNN in task-specific architectures improves overall results for some tasks. As shown in Table 3, including ELMo at both the input and output layers for SNLI and SQuAD improves over just the input layer, but for SRL (and coreference resolution, not shown) performance is highest when it is included at just the input layer. One possible explanation for this result is that both the SNLI and SQuAD architectures use attention layers after the biRNN, so introducing ELMo at this layer allows the model to attend directly to the biLM's internal representations. In the SRL case,

	Source	Nearest Neighbors
GloVe	play	playing, game, games, played, players, plays, player, Play, football, multiplayer
biLM	Chico Ruiz made a spectacular play on Alusik 's grounder {...}	Kieffer , the only junior in the group , was commended for his ability to hit in the clutch , as well as his all-round excellent play .
	Olivia De Havilland signed to do a Broadway play for Garson {...}	{...} they were actors who had been handed fat roles in a successful play , and had talent enough to fill the roles competently , with nice understatement .

Table 4: Nearest neighbors to "play" using GloVe and the context embeddings from a biLM.

Model	**F_1**
WordNet 1st Sense Baseline	65.9
Raganato et al. (2017a)	69.9
Iacobacci et al. (2016)	**70.1**
CoVe, First Layer	59.4
CoVe, Second Layer	*64.7*
biLM, First layer	67.4
biLM, Second layer	*69.0*

Table 5: All-words fine grained WSD F_1. For CoVe and the biLM, we report scores for both the first and second layer biLSTMs.

Model	**Acc.**
Collobert et al. (2011)	97.3
Ma and Hovy (2016)	97.6
Ling et al. (2015)	**97.8**
CoVe, First Layer	*93.3*
CoVe, Second Layer	92.8
biLM, First Layer	*97.3*
biLM, Second Layer	96.8

Table 6: Test set POS tagging accuracies for PTB. For CoVe and the biLM, we report scores for both the first and second layer biLSTMs.

the task-specific context representations are likely more important than those from the biLM.

5.3 What information is captured by the biLM's representations?

Since adding ELMo improves task performance over word vectors alone, the biLM's contextual representations must encode information generally useful for NLP tasks that is not captured in word vectors. Intuitively, the biLM must be disambiguating the meaning of words using their context. Consider "play", a highly polysemous word. The top of Table 4 lists nearest neighbors to "play" using GloVe vectors. They are spread across several parts of speech (e.g., "played", "playing" as verbs, and "player", "game" as nouns) but concentrated in the sports-related senses of "play". In contrast, the bottom two rows show nearest neighbor sentences from the SemCor dataset (see below) using the biLM's context representation of "play" in the source sentence. In these cases, the biLM is able to disambiguate both the part of speech and word sense in the source sentence.

These observations can be quantified using an intrinsic evaluation of the contextual representations similar to Belinkov et al. (2017). To isolate the information encoded by the biLM, the representations are used to directly make predictions for a fine grained word sense disambiguation (WSD) task and a POS tagging task. Using this approach, it is also possible to compare to CoVe, and across each of the individual layers.

Word sense disambiguation Given a sentence, we can use the biLM representations to predict the sense of a target word using a simple 1-nearest neighbor approach, similar to Melamud et al. (2016). To do so, we first use the biLM to compute representations for all words in SemCor 3.0, our training corpus (Miller et al., 1994), and then take the average representation for each sense. At test time, we again use the biLM to compute representations for a given target word and take the nearest neighbor sense from the training set, falling back to the first sense from WordNet for lemmas not observed during training.

Table 5 compares WSD results using the evaluation framework from Raganato et al. (2017b) across the same suite of four test sets in Raganato et al. (2017a). Overall, the biLM top layer rep-

resentations have F_1 of 69.0 and are better at WSD then the first layer. This is competitive with a state-of-the-art WSD-specific supervised model using hand crafted features (Iacobacci et al., 2016) and a task specific biLSTM that is also trained with auxiliary coarse-grained semantic labels and POS tags (Raganato et al., 2017a). The CoVe biLSTM layers follow a similar pattern to those from the biLM (higher overall performance at the second layer compared to the first); however, our biLM outperforms the CoVe biLSTM, which trails the WordNet first sense baseline.

POS tagging To examine whether the biLM captures basic syntax, we used the context representations as input to a linear classifier that predicts POS tags with the Wall Street Journal portion of the Penn Treebank (PTB) (Marcus et al., 1993). As the linear classifier adds only a small amount of model capacity, this is direct test of the biLM's representations. Similar to WSD, the biLM representations are competitive with carefully tuned, task specific biLSTMs (Ling et al., 2015; Ma and Hovy, 2016). However, unlike WSD, accuracies using the first biLM layer are higher than the top layer, consistent with results from deep biLSTMs in multi-task training (Søgaard and Goldberg, 2016; Hashimoto et al., 2017) and MT (Belinkov et al., 2017). CoVe POS tagging accuracies follow the same pattern as those from the biLM, and just like for WSD, the biLM achieves higher accuracies than the CoVe encoder.

Implications for supervised tasks Taken together, these experiments confirm different layers in the biLM represent different types of information and explain why including all biLM layers is important for the highest performance in downstream tasks. In addition, the biLM's representations are more transferable to WSD and POS tagging than those in CoVe, helping to illustrate why ELMo outperforms CoVe in downstream tasks.

5.4 Sample efficiency

Adding ELMo to a model increases the sample efficiency considerably, both in terms of number of parameter updates to reach state-of-the-art performance and the overall training set size. For example, the SRL model reaches a maximum development F_1 after 486 epochs of training without ELMo. After adding ELMo, the model exceeds the baseline maximum at epoch 10, a 98% relative decrease in the number of updates needed to reach the same level of performance.

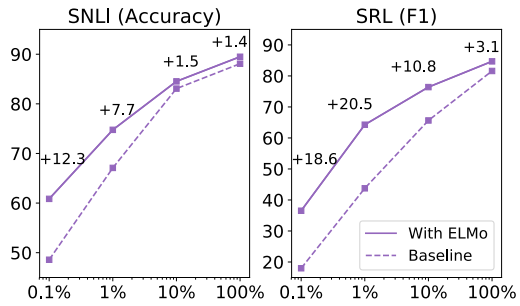

Figure 1: Comparison of baseline vs. ELMo performance for SNLI and SRL as the training set size is varied from 0.1% to 100%.

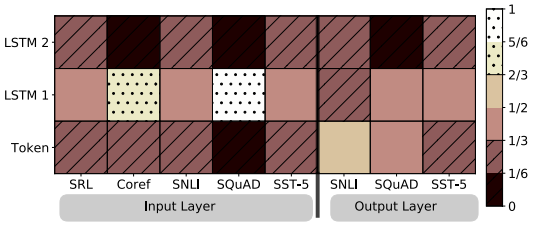

Figure 2: Visualization of softmax normalized biLM layer weights across tasks and ELMo locations. Normalized weights less then $1/3$ are hatched with horizontal lines and those greater then $2/3$ are speckled.

In addition, ELMo-enhanced models use smaller training sets more efficiently than models without ELMo. Figure 1 compares the performance of baselines models with and without ELMo as the percentage of the full training set is varied from 0.1% to 100%. Improvements with ELMo are largest for smaller training sets and significantly reduce the amount of training data needed to reach a given level of performance. In the SRL case, the ELMo model with 1% of the training set has about the same F_1 as the baseline model with 10% of the training set.

5.5 Visualization of learned weights

Figure 2 visualizes the softmax-normalized learned layer weights. At the input layer, the task model favors the first biLSTM layer. For coreference and SQuAD, the this is strongly favored, but the distribution is less peaked for the other tasks. The output layer weights are relatively balanced, with a slight preference for the lower layers.

Task	GloVe	ELMo type	ELMo	ELMo + GloVe
SQuAD	80.8	81.4	85.3	85.6
SNLI	88.1	88.5	89.1	89.5
SRL	81.6	81.7	84.5	84.7

Table 7: Development set ablation analysis for SQuAD, SNLI and SRL comparing different choices for the context-independent type representation and contextual representation. From left to right, the table compares systems with only GloVe vectors; only the ELMo context-independent type representation without the ELMo biLSTM layers; full ELMo representations without GloVe; both GloVe and ELMo.

5.6 Contextual vs. sub-word information

In addition to the contextual information captured in the biLM's biLSTM layers, ELMo representations also contain sub-word information in the fully character based context insensitive type layer, x_k^{LM}. To analyze the relative contribution of the contextual information compared to the sub-word information, we ran an additional ablation that replaced the GloVe vectors with just the biLM character based x_k^{LM} layer without the biLM biLSTM layers. Table 7 summarizes the results for SQuAD, SNLI and SNLI. Replacing the GloVe vectors with the biLM character layer gives a slight improvement for all tasks (e.g. from 80.8 to 81.4 F_1 for SQuAD), but overall the improvements are small compared to the full ELMo model. From this, we conclude that most of the gains in the downstream tasks are due to the contextual information and not the sub-word information.

5.7 Are pre-trained vectors necessary with ELMo?

All of the results presented in Sec.4 include pre-trained word vectors in addition to ELMo representations. However, it is natural to ask whether pre-trained vectors are still necessary with high quality contextualized representations. As shown in the two right hand columns of Table 7, adding GloVe to models with ELMo generally provides a marginal improvement over ELMo only models (e.g. 0.2% F_1 improvement for SRL from 84.5 to 84.7).

6 Conclusion

We have introduced a general approach for learning high-quality deep context-dependent representations from biLMs, and shown large improvements when applying ELMo to a broad range of NLP tasks. Through ablations and other controlled experiments, we have also confirmed that the biLM layers efficiently encode different types of syntactic and semantic information about words-in-context, and that using all layers improves overall task performance.

Abstract

We propose a context-dependent model to map utterances within an interaction to executable formal queries. To incorporate interaction history, the model maintains an interaction-level encoder that updates after each turn, and can copy sub-sequences of previously predicted queries during generation. Our approach combines implicit and explicit modeling of references between utterances. We evaluate our model on the ATIS flight planning interactions, and demonstrate the benefits of modeling context and explicit references.

1 Introduction

The meaning of conversational utterances depends strongly on the history of the interaction. Consider a user querying a flight database using natural language (Figure 1). Given a user utterance, the system must generate a query, execute it, and display results to the user, who then provides the next request. Key to correctly mapping utterances to executable queries is resolving references. For example, the second utterance implicitly depends on the first, and the reference *ones* in the third utterance explicitly refers to the response to the second utterance. Within an interactive system, this information needs to be composed with mentions of database entries (e.g., *Seattle*, *next Monday*) to generate a formal executable representation. In this paper, we propose encoder-decoder models that directly map user utterances to executable queries, while considering the history of the interaction, including both previous utterances and their generated queries.

Reasoning about how the meaning of an utterance depends on the history of the interaction is critical to correctly respond to user requests. As interactions progress, users may omit previously-mentioned constraints and entities, and an increasing portion of the utterance meaning must be derived from the interaction history. Figure 2 shows SQL queries for the utterances in Figure 1. As the interaction progresses, the majority of the generated query is derived from the interaction history (underlined), rather than from the current utterance. A key challenge is resolving what past information is incorporated and how. For example, in the figure, the second utterance depends on the set of flights defined by the first, while adding a new constraint. The third utterance further refines this set by adding a constraint to the constraints from both previous utterances. In contrast, the fourth utterance refers only to the first one, and skips the two utterances in between.[1] Correctly generating the fourth query requires understanding that the time constraint (*at 7pm*) can be ignored as it follows an airline constraint that has been replaced.

Figure 1: An excerpt of an interaction from the ATIS flight planning system (Hemphill et al., 1990; Dahl et al., 1994). Each request is followed by a description of the system response.

We study complementary methods to enable this type of reasoning. The first set of methods implicitly reason about references by modifying the encoder-decoder architecture to encode information from previous utterances for generation decisions. We experiment with attending over previous utterances and using an interaction-level recurrent encoder. We also study explicitly maintaining a set of referents using segments from pre-

[1] An alternative explanation is that utterance four refers to utterance three, and deletes the time and airline constraints.

Figure 2: Annotated SQL queries ($\bar{y}_1$,...,$\bar{y}_4$) in the ATIS (Hemphill et al., 1990) domain for utterances ($\bar{x}_1$,...,$\bar{x}_4$) from Figure 1. Underlining (not part of the annotation) indicates segments originating from the interaction context.

vious queries. At each step, the decoder chooses whether to output a token or select a segment from the set, which is appended to the output in a single decoding step. In addition to enabling references to previously mentioned entities, sets, and constraints, this method also reduces the number of generation steps required, illustrated by the underlined segments in Figure 2. For example, the query $\bar{y}_2$ will require 17 steps instead of 94.

We evaluate our approach using the ATIS (Hemphill et al., 1990; Dahl et al., 1994) task, where a user interacts with a SQL flight database using natural language requests, and almost all queries require joins across multiple tables. In addition to reasoning about contextual phenomena, we design our system to effectively resolve database values, including resolution of time expressions (e.g., *next monday* in Figure 1) using an existing semantic parser. Our evaluation shows that reasoning about the history of the interaction is necessary, relatively increasing performance by 28.6% over a baseline with no access to this information, and that combining the implicit and explicit methods provides the best performance. Furthermore, our analysis shows that our full approach maintains its performance as interaction length increases, while the performance of systems without explicit modeling deteriorates. Our code is available at https://github.com/clic-lab/atis.

2 Technical Overview

Our goal is to map utterances in interactions to formal executable queries. We evaluate our approach with the ATIS corpus (Hemphill et al., 1990; Dahl et al., 1994), where users query a realistic flight planning system using natural language. The system responds by displaying tables and database entries. User utterances are mapped to SQL to query a complex database with 27 tables and 162K entries. 96.6% of the queries require joins of different tables. Section 7 describes ATIS.

Task Notation Let $\mathcal{I}$ be the set of all interactions, $\mathcal{X}$ the set of all utterances, and $\mathcal{Y}$ the set of all formal queries. A user utterance $\bar{x} \in \mathcal{X}$ of length $|\bar{x}|$ is a sequence $\langle x_1, \ldots, x_{|\bar{x}|} \rangle$, where each x_i is a natural language token. A formal query $\bar{y} \in \mathcal{Y}$ of length $|\bar{y}|$ is a sequence $\langle y_1, \ldots, y_{|\bar{y}|} \rangle$, where each y_i is a formal query token. An interaction $\bar{I} \in \mathcal{I}$ is a sequence of n utterance-query pairs $\langle (\bar{x}_1, \bar{y}_1), \ldots, (\bar{x}_n, \bar{y}_n) \rangle$ representing an interaction with n turns. To refer to indexed interactions and their content, we mark $\bar{I}^{(l)}$ as an interaction with index l, the i-th utterance and query in $\bar{I}^{(l)}$ as $\bar{x}_i^{(l)}$ and $\bar{y}_i^{(l)}$, and the j-th tokens in $\bar{x}_i^{(l)}$ and $\bar{y}_i^{(l)}$ as $x_{i,j}^{(l)}$ and $y_{i,j}^{(l)}$. At turn i, we denote the interaction history of length $i-1$ as $\bar{I}[:i-1] = \langle (\bar{x}_1, \bar{y}_1), \ldots, (\bar{x}_{i-1}, \bar{y}_{i-1}) \rangle$. Given $\bar{I}[:i-1]$ and utterance $\bar{x}_i$ our goal is to generate $\bar{y}_i$, while considering both $\bar{x}_i$ and $\bar{I}[:i-1]$. Following the ex-

ecution of $\bar{y}_i$, the interaction history at turn $i+1$ becomes $\bar{I}[:i] = \langle (\bar{x}_1, \bar{y}_1), \ldots, (\bar{x}_i, \bar{y}_i) \rangle$.

Model Our model is based on the recurrent neural network (RNN; Elman, 1990) encoder-decoder framework with attention (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015). We modify the model in three ways to reason about context from the interaction history by attending over previous utterances (Section 4.2), adding a turn-level recurrent encoder that updates after each turn (Section 4.3), and adding a mechanism to copy segments of queries from previous utterances (Section 4.4). We also design a scoring function to score values that are abstracted during pre-processing, including entities and times (Section 6). The full model selects between generating query tokens and copying complete segments from previous queries.

Learning We assume access to a training set that contains N interactions $\{\bar{I}^{(l)}\}_{l=1}^{N}$. We train using a token-level cross-entropy objective (Section 5). For models that use the turn-level encoder, we construct computational graphs for the entire interaction and back-propagate the loss for all queries together. Without the turn-level encoder, each utterance is processed separately.

Evaluation We evaluate using a test set $\{\bar{I}^{(l)}\}_{l=1}^{M}$ of M interactions. We measure the accuracy of each utterance for each test interaction against the annotated query and its execution result. For models that copy segments from previous queries, we evaluate using both predicted and gold previous queries.

3 Related Work

Mapping sentences to formal representations, commonly known as semantic parsing, has been studied extensively with linguistically-motivated compositional representations, including variable-free logic (e.g., Zelle and Mooney, 1996; Clarke et al., 2010), lambda calculus (e.g., Zettlemoyer and Collins, 2005; Artzi and Zettlemoyer, 2011; Kushman and Barzilay, 2013), and dependency-based compositional semantics (e.g., Liang et al., 2011; Berant et al., 2013). Recovering lambda-calculus representations was also studied with ATIS with focus on context-independent meaning using grammar-based approaches (Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011; Wang et al., 2014) and neural networks (Dong and Lapata, 2016; Jia and Liang, 2016).

Recovering context-independent executable representations has been receiving increasing attention. Mapping sentence in isolation to SQL queries has been studied with ATIS using statistical parsing (Popescu et al., 2004; Poon, 2013) and sequence-to-sequence models (Iyer et al., 2017). Generating executable programs was studied with other domains and formal languages (Giordani and Moschitti, 2012; Ling et al., 2016; Zhong et al., 2017; Xu et al., 2017). Recently, various approaches were proposed to use the formal language syntax to constrain the search space (Yin and Neubig, 2017; Rabinovich et al., 2017; Krishnamurthy et al., 2017; Cheng et al., 2017) making all outputs valid programs. These contributions are orthogonal to ours, and can be directly integrated into our decoder.

Generating context-dependent formal representations has received less attention. Miller et al. (1996) used ATIS and mapped utterances to semantic frames, which were then mapped to SQL queries. For learning, they required full supervision, including annotated parse trees and contextual dependencies.[2] Zettlemoyer and Collins (2009) addressed the problem with lambda calculus, using a semantic parser trained separately with context-independent data. In contrast, we generate executable formal queries and require only interaction query annotations for training.

Recovering context-dependent meaning was also studied with the SCONE (Long et al., 2016) and SequentialQA (Iyyer et al., 2017) corpora. We compare ATIS to these corpora in Section 7. Resolving explicit references, a part of our problem, has been studied as co-reference resolution (Ng, 2010). Context-dependent language understanding was also studied for dialogue systems, including with ATIS, as surveyed by Tür et al. (2010). More recently, encoder-decoder methods were applied to dialogue systems (Peng et al., 2017; Li et al., 2017), including using hierarchical RNNs (Serban et al., 2016, 2017), an architecture related to our turn-level encoder. These approaches use slot-filling frames with limited expressivity, while we focus on the original representation of unconstrained SQL queries.

[2] Miller et al. (1996) provide limited details about their evaluation. Later work notes that they evaluate SQL query correctness (Zettlemoyer and Collins, 2009) with an accuracy of 78.4%, higher than our results. However, the lack of details (e.g., if the metric is strict or relaxed) makes comparison difficult. In addition, we use significantly less supervision, and re-split the data to avoid scenario bias (Section 7).

4 Context-dependent Model

We base our model on an encoder-decoder architecture with attention (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015). At each interaction turn i, given the current utterance $\bar{x}_i$ and the interaction history $\bar{I}[:i-1]$, the model generates the formal query $\bar{y}_i$. Figure 3 illustrates our architecture. We describe the base architecture, and gradually add components.

4.1 Base Encoder-Decoder Architecture

Our base architecture uses an encoder to process the user utterance $\bar{x}_i = \langle x_{i,1}, \ldots, x_{i,|\bar{x}_i|} \rangle$ and a decoder to generate the output query $\bar{y}_i$ token-by-token. This architecture does not observe the interaction history $\bar{I}[:i-1]$.

The encoder computes a hidden state $\mathbf{h}_j^E = [\mathbf{h}_j^{\overrightarrow{E}}; \mathbf{h}_j^{\overleftarrow{E}}]$ for each token $x_{i,j}$ using a bi-directional RNN. The forward RNN is defined by: [3]

$$\mathbf{h}_j^{\overrightarrow{E}} = \text{LSTM}^{\overrightarrow{E}}\left(\phi^x(x_{i,j}); \mathbf{h}_{j-1}^{\overrightarrow{E}}\right) \quad , \tag{1}$$

where $\text{LSTM}^{\overrightarrow{E}}$ is a long short-term memory recurrence (LSTM; Hochreiter and Schmidhuber, 1997) and ϕ^x is a learned embedding function for input tokens. The backward RNN recurs in the opposite direction with separate parameters.

We generate the query with an RNN decoder. The decoder state at step k is:

$$\mathbf{h}_k^D = \text{LSTM}^D\left([\phi^y(y_{i,k-1}); \mathbf{c}_{k-1}]; \mathbf{h}_{k-1}^D\right) \quad ,$$

where LSTM^D is a two-layer LSTM recurrence, ϕ^y is a learned embedding function for query tokens, and $\mathbf{c}_k$ is an attention vector computed from the encoder states. $y_{i,0}$ is a special start token, and $\mathbf{c}_0$ is a zero-vector. The initial hidden state and cell memory of each layer are initialized as $\mathbf{h}_{|\bar{x}_i|}^E$ and $\mathbf{c}_{|\bar{x}_i|}^E$. The attention vector $\mathbf{c}_k$ is a weighted sum of the encoder hidden states:

$$s_k(j) = \mathbf{h}_j^E \mathbf{W}^{\mathbf{A}} \mathbf{h}_k^D \tag{2}$$

$$\alpha_k = \text{softmax}(\mathbf{s}_k) \tag{3}$$

$$\mathbf{c}_k = \sum_{j=1}^{|\bar{x}_i|} \mathbf{h}_j^E \alpha_k(j) \quad , \tag{4}$$

where $\mathbf{W}^{\mathbf{A}}$ is a learned matrix. The probabilities of output query tokens are computed as:

$$\mathbf{m}_k = \tanh\left([\mathbf{h}_k^D; \mathbf{c}_k]\mathbf{W}^m\right) \tag{5}$$

$$P(y_{i,k} = w \mid \bar{x}_i, \bar{y}_{i,1:k-1}) \propto \exp(\mathbf{m}_k \mathbf{W}_w^o + \mathbf{b}_w^o) \tag{6}$$

where $\mathbf{W}^m$, $\mathbf{W}^o$, and $\mathbf{b}^o$ are learned.

[3] We omit the memory cell (often denoted as $\mathbf{c}_j$) from all LSTM descriptions. We use only the LSTM hidden state $\mathbf{h}_j$ in other parts of the architecture unless explicitly noted.

4.2 Incorporating Recent History

We provide the model with the most recent interaction history by concatenating the previous h utterances $\langle \bar{x}_{i-h}, ..., \bar{x}_{i-1} \rangle$ with the current utterance in order, adding a special delimiter token between each utterance. The concatenated input provides the model access to previous utterances, but not to previously generated queries, or utterances that are more than h turns in the past. The architecture remains the same, except that the encoder and attention are computed over the concatenated sequence of tokens. The probability of an output query token is computed the same, but is now conditioned on the interaction history:

$$P(y_{i,k} = w \mid \bar{x}_i, \bar{y}_{i,1:k-1}, \bar{I}[:i-1]) \propto \exp(\mathbf{m}_k \mathbf{W}_w^o + \mathbf{b}_w^o) \quad . \tag{7}$$

4.3 Turn-level Encoder

Concatenating recent utterances to provide access to recent history has computational drawbacks. The encoding of the utterance depends on its location in the concatenated string. This requires encoding all recent history for each new utterance, and does not allow re-use of computation between utterances during encoding. It also introduces a tradeoff between computation cost and expressivity: attending over the h previous utterances allows the decoder access to the information in these utterances when generating a query, but is computationally more expensive as h increases. We address this by encoding each utterance once. To account for the influence of the interaction history on utterance encoding, we maintain a discourse state encoding $\mathbf{h}_i^I$ computed with a turn-level recurrence, and use it during utterance encoding. The state is maintained and updated over the entire interaction. At turn i, this model has access to the complete prefix of the interaction $\bar{I}[:i-1]$ and the current request $\bar{x}_i$. In contrast, the concatenation-based encoder (Section 4.2) has access only to information from the previous h utterances. We also use positional encoding in the attention computation to account for the position of each utterance relative to the current utterance.

Formally, we modify Equation 1 to encode $\bar{x}_i$:

$$\mathbf{h}_{i,j}^{\overrightarrow{E}} = \text{LSTM}^{\overrightarrow{E}}\left(\left[\phi^x(x_{i,j}); \mathbf{h}_{i-1}^I\right]; \mathbf{h}_{i,j-1}^{\overrightarrow{E}}\right) \quad ,$$

where $\mathbf{h}_{i-1}^I$ is the discourse state following utterance $\bar{x}_{i-1}$. $\text{LSTM}^{\overleftarrow{E}}$ is modified analogously. In contrast to the concatenation-based model, the recurrence processes a single utterance. The dis-

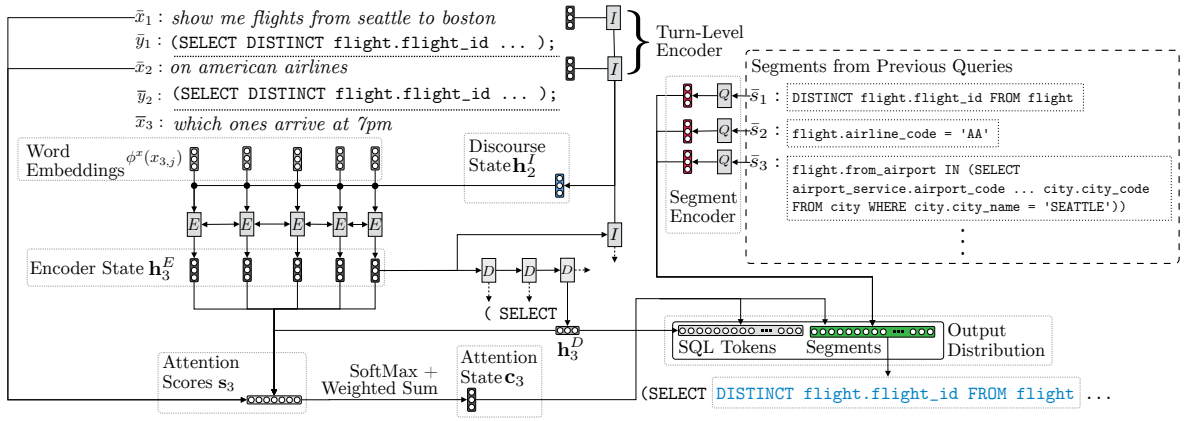

Figure 3: Illustration of the model architecture during the third decoding step while processing the instruction *which ones arrive at 7pm* from the interaction in Figure 2. The current discourse state $\mathbf{h}_2^I$ is used to encode the current utterance $\bar{x}_3$ (Section 4.3). Query segments from previous queries are encoded into vector representations (Section 4.4). In each generation step, the decoder attends over the previous and current utterances, and a probability distribution is computed over SQL tokens and query segments. Here, segment $\bar{s}_1$ is selected.

course state $\mathbf{h}_i^I$ is computed as

$$\mathbf{h}_i^I = \text{LSTM}^I\left(\mathbf{h}_{i,|\bar{x}_i|}^E; \mathbf{h}_{i-1}^I\right) \quad .$$

Similar to the concatenation-based model, we attend over the current utterance and the h previous utterances. We add relative position embeddings ϕ^I to each hidden state. These embeddings are learned for each possible distance $0, \ldots, h-1$ from the current utterance. We modify Equation 2 to index over both utterances and tokens:

$$s_k(t,j) = \left[\mathbf{h}_{t,j}^E; \phi^I(i-t)\right] \mathbf{W}^{\mathbf{A}} \mathbf{h}_k^D \quad . \tag{8}$$

In contrast to the concatenation model, without position embeddings, the attention computation has no indication of the utterance position, as our ablation shows in Section 8. The attention distribution is computed as in Equation 3, and normalized across all utterances. The position embedding is also used to compute the context vector $\mathbf{c}_k$:

$$\mathbf{c}_k = \sum_{t=i-h}^{i} \sum_{j=1}^{|\bar{x}_t|} \left[\mathbf{h}_{t,j}^E; \phi^I(i-t)\right] \alpha_k(t,j) \quad .$$

4.4 Copying Query Segments

The discourse state and attention over previous utterances allow the model to consider the interaction history when generating queries. However, we observe that context-dependent reasoning often requires generating sequences that were generated in previous turns. Figure 2 shows how segments (underlined) extracted from previous utterances are predominant in later queries. To take advantage of what was previously generated, we add copying of complete segments from previous queries by expanding the set of outputs at each generation step. This mechanism explicitly models references, reduces the number of steps required to generate queries, and provides an interpretable view of what parts of a query originate in context. Figure 3 illustrates this architecture.

Extracting Segments Given the interaction history $\bar{I}[:\ i-1]$, we construct the set of segments S_{i-1} by deterministically extracting subtrees from previously generated queries.[4] In our data, we extract 13 ± 5.9 ($\mu \pm \sigma$) segments for each annotated query. Each segment $\bar{s} \in S_{i-1}$ is a tuple $\langle a, b, l, r \rangle$, where a and b are the indices of the first and most recent queries, $\bar{y}_a$ and $\bar{y}_b$, in the interaction that contain the segment. l and r are the start and end indices of the segment in $\bar{y}_b$.

Encoding Segments We represent a segment $\bar{s} = \langle a, b, l, r \rangle$ using the hidden states of an RNN encoding of the query $\bar{y}_b$. The hidden states $\langle \mathbf{h}^Q{}_1, ..., \mathbf{h}^Q{}_{|\bar{y}_b|} \rangle$ are computed using a bi-directional LSTM RNN similar to the utterance encoder (Equation 1), except using separate LSTM parameters and ϕ^y to embed the query tokens. The embedded representation of a segment is a concatenation of the hidden states at the segment endpoints and an embedding of the relative position of the utterance where it appears first:

$$\mathbf{h}^S = \left[\mathbf{h}_l^Q; \mathbf{h}_r^Q; \phi^g(\min(g, i-a))\right] \quad ,$$

where ϕ^g is a learned embedding function of the position of the initial query $\bar{y}_a$ relative to the current turn index i. We learn an embedding for each relative position that is smaller than g, and use the same embedding for all other positions.

Generation with Segments At each generation step, the decoder selects between a single query token or a segment. When a segment is selected, it

[4] The process of extracting sub-trees is described in the supplementary material.

is appended to the generated query, an embedded segment representation for the next step is computed, and generation continues. The probability of a segment $\bar{s} = \langle a, b, l, r \rangle$ at decoding step k is:

$$P(y_{i,k} = \bar{s} \mid \bar{x}_i, \bar{y}_{i,1:k-1}, \bar{I}[:i-1]) \propto \exp\left(\mathbf{m}_k \mathbf{W}^S \mathbf{h}^S\right) \quad (9)$$

where $\mathbf{m}_k$ is computed in Equation 5 and $\mathbf{W}^S$ is a learned matrix. To simplify the notation, we assign the segment to a single output token. The output probabilities (Equations 7 and 9) are normalized together to a single probability distribution. When a segment is selected, the embedding used as input for the next generation step is a bag-of-words encoding of the segment. We extend the output token function ϕ^y to take segments:

$$\phi^y(\bar{s} = \langle a, b, l, r \rangle) = \frac{1}{r-l} \sum_{k=l}^{r} \phi^y(y_{b,k}) \quad .$$

The recursion in ϕ^y is limited to depth one because segments do not contain other segments.

4.5 Inference with Full Model

Given an utterance $\bar{x}_i$ and the history of interaction $\bar{I}[:i-1]$, we generate the query $\bar{y}_i$. An interaction starts with the user providing the first utterance $\bar{x}_1$. The utterance is encoded using the initial discourse state $\mathbf{h}_0^I$, the discourse state $\mathbf{h}_1^I$ is computed, the query $\bar{y}_1$ is generated, and the set of segments S_1 is created. The initial discourse state $\mathbf{h}_0^I$ is learned, and the set of segments S_0 used when generating $\bar{y}_1$ is the empty set. The attention is computed only over the first utterance because no previous utterances exist. The user then provides the next utterance or concludes the interaction. At turn i, the utterance $\bar{x}_i$ is encoded using the discourse state $\mathbf{h}_{i-1}^I$, the discourse state $\mathbf{h}_i^I$ is computed, and the query $\bar{y}_i$ is generated using the set of segments S_{i-1}. The model has no access to future utterances. We use greedy inference for generation. Figure 3 illustrates a single decoding step.

5 Learning

We assume access to a training set of N interactions $\{\bar{I}^{(l)}\}_{l=1}^N$. Given an interaction $\bar{I}^{(l)}$, each utterance $\bar{x}_i^{(l)}$ where $1 \leq i \leq |\bar{I}^{(l)}|$, is paired with an annotated query $\bar{y}_i^{(l)}$. The set of segments from previous utterances is deterministically extracted from the annotated queries during learning. However, the data does not indicate what parts of each query originate in segments copied from previous utterances. We adopt a simple approach and heuristically identify context-dependent segments based on entities that appear in the utterance and the query.[5] Once we identify a segment in the annotated query, we replace it with a unique placeholder token, and it appears to the learning algorithm as a single generation decision. Treating this decision as latent is an important direction for future work. Given the segment copy decisions, we minimize the token cross-entropy loss:

$$\mathcal{L}(y_{i,k}^{(l)}) = -\log P\left(y_{i,k}^{(l)} \mid \bar{x}_i^{(l)}, \bar{y}_{i,1:k-1}^{(l)}, \bar{I}^{(l)}[:i-1]\right) \quad ,$$

where k is the index of the output token. The base and recent-history encoders (Sections 4.1 and 4.2) can be trained by processing each utterance separately. For these models, given a mini-batch $\mathcal{B}$ of utterances, each identified by an interaction-utterance index pair, the loss is the mean token loss

$$\mathcal{L} = \frac{1}{\sum_{(i,j)\in\mathcal{B}} |\bar{y}_i^{(j)}|} \sum_{(i,j)\in\mathcal{B}} \sum_{k=1}^{|\bar{y}_i^{(j)}|} \mathcal{L}(y_{i,k}^{(j)}) \quad .$$

The turn-level encoder (Section 4.3) requires building a computation graph for the entire interaction. We update the model parameters for each interaction. The interaction loss is

$$\mathcal{L} = \frac{n}{B} \frac{1}{\sum_{i=1}^{n} |\bar{y}_i^{(j)}|} \sum_{i=1}^{n} \sum_{k=1}^{|\bar{y}_i^{(j)}|} \mathcal{L}(y_{i,k}^{(j)}) \quad ,$$

where B is the batch size, and $\frac{n}{B}$ re-normalizes the loss so the gradient magnitude is not dependent on the number of utterances in the interaction. Our ablations ($-$batch re-weight in Table 2) shows the importance of this term. For both cases, we use teacher forcing (Williams and Zipser, 1989).

6 Reasoning with Anonymized Tokens

An important practical consideration for generation in ATIS and other database domains is reasoning about database values, such as entities, times, and dates. For example, the first utterance in Figure 2 includes two entities and a date reference. With limited data, learning to both reason about a large number of entities and to resolve dates are challenging for neural network models. Following previous work (Dong and Lapata, 2016; Iyer et al., 2017), we address this with anonymization, where the data is pre- and post-processed to abstract over tokens that can be heuristically resolved to tokens in the query language. In contrast to previous work, we design a special scoring function to anonymized tokens to reflect how they are used in the input utterances. Figure 4 illustrates preprocessing in ATIS. For example, we use a temporal semantic parser to resolve dates (e.g., *next*

[5] The alignment is detailed in the supplementary material.

Original utterance and query:

$\bar{x}_1$: *show me flights from seattle to boston next monday*

```
ȳ1: ( SELECT DISTINCT flight.flight_id ...
    city.city_name = 'SEATTLE' ...  city.city_name
    = 'BOSTON' ...  date_day.year = 1993 AND
    date_day.month_number = 2 AND date_day.day_number
    = 8 ...
```

Anonymized utterance and query:

$\bar{x}'_1$: *show me flights from CITY#1 to CITY#2 DAY#1 MONTH#1 YEAR#1*

```
ȳ'1: ( SELECT DISTINCT flight.flight_id ...
    city.city_name = CITY#1 ...  city.city_name
    = CITY#2 ...  date_day.year = YEAR#1
    AND date_day.month_number = MONTH#1 AND
    date_day.day_number = DAY#1 ...
```

Anonymization mapping:

CITY#1	'SEATTLE'	MONTH#1	2
CITY#2	'BOSTON'	YEAR#1	1993
DAY#1	8		

Figure 4: An example of date and entity anonymization pre-processing for $\bar{x}_1$ and $\bar{y}_1$ in Figure 2.

Monday) and replace them with day, month, and year placeholders. To anonymize database entries, we use a dictionary compiled from the database (e.g., to map *Seattle* to `SEATTLE`). The full details of the anonymization procedure are provided in the supplementary material. Following preprocessing, the model reasons about encoding and generation of anonymized tokens (e.g., `CITY#1`) in addition to regular output tokens and query segments from the interaction history. Anonymized tokens are typed (e.g., `CITY`), map to a token in the query language (e.g., `'BOSTON'`), and appear both in input utterances and generated queries.

We modify our encoder and decoder embedding functions (ϕ^x and ϕ^y) to map anonymized tokens to the embeddings of their types (e.g., `CITY`). The type embeddings in ϕ^x and ϕ^y are separate. Using the types only, while ignoring the indices, avoids learning biases that arise from the arbitrary ordering of the tokens in the training data. However, it does not allow distinguishing between entries with the same type for generation decisions; for example, the common case where multiple cities are mentioned in an interaction. We address this by scoring anonymized token based on the magnitude of attention assigned to them at generation step k. The attention magnitude is computed from the encoder hidden states. This computation considers both the decoder state and the location of the anonymized tokens in the input utterances to account for how they are used in the interaction. The probability of an anonymized token w at generation step k is

$$P(y_{i,k} = w \mid \bar{x}_i, \bar{y}_{i,1:k-1}, \bar{I}[:i-1]) \propto \sum_{t=i-h}^{i} \sum_{j=1}^{|\bar{x}_t|} (\exp(s_k(t,j)))$$

where $s_k(t,j)$ is the attention score computed in Equation 8. This probability is normalized together with the probabilities in Equations 7 and 9 to form the complete output probability.

Mean/max utterances per interaction	7.0 / 64
Mean/max tokens per utterance	10.2 / 47
Mean/max token per SQL query	102.9 / 1286
Input vocabulary size	1582
Output vocabulary size	982

Table 1: ATIS data statistics.

7 Experimental Setup

Hyperparameters, architecture details, and other experimental choices are detailed in the supplementary material.

Data We use ATIS (Hemphill et al., 1990; Dahl et al., 1994) to evaluate our approach. The data was originally collected using wizard-of-oz experiments, and annotated with SQL queries. Each interaction was based on a scenario given to a user. We observed that the original data split shares scenarios between the train, development, and test splits. This introduces biases, where travel patterns that appeared during training repeat in testing. For example, a model trained on the original data split often correctly resolves the exact referenced by *on Saturday* with no pre-processing or access to the document date. We evaluate this overfitting empirically in the supplementary material. We re-split the data to avoid this bias. We evenly distribute scenarios across splits so that each split contains both scenarios with many and few representative interactions. The new split follows the original split sizes with 1148/380/130 train/dev/test interactions. Table 1 shows data statistics. The system uses a SQL database of 27 tables and 162K entries. 96.6% of the queries require at least one join, and 93% at least two joins. The most related work on ATIS to ours is Miller et al. (1996), which we discuss in Section 3.

The most related corpora to ATIS are SCONE (Long et al., 2016) and SequentialQA (Iyyer et al., 2017). SCONE (Long et al., 2016) contains micro-domains consisting of stack- or list-like elements. The formal representation is linguistically-motivated and the majority of queries include a single binary predicate. All interactions include five turns. SequentialQA (Iyyer et al., 2017) contains sequences of questions on a single Wikipedia table. Interactions are on average 2.9 turns long, and were created by re-phrasing a question from a context-independent corpus (Pasupat and Liang, 2015). In contrast, ATIS uses a significantly larger

database, requires generating complex queries with multiple joins, includes longer interactions, and was collected through interaction with users. The supplementary material contains analysis of the contextual phenomena observed in ATIS.

Pre-processing We pre-process the data to identify and anonymize entities (e.g., cities), numbers, times, and dates. We use string matching heuristics to identify entities and numbers, and identify and resolve times and dates using UWTime (Lee et al., 2014). When resolving dates we use the original interaction date as the document time. The supplementary material details this process.

Metrics We evaluate using query accuracy, strict denotation accuracy, and relaxed denotation accuracy. Query accuracy is the percentage of predicted queries that match the reference query. Strict denotation accuracy is the percentage of predicted queries that execute to exactly the same table as the reference query. In contrast to strict, relaxed gives credit to a prediction query that fails to execute if the reference table is empty. In cases when the utterance is ambiguous and there are multiple gold queries, we consider the query or table correct if they match any of the gold labels.

Systems We evaluate four systems: (a) SEQ2SEQ-0: the baseline encoder-decoder model (Section 4.1); (b) SEQ2SEQ-H: encoder-decoder with attention on current and previous utterances (Section 4.2); (c) S2S+ANON: encoder-decoder with attention on previous utterances and anonymization scoring (Section 6); and (d) FULL: the complete approach including segment copying (Section 4.4). For FULL, we evaluate with predicted and gold (FULL-GOLD) previous queries, and without attention on previous utterances (FULL-0). All models except SEQ2SEQ-0 and FULL-0 use $h = 3$ previous utterances. We limit segment copying to segments that appear in the most recent query only.[6] Unless specifically ablated, all experiments use pre-processing.

8 Results

Table 2 shows development and test results. We run each experiment five times and report mean and standard deviation. The main metric we focus on is strict denotation accuracy. The relatively low performance of SEQ2SEQ-0 demonstrates the need for context in this task. Attending on recent history significantly increases performance. Both SEQ2SEQ models score anonymized tokens as regular vocabulary tokens. Adding anonymized token scoring further increases performance (S2S+ANON). FULL-0 and FULL add segment copying and the turn-level encoder. The relatively high performance of FULL-0 shows that substituting segment copying with attention maintains and even improves the system effectiveness. However, the best performance is provided with FULL, which combines both. This shows the benefit of redundancy in accessing contextual information. Unlike the other systems, both FULL and FULL-0 suffer from cascading errors due to selecting query segments from previously incorrect predictions. The higher FULL-GOLD performance illustrates the influence of error propagation. While part of this error can be mitigated by having both attention and segment copying, this behavior is unlikely to be learned from supervised learning, where errors are never observed.

Model	Query	Denotation	
		Relaxed	Strict
Development Results			
SEQ2SEQ-0	28.7±1.7	48.8±1.4	43.2±1.8
SEQ2SEQ-H	35.1±2.2	59.4±2.4	56.7±3.2
S2S+ANON	37.6±0.7	61.6±0.7	60.6±0.7

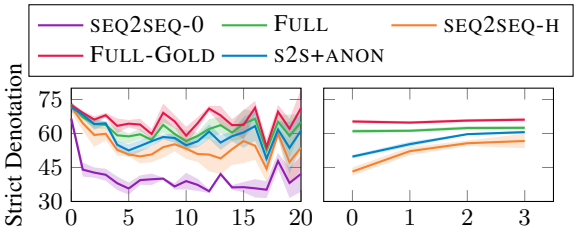
FULL	43.6±1.0	69.3±0.8	**69.2**±0.8
FULL-GOLD	47.4±1.3	72.3±0.5	72.0±0.5

Table 2: Mean and standard deviation development and test results, including ablations on the FULL model.

Ablations show that all components contribute to the system performance. Performance drops when using a concatenation-based encoder instead of the turn-level encoder (−turn-level enc.; Section 4.3). Using batch-reweighting (−batch-reweight; Section 5) and input position embeddings (−input pos. embs.; Section 4.3) are critical to the performance of the turn-level encoder. Removing copying of query segments

[6] While we only use segments from the most recent query, they often appear for the first time much earlier in the interaction, which influences their absolute position value a.



(a) Interaction turns (b) History length h

Figure 5: Mean development strict denotation accuracy as function of turns and h.

Model	Query	Denotation	
		Relaxed	Strict
Development Results			
S2S+ANON	44.4±1.2	69.9±0.3	68.9±0.3
FULL	42.8±0.2	68.8±0.2	68.4±0.2
FULL-GOLD	47.5±0.2	71.5±0.4	70.7±0.6
Test Results			
S2S+ANON	43.9±0.3	67.4±1.0	67.2±1.0
FULL	44.3±0.2	66.3±0.3	66.3±0.4
FULL-GOLD	47.2±0.3	68.2±0.5	67.9±0.4

Table 3: Results on the original split of the data.

from the interaction history lowers performance (−query segments; Section 4.4). Treating indexed anonymized tokens as regular tokens, rather than using attention-based scoring and type embeddings, lowers performance (−anon. scoring; Section 6). Finally, pre-processing, which includes anonymization, is critical (−pre-processing).

Figure 5(a) shows the performance as interactions progress. All systems show a drop in performance after the first utterance, which is always context-independent. As expected, SEQ2SEQ-0 shows the biggest drop. The FULL approach is the most stable as the interaction progresses.

Figure 5(b) shows the performance as we decrease the number of previous utterances used for attention h. Without the turn-level encoder and segment copying (SEQ2SEQ-H and S2S+ANON), performance decreases significantly as h decreases. In contrast, the FULL model shows a smaller decrease (1.5%). The supplementary material includes attention analysis demonstrating the importance of previous-utterance attention. However, attending on fewer utterances improves inference speed: FULL-0 is 30% faster than FULL.

Finally, while we re-split the data due to scenario sharing between train and test early in development and used this split only for development, we also evaluate on the original split (Table 3). We report mean and standard deviation over three trials. The high performance of S2S+ANON potentially indicates it benefits more from the differences between the splitting procedures.

9 Analysis

We analyze errors made by the full model on thirty development interactions. When analyzing the output of FULL, we focus on error propagation and analyze predictions that resulted in an incorrect table when using FULL, but a correct table when using FULL-GOLD. 56.7% are due to selection of a segment that contained an incorrect constraint. 43.4% of the errors are caused by a necessary segment missing during generation. 93.0% of all predictions are valid SQL and follow the database schema. We also analyze the errors of FULL-GOLD. We observe that 30.0% of errors are due to generating constraints that were not mentioned by the user. Other common errors include generating relevant constraints with incorrect values (23.3%) and missing constraints (23.3%).

We also evaluate our model's ability to recover long-distance references while constraints are added, changed, or removed, and when target attributes change. The supplementary material includes the analysis details. In general, the model resolves references well. However, it fails to recover constraints mentioned in the past following a user focus state change (Grosz and Sidner, 1986).

10 Discussion

We study models that recover context-dependent executable representations from user utterances by reasoning about interaction history. We observe that our segment-copying models suffer from error propagation when extracting segments from previously-generated queries. This could be mitigated by training a model to ignore erroneous segments, and recover by relying on attention for generation. However, because supervised learning does not expose the model to erroneous states, a different learning approach is required. Our analysis demonstrates that our model is relatively insensitive to interaction length, and is able to recover both explicit and implicit references to previously-mentioned entities and constraints. Further study of user focus change is required, an important phenomenon that is relatively rare in ATIS.

Neural Text Generation in Stories Using Entity Representations as Context

Abstract

We introduce an approach to neural text generation that explicitly represents entities mentioned in the text. Entity representations are vectors that are updated as the text proceeds; they are designed specifically for narrative text like fiction or news stories. Our experiments demonstrate that modeling entities offers a benefit in two automatic evaluations: mention generation (in which a model chooses which entity to mention next and which words to use in the mention) and selection between a correct next sentence and a distractor from later in the same story. We also conduct a human evaluation on automatically generated text in story contexts; this study supports our emphasis on entities and suggests directions for further research.

1 Introduction

We consider the problem of automatically generating narrative text, a challenging problem at the junction of computational creativity and language technologies (Gervás, 2009). We are motivated in particular by potential applications in personalized education and assistive tools for human authors, though we believe narrative might also play a role in social conversational agents (Sordoni et al., 2015). In this work, the term "narrative text" refers primarily to fiction but might also include news and other kinds of stories.

A notable difference between longstanding work in natural language generation and recent "neural" models is in the treatment of *entities* and the words used to refer to them. Particularly in the generation of narrative text, character-centered generation has been shown important in character dialogue generation (Walker et al., 2011; Cavazza and Charles, 2005) and story planning (Cavazza et al., 2002). Neural models, on the other hand, treat mentions as just more words, relying on representation learning to relate the people in a story through the words alone.

Context	All of a sudden, [*Emily*]$_1$ walked towards [*the dragon*]$_2$.
Current Sentence	[*Seth*]$_3$ yelled at [*her*]$_1$ to get back but _____

Figure 1: An example of entity-labeled story data. The brackets indicate which words are part of entity mentions. Mentions marked with the same number refer to the same entity. The goal is to continue the story in a coherent way. The actual story reads, "*Seth yelled at her to get back but she ignored him.*"

Entities are an important element of narrative text. Centering Theory places entities at the center of explaining what makes text coherent (Grosz et al., 1995). In this work, we incorporate entities into neural text generation models; each entity in a story is given its own vector representation, which is updated as the story unfolds. These representations are learned specifically to predict words—both mentions of the entity itself and also the following context. At a given moment in the story, the current representations of the entities help to predict what happens next.

Consider the example in Figure 1. Given the context, the reader expects the subsequent words and sentences of the passage to track the results of Emily approaching the dragon. Future text should include references to Emily's character and the dragon and the result of their interaction. The choice of entity generated next in the sentence will change what language should follow that mention and will shape and drive the direction of the story. For this reason, we propose using entity representations as context for generation.

Of course, entities are not the only context needed for coherent language generation; previously generated content remains an important source of information. We use a simple, parameter-free method for combining preceding context with entity context within an end-to-end–

Proceedings of NAACL-HLT 2018, pages 2250–2260
New Orleans, Louisiana, June 1 - 6, 2018.

trainable neural language generator.

We evaluate our model's performance through two automatic evaluation tasks. The first is a new mention generation task inspired by earlier work in referring expression generation (Dale and Reiter, 1995). The second is a sentence selection task inspired by coherence tests from Barzilay and Lapata (2008). Our model outperforms strong baselines on both tasks.

We further conduct a human evaluation in which our model's generated sentences are compared to a strong baseline model. This evaluation elucidates strengths and weaknesses of our model and offers guidance for future work on narrative text generation.

2 Model Description

We propose an entity-based generation model (ENGEN)[1] that combines three different sources of contextual information for text generation:

1. The content that has already been generated within the current sentence
2. The content that was generated in the previous sentence
3. The current state of the entities mentioned in the document so far

Each of these types of information is encoded in vector form, following extensive past work on recurrent neural network (RNN) language models. The first source of context is the familiar hidden state vector of the RNN; more precisely, our starting point is a sequence-to-sequence model (Sutskever et al., 2014). Representations of the second and third forms of context are discussed in §2.1 and §2.2, respectively. The combination of all three context representations is described in §2.3.

2.1 Context from Previous Sentence

As noted, our starting point is a sequence-to-sequence model (Sutskever et al., 2014); the last hidden state from the previous sentence offers a representation of the preceding context. We add an attention mechanism (Bahdanau et al., 2015). Let $\boldsymbol{h}_{t,i}$ and $\boldsymbol{h}_{t-1,j}$ be the LSTM hidden states of sentence t at timestep i and the previous sentence $t-1$ at timestep j, where j ranges over the number of words in the previous sentence. To summarize the contextual information from the previous sentence for predicting the next word at timestep $i+1$ in sentence t, we have

$$\boldsymbol{p}_{t-1,i} = \sum_j \alpha_{i,j} \boldsymbol{h}_{t-1,j}, \text{where} \quad (1)$$

$$\alpha_{i,j} = \frac{\exp(\boldsymbol{h}_{t-1,j} \mathbf{W}_a \boldsymbol{h}_{t,i})}{\sum_{j'} \exp(\boldsymbol{h}_{t-1,j'} \mathbf{W}_a \boldsymbol{h}_{t,i})} \quad (2)$$

is the attention weight for $\boldsymbol{h}_{t-1,j}$. Unlike the definition of attention in Bahdanau et al. (2015), here we use the bilinear product in Equation 2 to encourage correlation between $\boldsymbol{h}_{t,i}$ and $\boldsymbol{h}_{t-1,j}$ for coherence in text generation. In §2.3, we will combine this with $\boldsymbol{h}_{t,i}$ for predicting the next word; we refer to that model as S2SA, and it serves as an entity-unaware baseline in our experiments.

2.2 Context from Entities

In S2SA, the context of a sentence is (at best) represented by compressing information about the words that have appeared in the previous sentence. Past research has suggested several approaches to capturing other contextual information. For example, Lau et al. (2017) and Ghosh et al. (2016) have sought to capture longer contexts by modeling topics. Recently, Ji et al. (2017) introduced a language model, ENTITYNLM, that adds explicit tracking of entities, which have their own representations that are updated as the document progresses.[2] That model was introduced for analysis tasks, such as language modeling and coreference resolution, where the texts (and their coreference information) are given, and the model is used to score the texts to help resolve coreference relationships.[3] ENTITYNLM's strong performance on language modeling suggests the potential of distributed entity representations as another source of contextual information for text generation. Inspired by that work, we maintain the dynamic representation of entities and use them as contextual information when generating text.

In general, every entity in a document (e.g., EMILY in Figure 1) is assigned a vector representation; this vector is updated every time the entity is mentioned. This is entirely appropriate for generating narrative stories in which characters develop and change over long contexts. When we

[1] Code available at github.com/eaclark07/engen.

[2] Because space does not permit a full exposition of all the details of ENTITYNLM, we refer the interested reader to Ji et al. (2017).

[3] The entity prediction task used in their work is relevant to our mention generation task, which will be discussed in §5.

generate text, the model will have access to the current representation of every participant (i.e., every entity) in the story at that time (denoted by $\boldsymbol{e}_{i,t}$ for entity i at timestep t).

When choosing which entity is referred to at timestep t, there are $m+1$ options, where m is the number of entities tracked in the document so far—the $(m+1)$th is for a new, previously unmentioned entity. Given that a word is part of an entity mention and given the previous hidden state, the probability that the word is referring to a given entity $i \in \{1, \ldots, m+1\}$ is proportional to:

$$\exp(\boldsymbol{h}_{t-1}^{\top} \mathbf{W}_{entity} \boldsymbol{e}_{i,t-1} + \boldsymbol{w}_{dist}^{\top} \boldsymbol{f}(i)), \quad (3)$$

where $\mathbf{W}_{entity}$ is a weight matrix for predicting the entities and $\boldsymbol{w}_{dist}^{\top} \boldsymbol{f}(i)$ is a term that takes into account distance features between the current and past entity mentions.

Once an entity is selected, its vector is assigned to $\boldsymbol{e}_{current}$, which is used to generate the word w_t. If the model decided the current word should not refer to an entity, then $\boldsymbol{e}_{current}$ is still used and will be the representation of the most recently mentioned entity. If the choice is a new, previously unmentioned entity, then $\boldsymbol{e}_{current}$ is initialized with a new embedding randomly generated from a normal distribution:

$$\boldsymbol{u} \sim \mathcal{N}(\boldsymbol{r}, \sigma^2 \mathbf{I}), \quad (4)$$

where $\sigma = 0.01$ and $\boldsymbol{r}$ is a parameter vector that is used to determine whether the next word should refer to an entity.

Once the word w_t has been generated, the entity representation is updated based on the new hidden state information, $\boldsymbol{h}_t$.

2.3 Combining Contexts

Our new model merges S2SA and ENTITYNLM. Both provide a representation of context: respectively, the previous sentence's representation ($\boldsymbol{p}_t$) and the most salient entity's representation ($\boldsymbol{e}_{current}$). The hidden state $\boldsymbol{h}_{t-1}$ is, of course, also available, and is intended to capture local contextual effects. The challenge is how to combine these representations effectively for text generation.

In this work, for simplicity, we choose a combination function without any extra parameters, and leave the detailed investigation of paramaterized composition functions as future work. We use a max-pooling function to form a context vector $\boldsymbol{c}_t$ with the same dimensionality as $\boldsymbol{h}_{t-1}$ (and, of course, $\boldsymbol{p}_t$ and $\boldsymbol{e}_{current}$). Specifically, at time step t, each element of the combined context vector $\boldsymbol{c}_t$ is calculated as follows. For $k \in \{1, ..., |\boldsymbol{c}_t|\}$,

$$\boldsymbol{c}_t[k] = \max(\boldsymbol{h}_{t-1}[k], \boldsymbol{p}_t[k], \boldsymbol{e}_{current}[k]). \quad (5)$$

The max pooling technique originates from the design of convolutional neural networks and has been found useful elsewhere in NLP (Kalchbrenner et al., 2014). Other alternatives, including average pooling, min pooling, and element-wise multiplication on all three vectors, were considered in informal preliminary experiments on development data and found less effective than max pooling.

This combined context vector $\boldsymbol{c}_t$ is used to generate word w_t by calculating the probability of each word type in the vocabulary. We use a class-factored softmax function (Goodman, 2001; Baltescu and Blunsom, 2015). This choice greatly reduces the runtime of word prediction. In practice, we often find it gives better performance than standard softmax.

2.4 Learning

The training objective is to maximize the log-probability of $\boldsymbol{X}$:

$$\ell(\boldsymbol{\theta}) = \log P(\boldsymbol{X}; \boldsymbol{\theta}) = \sum_t \log P(X_t; \boldsymbol{\theta}) \quad (6)$$

$\boldsymbol{\theta}$ denotes all of the model's parameters. X_t represents all decisions at timestep t about the word (whether it is part of a entity mention, and if so, the entity the mention refers to, the length of the mention, and the word itself).

These decisions are made by calculating probabilities for each available option using the current state of the neural network (a vector) and the current vector representations of the entities. Given the probabilities, the next word is assumed to have been randomly generated by sampling.

While we might consider training the model to maximize the probability of the generated words directly, treating the entity-related variables as *latent*, this would create a mismatch between how we train and use the model. For generation, the model explicitly predicts not just the word, but also the entity information associated with that word. Training with latent variables is also expensive. For these reasons, we use the same training method used for ENTITYNLM, which requires

training data annotated with mention and coreference information (entity clusters).

2.5 Variants

In our experiments, we consider the combined model (ENGEN) and two ablations: S2SA and a model similar to ENTITYNLM. Note that, unlike past work with previous-sentence context, S2SA uses max pooling for $\boldsymbol{h}_{t-1}$ and $\boldsymbol{p}_t$ and class-factored softmax; our version of ENTITYNLM also uses max pooling and class-factored softmax. All of these models are trained in a similar way.

3 Implementation Details

The models are implemented using DyNet (Neubig et al., 2017) with GPU support. We optimize with SGD, with a learning rate of $\lambda = 0.1$. The dimensions of input layer, hidden layer, and entity representation are fixed at 512 (hyperparameter optimization might lead to better solutions). The input word embeddings are randomly initialized with the default method in DyNet and updated during training jointly with other parameters. For class-factored softmax, we use 160 Brown clusters (Brown et al., 1992; Liang, 2005) estimated from the training data.

4 Data

We trained all models on 312 adventure books from the Toronto Book Corpus (Zhu et al., 2015), with development and test sets of an additional 39 books each. We divided the books into smaller segments, where each segment includes up to 50 sentences. There are 33,279 segments in the training set, 4,577 in the dev. set, and 4,037 in the test set. This helps with memory efficiency, allowing us to train the model without building a recurrent neural network on the entire book.

All the tokens in the data were downcased, and numbers were replaced with a special NUM token. The vocabulary was selected by replacing the lowest frequency (less than 10) word types with a special UNK token. There are 43 million tokens, and the vocabulary size is 35,443.

To obtain entity annotations, we used the Stanford CoreNLP system (Clark and Manning, 2016a,b), version 3.8.0. From the coreference resolution results, we noticed that some entity mentions include more than 70 tokens, which is likely in error. To simplify the problem, we only kept the mentions consisting of three words or fewer, which covers more than 95% of the mentions in the training data. For mentions of more than three words, we replaced them with their head word, as determined by the Stanford CoreNLP system. While truncating these mentions sacrifices some information, we believe this preprocessing step is justifed as it retains most character names and pronouns, an especially important entity type for stories.

Of course, the use of automatic annotations from a coreference system will introduce noise and risks "confusing" the entity-aware models. The benefit is that we were able to train on a much larger corpus than any existing coreference dataset (e.g., the CoNLL 2012 English shared task training set has only 1.3 million tokens; Pradhan et al., 2012). Further, a corpus of books offers language that is much closer to our intended narrative text generation applications. Our experiments aim to measure some aspects of our models' intrinsic correctness, though we emphasize that even if entity information is incorrect at training time, it may still be helpful.

For all experiments, the same preprocessed dataset and trained models were used. The best models were selected based on development set log likelihood (Equation 6).

5 Experiment: Mention Generation

The goal of our first experiment is to investigate each model's capacity to mention an entity in context. For example, in Figure 1, *Emily* and *her* are both possible mentions of EMILY's character, but the two cannot be used interchangeably. Inspired by early work on referring expression generation (Dale and Reiter, 1995) and recent work on entity prediction (Modi et al., 2017), we propose a new task we call *mention generation*. Given a text and a slot to be filled with an entity mention, a model must choose among all preceding entity mentions and the correct mention. So if the model was choosing the next entity mention to be generated in Figure 1, it would select between all the previous entity mentions (*Emily*, *the dragon*, *Seth*, and *her*) and the correct mention (*she*).

In our model, each candidate mention is augmented with the index of its entity. Therefore, performing well on this task requires choosing both the entity and the words used to refer to it; this notion of quality is our most stringent evaluation measure. It requires the greatest precision, as it is

model	cluster and mention	cluster only	mention only
1. Reverse order	0.12	0.38	0.15
2. S2SA	—	—	0.44
3. EntityNLM	0.52	0.46	0.54
4. EnGen	0.53	0.46	0.55

Table 1: MAP on the mention generation task. Note that these results can only be compared between models, not between tasks, as there are a different number of candidates for each of the tasks.

cluster and mention	cluster only	mention only
[*Emily*]$_1$	*Emily	Emily
[*the dragon*]$_2$	The Dragon	the dragon
[*Seth*]$_3$	Seth	Seth
[*her*]$_1$		her
*[*she*]$_1$		*she

Figure 2: Candidate lists for each of the mention generation tasks for completing the blank in Figure 1. The asterisk (*) indicates the correct choice.

possible to select the correct mention but not the correct cluster and vice versa. Since S2SA does not model entities, we also compare systems on quality of mentions alone (without entity clusters). For completeness, we include cluster quality for the entity-aware models. Candidate lists for each task to generate the next mention in the example in Figure 1 are shown in Figure 2.

The experiment setup does not require manual creation of candidate lists. However, it makes the mention generation task even more challenging, because the size of a candidate list can exceed 100 mention candidates.

We note that the difficulty of this task increases as we consider mention slots later and later in the document. The first mention generation choice is a trivial one, with a single candidate that is by definition correct. As more entity mentions are observed, the number of options will increase.[4] To enable aggregation across contexts of all lengths, we report the mean average precision (MAP) of the correct candidates, where the language model scores are used to rank candidates.

Baselines Along with the two ablated models (S2SA and EntityNLM), we include a "reverse order" baseline, which ranks mentions by recency (the first element in the ranking is the most recent mention, then the second-most-recent, and so on).

Results The ranking results of EnGen and other systems are reported in Table 1. A higher MAP score implies a better system. We measure the overall performance of all the systems, along with their performance on selecting the *mention only* and *entity cluster only*. Across all the evaluation measures, EnGen gives the highest MAP numbers. Recall that S2SA does not have a component for entity prediction, therefore we only compare it with EnGen in the *mention only* case. The difference between line 4 and line 2 on the *mention only* column shows the benefit of adding entity representations for text generation. The difference between lines 3 and 4 shows that local context also gives a small boost. Although the distance between the current slot and previous entity mention has been shown as a useful feature in coreference resolution (Clark and Manning, 2016b), line 1 shows distance alone is not an effective heuristic for mention generation.

6 Experiment: Pairwise Sentence Selection

The sentence selection task is inspired by tests of coherence used to assess text generation components automatically, without human evaluation (Barzilay and Lapata, 2008). It serves as a sanity check, as it was conducted prior to full generation and human evaluations (§7). Since the models under consideration are generative, they can be used to assign scores to candidate sentences, given a context.

In our version of this task, we provide a model with $n - 1 = 49$ sentences of preceding context, and offer two choices for the nth (50th) sentence: the actual 50th sentence or a distractor sentence randomly chosen from the next 50 sentences. A random baseline would achieve 50% accuracy.

Because the distractor comes from the same

[4] Note that the list of candidates may include duplicate entries with the same mention words and cluster. These are collapsed since they will have the same score under a language model.

Context	All of a sudden, [*Emily*]$_1$ walked towards [*the dragon*]$_2$.
1.	[*Seth*]$_3$ yelled at [*her*]$_1$ to get back but [*she*]$_1$ ignored [*him*]$_3$.
2.	[*She*]$_1$ patted [*its head*]$_4$ and [*it*]$_2$ curled up outside [*the cave*]$_5$.
3.	"[*Emily*]$_1$, how did [*you*]$_1$ keep [*that dragon*]$_2$ from attacking [*us*]$_6$?"

Figure 3: A passage's last sentence of context, and 3 sentences from various points in the next passage.

model	mean accuracy	s.d.
1. S2SA	0.546	0.01
2. ENTITYNLM	0.534	0.006
3. ENGEN	*0.566	0.008

* signficantly better than lines 1 and 2 with $p < 0.05$.

Table 2: Accuracy in choosing the actual next sentence, given 49 sentences of context, with a distractor from slightly later in the story. The mean accuracies and standard deviation are calculated across the five rounds of pairwise sentence selection.

story (with similar language, characters, and topics) and relatively nearby (in 2% cases, the very next sentence), this is not a trivial task. Consider the example in Figure 3. All of the sentences share lexical and entity information with the last line of the context. However, the first sentence immediately follows the context, while the second and third sentences are 10 lines and 48 lines away from the context, respectively. These entity and lexical similarities make distinguishing the actual sentence from the random sentence a challenging problem for the model.

To select the sentence, the model scores each of the two candidate sentences based on its probability on words and all entity-related information as defined in Equation 6. (Both candidate sentences come from the preprocessed data and have the entity annotations described in §4.)

The sentence that receives the higher probability is chosen. For each of the 4,037 segments of context in the test set, we calculated the accuracy of each model at distinguishing the gold sentence from a distractor sentence. We ran this pairwise decision 5 times, each time with a different set of randomly selected distractor sentences and averaged their performance across all 5 rounds.

Results The accuracy of each of the models is reported in Table 2. The best performance is obtained by ENGEN, which is significantly better than the other two models ($p < 0.05$, binomial test). Unlike the mention generation task, S2SA beats ENTITYNLM at this task; this difference in performance shows the importance of local context. Although we performed five different rounds of random sampling to choose a sentence from the following segment as the distractor sentence, the standard deviations in Table 2 show the results are generally consistent across rounds, regardless of the distractor's distance from the gold sentence.

7 Human Evaluation: Sentence Generation

The task motivating the work in this paper is narrative text generation. As such, evaluation by human judges of the quality of generated text is the best measure of our methods' quality. This study simplifies that evaluation by distilling the judgment down to a forced choice between contextually generated sentences generated by two different models. We use this task to investigate the strengths and weaknesses of our model in a downstream application. By asking humans to decide which sentences they prefer (in a given context) and to explain why, we can analyze where our model is helping and where text generation for stories still needs to improve, both with respect to entities and to other aspects of language. Here we control for training data and assess the benefit of including entity information for generating sentences to continue a story.

We presented Amazon Mechanical Turkers[5] with a short excerpt from a story and two generated sentences, one generated by ENGEN and one generated by the entity-unaware S2SA. We asked them to *"choose a sentence to continue the story"* and to briefly explain why they made the choice they did, an approach similar to that in other story-based work such as Lukin et al. (2015).

Note that we did not prime Turkers to focus on entities. Rather, the purpose of this experiment was to examine the performance of the model in a story generation setting and to get feedback on what people generally notice in generated text, not only with regard to entities. By keeping the task

[5]We selected workers who had completed over 1,000 tasks, had over a 95% task acceptance rate, and were from the United States.

open-ended, we can better analyze what people value in generated text for stories, and where our model supports that and where it doesn't.

We used a subset of 50 randomly selected text segments from the test set described in §4. However, for the human evaluation, we only used the final 60 words[6] of the story segments to keep the amount of reading and context manageable for Turkers. The models had access to the same subset of the context that the evaluator saw, not all 50 sentences from the original segment as in earlier experiments. For each context, we randomly sampled a sentence to continue the document, using each of two models: ENGEN and S2SA. These two models allowed us to see if adding the entity information noticeably improved the quality of the generation to evaluators.

Initial experiments showed that fluency remains a problem for neural text generation. To reduce the effect of fluency on Turkers' judgments, we generated 100 samples for each context/model pair and then reranked them with a 5-gram language model (Heafield, 2011) that was trained on the same training data. The two top ranked sentences (one for ENGEN and one for S2SA) were presented in random order and without reference to the models that generated them.

For each of the 50 contexts, we had 11 Turkers pick a candidate sentence to continue the story passage. Turkers were paid $0.10 for each evaluation they completed. In total, 93 Turkers completed the task. The number of passages Turkers completed ranged from 1 to all 50 story segments (with an average of 6.1). While the quantitative portion of this task would be easy to scale, the qualitative portion is not; we kept the human evaluation small, running it until reaching saturation.

Results Each pair of sentences was evaluated by 11 Turkers, so each of the passages could receive up to 11 votes for ENGEN. For 27 of the passages, the majority of Turkers (6 or more) chose the sentence from ENGEN, versus 23 passages that went to the baseline model, S2SA. The scores were close in many cases, and for several passages, Turkers noted in their explanations that while they were required to choose one sentence, both would have worked. Examples of the context and sentence pairs that were strongly in favor of ENGEN, strongly in favor of S2SA, and that received mixed reviews are shown in Table 3.

When asked to explain why they selected the sentence they did, a few Turkers attributed their choices to connections between pronouns in ENGEN's suggestions to characters mentioned in the story excerpt. However, a more frequent occurrence was Turkers citing a mismatch in entities as their reason for rejecting an option. For example, one Turker said they chose ENGEN's sentence because the S2SA sentence began with "she," and there were no female characters in the context.

Interestingly, while pronouns not mentioned in the context were cited as a reason for rejecting candidate sentences, new proper noun entity mentions were seen as an asset by some. One Turker chose a S2SA sentence that referenced "Richard," a character not present in the context, saying, *"I believe including Richard as a name gives some context of the characters of the story."* This demonstrates the importance of the ability to generate new entities, in addition to referring back to exisiting entities.

However, due to the open-ended nature of the task, the reasons Turkers cited for selecting sentences extended far beyond characters and entity mentions. In fact, most of the responses credited other aspects of stories and language for their choice. Some chose sentences based on their potential to move the plot forward or because they fit better with *"the theme"* or *"the tone"* of the context. Others made decisions based on whether they thought a sentence of dialogue or a descriptive sentence was more appropriate, or a statement versus a question. Many made their decisions using deeper knowledge about the story's context. For example, in the second story listed in Table 3, one Turker used social knowledge to choose the S2SA sentence because *"the introduction makes the man sound like he is a stranger, so 'I'm proud of you' seems out of place."* In this case, even though the sentence from ENGEN correctly generated pronouns that refer to entities in the context, the mismatch in the social aspects of the context and ENGEN's sentence contributed to 7 out of 11 Turkers choosing the vaguer S2SA sentence.

While neither S2SA nor ENGEN explicitly encodes these types of information, these qualities are important to human evaluators of generated text and should influence future work on narrative text generation.

[6]We included the whole sentence that contained the 60th word, so most documents were slightly over 60 words.

Context	ENGEN	S2SA	#
he says that it was supposed to look random , but he feels it was planned . i was the target . he 's not sure , but he feels that you might have something to do with this , " cassey said sadly . " he ca n't do that ! " manny yelled . " he ca n't accuse me with no justification .	it 's not me . "	he has nothing to do with my life	10
he was wearing brown slacks and a tan button-down shirt , with wool slippers . he looked about sixty , a little paunchy , with balding brown hair and a bushy mustache . ice blue eyes observed alejo keenly , then drifted over to wara ." welcome to my home . " the man 's voice was deep and calm .	" i 'm proud of you , " he said .	" what 's going on ? '	4
bearl looked on the scene , and gasped . this was the white rock of legend , the rock that had lured him to this land . then he stopped . " look , geron . the white rock we saw from the sea . " the struggle was taking place on the white rock . the monster had his back to bearl .	" oh my god ! "	he could not believe his eyes	1

Table 3: Example generated sentences, for three different contexts. The last column indicates the number of Turkers who voted for ENGEN's sentence (out of 11). While entity mentions appear in most of the generated texts, correct entity mentions are not sufficient to guarantee a win, as seen in the second example.

8 Related Work

Beyond past work already discussed, we note a few additional important areas of research relevant to our work.

Neural models for text generation Natural language generation is a classic problem in artificial intelligence. Recent use of RNNs (Sutskever et al., 2011) has reignited interest in this area. Our work provides an additional way to address the well-known drawback of RNNs: they use only limited context. This has been noted as a serious problem in conversational modeling (Sordoni et al., 2015) and text generation with multiple sentences (Lau et al., 2017). Recent work on context-aware text generation (or the related task, language modeling) has studied the possibilities of using different granularity of context. For example, in the scenario of response generation, Sordoni et al. (2015) showed a consistent gain by including one more utterance from context. Similar effects are also observed by adding topical information for language modeling and generation (Lau et al., 2017).

Entity-related generation Choosing an appropriate entity and its mention has a big influence on the coherence of a text, as studied in Centering Theory (Grosz et al., 1995). Recently, the ENTITYNLM proposed by Ji et al. (2017) shows that adding entity related information can improve the performance of language modeling, which potentially provides a method for entity related text generation. We build on ENTITYNLM, combining entity context with previous-sentence context, and demonstrate the importance of the latter in a coherence test (§6). The max pooling combination we propose is simple but effective.

Another line of related work on recipe generation included special treatment of entities as candidates in generating sentences, but not as context (Kiddon et al., 2016). Bosselut et al. (2018) also generated recipes, using neural process networks to track and update entity representations with the goal of modeling actions and their causal effects on entities. However, the entity representations are frozen during generation, rather than dynamically updated.

Mention generation Our novel mention generation task is inspired by both referring expression generation (Dale and Reiter, 1995) and entity prediction (Modi et al., 2017). The major difference is that, unlike referring expression generation, our

task includes all the mentions used for entities, including pronouns; we believe it is a more realistic test of a model's handling of entities. Krahmer and Van Deemter (2012) give a comprehensive survey on early work of referring expression generation.

The mention only version of the mention generation task is related to cloze tests like the Children's Book Test (Hill et al., 2016), the "Who-did-What" Test (Onishi et al., 2016), and the CNN and Daily Mail test described by Hermann et al. (2015). However, unlike these tests, we predict all entity mentions in the text and from a dynamically expanding candidate list, typically much larger than those in other cloze tests.

Story generation Work in story generation has incorporated structure and context through event representations (Martin et al., 2017) or semantic representations, like story graphs (Rishes et al., 2013; Elson and McKeown, 2009). In this work, we provide evidence for the value of entity representations as an additional form of structure, following work by Walker et al. (2011), Cavazza and Charles (2005), and Cavazza et al. (2002).

9 Conclusion

Inspired by Centering Theory and the importance of characters in stories, we propose a neural model for text generation that incorporates context via entities. We found that combining entity representations with representations of the previous sentence and the hidden state (from a neural language model) improves performance on three tasks: mention generation, sentence selection, and sentence generation. By collecting human evaluations of sentences generated with entity information, we find that while coherently referring back to entities in the context was cited by several Turkers as a factor in their decision, the introduction of new entities and moving the narrative forward were also valued.

Therefore, while entities are a useful structure to incorporate in story generation, other structures may also prove useful, including other aspects of discourse (e.g., discourse relations or planning) or story-related structures (e.g., narrative structure).

Abstract

We investigate the computational complexity of various problems for simple recurrent neural networks (RNNs) as formal models for recognizing weighted languages. We focus on the single-layer, ReLU-activation, rational-weight RNNs with softmax, which are commonly used in natural language processing applications. We show that most problems for such RNNs are undecidable, including consistency, equivalence, minimization, and the determination of the highest-weighted string. However, for consistent RNNs the last problem becomes decidable, although the solution length can surpass all computable bounds. If additionally the string is limited to polynomial length, the problem becomes NP-complete. In summary, this shows that approximations and heuristic algorithms are necessary in practical applications of those RNNs.

1 Introduction

Recurrent neural networks (RNNs) are an attractive apparatus for probabilistic language modeling (Mikolov and Zweig, 2012). Recent experiments show that RNNs significantly outperform other methods in assigning high probability to held-out English text (Jozefowicz et al., 2016).

Roughly speaking, an RNN works as follows. At each time step, it consumes one input token, updates its hidden state vector, and predicts the next token by generating a probability distribution over all permissible tokens. The probability of an input string is simply obtained as the product of the predictions of the tokens constituting the string followed by a terminating token. In this manner, each RNN defines a *weighted language*; i.e. a total function from strings to weights. Siegelmann and Sontag (1995) showed that single-layer rational-weight RNNs with saturated linear activation can compute any computable function. To this end, a specific architecture with 886 hidden units can simulate any Turing machine in real-time (i.e., each Turing machine step is simulated in a single time step). However, their RNN encodes the whole input in its internal state, performs the actual computation of the Turing machine when reading the terminating token, and then encodes the output (provided an output is produced) in a particular hidden unit. In this way, their RNN allows "thinking" time (equivalent to the computation time of the Turing machine) after the input has been encoded.

We consider a different variant of RNNs that is commonly used in natural language processing applications. It uses ReLU activations, consumes an input token at each time step, and produces softmax predictions for the next token. It thus immediately halts after reading the last input token and the weight assigned to the input is simply the product of the input token predictions in each step.

Other formal models that are currently used to implement probabilistic language models such as finite-state automata and context-free grammars are by now well-understood. A fair share of their utility directly derives from their nice algorithmic properties. For example, the weighted languages computed by weighted finite-state automata are closed under intersection (pointwise product) and union (pointwise sum), and the corresponding unweighted languages are closed under intersection, union, difference, and complementation (Droste et al., 2013). Moreover, toolkits like OpenFST (Allauzen et al., 2007) and Carmel[1] implement efficient algorithms on automata like minimization, intersection, finding the highest-weighted path and the highest-weighted string.

RNN practitioners naturally face many of these same problems. For example, an RNN-

Proceedings of NAACL-HLT 2018, pages 2261–2271
New Orleans, Louisiana, June 1 - 6, 2018.

based machine translation system should extract the highest-weighted output string (i.e., the most likely translation) generated by an RNN, (Sutskever et al., 2014; Bahdanau et al., 2014). Currently this task is solved by approximation techniques like heuristic greedy and beam searches. To facilitate the deployment of large RNNs onto limited memory devices (like mobile phones) minimization techniques would be beneficial. Again currently only heuristic approaches like knowledge distillation (Kim and Rush, 2016) are available. Meanwhile, it is unclear whether we can determine if the computed weighted language is consistent; i.e., if it is a probability distribution on the set of all strings. Without a determination of the overall probability mass assigned to all finite strings, a fair comparison of language models with regard to perplexity is simply impossible.

The goal of this paper is to study the above problems for the mentioned ReLU-variant of RNNs. More specifically, we ask and answer the following questions:

- Consistency: Do RNNs compute consistent weighted languages? Is the consistency of the computed weighted language decidable?
- Highest-weighted string: Can we (efficiently) determine the highest-weighted string in a computed weighted language?
- Equivalence: Can we decide whether two given RNNs compute the same weighted language?
- Minimization: Can we minimize the number of neurons for a given RNN?

2 Definitions and notations

Before we introduce our RNN model formally, we recall some basic notions and notation. An *alphabet* Σ is a finite set of symbols, and we write $|\Sigma|$ for the number of symbols in Σ. A *string* s over the alphabet Σ is a finite sequence of zero or more symbols drawn from Σ, and we write Σ^* for the set of all strings over Σ, of which ϵ is the empty string. The length of the string $s \in \Sigma^*$ is denoted $|s|$ and coincides with the number of symbols constituting the string. As usual, we write A^B for the set of functions $\{f \mid f\colon B \to A\}$. A *weighted language* L is a total function $L\colon \Sigma^* \to \mathbb{R}$ from strings to real-valued weights. For example, $L(a^n) = e^{-n}$ for all $n \geq 0$ is such a weighted language.

We restrict the weights in our RNNs to the rational numbers $\mathbb{Q}$. In addition, we reserve the use of a special symbol \$ to mark the start and end of an input string. To this end, we assume that $\$ \notin \Sigma$ for all considered alphabets, and we let $\Sigma_\$ = \Sigma \cup \{\$\}$.

Definition 1. *A single-layer RNN R is a 7-tuple $\langle \Sigma, N, h_{-1}, W, W', E, E' \rangle$, in which*

- *Σ is an* input alphabet,
- *N is a finite set of* neurons,
- *$h_{-1} \in \mathbb{Q}^N$ is an* initial activation vector,
- *$W \in \mathbb{Q}^{N \times N}$ is a* transition matrix,
- *$W' = (W'_a)_{a \in \Sigma_\$}$ is a $\Sigma_\$$-indexed family of* bias vectors *$W'_a \in \mathbb{Q}^N$,*
- *$E \in \mathbb{Q}^{\Sigma_\$ \times N}$ is a* prediction matrix, *and*
- *$E' \in \mathbb{Q}^{\Sigma_\$}$ is a* prediction bias vector.

Next, let us define how such an RNN works. We first prepare our input encoding and the effect of our activation function. For an input string $s = s_1 s_2 \cdots s_n \in \Sigma^*$ with $s_1, \ldots, s_n \in \Sigma$, we encode this input as $\$s\$$ and thus assume that $s_0 = \$$ and $s_{n+1} = \$$. Our RNNs use ReLUs (Rectified Linear Units), so for every $v \in \mathbb{Q}^N$ we let $\sigma\langle v \rangle$ (the ReLU activation) be the vector $\sigma\langle v \rangle \in \mathbb{Q}^N$ such that

$$\sigma\langle v \rangle(n) = \max\big(0, v(n)\big) \qquad \text{for every } n \in N.$$

In other words, the ReLUs act like identities on nonnegative inputs, but clip negative inputs to 0. We use softmax-predictions, so for every vector $p \in \mathbb{Q}^{\Sigma_\$}$ and $a \in \Sigma_\$$ we let

$$\operatorname{softmax}\langle p \rangle(a) = \frac{e^{p(a)}}{\sum_{a' \in \Sigma_\$} e^{p(a')}} \ .$$

RNNs act in discrete time steps reading a single letter at each step. We now define the semantics of our RNNs.

Definition 2. *Let $R = \langle \Sigma, N, h_{-1}, W, W', E, E' \rangle$ be an RNN, s an input string of length n and $0 \leq t \leq n$ a time step. We define*

- *the* hidden state vector $h_{s,t} \in \mathbb{Q}^N$ *given by*

$$h_{s,t} = \sigma\langle W \cdot h_{s,t-1} + W'_{s_t} \rangle \ ,$$

  where $h_{s,-1} = h_{-1}$ and we use standard matrix product and point-wise vector addition,
- *the* next-token prediction vector $E_{s,t} \in \mathbb{Q}^{\Sigma_\$}$

$$E_{s,t} = E \cdot h_{s,t} + E'$$

- *the* next-token distribution $E'_{s,t} \in \mathbb{R}^{\Sigma_\$}$

$$E'_{s,t} = \operatorname{softmax}\langle E_{s,t} \rangle \ .$$

Finally, the RNN R computes the weighted language $R\colon \Sigma^* \to \mathbb{R}$, which is given for every input $s = s_1 \cdots s_n$ as above by

$$R(s) = \prod_{t=0}^{n} E'_{s,t}(s_{t+1}) \ .$$

In other words, each component $h_{s,t}(n)$ of the hidden state vector is the ReLU activation applied to a linear combination of all the components of the previous hidden state vector $h_{s,t-1}$ together with a summand W'_{s_t} that depends on the t-th input letter s_t. Thus, we often specify $h_{s,t}(n)$ as linear combination instead of specifying the matrix W and the vectors W'_a. The semantics is then obtained by predicting the letters $s_1, \ldots, s_n$ of the input s and the final terminator \$ and multiplying the probabilities of the individual predictions.

Let us illustrate these notions on an example. We consider the RNN $\langle \Sigma, N, h_{-1}, W, W', E, E' \rangle$ with $\gamma \in \mathbb{Q}$ and

- $\Sigma = \{a\}$ and $N = \{1, 2\}$,
- $h_{-1} = (-1, 0)^T$ and

$$W = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix} \quad \text{and} \quad W'_{\$} = W'_a = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$$

- $E(\$, \cdot) = (M + 1, -(M + 1))$ and $E(a, \cdot) = (1, -1)$ and
- $E'(\$) = -M$ and $E'(a) = 0$.

In this case, we obtain the linear combinations

$$h_{s,t} = \sigma \left\langle \begin{matrix} h_{s,t-1}(1) + 1 \\ h_{s,t-1}(1) \end{matrix} \right\rangle$$

computing the next hidden state components. Given the initial activation, we thus obtain $h_{s,t} = \sigma\langle t, t-1 \rangle$. Using this information, we obtain

$$\begin{aligned} E_{s,t}(\$) &= (M+1) \cdot (t - \sigma\langle t-1 \rangle) - M \\ E_{s,t}(a) &= t - \sigma\langle t-1 \rangle \ . \end{aligned}$$

Consequently, we assign weight $\frac{e^{-M}}{1+e^{-M}}$ to input ε, weight $\frac{1}{1+e^{-M}} \cdot \frac{e^1}{e^1+e^1}$ to a, and, more generally, weight $\frac{1}{1+e^{-M}} \cdot \frac{1}{2^n}$ to a^n.

Clearly the weight assigned by an RNN is always in the interval $(0, 1)$, which enables a probabilistic view. Similar to weighted finite-state automata or weighted context-free grammars, each RNN is a compact, finite representation of a weighted language. The softmax-operation enforces that the probability 0 is impossible as assigned weight, so each input string is principally possible. In practical language modeling, smoothing methods are used to change distributions such that impossibility (probability 0) is removed. Our RNNs avoid impossibility outright, so this can be considered a feature instead of a disadvantage.

The hidden state $h_{s,t}$ of an RNN can be used as scratch space for computation. For example, with a single neuron n we can count symbols in s via:

$$h_{s,t}(n) = \sigma\langle h_{s,t-1}(n) + 1 \rangle \ .$$

Here the letter-dependent summand W'_a is universally 1. Similarly, for an alphabet $\Sigma = \{a_1, \ldots, a_m\}$ we can use the method of Siegelmann and Sontag (1995) to encode the complete input string s in base $m + 1$ using:

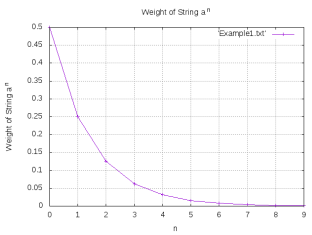
$$h_{s,t}(n) = \sigma\langle (m+1) h_{s,t-1}(n) + c(s_t) \rangle \ ,$$

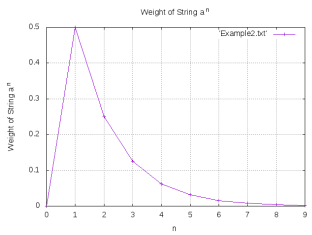
where $c\colon \Sigma_{\$} \to \{0, \ldots, m\}$ is a bijection. In principle, we can thus store the entire input string (of unbounded length) in the hidden state value $h_{s,t}(n)$, but our RNN model outputs weights at each step and terminates immediately once the final delimiter \$ is read. It must assign a probability to a string *incrementally* using the chain rule decomposition $p(s_1 \cdots s_n) = p(s_1) \cdot \ldots \cdot p(s_n \mid s_1 \cdots s_{n-1})$.

Let us illustrate our notion of RNNs on some additional examples. They all use the alphabet $\Sigma = \{a\}$ and are illustrated and formally specified in Figure 1. The first column shows an RNN R_1 that assigns $R_1(a^n) = 2^{-(n+1)}$. The next-token prediction matrix ensures equal values for a and \$ at every time step. The second column shows the RNN R_2, which we already discussed. In the beginning, it heavily biases the next symbol prediction towards a, but counters it starting at $t = 1$. The third RNN R_3 uses another counting mechanism with $h_{s,t} = \sigma\langle t - 100, t - 101, t \rangle$. The first two components are ReLU-thresholded to zero until $t > 101$, at which point they overwhelm the bias towards a turning all future predictions to \$.

3 Consistency

We first investigate the consistency problem for an RNN R, which asks whether the recognized weighted language R is indeed a probability distribution. Consequently, an RNN R is *consistent*

	$R_1(a^n) = 2^{-(n+1)}$	$R_2(\varepsilon) \approx 0$ $R_2(a^n) \approx 2^{-n}$ $(n \geq 1)$	$R_3(a^{100}) \approx 1$ $R_3(a^n) \approx 0$ $(n \neq 100)$
N	$\{1\}$	$\{1, 2\}$	$\{1, 2, 3\}$
h_{-1}	$\begin{pmatrix} 0 \end{pmatrix}$	$\begin{pmatrix} -1 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$
W	$\begin{pmatrix} 0 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}$	$\begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix}$
$W'_{\$}$ W'_a	$\begin{pmatrix} 0 \end{pmatrix}$ $\begin{pmatrix} 0 \end{pmatrix}$	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$	$\begin{pmatrix} -99 \\ -100 \\ 1 \end{pmatrix}$ $\begin{pmatrix} -99 \\ -100 \\ 1 \end{pmatrix}$
$E_{\$}$ E_a	$\begin{pmatrix} 0 \end{pmatrix}$ $\begin{pmatrix} 0 \end{pmatrix}$	$\begin{pmatrix} M+1 \\ -(M+1) \end{pmatrix}$ $\begin{pmatrix} 1 \\ -1 \end{pmatrix}$	$\begin{pmatrix} M \\ -M \\ 0 \end{pmatrix}$ $\begin{pmatrix} -M \\ M \\ 0 \end{pmatrix}$
$E'_{\$}$ E'_a	0 0	$-M$ 0	$-M$ 0
			




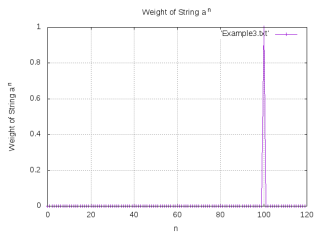


Figure 1: Sample RNNs over single-letter alphabets, and the weighted languages they recognize. M is some positive rational number which depends on the desired error margin. If we want to express the second and the third languages with error margin δ, M is chosen so that $M > -\ln \frac{\delta}{1-\delta}$ in column 2, and chosen so that $(1 + e^{-M})^{100} < \frac{1}{1-\delta}$ in column 3.

if $\sum_{s \in \Sigma^*} R(s) = 1$. We first show that there is an inconsistent RNN, which together with our examples shows that consistency is a nontrivial property of RNNs.[2]

We immediately use a slightly more complex example, which we will later reuse.

Example 3. Let us consider an arbitrary RNN

$$R = \langle \Sigma, N, h_{-1}, W, W', E, E' \rangle$$

with the single-letter alphabet $\Sigma = \{a\}$, the neurons $\{1, 2, 3, n, n'\} \subseteq N$, initial activation $h_{-1}(i) = 0$ for all $i \in \{1, 2, 3, n, n'\}$, and the following linear combinations:

$$h_{s,t}(1) = \sigma\langle h_{s,t-1}(1) + h_{s,t-1}(n) - h_{s,t-1}(n') \rangle$$
$$h_{s,t}(2) = \sigma\langle h_{s,t-1}(2) + 1 \rangle$$
$$h_{s,t}(3) = \sigma\langle h_{s,t-1}(3) + 3h_{s,t-1}(1) \rangle$$
$$E_{s,t}(\$) = h_{s,t}(3) - h_{s,t}(2)$$
$$E_{s,t}(a) = h_{s,t}(2)$$

Now we distinguish two cases:
Case 1: If $h_{s,t}(n) - h_{s,t}(n') = 0$ for all $t \in \mathbb{N}$, then $h_{s,t}(1) = 0$ and $h_{s,t}(2) = t + 1$ and $h_{s,t}(3) = 0$. Hence we have $E_{s,t}(\$) = -(t + 1)$ and $E_{s,t}(a) = t + 1$. In this case the termination probability

$$E'_{s,t}(\$) = \frac{e^{-(t+1)}}{e^{-(t+1)} + e^{t+1}} = \frac{1}{1 + e^{2(t+1)}}$$

(i.e., the likelihood of predicting \$) shrinks rapidly towards 0, so the RNN assigns less than 15% of the probability mass to the terminating sequences (i.e., the finite strings), so the RNN is inconsistent (see Lemma 15 in the appendix).

Case 2: Suppose that there exists a time

[2] For comparison, all probabilistic finite-state automata are consistent, provided no transitions exit final states. Not all probabilistic context-free grammars are consistent; necessary and sufficient conditions for consistency are given by Booth and Thompson (1973). However, probabilistic context-free grammars obtained by training on a finite corpus using popular methods (such as expectation-maximization) are guaranteed to be consistent (Nederhof and Satta, 2006).

point $T \in \mathbb{N}$ such that for all $t \in \mathbb{N}$

$$h_{s,t}(n) - h_{s,t}(n') = \begin{cases} 1 & \text{if } t = T \\ 0 & \text{otherwise.} \end{cases}$$

Then $h_{s,t}(1) = 0$ for all $t \leq T$ and $h_{s,t}(1) = 1$ otherwise. In addition, we have $h_{s,t}(2) = t + 1$ and $h_{s,t}(3) = \sigma\langle 3(t - T - 1)\rangle$. Hence we have

$$\begin{aligned} E_{s,t}(\$) &= \sigma\langle 3(t - T - 1)\rangle - (t + 1) \\ &= \begin{cases} -(t+1) & \text{if } t \leq T \\ 2t - 3T - 4 & \text{otherwise} \end{cases} \\ E_{s,t}(a) &= t + 1 \ , \end{aligned}$$

which shows that the probability

$$E'_{s,t}(\$) = \begin{cases} \frac{1}{1+e^{2(t+1)}} & \text{if } t \leq T \\ \frac{e^{t-3T-5}}{1+e^{t-3T-5}} & \text{otherwise} \end{cases}$$

of predicting \$ increases over time and eventually (for $t \gg 3T$) far outweighs the probability of predicting a. Consequently, in this case the RNN is consistent (see Lemma 16 in the appendix).

We have seen in the previous example that consistency is not trivial for RNNs, which takes us to the consistency problem for RNNs:

Consistency: Given an RNN R, return "yes" if R is consistent and "no" otherwise.

We recall the following theorem, which, combined with our example, will prove that consistency is unfortunately undecidable for RNNs.

Theorem 4 (Theorem 2 of Siegelmann and Sontag (1995))**.** *Let M be an arbitrary deterministic Turing machine. There exists an RNN*

$$R = \langle \Sigma, N, h_{-1}, W, W', E, E' \rangle$$

with saturated linear activation, input alphabet $\Sigma = \{a\}$, and 1 designated neuron $n \in N$ such that for all $s \in \Sigma^*$ and $0 \leq t \leq |s|$

- *$h_{s,t}(n) = 0$ if M does not halt on ε, and*
- *if M does halt on empty input after T steps, then*

$$h_{s,t}(n) = \begin{cases} 1 & \text{if } t = T \\ 0 & \text{otherwise.} \end{cases}$$

In other words, such RNNs with saturated linear activation can semi-decide halting of an arbitrary Turing machine in the sense that a particular neuron achieves value 1 at some point during the evolution if and only if the Turing machine halts on empty input. An RNN with saturated linear activation is an RNN following our definition with the only difference that instead of our ReLU-activation σ the following saturated linear activation $\sigma' \colon \mathbb{Q}^N \to \mathbb{Q}^N$ is used. For every vector $v \in \mathbb{Q}^N$ and $n \in N$, let

$$\sigma'\langle v \rangle(n) = \begin{cases} 0 & \text{if } v(n) < 0 \\ v(n) & \text{if } 0 \leq v(n) \leq 1 \\ 1 & \text{if } v(n) > 1 \ . \end{cases}$$

Since $\sigma'\langle v \rangle = \sigma\langle v \rangle - \sigma\langle v - \vec{1} \rangle$ for all $v \in \mathbb{Q}^N$, and the right-hand side is a linear transformation, we can easily simulate saturated linear activation in our RNNs. To this end, each neuron $n \in N$ of the original RNN $R = \langle \Sigma, N, h_{-1}, U, U', E, E' \rangle$ is replaced by two neurons n_1 and n_2 in the new RNN $R' = \langle \Sigma, N', h'_{-1}, V, V', F, F' \rangle$ such that $h_{s,t}(n) = h'_{s,t}(n_1) - h'_{s,t}(n_2)$ for all $s \in \Sigma^*$ and $0 \leq t \leq |s|$, where the evaluation of $h'_{s,t}$ is performed in the RNN R'. More precisely, we use the transition matrix V and bias function V', which is given by

$$\begin{aligned} V(n_1, n'_1) &= V(n_2, n'_1) = U(n, n') \\ V(n_1, n'_2) &= V(n_2, n'_2) = -U(n, n') \\ V'_a(n_1) &= U'_a(n) \\ V'_a(n_2) &= U'_a(n) - 1 \\ h'_{-1}(n_1) &= h_{-1}(n) \\ h'_{-1}(n_2) &= 0 \end{aligned}$$

for all $n, n' \in N$ and $a \in \Sigma \cup \{\$\}$, where n_1 and n_2 are the two neurons corresponding to n and n'_1 and n'_2 are the two neurons corresponding to n' (see Lemma 17 in the appendix).

Corollary 5. *Let M be an arbitrary deterministic Turing machine. There exists an RNN*

$$R = \langle \Sigma, N, h_{-1}, W, W', E, E' \rangle$$

with input alphabet $\Sigma = \{a\}$ and 2 designated neurons $n_1, n_2 \in N$ such that for all $s \in \Sigma^*$ and $0 \leq t \leq |s|$

- *$h_{s,t}(n_1) - h_{s,t}(n_2) = 0$ if M does not halt on ε, and*
- *if M does halt on empty input after T steps, then*

$$h_{s,t}(n_1) - h_{s,t}(n_2) = \begin{cases} 1 & \text{if } t = T \\ 0 & \text{otherwise.} \end{cases}$$

We can now use this corollary together with the RNN R of Example 3 to show that the consistency problem is undecidable. To this end, we simulate a given Turing machine M and identify the two designated neurons of Corollary 5 as n and n' in Example 3. It follows that M halts if and only if R is consistent. Hence we reduced the undecidable halting problem to the consistency problem, which shows the undecidability of the consistency problem.

Theorem 6. *The consistency problem for RNNs is undecidable.*

As mentioned in Footnote 2, probabilistic context-free grammars obtained after training on a finite corpus using the most popular methods are guaranteed to be consistent. At least for 2-layer RNNs this does not hold.

Theorem 7. *A two-layer RNN trained to a local optimum using Back-propagation-through-time (BPTT) on a finite corpus is not necessarily consistent.*

Proof. The first layer of the RNN R with a single alphabet symbol a uses one neuron n' and has the following behavior:

$$h_{-1}(n') = 0$$
$$h_{s,t}(n') = \sigma\langle h_{s,t-1}(n') + 1\rangle$$

The second layer uses neuron n and takes $h_{s,t}(n')$ as input at time t:

$$h_{s,t}(n) = \sigma\langle h_{s,t}(n') - 2\rangle$$
$$E_{s,t}(a) = h_{s,t}(n) \qquad E_{s,t}(\$) = 0$$
$$E'_{s,t}(a) = \begin{cases} \frac{1}{2} & \text{if } t \leq 1 \\ \frac{e^{(t-1)}}{1+e^{(t-1)}} & \text{otherwise.} \end{cases}$$

Let the training data be $\{a\}$. Then the objective we wish to maximize is simply $R(a)$. The derivative of this objective with respect to each parameter is 0, so applying gradient descent updates does not change any of the parameters and we have converged to an inconsistent RNN. □

It remains an open question whether there is a single-layer RNN that also exhibits this behavior.

4 Highest-weighted string

Given a function $f\colon \Sigma^* \to \mathbb{R}$ we are often interested in the highest-weighted string. This corresponds to the most likely sentence in a language model or the most likely translation for a decoder RNN in machine translation.

	Best-path	Best-string
General RNN	**Undecidable**	
Consistent RNN	**NP-c** [3]	
Det. PFSA/PCFG	P [4]	
Nondet. PFSA/PCFG		NP-c [5]

Table 1: Comparison of the difficulty of identifying the most probable derivation (Best-path) and the highest-weighted string (Best-string) for various models.

For deterministic probabilistic finite-state automata or context-free grammars only one path or derivation exists for any given string, so the identification of the highest-weighted string is the same task as the identification of the most probable path or derivation. However, for nondeterministic devices, the highest-weighted string is often harder to identify, since the weight of a string is the sum of the probabilities of all possible paths or derivations for that string. A comparison of the difficulty of identifying the most probable derivation and the highest-weighted string for various models is summarized in Table 1, in which we marked our results in bold face.

We present various results concerning the difficulty of identifying the highest-weighted string in a weighted language computed by an RNN. We also summarize some available algorithms. We start with the formal presentation of the three studied problems.

1. **Best string:** Given an RNN R and $c \in (0, 1)$, does there exist $s \in \Sigma^*$ with $R(s) > c$?
2. **Consistent best string:** Given a consistent RNN R and $c \in (0, 1)$, does there exist $s \in \Sigma^*$ with $R(s) > c$?
3. **Consistent best string of polynomial length:** Given a consistent RNN R, polynomial $\mathcal{P}$ with $\mathcal{P}(x) \geq x$ for $x \in \mathbb{N}^+$, and $c \in (0, 1)$, does there exist $s \in \Sigma^*$ with $|s| \leq \mathcal{P}(|R|)$ and $R(s) > c$?

As usual the corresponding optimization problems are not significantly simpler than these decision problems. Unfortunately, the general problem is also undecidable, which can easily be shown using our example.

[3] Restricted to solutions of polynomial length
[4] Dijkstra shortest path / (Knuth, 1977)
[5] (Casacuberta and de la Higuera, 2000) / (Simaan, 1996)

Theorem 8. *The best string problem for RNNs is undecidable.*

Proof. Let M be an arbitrary Turing machine and again consider the RNN R of Example 3 with the neurons n and n' identified with the designated neurons of Corollary 5. We note that $R(\varepsilon) = \frac{1}{1+e^2} < 0.12$ in both cases. If M does not halt, then $R(a^n) \leq \frac{1}{1+e^{2(n+1)}} \leq \frac{1}{1+e^2} < 0.12$ for all $n \in \mathbb{N}$. On the other hand, if M halts after T steps, then

$$\begin{aligned} & R(a^{3T-5}) \\ &= \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{1+e^{2(t+1)}}\Big) \cdot \Big(\prod_{t=T+1}^{3T-6} \frac{1}{1+e^{t-3T-5}}\Big) \cdot \frac{1}{2} \\ &\geq \frac{2}{(-1,e^{-2})_\infty} \cdot \Big(\prod_{t=T+1}^{3T-6} \frac{e^{3T+5-t}}{e^{3T+5-t+1}}\Big) \cdot \frac{1}{2} \\ &\geq \frac{2}{(-1,e^{-2})_\infty \cdot (-1,e^{-1})_\infty} \geq 0.25 \end{aligned}$$

using Lemma 14 in the appendix. Consequently, a string with weight above 0.12 exists if and only if M halts, so the best string problem is also undecidable. □

If we restrict the RNNs to be consistent, then we can easily decide the best string problem by simple enumeration.

Theorem 9. *The consistent best string problem for RNNs is decidable.*

Proof. Let R be the RNN over alphabet Σ and $c \in (0,1)$ be the bound. Since Σ^* is countable, we can enumerate it via $f\colon \mathbb{N} \to \Sigma^*$. In the algorithm we compute $S_n = \sum_{i=0}^{n} R(f(i))$ for increasing values of n. If we encounter a weight $R(f(n)) > c$, then we stop with answer "yes." Otherwise we continue until $S_n > 1 - c$, at which point we stop with answer "no."

Since R is consistent, $\lim_{i\to\infty} S_i = 1$, so this algorithm is guaranteed to terminate and it obviously decides the problem. □

Next, we investigate the length $|w_R^{\max}|$ of the shortest string $w_R^{\max}$ of maximal weight in the weighted language R generated by a consistent RNN R in terms of its (binary storage) size $|R|$. As already mentioned by Siegelmann and Sontag (1995) and evidenced here, only small precision rational numbers are needed in our constructions, so we assume that $|R| \leq c \cdot |N|^2$ for a (reasonably small) constant c, where N is the set of neurons of R. We show that no computable bound on the length of the best string can exist, so its length can surpass all reasonable bounds.

Theorem 10. *Let $f\colon \mathbb{N}_+ \to \mathbb{N}$ be the function with*

$$f(n) = \max_{\substack{\text{consistent RNN } R \\ |R| \leq n}} |w_R^{max}|$$

for all $n \in \mathbb{N}_+$. There exists no computable function $g\colon \mathbb{N} \to \mathbb{N}$ with $g(n) \geq f(n)$ for all $n \in \mathbb{N}$.

Proof. In the previous section (before Theorem 6) we presented an RNN R_M that simulates an arbitrary (single-track) Turing machine M with n states. By Siegelmann and Sontag (1995) we have $|R_M| \leq c \cdot (4n + 16)$. Moreover, we observed that this RNN R_M is consistent if and only if the Turing machine M halts on empty input. In the proof of Theorem 8 we have additionally seen that the length $|w_R^{\max}|$ of its best string exceeds the number T_M of steps required to halt.

For every $n \in \mathbb{N}$, let $BB(n)$ be the n-th "Busy Beaver" number (Radó, 1962), which is

$$BB(n) = \max_{\substack{\text{normalized } n\text{-state Turing machine } M \text{ with} \\ \text{2 tape symbols that halts on empty input}}} T_M$$

It is well-known that $BB\colon \mathbb{N}_+ \to \mathbb{N}$ cannot be bounded by any computable function. However,

$$\begin{aligned} BB(n) &\leq \max_{\substack{\text{normalized } n\text{-state Turing machine } M \text{ with} \\ \text{and 2 tape symbols that halts on empty input}}} |w_{R_M}^{\max}| \\ &\leq \max_{\substack{\text{consistent RNN } R \\ |R| \leq c\cdot(4n+16)}} |w_R^{\max}| \\ &= f(4nc + 16c) \ , \end{aligned}$$

so f clearly cannot be computable and no computable function g can provide bounds for f. □

Finally, we investigate the difficulty of the best string problem for consistent RNN restricted to solutions of polynomial length.

Theorem 11. *Identifying the best string of polynomial length in a consistent RNN is NP-complete.*

Proof. To show NP-hardness, we reduce from the 3-SAT problem. Let $x_1, \ldots, x_m$ be m Boolean variables and

$$F = \bigwedge_{i=1}^{k} \Big(\ell_{i1} \vee \ell_{i2} \vee \ell_{i3}\Big) \ ,$$

be a formula in conjunctive normal form, where $\ell_{ij} \in \{x_1, \ldots, x_m, \neg x_1, \ldots, \neg x_m\}$. 3-SAT asks whether there is a setting of x_is that makes F true.

We initialize $h_{-1}(n) = 0, \forall\ n \in N = \{x_1, \ldots, x_m, c_1, \ldots, c_k, c'_1, \ldots, c'_k, F, n_1, n_2, n_3, \star\}$. Let $s \in \{0,1\}^*$ be the input string. Denote the value of F when $x_j = s_j$ for all $j \in [m]$ as $F(s)$. Let $t \in \mathbb{N}$ with $t \leq |s|$. Set $h_{s,t}(x_m) = \sigma\langle I(s_t)\rangle$, where $I(0) = I(\$) = 0$ and $I(1) = 1$. This stores the current input symbol in neuron x_m, so $h_{s,t}(x_m) = I(s_t)$. In addition, we let $h_{s,t}(x_j) = \sigma\langle h_{s,t-1}(x_{j+1})\rangle$ for all $j \in [m-1]$. Consequently, for all $j \in [m]$

$$h_{s,t}(x_j) = \begin{cases} I(s_{t-(m-j)}) & \text{if } m-j \leq t \\ 0 & \text{otherwise.} \end{cases}$$

Next, we evaluate the clauses. For each $i \in [k]$, we use two neurons c_i and c'_i such that

$$h_{s,t}(c_i) = \sigma\langle f_{s,t}(\ell_{i1}) + f_{s,t}(\ell_{i2}) + f_{s,t}(\ell_{i3})\rangle$$
$$h_{s,t}(c'_i) = \sigma\langle f_{s,t}(\ell_{i1}) + f_{s,t}(\ell_{i2}) + f_{s,t}(\ell_{i3}) - 1\rangle,$$

where $f_{s,t}(x_m) = I(s_t)$, $f_{s,t}(\neg x_m) = 1 - I(s_t)$, and $\forall j \in [m-1], f_{s,t}(x_j) = h_{s,t-1}(x_{j+1})$, $f_{s,t}(\neg x_j) = 1 - h_{s,t-1}(x_{j+1})$. Note that $h_{s,t}(c_i) - h_{s,t}(c'_i)$ contains the evaluation of the clause $\ell_{i1} \vee \ell_{i2} \vee \ell_{i3}$. Let

$$h_{s,t}(F) = \sigma\Big\langle \sum_{i=1}^{k} \Big(h_{s,t-1}(c_i) - h_{s,t-1}(c'_i)\Big) - k + 1 \Big\rangle,$$

so $h_{s,t}(F) = F(s)$ contains the evaluation of the formula F using the values in neurons $x_1, \ldots, x_m$.

We use three counters n_1, n_2, n_3 to ensure that the only relevant inputs are of length $m+2$:

$$h_{s,t}(n_1) = \sigma\langle h_{s,t-1}(n_3) - (m+2)\rangle$$
$$h_{s,t}(n_2) = \sigma\langle h_{s,t-1}(n_3) - (m+1)\rangle$$
$$h_{s,t}(n_3) = \sigma\langle h_{s,t-1}(n_3) + 1\rangle\ ,$$

which yields $h_{s,t}(n_3) = t + 1$, $h_{s,t}(n_2) = \sigma\langle t - (m+1)\rangle$, and $h_{s,t}(n_1) = \sigma\langle t - (m+2)\rangle$.

Our goal neuron is $\star$, which we set to

$$h_{s,t}(\star) = \sigma\langle h_{s,t-1}(F) - h_{s,t-1}(n_1) + h_{s,t-1}(n_2) - 1\rangle$$

so that

$$h_{s,t}(\star) = \begin{cases} h_{s,t-1}(F) & \text{if } t = m+2 \\ 0 & \text{otherwise,} \end{cases}$$

so $h_{s,t}(\star) = 1$ if and only if $t = m+2$ and $F(s) = 1$.

Let $m' = m + 4$. The output is set as follows:

$$E_{s,t}(0) = E_{s,t}(1) = m'\big(1 - 2h_{s,t}(\star)\big)$$
$$E_{s,t}(\$) = -m'\big(1 - 2h_{s,t}(\star)\big)\ ,$$

This yields $E_{s,t}(0) = E_{s,t}(1) = -E_{s,t}(\$) = -m'$ if $t = m+2$ and $F(s) = 1$, and m' otherwise. For $a \in \{0,1\}$,

$$E'_{s,t}(a) = \begin{cases} \frac{e^{-m'}}{2e^{-m'}+e^{m'}} & \text{if } t = m+2 \text{ and } F(s) = 1 \\ \frac{e^{m'}}{2e^{m'}+e^{-m'}} & \text{otherwise} \end{cases}$$

$$E'_{s,t}(\$) = \begin{cases} \frac{e^{m'}}{2e^{-m'}+e^{m'}} & \text{if } t = m+2 \text{ and } F(s) = 1 \\ \frac{e^{-m'}}{2e^{m'}+e^{-m'}} & \text{otherwise.} \end{cases}$$

Finally, we set the threshold $\xi = 3^{-m'}$. When $|s| \neq m+2$, $s_{m+3} \neq \$$, so the weight of s contains the factor $\frac{e^{-m'}}{2e^{-m'}+e^{m'}} = \frac{1}{2+e^{2m'}}$ and thus is upper-bounded by $\frac{1}{2+e^{2m'}} < \xi$. Hence no input of length different from $m+2$ achieves a weight that exceeds ξ. A string s of length $m+2$ achieves the weight w_s given by

$$w_s = \begin{cases} \frac{e^{m'}}{2e^{-m'}+e^{m'}} \cdot \prod_{i=1}^{m+2} \frac{e^{m'}}{2e^{m'}+e^{-m'}} & \text{if } F(s) = 1 \\ \frac{e^{-m'}}{2e^{m'}+e^{-m'}} \cdot \prod_{i=1}^{m+2} \frac{e^{m'}}{2e^{m'}+e^{-m'}} & \text{otherwise.} \end{cases}$$

When $F(s) = 0$, $w_s < \frac{e^{-m'}}{2e^{m'}+e^{-m'}} < \xi$, so if F is unsatisfiable, no input string achieves a weight above the threshold ξ. When $F(s) = 1$, $w_s = \frac{e^{m'}}{2e^{-m'}+e^{m'}} \cdot \left(\frac{e^{m'}}{2e^{m'}+e^{-m'}}\right)^{m+2} > \xi$. An input string with weight above ξ exists if and only if F is satisfiable. Obviously, the reduction can be computed in polynomial time since all constants can be computed in logarithmic space. The constructed RNN is consistent, since the output prediction is constant after $m+3$ steps. □

5 Equivalence

We prove that equivalence of two RNNs is undecidable. For comparison, equivalence of two deterministic WFSAs can be tested in time $O(|\Sigma|(|Q_A| + |Q_B|)^3)$, where $|Q_A|$, $|Q_B|$ are the number of states of the two WFSAs and $|\Sigma|$ is the size of the alphabet (Cortes et al., 2007); equivalence of nondeterministic WFSAs are undecidable (Griffiths, 1968). The decidability of language equivalence for deterministic probabilistic pushdowntown automata (PPDA) is still open (Forejt et al., 2014), although equivalence for deterministic unweighted push-downtown automata (PDA) is decidable (Sénizergues, 1997).

The equivalence problem is formulated as follows:

Equivalence: Given two RNNs R and R', return "yes" if $R(s) = R'(s)$ for all $s \in \Sigma^*$, and "no" otherwise.

Theorem 12. *The equivalence problem for RNNs is undecidable.*

Proof. We prove by contradiction. Suppose Turing machine M decides the equivalence problem. Given any deterministic Turing Machine M', construct the RNN R that simulates M' on input ϵ as described in Corollary 5. Let $E_{s,t}(a) = 0$ and $E_{s,t}(\$) = h_{s,t}(n_1) - h_{s,t}(n_2)$. If M' does not halt on ϵ, for all $t \in \mathbb{N}$, $E'_{s,t}(a) = E'_{s,t}(\$) = 1/2$; if M' halts after T steps, $E'_{s,T}(a) = 1/(e+1)$, $E_{s,T}(\$) = e/(e+1)$. Let R' be the trivial RNN that computes $\{a^n : P(a^n) = 2^{-(n+1)}, n \geq 0\}$. We run M on input $\langle R, R' \rangle$. If M returns "no", M' halts on x, else it does not halt. Therefore the Halting Problem would be decidable if equivalence is decidable. Therefore equivalence is undecidable. □

6 Minimization

We look next at minimization of RNNs. For comparison, state-minimization of a deterministic PFSA is $O(|E| \log |Q|)$ where $|E|$ is the number of transitions and $|Q|$ is the number of states (Aho et al., 1974). Minimization of a non-deterministic PFSA is PSPACE-complete (Jiang and Ravikumar, 1993).

We focus on minimizing the number of hidden neurons ($|N|$) in RNNs:

Minimization: Given RNN R and non-negative integer n, return "yes" if $\exists$ RNN R' with number of hidden units $|N'| \leq n$ such that $R(s) = R'(s)$ for all $s \in \Sigma^*$, and "no" otherwise.

Theorem 13. *RNN minimization is undecidable.*

Proof. We reduce from the Halting Problem. Suppose Turing Machine M decides the minimization problem. For any Turing Machine M', construct the same RNN R as in Theorem 12. We run M on input $\langle R, 0 \rangle$. Note that an RNN with no hidden unit can only output constant $E'_{s,t}$ for all t. Therefore the number of hidden units in R can be minimized to 0 if and only if it always outputs $E'_{s,t}(a) = E'_{s,t}(\$) = 1/2$. If M returns "yes", M' does not halt on ϵ, else it halts. □

7 Conclusion

We proved the following hardness results regarding RNN as a recognizer of weighted languages:

1. Consistency:
   (a) Inconsistent RNNs exist.
   (b) Consistency of RNNs is undecidable.
2. Highest-weighted string:
   (a) Finding the highest-weighted string for an arbitrary RNN is undecidable.
   (b) Finding the highest-weighted string for a consistent RNN is decidable, but the solution length can surpass all computable bounds.
   (c) Restricting to solutions of polynomial length, finding the highest-weighted string is NP-complete.
3. Testing equivalence of RNNs and minimizing the number of neurons in an RNN are both undecidable.

Although our undecidability results are upshots of the Turing-completeness of RNN (Siegelmann and Sontag, 1995), our NP-completeness result is original, and surprising, since the analogous hardness results in PFSA relies on the fact that there are multiple derivations for a single string (Casacuberta and de la Higuera, 2000). The fact that these results hold for the relatively simple RNNs we used in this paper suggests that the case would be the same for more complicated models used in NLP, such as long short term memory networks (LSTMs; Hochreiter and Schmidhuber 1997).

Our results show the non-existence of (efficient) algorithms for interesting problems that researchers using RNN in natural language processing tasks may have hoped to find. On the other hand, the non-existence of such efficient or exact algorithms gives evidence for the necessity of approximation, greedy or heuristic algorithms to solve those problems in practice. In particular, since finding the highest-weighted string in RNN is the same as finding the most-likely translation in a sequence-to-sequence RNN decoder, our NP-completeness result provides some justification for employing greedy and beam search algorithms in practice.

Appendix

Lemma 14. *For every* $k \in \mathbb{N}_+$

$$\prod_{t\in\mathbb{N}} \frac{e^{k(t+1)}}{e^{k(t+1)}+1} = \frac{2}{(-1;\, e^{-k})_\infty} \ ,$$

where $(-1; e^{-k})_\infty$ *is the infinite* e^{-k}*-Pochhammer symbol.*

Proof.

$$\prod_{t\in\mathbb{N}} \frac{e^{k(t+1)}}{e^{k(t+1)}+1} = \prod_{t\in\mathbb{N}_+} \left(\frac{e^{kt}}{e^{kt}+1}\cdot\frac{e^{-kt}}{e^{-kt}}\right)$$

$$= \prod_{t\in\mathbb{N}_+} \frac{1}{1+e^{-kt}} = \left(\left(\prod_{t\in\mathbb{N}_+} \frac{1}{1+e^{-kt}}\right)^{-1}\right)^{-1}$$

$$= \Big(\prod_{t\in\mathbb{N}_+} (1+e^{-kt}) \Big)^{-1} = \Big(\frac{1}{2} \prod_{t\in\mathbb{N}} (1+e^{-kt}) \Big)^{-1}$$
$$= \frac{2}{(-1;\, e^{-k})_\infty} \qquad \square$$

Lemma 15. *Reconsider the RNN of Example 3 and suppose that $h_{s,t}(n) - h_{s,t}(n') = 0$ for all $t \in \mathbb{N}$. Then*

$$\sum_{s\in\Sigma^*} R(s) = 1 - \frac{2}{(-1;\, e^{-2})_\infty} \approx 0.14$$

Proof.

$$\sum_{s\in\Sigma^*} R(s) = \sum_{n\in\mathbb{N}} R(a^n)$$
$$= \sum_{n\in\mathbb{N}} \Big(\frac{e^{-(n+1)}}{e^{n+1}+e^{-(n+1)}} \cdot \prod_{t=0}^{n-1} \frac{e^{t+1}}{e^{t+1}+e^{-(t+1)}} \Big)$$
$$= 1 - \prod_{t\in\mathbb{N}} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} = 1 - \frac{2}{(-1;\, e^{-2})_\infty}$$
$$\approx 0.14 \ ,$$

where the final equality utilizes Lemma 14. $\square$

Lemma 16. *Reconsider the RNN of Example 3 and suppose that there exists a time point $T \in \mathbb{N}$ such that for all $t \in \mathbb{N}$*

$$h_{s,t}(n) - h_{s,t}(n') = \begin{cases} 1 & \text{if } t = T \\ 0 & \text{otherwise.} \end{cases}$$

Then

$$\sum_{s\in\Sigma^*} R(s) = 1$$

Proof.

$$\sum_{s\in\Sigma^*} R(s) = \sum_{n\in\mathbb{N}} R(a^n)$$
$$= \Big(\sum_{n=0}^{T} R(a^n) \Big) + \Big(\sum_{n=T+1}^{\infty} R(a^n) \Big)$$
$$= \sum_{n=0}^{T} \Big(\frac{e^{-(n+1)}}{e^{n+1}+e^{-(n+1)}} \cdot \prod_{t=0}^{n-1} \frac{e^{t+1}}{e^{t+1}+e^{-(t+1)}} \Big)$$
$$+ \sum_{n=T+1}^{\infty} \frac{e^{2n-3T-4}}{e^{n+1}+e^{2n-3T-4}}$$
$$\cdot \Big(\prod_{t=0}^{T} \frac{e^{t+1}}{e^{t+1}+e^{-(t+1)}} \Big) \cdot \Big(\prod_{t=T+1}^{n-1} \frac{e^{t+1}}{e^{t+1}+e^{2t-3T-4}} \Big)$$
$$= \sum_{n=0}^{T} \Big(\frac{1}{e^{2(n+1)}+1} \cdot \prod_{t=0}^{n-1} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big)$$
$$+ \sum_{n=T+1}^{\infty} \frac{e^{n-3T-5}}{1+e^{n-3T-5}} \cdot \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big)$$
$$\cdot \Big(\prod_{t=T+1}^{n-1} \frac{1}{1+e^{t-3T-5}} \Big)$$
$$= 1 - \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big) + \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big)$$
$$\cdot \sum_{n=T+1}^{\infty} \frac{e^{n-3T-5}}{1+e^{n-3T-5}} \cdot \Big(\prod_{t=T+1}^{n-1} \frac{1}{1+e^{t-3T-5}} \Big)$$
$$= 1 - \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big)$$
$$\cdot \left(1 - 1 + \prod_{t=T+1}^{\infty} \frac{1}{1+e^{t-3T-5}} \right)$$
$$= 1 - \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big) \cdot \Big(\prod_{t=T+1}^{\infty} \frac{1}{1+e^{t-3T-5}} \Big)$$
$$\geq 1 - \Big(\prod_{t=0}^{T} \frac{e^{2(t+1)}}{e^{2(t+1)}+1} \Big) \cdot \Big(\prod_{t\in\mathbb{N}} \frac{1}{1+e^{t}} \Big)$$
$$= 1 \qquad \square$$

Lemma 17.

Proof. We set $h_{s,-1}(n) = h_{-1}(n)$ for all $n \in N$ and $h'_{s,-1}(n') = h'_{-1}(n')$ for all $n' \in N'$. Then trivially $h'_{s,-1}(n_1) - h'_{s,-1}(n_2) = h_{-1}(n) - 0 = h_{s,-1}(n)$. Moreover, $h'_{s,t}(n_1) = \sigma\langle V \cdot h'_{s,t-1} + V'_{s[t]} \rangle(n_1)$

$$= \sigma\langle \sum_{n'\in N'} V(n_1,n') \cdot h'_{s,t-1}(n')$$
$$+ V'_{s[t]}(n_1) \rangle$$
$$= \sigma\langle \sum_{n'\in N} \big(V(n_1,n'_1) \cdot h'_{s,t-1}(n'_1)$$
$$+ V(n_1,n'_2) \cdot h'_{s,t-1}(n'_2) \big) + V'_{s[t]}(n_1) \rangle$$
$$= \sigma\langle \sum_{n'\in N} U(n,n') \cdot \big(h'_{s,t-1}(n'_1) - h'_{s,t-1}(n'_2) \big)$$
$$+ U'_{s[t]}(n) \rangle$$
$$= \sigma\langle \sum_{n'\in N} U(n,n') \cdot h_{s,t-1}(n') + U'_{s[t]}(n) \rangle$$

Similarly, we can show that $h'_{s,t}(n_2) =$

$$\sigma\langle \sum_{n'\in N} U(n,n') \cdot h_{s,t-1}(n') + U'_{s[t]}(n) - 1 \rangle$$

Hence $h'_{s,t}(n_1) - h'_{s,t}(n_2) = h_{s,t}(n)$ as required. $\square$
